Interpretation and Analysis: Histopathology analysis reveals the presence of a high percentage of benign nodules (e.g., n = 533 or 81.1%), including follicular adenomas (e.g., n = 251 or 38.2%) and thyroid carcinomas (e.g., n = 124 or 18.9%). The sensitivity, specificity, positive predictive value, negative predictive value, and accuracy in the detection of thyroid cancer is approximately 95.8%, 21.1%, 22.6%, 95.5%, and 35.7% for TS, and 81.4%, 99.4%, 97.1%, 95.8%, and 96.0% for FNA cytology, respectively. The presence of thyroid cancer may be confirmed in approximately 22.6% of cases examined with a "cold" nodule (e.g., n = 92/407); in about 4.5% of cases with normal or increased uptake on TS (e.g., n = 4/89); in approximately 97.1% of cases with smears suggesting malignancy (e.g., n = 101/104); and in about 0.6% of cases with smears suggestive of a benign lesion (e.g., n = 3/533). In conclusion, the specificity of TS is low and this technique should be abandoned as a routine test in patients with non-toxic thyroid nodules. However, a more careful evaluation should be suggested for patients with cold thyroid nodules and an FNA cytology that reads follicular neoplasm.

An advantage of [^{99m}Tc] is that in the normal individual, the intensity of uptake by the salivary and thyroid gland are approximately equal. Conversely, the intensity of [^{99m}Tc] uptake is much greater within the thyroid gland of cases with hyperthyroidism compared to that of the salivary gland.

Usefulness of [^{99m}Tc]-pertechnetate scintigraphy and fine-needle aspiration cytology in patients with solitary thyroid nodules and thyroid cancer. Lumachi F, Varotto L, Borsato S, Tregnaghi A, Zucchetta P, Marzola MC, Cecchin D, Bui F. Anticancer Res 2004 Jul–Aug; 24 (4), pp. 2531–4.

Thyroid Gland Function and Anatomical Configuration/Differentiated Thyroid Cancer (DTC)/Hyperthyroidism/Prediction of Response to Therapy

Radioiodine/[^{123}I]/[^{131}I]

Cellular/Molecular Mechanism of Action: Radioiodine is assimilated by the thyroid gland for synthetic processes in a manner essentially identical to non-radioactive iodine.

Diagnostic Application: Radioactive iodine [^{131}I] plays a major role in the diagnosis and management of DTC; however, data on the use of the [^{123}I] isotope in DTC are limited. Measurement of serum thyroglobulin (Tg) levels and [^{131}I] whole-body scintigraphy (WBS) can be used in monitoring conditions of DTC. Radioiodine can be applied to aid in the characterization of other abnormalities affecting the thyroid gland, including hyperthyoidism, hypothyroidism, and goiter.

Route of Administration: [^{123}I] (intravenous).

Dosage: [^{123}I] (185 MBq). Feline hyperthyroid: 4 mCi of radioiodine.

Considerations: Of differentiated thyroid cancer scans with elevated Tg and negative pretreatment scans, some posttreatment scans can remain negative, with a small proportion of posttreatment scans showing thyroid bed uptake, or they can display posttreatment scans with lung uptake in cases that had computed tomography (CT) scans of the chest showing only bronchiectasis and/or lung scarring without evidence of lung metastases.

Implementation #1: Evaluate the significance of persistent [^{131}I] uptake in the thyroid bed in patients with DTC following surgery and/or radioactive iodine ablation. [^{99m}Tc] thyroid scintigraphy (TS) and [^{131}I] thyroid uptake (IU) are also performed to determine their clinical impact on case management.

Implementation #2: Evaluate by comparison 238 diagnostic whole-body scans performed 24 hours after oral ingestion of 185–555 MBq [^{123}I] with their corresponding [^{131}I] posttherapy whole-body scans obtained 4–5 days after [^{131}I] therapy. Scans can be employed in 3 clinical situations: with the 1st [^{131}I] therapy, with the 2nd [^{131}I] therapy, and in cases of elevated Tg and negative diagnostic scan.

Implementation #3: In veterinary medicine radioiodine has been applied to evaluate hyperthyroid cats for pretreatment factors that would predict response to radioiodine therapy. Cats can be treated with an intravenous bolus of radioiodine and follow-up serum thyroxine levels evaluated at 1 week and 1, 3, 6, and 12 months posttherapy. Complementary investigations can include the evaluation of methimazole pretreatment to determine the effect of this drug on therapy response.

Human Model #1: Sixty-two non-metastatic patients (14 men, 48 women) with a mean age of 44 years (range: 16–75) who have undergone surgical thyroidectomy for DTC evaluated prospectively. All patients have undergone technetium and iodine scintigraphy (IS). Serum Tg levels are measured in all patients, (IU available for n = 36).

Human Model #2: Differentiated thyroid carcinoma cases (e.g., n = 238) yielding approximately 177 pairs of thyroid scintigraphic images. Following a 2nd [^{131}I] administration, 34 pairs are obtained.

Animal Model: Hyperthyroid cats (e.g., n = 193) based on elevated serum thyroxine levels and/or elevated thyroid to salivary gland ratios on thyroid scintigraphy. Metrimazole pretreatment evaluation (n = 98 cats) with administration discontinued ≥ days before radioiodine therapy (e.g., n = 58 cats) or < 5 days (e.g., n = 31 cats), or unknown number of days off methimazole (e.g., n = 9 cats).

Interpretation and Analysis: In human cases of DTC that have undergone surgical thyroidectomy, Tg values are in the range of 0.2 to 24 ng/ml (median: 0.2 ng/ml) when cases are in the hypothyroid state. [^{131}I] WBS can detect residual tissue in the neck in 48% of cases (e.g., n = 30); however, TS may be positive in only 19% of cases (e.g., n = 12). [^{131}I] uptake in the thyroid bed ranges from 0 to 14% (median: 0.1%). A large percentage of cases with positive IS and negative TS have uptake values ≤ 0.3% ($p < 0.00001$ for n = 12/13 or 93.2%). When IU values are ≤ 0.3%, about 54% of cases will not have any uptake in the thyroid bed on TS or IS, whereas when the IU is > 0.3%, approximately 80% of cases will have neck uptake on both TS and IS ($p < 0.00001$). Such findings demonstrate that the concordance of IS and TS depends on the IU level after suspension of replacement therapy. Measurements of IU and TS are of considerable value in evaluating patient response to therapy and will substantially reduce the need for repetitive radioiodine scans and unnecessary treatment doses in patients with undetectable Tg values.

In another study of cases affected by DTC, paired images of the thyroid acquired with the first [^{131}I] administration show complete concordance between pretreatment and posttreatment scans in most instances (e.g., n = 166 pairs with a concordance rate = 93.8%). Some posttreatment scans may show more foci in the thyroid bed than the pretreatment scans, but no evidence of uptake in new areas (e.g., n = 6). Only a small number of posttreatment scans reveal foci in new locations (e.g., n = 5 with n = 3/5 in cervical lymph nodes (CLN), n = 1/5 in the lung, n = 1/5 new bone metastasis). Following a 2nd [^{131}I] administration yielding 34 pairs of images, analysis also reveals complete concordance at a relatively high level (e.g., n = 28 pairs and concordance rate = 82.4%). A relatively small number of discordant pairs have additional foci in areas that are already positive

on pretreatment scans (e.g., n = 5; n = 1 posttreatment scan detecting new bone metastasis in a different site from the bone metastases that were seen on its corresponding pretreatment scan).

Slightly greater that 50% of paired scans in cases with elevated Tg and negative pretreatment scans will have posttreatment scans that remain negative (e.g., n = 15/27), while others may show uptake in the thyroid bed (e.g., n = 6). Additionally, posttreatment scans may show lung uptake in cases whose computed tomography scans of the chest show only bronchiectasis (e.g., n = 2/3 cases) and lung scarring (e.g., n = 1/3) in conditions without evidence of lung metastases. A small number of posttreatment scans (e.g., n = 3) show definite uptake (in thyroid bed, thyroid bed and lung, and CLN) compared with their corresponding pretreatment scans initially reported negative but retrospectively may be considered to have faint uptake. In pretreatment scans with a [^{123}I] diagnostic activity of 185 MBq, results reveal complete concordance in a large number of pairs (e.g. n = 54/56). A small number of posttreatment scans show additional uptake (e.g., n = 2; with n = 1 in the bone, n = 1 in CLN). Such findings suggest that pretreatment scanning using [^{123}I] is highly comparable to [^{131}I] posttreatment scanning and that [^{123}I] is an excellent diagnostic agent in DTC.

In hyperthyroid cats, there is a significant relationship between pretreatment thyroxine values and posttreatment thyroxine values at all of the follow-up time points ($p < 0.001$). There is also a relationship between thyroid to salivary gland technetium scan ratio results and serum thyroxine values at pretreatment and at 1 week posttreatment ($p = 0.02, 0.005$, respectively). A greater scan ratio is associated with higher thyroxine levels at those time points, but not at 1, 3, 6, or 12 months posttherapy. There is no difference in response to radioiodine based upon when methimazole was discontinued ($p = 0.70$).

Thyroid Nodules (Solitary)/Thyrotoxicosis *[^{99m}TcO^{-4}]/[^{123}I]/[^{201}T1]*

Background Information: Palpable thyroid nodules occur in 4 to 7% of the population, but nodules found incidentally on ultrasonography suggest a prevalence of 19 to 67%. The majority of thyroid nodules are asymptomatic. Because about 5% of all palpable nodules are found to be malignant, the main objective of evaluating thyroid nodules is to exclude malignancy. Laboratory evaluation, including a thyroid-stimulating hormone test, can help differentiate a thyrotoxic nodule from a euthyroid nodule. In euthyroid patients with a nodule, fine-needle aspiration should be performed, and radionuclide scanning should be reserved for patients with indeterminate cytology or thyrotoxicosis. Insufficient specimens from fine-needle aspiration is less of a problem when ultrasound guidance is used. Surgery is the primary treatment for malignant lesions, and the extent of surgery depends on the extent and type of disease. Ablation by postoperative radioactive iodine is done for high-risk patients—identified as those with metastatic or residual disease. While suppressive therapy with thyroxine is frequently used postoperatively for malignant lesions, its use for management of benign solitary thyroid nodules remains controversial.

Nuclear medicine has a distinct role to play in otolaryngological practice. Accurate diagnosis of endocrine conditions is now possible using precise *in vitro* hormone measurement. Specific clinical questions can be answered using *in vivo* investigations. [^{99m}TcO$_4^-$]/[^{123}I] scintigraphy is used to evaluate thyrotoxicosis and solitary thyroid nodules. [^{99m}Tc]/[^{201}T1] subtraction scanning is of value in the preoperative localization of parathyroid adenomas, and [^{99m}Tc] is particularly useful in assessing salivary and lachrymal gland function and drainage. [^{99m}Tc]- methylene diphosphonate (MDP) bone scanning is useful in the evaluation of osteomyelitis, temporomandibular joint dysfunction, bone graft viability, and some facial fractures. The role of radioisotopes in the management of differentiated and medullary carcinoma of the thyroid is now well established. Although there are many other agents available to image head and neck cancer, few can actually achieve the required diagnostic sensitivity and specificity. The introduction of monoclonal antibodies into routine imaging has been hampered by distinct practical problems, and the search is now on for more sensitive non-specific diagnostic agents. It is now possible to evaluate new [^{99m}Tc]-labeled tumor-imaging agents using animal tumor model systems, and the use of radioactivity in all aspects of otolaryngological research adds an extra quantitive dimension. Together with single photon emission computed tomography (SPECT), and the introduction of positron emission tomography (PET) to image the physiology of normal tissues and tumors, the use of radionuclide investigations can lead only to an increase in ear, nose, and throat (ENT) diagnostic sensitivity and specificity and, subsequently, to an overall improvement in the way head and neck cancer is diagnosed, staged, and treated.

Application: Detection and differentiation between thyrotoxicosis and solitary thyroid nodules by scintigraphic imaging.

GASTROINTESTINAL SYSTEM

Gastroesophageal Reflux/Gastric Motility *[^{99m}Technetium] ([^{99m}Tc])-Hydroxy Ethyl Starch*

Cellular/Molecular Mechanism of Action: [^{99m}Tc]-hydroxy ethyl starch functions as a passive radioactive marker when mixed in a "meal" for the purpose of assessing gastroesophageal reflux while performing gastric motility studies.

Application: [^{99m}Tc]-hydroxy ethyl starch is an agent that is suitable for studies assessing gastroesophageal reflux and gastric motility.

Semi-Synthetic Methods: A reduction method based on stannous chloride has been developed for preparing hydroxy ethyl starch kits developed to characterize conditions of gastrointestinal reflux and gastric motility function. Verification of the consistency of radiolabeling reveals that high labeling efficiencies can consistently be achieved (> 95% when prepared at neutral pH) and products remain stable under conditions simulating the gastric environment.

Implementation: Evaluation and validation of [^{99m}Tc]-hydroxy ethyl starch as a liquid phase and solid phase gastric motility imaging radiotracer. Gastroesophageal reflux, liquid phase, and solid phase studies can then be conducted *in vivo* to assess the radiotracer stability.

Human Model: Case volunteers (n = 13).

Interpretation and Analysis: No absorption of any radioactivity from the gastrointestinal tract can be detected and suggests that [^{99m}Tc]-hydroxy ethyl starch is an agent that is suitable for gastroesophageal reflux and gastric motility studies. It is available in kit form and is a more "physiologically appropriate" agent compared to [^{99m}Tc]-sulphur colloid when used to prepare solid radioactive meals. [^{99m}Tc]-hydroxy ethyl starch represents a true carbohydrate meal and, unlike [^{99m}Tc]-sulphur colloid, is easy to prepare and can be conveniently optimized to produce a standardized vegetarian meal.

Development and validation of hydroxy ethyl starch kits for instant use in gastroesophageal reflux and gastric motility studies. Singh AK, Bhatnagar A, Singh T, Shankar LR. Nucl Med Commun 2002 Apr; 23 (4), pp. 373–7.

Inflammation/Absorption of the Intestine/ Intestinal Lesions: Non-Steroidal Anti-Inflammatory Drug (NSAID)-Associated/Intestinal Lesions: Crohn's Ileitis
[^{111}Indium] ([^{111}In]) Leukocytes/Tauro 23 [^{75}Se]-Selena-25-Homocholic Acid/ [^{58}Co]-Labeled Cyanocobalamine

Cellular/Molecular Mechanism of Action: The agent tauro 23 [^{75}Se]-selena-25-homocholic acid is a bile acid analog, while [^{58}Co]-labeled cyanocobalamine is an analogue of vitamin B_{12}. Radiolabeled [^{111}In] leukocytes behave *in vivo* like endogenous leukocytes of the same cell type.

Application: The agents tauro 23 [^{75}Se]-selena-25-homocholic acid and [^{58}Co]-labeled cyanocobalamine can be applied to evaluate intestinal absorption. Conversely, [^{111}In] leukocytes can be used to detect foci of septic and non-septic inflammation.

Route of Administration: Intravenous.

Implementation: Evaluation of residual inflammatory lesions following discontinuation of NSAIDs using [^{111}In] leukocyte scintigraphy imaging methodologies.

Human Model #1: Cases of rheumatoid arthritis (n = 90) and osteoarthritis (n = 7).

Human Model #2: Cases treated with NSAIDs (n = 19); healthy controls (n = 20); and Crohn's ileitis (n = 13).

Interpretation and Analysis: Using a [^{111}In] leukocyte imaging technique reveals that cases of rheumatoid arthritis and osteoarthritis administered NSAIDs are accompanied by the development of gastrointestinal lesions. More specifically, approximately two-thirds of all cases evaluated on long-term treatment display inflammatory lesions that may persist for up to 16 months following discontinuation. The prevalence and magnitude of intestinal inflammation is unrelated to the type and dose of non-steroidal drugs and previous or concomitant 2nd-line drug treatment. There is a significant inverse correlation ($r = -0.29$, $p < 0.05$) between fecal [^{111}In] excretion and hemoglobin levels in cases treated with NSAIDs. The kinetics of fecal [^{111}In] excretion in cases treated with NSAIDs is almost identical to that of cases with small bowel Crohn's disease. Small bowel radiological examination of cases on NSAIDs reveals that approximately one-sixth have asymptomatic ileal disease with ulceration and strictures (e.g., n = 3/18 cases). Evaluation of cases on anti-inflammatory agents, normal healthy controls, and cases of Crohn's ileitis with tauro 23 [^{75}Se]-selena-25-homocholic acid and [^{58}Co]-labeled cyanocobalamine reveals several abnormalities. On day 4, more than half the cases with rheumatoid arthritis have evidence of bile acid malabsorption, but the ileal dysfunction is much milder than seen in patients with Crohn's ileitis.

Non-steroidal anti-inflammatory drug–induced intestinal inflammation in humans. Bjarnason I, Zanelli G, Smith T, Prouse P, Williams P, Smethurst P, Delacey G, Gumpel MJ, Levi AJ. Gastroenterology 1987 Sep; 93 (3), pp. 480–9.

Lymphangiectasia: Intestinal
[^{99m}Technetium] ([^{99m}Tc])-Dextran

Background Information: Intestinal lymphangiectasia is a well-recognized complication of the Fontan procedure, occurring in up to 24% of cases. Because of the loss of chylous fluid into the gut lumen, protein-losing enteropathy results, as well as lymphopenia and hypogammaglobulinemia. In some cases, dilated lymphatics in the intestinal serosa or mesentery also rupture, causing chylous ascites. Standard medical and cardiac surgical interventions are generally ineffective and the condition is frequently fatal.

Application: Detection and characterization of protein-losing enteropathy.

Considerations: Condition is refractory to all standard medical therapies (e.g., dietary modifications, diuretics, corticosteroid therapy, albumin infusions, octreotide, heparin, bowel rest, and parenteral nutrition). Cardiac surgery to optimize hemodynamic status is also ineffective (continued loss of large volumes of pleural and ascitic fluid).

Implementation: Evaluation of intractable and life-threatening chylous ascites and chylothorax associated with intestinal lymphangiectasia and protein-losing enteropathy after a Fontan procedure for tricuspid atresia. One strategy includes [^{99m}Tc]-dextran scintigraphy performed to assess the extent of intestinal protein loss and the potential for surgical intervention. Scintigraphy can localize protein loss from the proximal jejunum and subsequent segmental resection can be effective. Postoperatively, ascites and pleural effusions can subsequently resolve without evidence of short bowel syndrome. Growth may ultimately increase and be accompanied by the onset of puberty if delayed. A mild intestinal protein loss may persist that may require diuretic therapy. Ascites or pleural effusions may be absent and cases remain asymptomatic for > 2 years postsurgery. Intestinal lymphangiectasia post-Fontan procedures has traditionally been ascribed to hemodynamic factors such as raised systemic venous pressure, which would predispose to a generalized intestinal lesion. However, scintigraphy can demonstrate a localized, surgically correctible lesion.

Successful resection of localized intestinal lymphangiectasia post-Fontan: Role of [^{99m}technetium]-dextran scintigraphy. Connor FL, Angelides S, Gibson M, Larden DW, Roman MR, Jones O, Currie BG, Day AS, Bohane TD. Pediatrics 2003 Sep; 112 (3 Pt 1), pp. e242–7.

Pancreatic Function and Disease
[^{125}I]-L-3 Iodo-α-Methyl Tyrosine ([^{125}I]-IMT)

Cellular/Molecular Mechanism of Action: [^{125}I]-IMT.

Considerations: The difficulty of a reliable diagnosis of pancreatic diseases by scintiscanning is due in part to the lack of adequate radiopharmaceuticals. The agent [^{125}I]-IMT has been previously applied for the purpose of diagnosing different kinds of brain tumors. Preliminary *in vivo* trials suggest that [^{125}I]-IMT can be used as a diagnostic agent for detecting pancreatic disease and can be produced using either [^{123}I] or [^{125}I] radioisotopes.

Experimental: L-α-methyl tyrosine can be labeled with [^{125}I] using I-/I03 and afterward purified by an anionic exchange resin. The labeling yield obtained is high (96.0 ± 0.5%) when the incubation time of 15 minutes is applied and no statistically significant difference can be appreciated with 1-hour incubation periods.
Interpretation and Analysis: Biodistribution studies (mice) show that the percentage of activity concentration within the pancreas is 34.24 ± 14.03% at 15 minutes postinjection and remains constant for 30 minutes. The pancreas/liver ratio 15 minutes after the injection of [^{125}I]-IMT approaches 12.22 ± 3.59 and remains constant for an additional 45 minutes.
Instrumentation: Computer-integrated nuclear medicine scintigraphic camera.

New methodology for pancreatic scintiscanning imaging using [^{125}I]-L-3 iodo-α-methyl tyrosine. Zubillaga MB, Bocciot JR, Gentile A, Mitta AE, Nicolini JO, Caro RA. Acta Physiol Pharmacol Ther Latinoam 1996; 46 (2), pp. 83–9.

Sepsis/Appendicitis/Inflammatory Bowel Disease (IBD)/Osteomyelitis/Soft Tissue Sepsis/Fever of Unknown Origin
[^{99m}Technetium] ([^{99m}Tc])-Hexamethylpropyleneamine Oxime (HMPAO)-Labeled Leukocytes

Cellular/Molecular Mechanism of Action: The preparation [^{99m}Tc]-HMPAO functions as a radiolabeling agent for leukocytes. Neutrophils are the cell type most widely used for labeling procedures of this nature. Radiolabeled neutrophils preferentially localize at sites of inflammation and sepsis in response to chemotactic stimuli.
Background Information: [^{99m}Tc]-HMPAO-labeled leukocytes are well established for their use in investigating inflammatory disease states. Their kinetics and normal distribution are similar to those of [^{111}In]-labeled leukocytes except for non-specific activity in urine, kidneys, gallbladder, and bowel, which results from the elution of secondary form of [^{99m}Tc]-labeled HMPAO complexes.
Application: Identification of septic and inflammatory foci (e.g., appendicitis).
Considerations: Diagnostic imaging with [^{99m}Tc]-HMPAO-labeled leukocytes is valuable for the detection of appendicitis and other intra-abdominal septic/inflammatory conditions. In 1 *in vivo* trial, 8 scans were interpreted as negative for acute appendicitis but were alternatively found to be positive for other conditions, including diverticulitis (n = 5 cases), neoplastic disease (n = 1 case), tuboovarian abscessation (n = 1 case), and small intestinal infarction (n = 1 case).
Interpretation and Analysis: In *in vivo* clinical trials, the sensitivity of [^{99m}Tc]-HMPAO leukocyte scans is 87%, with a specificity rate of 92% and an overall accuracy rate of 89% for the detection of septic/inflammatory foci.

The principal clinical indications for [^{99m}Tc]-HMPAO leukocytes include IBD, osteomyelitis, soft tissue sepsis, and, to a lesser extent, occult fever. The superior resolution and count density of [^{99m}Tc] places [^{99m}Tc]-HMPAO leukocytes at an advantage over [^{111}In] leukocytes in IBD, especially for the identification of small bowel involvement in patients with Crohn's disease. However, quantification of disease activity is more difficult than with [^{111}In]. [^{99m}Tc]-HMPAO leukocytes are indicated for most forms of acute soft tissue and abdominal sepsis, although when compared with [^{111}In], it may be more difficult to demonstrate communication between an abdominal abscess and bowel lumen. Chronic osteomyelitis, including infected joint prostheses, is better characterized with [^{111}In]-labeled leukocytes. Occult fever and fever of unknown origin (FUO) are more controversial. There is still a place for [^{67}Ga] in FUO, of which there is a wide spectrum of causes. Occult fever implies a pyogenic cause for an undiagnosed fever and should probably be imaged with [^{111}In] leukocytes. With the advances being made in other imaging modalities and in interventional radiology, there is a clear need for radionuclide agents that can be used for whole-body screening in cases with undiagnosed fever. Such agents may include [^{18}F]-fluorodeoxy-glucose and radiolabeled monoclonal antibodies to endothelial adhesion molecules activated at the foci of inflammation.

The utility of [^{99m}Tc]-HMPAO leukocytes for imaging infection. Peters AM. Semin Nucl Med 1994 Apr; 24 (2), pp. 110–27.

Sepsis/Appendicitis
[^{99m}Technetium] ([^{99m}Tc])-Labeled Anti-CD15 IgM Immunoglobulin

Cellular/Molecular Mechanism of Action: Anti-CD15 immunoglobulin M monoclonal antibody recognizes and binds to CD15 complexes expressed on the exterior surface membrane of polymorphonuclear neutrophils. The difference between IgG and IgM immunoglobulin is that IgM is the principal immunoglobulin produced after the 1st exposure to an antigen, while IgG is the principal immunoglobulin produced after 2nd exposure to the same antigen. IgM is composed of a pentomer of IgG-like molecules and generally has less specific antigen-binding properties than does IgG. In addition, IgM has a higher propensity to generate multimolecular antigen/antibody complexes.
Application: Detection and monitoring of septic foci and lesions.
Route of Administration: Anti-CD15 immunoglobulin M monoclonal antibody (LeuTech: intravenous).
Dosage: Anti-CD15 immunoglobulin M monoclonal antibody (LeuTech: 10–20 mCi of [^{99m}Tc]).
Semi-Synthetic Methods: Preparations of anti-CD15 immunoglobulin M monoclonal antibody (e.g., LeuTech) avidly bind to circulating and sequestered human polymorphonuclear neutrophils *in vivo,* eliminating the need for *in vitro* cell labeling and the risks of blood handling.
Implementation: Evaluation of the safety and efficacy of anti-CD15 immunoglobulin M monoclonal antibody (LeuTech) imaging in cases of suspected acute appendicitis. An effective procedure includes the acquisition of serial dynamic and static planar images for up to 3 hours after intravenous administration. Scans are then interpreted as either positive or negative for acute appendicitis or other intra-abdominal (septic) infection. The institutional diagnosis is validated by surgery and histopathology of the appendix, results from other diagnostic studies, or 2-week clinical follow-up.

Human Model: Cases presenting with equivocal clinical signs (e.g., n = 99).
Interpretation and Analysis: Scans are usually positive in a very high percentage of cases of suspected appendicitis with validation of the condition at surgery (e.g., n = 39/40; sensitivity 98%). Conversely, images are negative for appendicitis in a large percentage of cases found not to have appendicitis (e.g., n = 49/58, specificity = 84%). Accuracy, positive predictive, and negative predictive values are approximately 90%, 81%, and 98%, respectively. In cases with appendicitis and positive scans more than 50% of the images are positive at 4 minutes, and essentially all images are positive by 1 hour. Mean time of 1st positive image is about 15 minutes. Serious adverse reactions are generally rare. Imaging with anti-CD15 immunoglobulin M monoclonal antibody (LeuTech) is considered a highly sensitive diagnostic agent for detecting appendicitis in equivocal

cases. Advantages of this agent over the other currently used radiotracers include greater convenience and shorter time to diagnosis, particularly with respect to the expedient nature with which acute appendicitis can be visualized on scintigraphic images.

Scintigraphic determination of equivocal appendicitis. Rypins EB, Kipper SL. Am Surg 2000 Sep; 66 (9), pp. 891–5.

HEMATOLOGY

Aluminum Overload/Toxicity/Hemodialysis/ Hematopoeitin/Iron Absorption: Iron Deficiency *Desferrioxamine/Deferoxamine/[^{59}Fe]*

Cellular/Molecular Mechanism of Action: Desferrioxamine and deferoxamine are metallic ion chelating agents. Desferrioxamine can induce elevations in basal plasma aluminum concentrations.

Background: The response to recombinant human erythropoietin (rHuEpo) is determined primarily by the availability of iron. In contrast to intravenous iron, oral iron supplementation is often insufficient for an optimal response.

Application: Estimation of iron and total iron binding capacity.

Implementation: Evaluation of iron absorption and the effects of iron status, aluminium status, and inflammation. In this context, iron mucosal uptake after 24 hours, iron retention after 2 weeks, and mucosal transfer of iron are determined with a whole-body counter using an oral dose of [^{59}Fe]. Iron absorption is measured once without and once after the ingestion of 2 g aluminium hydroxide.

Human Model: Cases on chronic hemodialysis and maintenance rHuEpo therapy (n = 19).

Interpretation and Analysis: On the basis of transferrin saturation, 2 dialysis case groups can be distinguished: cases with a functional iron deficiency (n = 9), and iron-replete cases (n = 10). In the iron-deficient dialysis case group, mucosal uptake, mucosal transfer, and iron retention are 49.9% ± 29.4, 0.73% ± 0.29, and 41.6% ± 32.2, being significantly lower than in a non-uremic iron deficient population ($p < 0.01$, $p < 0.05$, $p < 0.01$, respectively). In iron-replete dialysis cases, mucosal uptake, mucosal transfer, and iron retention are 20.0 ± 12.3, 0.59 ± 0.18, and 11.1 ± 6.7, mucosal uptake and iron retention being lower than in a normal iron-replete population ($p < 0.0005$ and $p < 0.003$ respectively). Dialysis cases with high C-reactive protein (CRP) values show lower iron absorption. Iron absorption data correlates significantly with transferrin saturation and CRP in the iron-deficient group, and with serum ferritin in the iron-replete group. Iron absorption decreases after an aluminium hydroxide challenge in the iron-deficient cases to the lower levels of the iron-replete subjects. Body aluminium stores, estimated by the desferrioxamine test, do not correlate with parameters of iron absorption. The absorption of iron in dialysis patients is decreased by hemodialysis, which may, at least in part, be due to inflammation. Aluminium ingestion further reduces absorption in functional iron-deficient patients.

Iron absorption in erythropoietin-treated hemodialysis patients: Effects of iron availability, inflammation, and aluminium. Kooistra MP, Niemantsverdriet EC, van Es A, Mol-Beermann NM, Struyvenberg A, Marx JJ. Nephrol Dial Transplant 1998 Jan; 13 (1), pp. 82–8.

Hepatic Function *[^{99m}Technetium] ([^{99m}Tc])-Diethylenetriamine Pentaacetic Acid-Galactosyl Human Serum Albumin*

Cellular/Molecular Mechanism of Action: Diethylenetriamine pentaacetic acid (DTPA) generally functions as a chelating agent, including heavy metal ion isotopes like [^{111}In]. [^{99m}Tc]-galactosyl human serum albumin (GSA) is removed from the intravascular compartment by viable hepatocytes.

Application: Characterization of hepatic function without collection of blood samples for *in vitro* sample analysis.

Route of Administration: Intravenous.

Implementation: Delineate the clinical utility of a graphical method for estimating liver uptake and blood retention of [^{99m}Tc]-GSA, using dynamic single photon emission computed tomography (SPECT) analysis. When considering the kinetics of [^{99m}Tc]-GSA, if it is assumed that (i) [^{99m}Tc]-GSA distributes only between blood and liver, and (ii) no metabolism of [^{99m}Tc]-GSA occurs during the observation period, a plot of liver counts vs cardiac blood-pool counts should, theoretically, be a straight line. From the slope and y-intercept of a regression line, coefficients for converting count based liver and blood-pool data to the percent injected dose (%ID) can be calculated. Applicability of the method can be delineated for dynamic SPECT data from cases of hepatic dysfunction. To validate this method, plasma concentrations (%ID/ml plasma) at 6, 15, and 30 minutes after the injection are estimated and compared with measured values. To investigate the clinical significance of the % liver uptake, the value obtained by this method is compared with results from conventional liver function tests, including serum albumin, the hepaplastin test, prothrombin time, and indocyanine green clearance.

Human Model: Hepatic disease (n = 30 cases with hepatic disease).

Interpretation and Analysis: In every data set, a plot of liver counts to cardiac blood-pool counts can be represented (fitted) well by a straight line ($p < 0.00001$). Plasma concentrations estimated by this method show good correlation with measured values at 6, 15, and 30 minutes after injection ($r = 0.748$, 0.838, 0.875, respectively; $p < 0.0001$). The liver uptake determined by the method shows good correlation with results from conventional hepatic function tests ($p < 0.002$). The described graphical method could provide an accurate estimate of %ID of [^{99m}Tc]-GSA in blood without the need for blood sampling. The liver uptake determined by this method could be a simple but useful quantitative indicator of hepatic function.

Estimation of fractional liver uptake and blood retention of [^{99m}Tc]-DTPA-galactosyl human serum albumin: An application of a simple graphical method to dynamic SPECT. Shuke N, Aburano T, Okizaki A, Zhao C, Nakajima K, Yokoyama K, Kinuya S, Watanabe N, Michigishi T, Tonami N. Nucl Med Commun 2003 May; 24 (5), pp. 503–11.

Hepatic Function *[^{99m}Technetium] ([^{99m}Tc])-Galactosyl-Neoglycoalbumin*

Application: Assess hepatic function.

Route of Administration: [^{99m}Tc]-galactosyl neoglycoalbumin (intravenous).

Dosage: [^{99m}Tc]-galactosyl neoglycoalbumin (150 mBq at a rate of 3.5 mg [50 nmol; 1 ml]).

Implementation: Simulation of [^{99m}Tc]-galactosyl neoglycoalbumin kinetics allows quantification of galactosyl neoglycoalbumin binding to (human) hepatic binding protein. In conditions of (i) viral hepatitis A, hepatitis B, non-A/b hepatitis with increases in hepatic binding protein concentration (up to 3 times the initial concentration), binding rate constant, and hepatic blood flow; and (ii) hepatitis B and cytomegalovirus infection, [^{99m}Tc]-galactosyl neoglycoalbumin can be a valuable agent used in conjuction with clinical pathology parameters to assess the return of hepatic function. In monitoring the prolonged course of such disease states, it can be noted that binding protein increases from 0.41 ± 0.11 μmol/L after the onset of acute hepatitis (n = 12) to 0.78 ± 0.21 μmol/L after 6 months of follow-up (n = 10 cases; $p < 0.001$). During this period, binding rate

constant (72.4 ± 12.6 vs 82 ± 11.5 μmol/L/sec; $p < 0.05$) and hepatic blood flow increases (0.027 ± 0.0051 vs 0.031 ± 0.0083 L/sec; $p < 0.05$). Hepatic binding protein concentration correlates highly with actual laboratory test results for liver function ($r = 0.98$; $p = 0.0001$).

Interpretation and Analysis: The liver is the exclusive site of trace uptake for [^{99m}Tc]-galactosyl neoglycoalbumin administered intravenously. Scintigraphic evaluation of functional liver cell mass using the receptor-tracer [^{99m}Tc]-galactosyl neoglycoalbumin can provide an *in vivo* diagnostic strategy for quantifying liver function and assessing liver morphology. In addition, research findings suggest that changes in hepatic binding protein-receptor concentration are likely to occur *in vivo.*

Liver function in acute viral hepatitis as determined by a hepatocyte-specific ligand: [^{99m}Tc]-galactosyl-neoglycoalbumin. Virgolini I, Müller C, Höbart J, Scheithauer W, Angelberger P, Bergmann H, O'Grady J, Sinzinger H. Hepatology 1992 Apr; 15 (4), pp. 593–8.

Hepatic Function
[^{123}I], [^{125}I], or [^{131}I] Radioiodinated Chylomicrons

Cellular/Molecular Mechanism of Action: Chylomicrons are rapidly assimilated and metabolized by the liver (hepatocytes). Cholesteryl is a normal constituent of the hydrophobic core of chylomicrons.

Application: Cholesteryl iopanoate (II), is an iodinated analogue of a normal constituent of the hydrophobic core of chylomicrons that mimics the biology and physiology of chylomicron assimilation and metabolism by the liver.

Route of Administration: Intravenous.

Synthetic Chemistry and Analysis: Cholesteryl iopanoate (II) is synthesized from cholesterol and iopanoic acid (I) and then subsequently radiohalogenated (e.g., [^{123}I], [^{125}I], or [^{131}I]).

Diagnostic Interpretation and Implications: Intravenous administration of cholesteryl iopanoate (II) in physiological saline results in the appearance of approximately 31% of the dose in the liver at 0.5 hours postinjection. Prior incorporation of cholesteryl iopanoate (II) into chylomicrons results in an almost 3-fold (87%) increase in the liver accumulation of cholesteryl iopanoate (II) during the same time period. A more gradual appearance of II in steroid-secreting tissues is consistent with the association of cholesteryl iopanoate (II) with high-density lipoproteins following administration.

Potential tumor- or organ-imaging agents XXIV: Chylomicron remnants as carriers for hepatographic agents. Damle NS, Seevers RH, Schwendner SW, Counsell RE. J Pharm Sci 1983 Aug; 72 (8), pp. 898–901.

Hepatic Function: Cirrhosis and Chronic Liver Disease
[^{99m}Technetium] ([^{99m}Tc])-Phytate Colloid

Cellular/Molecular Mechanism of Action: Colloid preparations are assimilated internally by perfused Kupffer cells within the hepatic sinusoids.

Background Information: Accurate quantitative determination of liver function is critical in cirrhotic conditions in order to predict an outcome, particularly in cases undergoing hepatic resection or non-hepatic surgery. As colloid uptake by perfused Kupffer cells is proportional to perfused hepatocyte mass, quantitative liver-spleen scan may be used as an index of perfused hepatocyte mass.

Application: Non-invasive quantitative test for assessment of hepatic function and severity of liver disease in cirrhotic patients.

Route of Administration: Intravenous.

Implementation: Evaluate hepatic function in cirrhotic conditions utilizing [^{99m}Tc]-phytate colloid uptake by the liver as a quantitative test assessed by single photon emission computed tomography (SPECT). In this context, quantitative SPECT can be used to measure liver volume as a function of quantitative colloid uptake by the liver and percentage of injected dose/ml of liver tissue.

Human Model: ($n = 75$ cirrhosis cases; $n = 52$ non-cirrhosis cases with chronic liver disease; $n = 36$ cases without hepatic disease).

Interpretation and Analysis: Although liver volume is similar among the 3 groups, the cirrhotic cases have significantly lower total quantitative uptake and quantitative uptake/ml compared to non-cirrhosis cases with chronic liver disease and cases without hepatic disease ($p < 0.001$). Quantitative liver uptake in cirrhotic conditions is highly correlated with Child-Pugh score values ($r = 0.64$, $p < 0.0001$) and with indocyanine green retention at 15 minutes ($r = 0.84$, $p < 0.0001$). Quantitative SPECT of the liver may be an additionally useful, non-invasive quantitative test for assessment of hepatic function and severity of liver disease in cirrhotic conditions.

Quantitative liver-spleen scan using single photon emission computerized tomography (SPECT) for assessment of hepatic function in cirrhotic patients. Zuckerman E, Slobodin G, Sabo E, Yeshurun D, Naschitz JE, Groshar D. J Hepatol 2003 Sep; 39 (3), pp. 326–32.

Hepatic Function: Jaundice/Infant Biliary Atresia/ Hepatic Jaundice in Frail and Compromised Patients
[^{131}I]-Rose Bengal (Fecal Excretion Test)/ [^{99m}Technetium] ([^{99m}Tc])-Pyridoxylidene Glutamate (PG)

Cellular/Molecular Mechanism of Action: Pyridoxylidene glutamate and rose bengal are both removed from the plasma by viable hepatocytes.

Application: Assess postoperative bile drainage with repeat scans in infants with biliary atresia. Scintigraphic imaging with [^{99m}Tc]-PG may also be useful as a screening test in difficult cases of jaundice, especially in frail patients, and cases with complications.

Route of Administration: Intravenous.

Implementation: Evaluation of hepatic function in cases of systemic jaundice applying [^{99m}Tc]-PG for nuclear scan imaging.

Human Model: Cases of systemic jaundice ($n = 24$ adults with mean total bilirubin = 255 μmol/l; $n = 11$ infants with prolonged obstructive jaundice and mean total bilirubin = 165 μmol/l).

Interpretation and Analysis: Absence of radioactivity in the gastrointestinal tract is interpreted as complete biliary obstruction and assumed to be the cause of jaundice (e.g., $n = 10/24$ adult; and $n = 6$ infant jaundice cases). Using this criterion, occlusion or patency of the bile ducts can be correctly determined in a high percentage of cases (e.g., $n = 21/24$ adults; and $n = 6/11$ infants). A low percentage of jaundice cases display either false-negative gut images (e.g., $n = 1/21$ adults; and $n = 2/11$ infants) or inconclusive results (e.g., $n = 2/24$ adult; and $n = 1/11$ infants). Scans are unable to show details about the site of obstruction or pathology but the technique is simple, atraumatic, and safely performed in cases with serious complications (e.g., renal failure, coagulation defects, septicemia). In infants, [^{99m}Tc]-PG scans compare well with the [^{131}I]-rose bengal fecal excretion tests and with liver biopsies in evaluations of prolonged obstructive jaundice.

Hepatobiliary imaging: The use of [^{99m}Tc]-pyridoxylidene glutamate scanning in jaundiced adults and infants. Jenner RE, Howard ER, Clarke MB, Barrett JJ. Br J Radiol 1978 Nov; 51 (611), pp. 862–6.

Hepatic/Hepatic Contrast Agent: Backdiffusion Phenomenon
Diethyl Iminodiacetic Analogues (Diethyl IDA)/ Mebrofenin

Background Information: The kinetics of organic anions is well described and backdiffusion from hepatocyte to plasma is accepted phenomenon. Although iminodiacetic (IDA) analogues, as organic anions, should also show bidirectional transport between hepatocyte and plasma, this has not been directly demonstrated.
Application: Hepatic contrast image-enhancing agent for magnetic resonance imaging modalities.
Route of Administration: Diethyl iminodiacetic analogues (diethyl IDA; intravascular); mebrofenin (intravascular).
Implementation: Evaluate backdiffusion characteristics of hepatic contrast agents into the intravascular compartment and quantify the corresponding fractional rate constant. Kinetics of diethyl IDA can be characterized through the analysis of femoral artery and hepatic venous samples collected following the injection of tracer preparations into a (i) peripheral vein, or (ii) hepatic artery or portal vein. Arterial time-concentration curves can also be compared between peripheral venous and either hepatic arterial or portal venous injections (canine). Complementary findings can be obtained by generating time-activity curves recorded from regions-of-interest (ROIs) over the cardiac blood-pool and peripheral hepatic parenchyma during routine IDA hepatobiliary imaging with diethyl IDA or mebrofenin and fractional rate constants for clearance of IDA from the hepatocyte compared to compartmental and deconvolution analyses (e.g., n = 30 cases).
Animal Model: Anesthetized dogs (e.g., n = 3).
Human Model: Hepatobilliary imaging with diethyl IDA (n = 30 cases).
Interpretation and Analysis: Following peripheral injection, there is an early arteriovenous concentration gradient that develops across the liver indicating a hepatocyte extraction fraction of 0.9 (dog #1), 0.8 (dog #2), and 0.6 (dog #3). The net extraction fraction decreases exponentially over a 40-minute period. Time-concentration curves for the hepatic vein and femoral artery are virtually superimposed following intrahepatic injections. Peripheral arterial curves, however, have different shapes according to whether injections are delivered intrahepatic or peripherally, and are consistent with the occurrence of significant backdiffusion. In human clinical cases, the blood disappearance curves can be fitted as the sum of 2 exponentials and the liver curves as the difference of 2 exponentials (rate constants = alpha1h and alpha2h). Based on compartmental analysis of the blood curves, the sum of the fractional rate constants of tracer movement from hepatocyte to bile canaliculus (k_{32}) and to plasma (k_{12}) is similar to and correlates with the rate constant, alpha, for the hepatocyte impulse response function ($r = 0.62$, $n = 30$, $p < 0.001$). In contrast, alpha1h and alpha2h are respectively clearly greater and smaller than alpha. Moreover, neither of these hepatic rate constants correlates with alpha. Diffusion of IDA from hepatocyte into the blood is significant and even in the presence of normal liver function accounts for about 50% of IDA transport out of the hepatocyte. It should be taken into account in pharmacokinetic studies based on either compartmental or deconvolution analysis.

Bidirectional transport of iminodiacetic organic anion analogues between plasma and hepatocyte. Peters AM, Myers MJ, Mohammadtaghi S, Mubashar M, Mathie RT. Eur J Nucl Med 1998 Jul; 25 (7), pp. 766–73.

IMMUNE SYSTEM AND INFLAMMATORY (SEPTIC/ NON-SEPTIC) RESPONSES

Refer to the neoplastic disease chapter (chapter 12) in Section II for references related to primary and metastatic neoplastic disease states and evaluation of sentinel lymph nodes.

Abscess Formation/Non-Septic Inflammatory Responses
[^{99m}Technetium] ([^{99m}Tc])-Interleukin-8 (IL-8)

Cellular/Molecular Mechanism of Action: Interleukin-8 recognizes and binds to IL-8 receptor complexes expressed on the exterior surface membrane of neutrophil and monocyte populations.
Physiological Mechanism of Action: Interleukin-8 can function as a neutrophil chemotactic agent, but this has little relevance to the use of this agent as an *in vivo* diagnostic agent in the field of nuclear medicine.
Route of Administration: [^{99m}Tc]-IL-8 (intravenous).
Implementation: Evaluation of the specificity of [^{99m}Tc]-IL-8 for detecting focal non-septic abscess lesions as a function of biodistribution patterns and pharmacokinetics profiles. Complementary analyses include determination of the interaction of [^{99m}Tc]-IL-8 with blood cells in circulation, which can be achieved through characterization of the radiolabel in circulating leukocytes, red blood cells, and plasma. The *in vivo* kinetics of [^{99m}Tc]-IL-8 can be studied by quantitative analysis of whole-body images acquired between 0 and 6 hours postinjection. The results of this analysis (*in vivo* biodistribution) can be validated by *ex vivo* counting of radioactivity in dissected tissues.
Animal Model: Rabbit (turpentine-induced abscesses in neutropenic and normal rabbits).
Interpretation and Analysis: Abscess uptake (percentage of injected dose per gram of tissue [%ID/g] ± standard error of measurement [SEM]) in immunocompetent scenarios (0.41 ± 0.05) is 10 times higher than in neutropenic conditions (0.038 ± 0.014), demonstrating target specificity for [^{99m}Tc]-IL-8 uptake. Abscess-to-muscle ratios ± SEM are also 10 times higher (110 ± 10 vs 10 ± 5). Lung and spleen uptake is 3-fold less with conditions of neutropenia compared to normal reference controls. The blood clearance of the radiolabel in conditions of neutropenia is similar to that in normal reference controls. In the vascular compartment, most of the [^{99m}Tc]-IL-8 (70%) is found in the plasma. Less than one-third is associated with red blood cells, and only a very low percentage (< 2.5%) is associated with white blood cell populations. Image analysis reveals a gradual increase in abscess uptake over time up to > 15 %ID, which can be confirmed by *ex vivo* gamma counting of infected muscle. The highest increase in abscess uptake is observed > 2 hours postinjection when most of [^{99m}Tc]-IL-8 has cleared from the blood, suggesting specific neutrophil-mediated accumulation of [^{99m}Tc]-IL-8 within abscesses. Furthermore, region-of-interest (ROI) analysis reveals that gradual accumulation of [^{99m}Tc]-IL-8 in abscesses is accompanied by a simultaneous clearance of activity from the lungs, suggesting that neutrophil-associated [^{99m}Tc]-IL-8 is initially trapped within the lungs but migrates to abscesses at a later time point (e.g., favoring neutrophil-bound transportation from the lungs to abscesses). Substantial support is given for the hypothesis that [^{99m}Tc]-IL-8 localizes within abscesses, primarily due to physical binding to peripheral neutrophils. Accumulation in abscesses is highly specific and a neutrophil-driven process. As assessed through *in vivo* and *ex vivo* analyses, the total fraction that accumulates in the inflamed tissue is extremely high (up to > 15 %ID) compared with that of other agents used for imaging infection and inflammation.

Kinetics of [^{99m}Tc]-labeled interleukin-8 in experimental inflammation and infection. Rennen HJ, Boerman OC, Oyen WJ, Corstens FH. J Nucl Med 2003 Sep; 44 (9), pp. 1502–9.

Abscess Formation/Septic Disease
[^{99m}Technetium] ([^{99m}Tc])-HYNIC-C5adR/ [^{99m}Tc]-HYNIC-C5a

Cellular/Molecular Mechanism of Action: Complement fraction C5a and its natural metabolite C5adR recognize and bind to receptor complexes expressed on the exterior surface membrane of neutrophil and monocyte populations.

Application: The complement anaphylatoxin C5a and its natural metabolite C5a des Arg(74) (C5adR) are involved in several stages of the inflammatory process. Both act on a common receptor expressed on different cell types, including neutrophils and monocytes. The receptor binding affinity of C5a is in the nanomolar range and exceeds that of C5adR by 1 to 2 orders of magnitude. The biological potency of C5a is considerably higher than that of C5adR.

Semi-Synthetic Methods: Labeling of proteins can be achieved utilizing [^{99m}Tc] facilitated by initial conjugation with the chelating agent hydrazinonicotinamide (HYNIC).

Implementation: Evaluation of intramuscular septic abscesses induced by bacterial injection utilizing [^{99m}Tc]-HYNIC-C5a and [^{99m}Tc]-HYNIC-C5adR as imaging agents. Biodistribution of the radiolabel can be determined by gamma camera imaging and by counting dissected tissues at 5 hours postinjection.

Interpretation and Analysis: Complement fractions [^{99m}Tc]-HYNIC-C5a and [^{99m}Tc]-HYNIC-C5adR display *in vivo* abscess uptake values of 0.12 and 0.025 %ID/g, abscess/muscle ratios of 76 and 14, abscess/blood ratios of 9.1 and 2.6, and region-of-interest (ROI)-derived target-to-background ratios of 5.9 and 2.1, respectively, at 5 hours postinjection. Therefore, [^{99m}Tc]-HYNIC-C5a provides superior capabilities as an agent for *in vivo* imaging of foci of sepsis (e.g., abscess formation). However, C5a is a very bioactive protein, a quality that impedes its clinical use as an infection imaging agent. The naturally occurring partial agonist C5adR has less biological effect but shows suboptimal imaging characteristics. Therefore, adequate localization of a receptor binding ligand with affinities for the receptor in the nanomolar range is required.

[^{99m}Tc]-labeled C5a and C5a des Arg74 for infection imaging. Rennen HJ, Oyen WJ, Cain SA, Monk PN, Corstens FH, Boerman OC. Nucl Med Biol 2003 Apr; 30 (3), pp. 267–72.

Abscess Formation/Septic Disease
[^{99m}Technetium] ([^{99m}Tc])-HYNIC-Interleukin-8 (IL-8)

Cellular/Molecular Mechanism of Action: Interleukin-8 recognizes and binds to IL-8 receptor complexes expressed on the exterior surface membrane of neutrophil and monocyte populations.

Background Information: Previous investigations have demonstrated that IL-8 can be labeled with [^{99m}Tc] using hydrazinonicotinamide (HYNIC) as bifunctional coupling agent and tricine as a coligand. Such preparations possess excellent characteristics for imaging infections (e.g., rabbit model of soft-tissue infection).

Route of Administration: [^{99m}Tc]-HYNIC-IL-8 (intravenous).

Semi-Synthetic Methods: Propylaldehyde hydrazone formulation of HYNIC can be introduced into stabilized HYNIC-IL-8 and [^{99m}Tc]-HYNIC-IL-8 prepared using 5 different coligand formulations. In this context, HYNIC-conjugated IL-8 can be radiolabeled with [^{99m}Tc] in the presence of either (i) tricine; (ii) ethylenediaminediacetic acid (EDDA); (iii) tricine and trisodium triphenylphosphinetrisulfonate (TPPTS); (iv) tricine and nicotinic acid (NIC); or (v) tricine and isonicotinic acid (ISONIC). These preparations can be characterized *in vitro* by (i) reverse-phase high-pressure liquid chromatography (RP-HPLC) analysis; (ii) measurement of octanol/water partition coefficient parameters; (iii) delineation of molecular stability; and (iv) receptor affinity analysis (ligand binding assays).

Implementation: Evaluation of the *in vivo* biodistribution of [^{99m}Tc]-HYNIC-IL-8 in conditions of induced localized sepsis (*Escherichia coli*–induced soft-tissue infection), which can be assessed by gamma camera imaging and counting of tissue samples at 6 hours postinjection.

Animal Model: Rabbit (*E. coli*–induced soft-tissue infection).

Interpretation and Analysis: Specific activity (MBq/μg) is highest for ISONIC (up to 80) > TPPTS (40) > tricine (15) > EDDA (7). RP-HPLC and octanol/water partition coefficients show a shift toward higher lipophilicity for TPPTS preparations. The leukocyte receptor binding fractions are around 40–55% for all preparations except for TPPTS, which displays predominantly nonspecific binding. All preparations are stabile in serum, but the stability in phosphate buffered saline (PBS) is highest for NIC and TPPTS > EDDA > ISONIC > tricine. The *in vivo* biodistribution shows highest abscess/muscle ratios for NIC and ISONIC (> 200) > EDDA and tricine (approximately 100) > TPPTS (< 40). Gamma camera imaging rapidly visualize abscess from 2 hours postinjection onward for all formulations. The abscess/background (A/B) at 6 hours postinjection for ISONIC is significantly higher ($p < 0.05$) than that of tricine and the A/B of TPPTS is significantly lower ($p < 0.05$). IL-8 can be rapidly and easily labeled with [^{99m}Tc] using HYNIC as a chelator group when applied in combination with various coligands. The most desirable infection-imaging characteristics can be realized with formulations using nicotinic acid/tricine as coligand system, which provides the features of high specific activity and high *in vitro* stability with high abscess/muscle ratios (> 200) and high abscess/background ratios (> 20). Protein doses administered are as low as 70 ng/kg body weight so side effects are not to be expected in the human system. This paves the way for infection-imaging studies in patients.

Instrumentation: Gamma camera imaging.

Effects of coligand variation on the *in vivo* characteristics of [^{99m}Tc]-labeled interleukin-8 in detection of infection. Rennen HJ, van Eerd JE, Oyen WJ, Corstens FH, Edwards DS, Boerman OC. Bioconjug Chem 2002 Mar–Apr; 13 (2), pp. 370–7.

Sepsis Abscess Formation/ Bacterial (*Escherichia Coli*)-Induced Abscesses/ Comparison of Radioiodination Methods/ Plasma Kinetic Profiles: $T_{1/2}$
[^{123}I]-Interleukin-8 (IL-8)

Background Information: Several small receptor-binding agents have been tested for imaging foci infection and inflammation. The potential of chemotactic peptides and of interleukins is promising and superior to that of conventional agents.

Application: Detect and characterize conditions of septic and non-septic inflammation.

Route of Administration: [^{123}I]-IL-8 (intravenous).

Dosage: [^{123}I]-IL-8 (18.5 MBq).

Semi-Synthetic Methods: Radiolabeling of biological protein fractions with radioiodine ([^{123}I], [^{124}I], [^{125}I], [^{127}I]) facilitated by the use of Bolton-Hunter reagent.

Implementation: Evaluate the potential of IL-8 to image infection (septic lesions). Similar to other biological protein fractions, IL-8 can be radiolabeled by several techniques, including the use of

[^{123}I] in concert with Bolton-Hunter reagent. Imaging of septic abscesses can be performed 24 hours postinduction with [^{123}I]-IL-8 preparations. Gamma camera images are obtained at 5 minutes and at 1, 4, and 8 hours after injection. Biodistribution is determined 8 hours after injection. Gamma camera imaging is then performed at 5 minutes and at 1, 4, and 8 hours postinjection with biodistribution profiles established at 8 hours postinjection.

Animal Model: Rabbits (*E. coli*-induced abscesses in the left thigh muscle).

Interpretation and Analysis: Radioiodinated [^{123}I]-IL-8 is rapidly cleared from the blood. Accumulation of [^{123}I]-IL-8 in abscesses is visible as early as 1 hour postinjection. The highest abscess uptake is obtained 4 hours after injection (2.6 ± percent injected dose [%ID]), whereas [^{123}I]-IL-8 rapidly clears from all other tissues. Approximate increases in abscess-to-background ratios are 13.0 ± 0.7 (8 hours postinjection), as determined by quantification of images. In tissue biodistribution evaluations (8 hours postinjection), abscess uptake is 0.057 ± 0.011 %ID/g with abscess-to-contralateral muscle ratios of 114.7 ± 23.0. The radioiodination method clearly affects the *in vivo* biodistribution of IL-8 because IL-8 iodinated using the Iodo-Gen method clears significantly slower from the blood and most other organs, resulting in poor visualization of the abscess. The superior characteristics of radioiodinated IL-8 using the Bolton-Hunter method include high abscess uptake and rapid background clearance within a few hours. These features make IL-8 a promising agent for imaging infection and inflammation.

Radiolabeled interleukin-8: Specific scintigraphic detection of infection within a few hours. van der Laken CJ, Boerman OC, Oyen WJ, van de Ven MT, van der Meer JW, Corstens FH. J Nucl Med 2000 Mar; 41 (3), pp. 463–9.

Abscess Formation: Septic Inflammatory Disease
[^{111}Indium] ([^{111}In])-DPC11870-11/ Leukotriene B_4 (LTB_4) Receptor-Binding Ligands

Cellular/Molecular Mechanism of Action: The agent DPC11870-11 is an antagonist of LTB_4 at its respective receptor complex.

Background Information: Several radiolabeled chemotactic peptides have been tested for their suitability to detect regions or foci of infection and inflammation. Leukotriene B_4 receptor-binding ligands can be useful agents for revealing neutrophil infiltrations because the LTB_4 receptor is abundantly expressed on neutrophils after an inflammatory stimulus.

Route of Administration: [^{111}In]-DPC11870-11 (intravenous).

Implementation: Evaluate the *in vivo* and *in vitro* characteristics of a hydrophilic [^{111}In]-labeled LTB_4 antagonist for detecting septic foci applying scintigraphic imaging techniques. The LTB_4 antagonist DPC11870-11 can be radiolabeled with [^{111}In] to produce an imaging agent for detecting infection and inflammation. Complementary investigations can entail the delineation of the pharmacokinetics and biodistribution of [^{111}In]-DPC11870-11 aided by utilizing serial scintigraphic imaging (0–24 hours after injection) and by *ex vivo* counting of dissected tissue samples (6 and 24 hours after injection). Receptor-mediated *in vivo* localization of the radiobiopharmaceutical agent can also be more precisely determined following the administration of an excess of non-radioactive indium-labeled agent 2 minutes before the administration of the [^{111}In]-labeled LTB_4 antagonist.

Animal Model: Rabbit (n = 3 New Zealand White rabbits with *Escherichia coli* infection induced in the left thigh muscle).

Interpretation and Analysis: In rabbits with intramuscular *E. coli* infection, abscesses can be visualized as early as 2 hours after injection. Accumulation in the abscess increases with time, resulting in the acquisition of excellent images at 6 hours postinjection. Blood clearance is rapid in the initial hours after injection (alpha-half-life = 30 ± 6 minutes, 85%; beta-half-life = 25.7 ± 0.8 hours, 15%). Abscess-to-background ratios, as derived from the region-of-interest (ROI) analysis, increase to 34 ± 7 at 24 hours after injection. Images of both groups show moderate uptake in the liver, spleen, kidneys, and bone marrow. No activity can be appreciated in the bladder, indicating almost complete retention in the kidneys. Accumulation within the abscess can be blocked completely by the injection of an excess of non-radioactive agent, indicating a specific receptor-ligand interaction of the radiolabeled agent in infected/septic tissues. Biodistribution data show that after saturation of the LTB_4 receptor, the abscess uptake, in percent injected dose per gram, is significantly reduced (0.03 ± 0.02 vs 0.24 ± 0.06, $p = 0.008$). The modified LTB_4 antagonist identifies/detects infectious foci rapidly after injection because of specific receptor-ligand interactions. Due to high abscess-to-background ratios, and the fact that no accumulation of radioactivity is observed in the gastrointestinal tract, this compound has excellent characteristics for revealing infectious and inflammatory foci.

A bivalent leukotriene B_4 antagonist for scintigraphic imaging of infectious foci. van Eerd JE, Oyen WJ, Harris TD, Rennen HJ, Edwards DS, Liu S, Ellars CE, Corstens FH, Boerman OC. J Nucl Med 2003 Jul; 44 (7), pp. 1087–91.

Abscess Formation: Sepsis/Leukotriene B_4 (LTB_4) Receptor Complexes
[^{99m}Technetium] ([^{99m}Tc])-RP517

Cellular/Molecular Mechanism of Action: The agent [^{99m}Tc]-RP517 recognizes and physically binds to LTB_4 receptor complexes.

Background Information: In a search for a rapid and accurate imaging agent for scintigraphic detection of infection and inflammation, an LTB_4 receptor antagonist, [^{99m}Tcm]-RP517, has been developed that contains a hydrazino nicotinamide moiety.

Application: Systemic detection and characterization of septic foci, including organized abscesses.

Route of Administration: [^{99m}Tc]-RP517 (intravenous).

Implementation: Determination of the *in vivo* behavior of [^{99m}Tc]-RP517 and its capacity to detect created abscesses utilizing gamma camera imaging in addition to establishing the *ex vivo* biodistribution of the agent several hours postinjection. Complementary studies entail cannulation of the choledochal duct for quantitative monitoring of hepatobiliary radiopharmaceutical clearance.

Animal Model: Rabbit septic abscesses induced by intravenous injection of *Escherichia coli* bacteria.

Animal Model: Rabbit (choledochal duct cannulation).

Interpretation and Analysis: The receptor binding fraction of the radiolabeled RP517 exceeds 70%. Accumulation of [^{99m}Tc]-RP517 within abscesses can be visualized as early as 1 hour postinjection. Due to rapid blood clearance ($t_{1/2}$ alpha = 18 ± 0.6 minutes, $t_{1/2}$ beta = 6.5 ± 0.4 hours) and high abscess uptake, the abscess-to-muscle ratios increase with time from 7.0 ± 2.3 at 1 hour postinjection to 44.3 ± 4.6 at 20 hours postinjection. The agent is mainly cleared via the hepatobiliary route: 50% of the radiolabel can be recovered in the small bowel at 1 hour postinjection, whereas 85% can be found in the cecum and sigmoid at 20 hours postinjection. In conclusion, [^{99m}Tc]-RP517 can facilitate rapid visualization of *E. coli* abscesses in rabbits. The agent is rapidly cleared from the blood, mainly via the hepatobiliary route. High abscess-to-background target ratios are feasible, but accumulation within the intestines may limit the applicability of the agent for detecting infectious processes within the abdominal cavity. The development of a more hydrophilic

analogue of [^{99m}Tc]-RP517 could improve the clinical applicability of the imaging agent.

A [^{99m}Tc]-labeled leukotriene B_4 receptor antagonist for scintigraphic detection of infection in rabbits. Brouwers AH, Laverman P, Boerman OC, Oyen WJ, Barrett JA, Harris TD, Edwards DS, Corstens FH. Nucl Med Commun 2000 Nov; 21 (11), pp. 1043–50.

Abscess Formation/Septic (*Staphylococcus Aureus*) *[^{99m}Technetium] ([^{99m}Tc])-Biotin-PEG-Distearoylphosphatidylethanolamine Avidin*

Cellular/Molecular Mechanism of Action: Avidin binds with high affinity to biotin to form a complex. In this investigation, Avidin is applied (injected) separately to accelerate the clearance of biotinlyated liposomes from the intravascular compartment after a portion of the dose has accumulated within the septic target lesion.
Application: Detection and characterization of localized regions of septic inflammation (e.g., abscess).
Route of Administration: Intravascular.
Semi-Synthetic Methods: Biotinylated liposomes can be radiolabeled with [^{99m}Tc]-hydrazinonicotinamide.
Implementation: Evaluation of biotin coupled to PEG-distearoylphosphatidylethanolamine (DSPE) that is incorporated into PEG liposomes and then radiolabeled with [^{99m}Tc]-hydrazinonicotinamide. *In vitro* binding studies can be performed to determine the optimal biotin concentration in liposomes. In rats the biodistribution of [^{99m}Tc]-biotin-PEG liposomes is then compared with the biodistribution of normal (non-biotinylated) [^{99m}Tc]-PEG liposomes. Complementary *in vivo* investigations can be employed to assess both the effect of the biotin content and the optimal avidin dose for efficient clearance of liposomes. Liposomes containing 0.5 or 1.0 mol% biotin-PEG-DSPE are then compared *in vivo* for their ability to accumulate within septic foci. Avidin is subsequently injected 4 hours after injection of liposomes.

Animal Model: Rats (septic foci created by injection of *S. aureus* into the left calf musculature). Avidin is then injected 4 hours after injection of liposome preparations.
Interpretation and Analysis: Biotinylation of the liposomes does not affect their *in vivo* behavior. All biotin-PEG liposome formulations show good *in vitro* avidin binding with 50% inhibitory concentrations ranging from 36 to 8 μmol/L. With avidin doses higher than 100 μg, both preparations are rapidly cleared from the circulation. As a result, abscess-to-blood ratios increase 5-fold. In an *in vivo* environment, avidin promotes clearance of radiolabeled PEG liposomes and improves the detection of subcutaneous *S. aureus* abscesses applying [^{99m}Tc]-biotin-PEG liposomes as an imaging agent. The infection can best be visualized only after injection of 100 μg avidin. Therefore, biotin-coated [^{99m}Tc]-PEG liposomes in combination with the injection of avidin can lead to improved imaging of infection or non-septic inflammation, especially when localized in regions with high blood-pool activity.

Improved imaging of infections by avidin-induced clearance of [^{99m}Tc]-biotin-PEG liposomes. Laverman P, Zalipsky S, Oyen WJ, Dams ET, Storm G, Mullah N, Corstens FH, Boerman OC. J Nucl Med 2000 May; 41 (5), pp. 912–8.

Abscess Formation: Septic/Targeting Method Optimization *Anti–Diethylenetriamine Pentaacetic Acid (DTPA) Antibody/[In]-DTPA-Bovine Serum Albumin/ [^{111}Indium] ([^{111}In])-DTPA (Bivalent)/ [3-Phase Injection Scheme]*

Application: A 3-step approach to imaging infectious and inflammatory foci has been developed and optimized. The approach relies on the non-specific localization of an anti-DTPA antibody in inflamed tissue.
Route of Administration: Anti-DTPA antibody, [In]-DTPA-bovine serum albumin, and [^{111}In]-diDTPA (intravenous).
Semi-Synthetic Methods: An N2S2 core is attached to the diDTPA compound, thereby allowing [^{99m}Tc] radiolabeling.
Implementation: Evaluation of a 3-step strategy involving the selection of the most suitable radiolabeled hapten in combination with tuning an optimal dosing schedule to achieve maximal targeting of focal septic inflammatory lesions. In this context, initial "priming" with the anti-DTPA antibody DTIn-1 (0.67, 2, or 6 nmol per rat) is performed. In the 2nd phase (1–24 hours later), the anti-DTPA activity within the intravascular department is blocked with unlabeled In-DTPA-bovine serum albumin (0.3, 1, or 3 nmol per rat). In the 3rd step (5–30 minutes later), the radiolabeled hapten (monovalent or bivalent [^{111}In]-DTPA) is administered. The *in vivo* distribution of the radiolabel is monitored by scintigraphic imaging and by *ex vivo* counting of dissected tissues.

Animal Model: Rat (Wistar strain) injected with *Staphylococcus aureus* in the left calf muscle.
Interpretation and Analysis: Scatchard analysis reveals that the affinity of DTIn-1 for bivalent [^{111}In]-diDTPA is 6 times higher than the affinity for monovalent [^{111}In]-DTPA ($K_a = 0.87 \times 10^{-9}$ mol/L vs 5.3×10^{-9} mol/L). The uptake of the bivalent chelate within abscesses is 2.5-fold higher than that for monovalent [^{111}In]-DTPA. Most important, the bivalent chelate is completely retained in the abscess over time. Using the bivalent chelate, the optimal dosing scheme can be determined with respect to the DTIn-1 dose (2 nmol per rat), the blocking agent dose (1 nmol per rat), and radiolabeled chelate dose (40 pmol per rat). The procedure is rapid; the infectious focus is clearly visualized at 1 hour postinjection of the [^{111}In]-labeled diDTPA (Note: 5 hours after administration of the anti-DTPA antibody). The non-targeted radiolabel is rapidly cleared into the urine and is only retained within abscess and the kidney (4–6% of injected dose). The 3-step diagnostic protocol enables rapid imaging of infectious foci with minimal uptake in non-inflamed tissues.

A 3-step pretargeting strategy to image infection. Boerman OC, van Eerd J, Oyen WJ, Corstens FH. J Nucl Med 2001 Sep; 42 (9), pp. 1405–11.

Colitis/Chemically Induced (Acute) *[^{99m}Technetium] ([^{99m}Tc])-HYNIC-Interleukin-8 (IL-8)/ [^{99m}Tc]-Granulocytes*

Cellular/Molecular Mechanism of Action: Interleukin-8 binds to its corresponding membrane-associated receptor complex expressed at relatively high densities by neutrophil and monocyte cell types. Granulocytes are chemotactically attracted to sites of septic and non-septic inflammation.
Physiological Mechanism of Action: Interleukin-8 can function as a chemotactic agent for granulocyte populations.
Implementation: Evaluation of acute colitis conditions facilitated by scintigraphic image analysis with [^{99m}Tc]-HYNIC-IL-8 and [^{99m}Tc]-granulocytes (purified cell populations). Gamma camera images are acquired at 2 minutes and at 1, 2, and 4 hours postinjection. At 4 hours after injection, the uptake of the radiolabel within specific tissues and organs can be determined (postmortem analysis). The dissected colon can be imaged and the inflammatory lesions scored macroscopically. For each affected colon segment, the colitis index (affected colon-to-normal colon uptake ratio, CI) is calculated and correlated with the macroscopically scored severity of inflammation.

Animal Model: Rabbit (chemically induced acute colitis).
Interpretation and Analysis: Both agents can facilitate visualization of colitis conditions within 1 hour after injection. [^{99m}Tc]-HYNIC-IL-8 images of colonic abnormalities are more accurate and

the intensity of uptake in regions of affected colon continuously increase up to 4 hours after injection, whereas no further increase 1 hour after injection is noticed scintigraphically with [^{99m}Tc]-HMPAO-granulocytes. Absolute uptake within affected colon is much higher for IL-8 than for radiolabeled granulocytes with the percentage of injected dose per gram (%ID/g) equal to 0.41 ± 0.04 %ID/g and 0.09 ± 0.054 %ID/g/hr after injection, respectively. With increasing severity, the CI at 4 hours after injection for [^{99m}Tc]-HYNIC-IL-8 is approximately 4.4 ± 0.6, 13.5 ± 0.5, and 25.8 ± 1.0; for granulocytes, the CI 4 hours after injection is 1.5 ± 0.1, 3.4 ± 0.2, and 6.4 ± 0.5, respectively. Values for CI correlate with the severity of tissue inflammation ($r = 0.95$, $p < 0.0001$ for IL-8; $r = 0.95$, $p < 0.0001$ for granulocytes). Therefore, within 1 hour after injection, visualization of the extent of colonic inflammation *in vivo* is possible with [^{99m}Tc]-HYNIC-IL-8 and [^{99m}Tc]-HMPAO-granulocytes. Within 2 hours after injection, [^{99m}Tc]-IL-8 allows a good evaluation, and within 4 hours after injection, a meticulous evaluation of the severity of inflammatory bowel disease (IBD) is possible. Although [^{99m}Tc]-HMPAO-granulocytes are able to delineate the extent of IBD within 2 hours after injection, an accurate estimation of the severity of inflammation is not possible. [^{99m}Tc]-HYNIC-IL-8 is an inflammation-imaging agent that has demonstrated promising results. [^{99m}Tc]-IL-8 can be prepared off-the-shelf and yields excellent imaging with high target-to-background ratios.

Instrumentation: Gamma camera imaging capabilities.

Rapid imaging of experimental colitis with [^{99m}Tc]-interleukin-8 in rabbits. Gratz S, Rennen HJ, Boerman OC, Oyen WJ, Corstens FH. J Nucl Med 2001 Jun; 42 (6), pp. 917–23.

Colitis/Inflammatory Bowel Disease (IBD) *[^{99m}Technetium] ([^{99m}Tc])-Liposome*

Cellular/Molecular Mechanism of Action: Liposomes have a marked tendency to accumulate in inflamed colon in an animal model of experimental colitis (rats).

Application: Selective accumulation of diagnostic agents or therapeutic pharmaceuticals within inflamed structures of the colon.

Considerations: Therapeutic intervention in IBDs is often associated with severe toxicity related to the non-specific and ubiquitous interaction of drugs with organs and tissues. In order to prevent side effects from aggressive and prolonged treatment with glucocorticoids and immunosuppressive agents, preferential accumulation of these potent drugs in diseased tissue is desired.

Implementation: Evaluation of the disposition of [^{99m}Tc]-liposomes monitored by gamma camera imaging and determination of the biodistribution of radioactivity in various organs.

Animal Model: Rat.

Interpretation and Analysis: Images reveal distinct accumulation of radioactivity in the colon within reagions of colitis, while the abdomen of normal rats is conspicuously free of any visible radioactivity. Although images acquired 4 hours after [^{99m}Tc]-liposome injection are clear enough for diagnostic purposes, the real potential of liposomes for drug delivery is evident in 24-hour images, where the major organs of liposome accumulation are dwarfed by intense colon activity in animals with colitis. On necropsy, 13.5% ± 5.48 of the activity is within the inflamed colon compared to only 0.1% in the normal colon, yeilding a 135:1 target-to-non-target ratio. Blood-borne radioactivity is 9% ± 2.12 (colitis) and 25.7% ± 4.27 (normal), indicating that the decrease in circulating liposomes is associated with an increase in liposome accumulation in the inflammatory site. The other 2 major organs that accumulate liposomes are the spleen (10.7% normal vs 11% colitis) and liver (8% normal vs 10.1% colitis). Liposomes therefore have an innate propensity to accumulate in sites of inflammation and they also have the potential of being loaded with therapeutic drugs or diagnostic agents for targeted delivery in colitis conditions.

Endothelial Inflammation (Acute)/ Bleomycin-Induced: Pulmonary Injury *[^{111}Indium] ([^{111}In])-Anti-ICAM-1 Monoclonal Antibody (MAb)*

Cellular/Molecular Mechanism of Action: The antibody component of [^{111}In]-anti-ICAM-1 monoclonal IgG antibody recognizes and physically binds to intracellular adhesion molecule-1 expressed on the exterior surface membrane of "activated" endothelial cells.

Application: Detection of endothelial injury and acute vascular inflammatory responses, including bleomycin-induced pulmonary injury.

Route of Administration: [^{111}In]-Anti-ICAM-1 monoclonal IgG antibody (intravenous).

Implementation: Evaluation of alterations in endothelial intracellular adhesion molecule expression following bleomycin-induced pulmonary injury employing [^{111}In]-anti-ICAM-1 monoclonal IgG antibody (^{111}In*αICAM-1) compared to [^{111}In]-labeled normal mouse IgG (^{111}In*nmIgG). Tissue samples are harvested 24 hours following image acquisition and their radioactivity measured. Lung tissue can be cryostat-sectioned to detect the presence of ICAM-1 by immunofluorescence, and the upregulation of LFA-1α identified in blood polymorphonuclear leukocytes (PMNs) using fluorescence-activated cell-sorter (FACS) analysis.

Animal Model: Rat (lung injury induced by intratracheal bleomycin injection 4 or 24 hours before humane sacrifice).

Interpretation and Analysis: The percent injected dose/organ of [^{111}In]-anti-ICAM-1 monoclonal IgG antibody in lungs both at 4 and 24 hours postbleomycin increases significantly with the application of [^{111}In]-anti-ICAM-1 monoclonal IgG antibody, in contrast to values in either uninjured control states or the administration of [^{111}In]*nmIgG. At 4 and 24 hours postinjury, the target-to-blood (T/B) ratio is 8/1 and 6/1, respectively. For [^{111}In]*nmIgG, the T/B ratio at 4 hours is 0.5/1 and 0.4/1 at 24 hours. [^{111}In]-anti-ICAM-1 monoclonal IgG antibody preparations administered postbleomycin-induced pulmonary injury produce 4- and 24-hour images that can easily be distinguished from uninjured reference controls. All images with [^{111}In]*nmIgG show only cardiac blood-pool and liver activity with little lung activity. Lung ICAM-1 immunofluorescence intensity increases in the bleomycin-treated pulmonary samples, compared to uninjured lungs. Expression of LFA-1α on PMNs increases 19% and 210% at 4 hours and 24 hours postinjury, respectively, compared to control values. Biodistribution and imaging data therefore are capable of demonstrating that [^{111}In]-anti-ICAM-1 monoclonal IgG antibody is capable of detecting early acute bleomycin-induced lung injury. Immunofluorescence and FACS data suggest that [^{111}In]-anti-ICAM-1 monoclonal IgG antibody uptake is a specific process. Monoclonal antibody preparations possessing such attributes has potential as an early radionuclide detector of acute inflammations.

Early detection of bleomycin-induced lung injury in rat using indium-111-labeled antibody directed against intercellular adhesion molecule-1. Weiner RE, Sasso DE, Gionfriddo MA, Syrbu SI, Smilowitz HM, Vento J, Thrall RS. J Nucl Med 1998 Apr; 39 (4), pp. 723–8.

Gastrointestinal Inflammation/Intestinal Lesions: Non-Steroidal Anti-Inflammatory Drug (NSAID)-Associated/Intestinal Lesions: Crohn's Ileitis *[^{111}Indium] ([^{111}In]) Leukocytes/Tauro 23 [^{75}Se]-Selena-25-Homocholic Acid/[^{58}Co]-Labeled Cyanocobalamine*

Cellular/Molecular Mechanism of Action: The agent tauro 23 [^{75}Se]-selena-25-homocholic acid is a bile acid analog, while

[^{58}Co]-labeled cyanocobalamine is an analogue of vitamin B_{12}. Radiolabeled [^{111}In] leukocytes behave *in vivo* in a manner highly analogous to normal endogenous leukocytes of the same cell type.

Application: The agents tauro 23 [^{75}Se]-selena-25-homocholic acid and [^{58}Co]-labeled cyanocobalamine can be applied to evaluate intestinal absorption. Conversely, [^{111}In] leukocytes can be used to detect foci of inflammation and sepsis.

Route of Administration: Intravenous.

Implementation: Evaluation of residual inflammatory lesions following discontinuation of NSAIDS using [^{111}In] leukocyte scintigraphy imaging methodologies.

Human Model #1: Cases of rheumatoid arthritis (n = 90) and osteoarthritis (n = 7).

Human Model #2: Cases treated with NSAIDs (n = 19); healthy controls (n = 20); and Crohn's ileitis (n = 13).

Interpretation and Analysis: [^{111}In] leukocyte facilitated scintigraphic imaging techniques reveal that cases of rheumatoid arthritis and osteoarthritis that have been treated with NSAIDs display gastrointestinal lesions. More specifically, approximately two-thirds of all cases evaluated on long-term treatment display inflammatory lesions that may persist for up to 16 months following discontinuation. The prevalence and magnitude of the intestinal inflammation is unrelated to the type and dose of non-steroidal drugs and previous or concomitant 2nd-line drug treatment. There is a significant inverse correlation ($r = -0.29$, $p < 0.05$) between fecal [^{111}In] excretion and hemoglobin levels in cases treated with NSAIDs. The kinetics of fecal [^{111}In] excretion in cases treated with NSAIDs is almost identical to that of cases with small bowel Crohn's disease. Small bowel radiological examination of cases on NSAIDs reveals that approximately one-sixth have asymptomatic ileal disease with ulceration and strictures (e.g., n = 3/18 cases). Evaluation of cases being treated with anti-inflammatory agents, normal healthy controls, and cases of Crohn's ileitis with tauro 23 [^{75}Se]-selena-25-homocholic acid and [^{58}Co]-labeled cyanocobalamine reveals several abnormalities. On day 4, more than half the cases with rheumatoid arthritis have evidence of bile acid malabsorption, but ileal dysfunction is much milder than seen in patients with Crohn's ileitis.

Non-steroidal anti-inflammatory drug–induced intestinal inflammation in humans. Bjarnason I, Zanelli G, Smith T, Prouse P, Williams P, Smethurst P, Delacey G, Gumpel MJ, Levi AJ. Gastroenterology 1987 Sep; 93 (3), pp. 480–9.

Gastrointestinal Septic Inflammation/Appendicitis *[^{99m}Technetium] ([^{99m}Tc])-Labeled Anti-CD15 IgM Immunoglobulin*

Cellular/Molecular Mechanism of Action: Anti-CD15 immunoglobulin M monoclonal antibody (MAb) recognizes and binds to CD15 complexes expressed on the exterior surface membrane of polymorphonuclear neutrophils. The difference between IgG and IgM immunoglobulin is that IgM is the principal immunoglobulin produced after the 1st exposure to a given antigen, while IgG is the principal immunoglobulin produced after a 2nd exposure to the same antigen. IgM is composed of a pentomer of IgG-like molecules and generally has less specific antigen-binding properties than does IgG, but IgM has a higher propensity to generate multimolecular antigen/antibody complexes.

Application: Detection and monitoring of septic foci and lesions.

Route of Administration: Anti-CD15 immunoglobulin M MAb (LeuTech: intravenous).

Dosage: Anti-CD15 immunoglobulin M MAb (LeuTech: 10–20 mCi of [^{99m}Tc]).

Semi-Synthetic Methods: Preparations of anti-CD15 immunoglobulin M MAb (e.g., LeuTech) avidly bind to circulating and sequestered human polymorphonuclear neutrophils *in vivo,* eliminating the need for *in vitro* cell labeling and the risks of blood handling.

Implementation: Evaluation of the safety and efficacy of anti-CD15 immunoglobulin M MAb (LeuTech) imaging in cases of suspected acute appendicitis. An effective procedure includes the acquisition of serial dynamic and static planar images for up to 3 hours after intravenous administration. Scans are read as positive or negative for acute appendicitis or the presence of other intra-abdominal infection (septic lesions). The institutional diagnosis is validated by surgery and histopathology of the appendix, results of other diagnostic studies, or 2-week clinical follow-up. Scans are positive for appendicitis in 39 of 40 patients with appendicitis at surgery (sensitivity 98%) and negative for appendicitis in 49 of 58 patients without appendicitis (specificity 84%). Accuracy, positive predictive value, and negative predictive value are 90, 81, and 98%, respectively. In patients with appendicitis and positive scans more than 50% of the images are positive at 4 minutes, and all are positive by 1 hour. Mean time of 1st positive image is 15 minutes. There are usually no serious adverse reactions. Imaging with LeuTech is a highly sensitive test for the detection of appendicitis in equivocal cases. There are advantages of this agent over the other currently used radiotracers in terms of convenience and time to diagnosis, particularly with respect to the rapidity with which acute appendicitis will be seen on the images.

Human Model: Cases presenting with equivocal clinical signs (e.g., n = 99).

Interpretation and Analysis: Scans are usually positive in a very high percentage of cases of suspected appendicitis with validation of the condition confirmed at surgery (e.g., n = 39/40; sensitivity 98%). Conversely, images are negative for appendicitis in a large percentage of suspect cases that do not have appendicitis (e.g., n = 49/58, specificity = 84%). Accuracy, positive predictive, and negative predictive values are approximately 90, 81, and 98%, respectively. In conditions with appendicitis and positive scans more than 50% of the images are positive at 4 minutes, and essentially all images are positive by 1 hour. Mean time of 1st positive image is about 15 minutes. Serious adverse reactions are generally rare. Imaging with anti-CD15 immunoglobulin M MAb (LeuTech) is considered a highly sensitive diagnostic agent for detecting appendicitis in equivocal cases. Advantages of this agent over the other currently used radiotracers include greater convenience and shorter time to diagnosis, particularly with regard to the expedient nature that acute appendicitis can be visualized on scintigraphic images.

Scintigraphic determination of equivocal appendicitis. Rypins EB, Kipper SL. Am Surg 2000 Sep; 66 (9), pp. 891–5.

Musculoskeletal/Osteomyelitis (Septic)/ Vascular Permeability *[^{99m}Techetium] ([^{99m}Tc])-Sulesomab/[^{99m}Tc]-Labeled Human Serum Albumin ([^{99m}Tc]-HSA)*

Cellular/Molecular Mechanism of Action: [^{99m}Tc]-sulesomab and [^{99m}Tc]-HSA have similar molecular weights (molecular mass). Human serum albumin within the intravascular compartment is primarily responsible for maintaining plasma oncotic pressure. However, when it is labeled and applied for diagnostic purposes, it per se does not exert any true biological/molecular mechanism of action.

Background Information: [^{99m}Tc]-sulesomab (Fab fragment of anti-NCA-90) is used as an *in vivo* granulocyte labeling agent for imaging foci of inflammation. It is not clear to what extent it targets cells that have already migrated into the interstitial space of an

inflammatory lesion, as opposed to circulating cells. The contribution to image signals from radioprotein diffusion in settings of increased vascular permeability has not been thoroughly documented.

Application: Detection and characterization of septic osteomyelitis conditions.

Route of Administration: [^{99m}Tc]-sulesomab and [^{99m}Tc]-HSA (intravascular).

Implementation: Evaluation of orthopedic infections (e.g., septic osteomyelitis) utilizing [^{99m}Tc]-sulesomab and [^{99m}Tc]-HSA as a function of their local kinetic profiles. [^{99m}Tc]-sulesomab and [^{99m}Tc]-HSA are administered in sequence separated by an interval of 2 to 6 days. Images are obtained 1, 3, 4, and 6 hours after injection, and multiple venous blood samples obtained for the calculation of blood clearance parameters. Patlak-Rutland (P-R) analysis is performed to measure lesion and control tissue protein clearance. Target-to-background tissue (T/Bkg) ratios are calculated for each radioprotein and compared with the T/Bkg ratio for [^{111}In] leukocytes. [^{99m}Tc]-Sulesomab binding to granulocytes can be measured *in vivo*, in *ex vivo* preparations, and *in vitro* to primed and activated granulocytes.

Human Model: Cases of septic osteomyelitis (n = 7) already previously detected as being clearly positive on [^{111}In] leukocyte scintigraphy analysis.

Interpretation and Analysis: After intravenous injection, $< 5\%$ of the circulating radioactivity is cell-bound with both radioproteins so that the P-R curves can therefore be assumed to represent extravascular uptake of free protein. The blood clearance (mean $\pm$ standard deviation) of sulesomab is 23.4 $\pm$ 11.7 mL/min, which is approximately 5 times greater than that of HSA (4.8 $\pm$ 3.1 mL/min). Similarly, clearance into the lesion by sulesomab is consistently higher than for HSA (on average about 3 times as high). Nevertheless, the T/Bkg ratios for sulesomab and HSA are similar, except at 6 hours when that of HSA (2.14 $\pm$ 0.6) is higher than that for sulesomab (1.93 $\pm$ 0.5; p approximately 0.01). Both values are considerably less than the T/Bkg ratio on the [^{111}In] leukocyte images, which, at 22 hours, is 12.3 $\pm$ 5.3. Moderate clearance of sulesomab, but not HSA, occurs in control tissue regions. Granulocytes bind significantly more [^{99m}Tc]-sulesomab *in vitro* when primed or activated. In conclusion, (i) sulesomab does not localize in inflammation as a result of binding to circulating granulocytes; (ii) sulesomab "diffuses" into sites of inflammation non-specifically as a function of increased vascular permeability; nevertheless, it may be cleared after local binding to primed granulocytes or bind to activated, migrated extravascular granulocytes; and (iii) HSA produces a similar or higher T/Bkg ratio than sulesomab because sulesomab is cleared into normal tissues and because image positivity in inflammation is significantly dependent on local blood-pool expansion.

Mechanism of accumulation of [^{99m}Tc]-sulesomab in inflammation. Skehan SJ, White JF, Evans JW, Parry-Jones DR, Solanki CK, Ballinger JR, Chilvers ER, Peters AM. J Nucl Med 2003 Jan; 44 (1), pp. 11–8.

Musculoskeletal/Osteomyelitis: Septic Inflammatory Response/[Diabetes Mellitus] *[^{131}I]-Interleukin-8 (IL-8) (Recombinant)/ [^{99m}Technetium] ([^{99m}Tc])-Hydroxyethylene Diphosphonate*

Cellular/Molecular Mechanism of Action: Neutrophils perceive IL-8 as a chemotactic factor and express membrane-associated IL-8 receptor complexes.

Background Information: The chemotactic cytokine IL-8 plays an important role in the attraction (chemotactic migration) and activation of polymorphonuclear leukocytes in conditions of septic (infection) and non-septic inflammation.

Application: Detection and characterization of septic inflammatory disease states. In this context, [^{131}I]-rhIL-8 accumulates rapidly within infected foci in osteomyelitis and cellulites.

Route of Administration: [^{131}I]-rhIL-8 (intravenous).

Semi-Synthetic Methods: Radioiodination of human recombinant IL-8 (rhIL-8) with [^{131}I] (specific activity, 0.4–0.7 MBq at 11–18 μCi [^{131}I]/μg IL-8).

Implementation: Evaluation of septic disease states applying [^{131}I]-rhIL-8 as an imaging agent.

Human Model: Cases of diabetes mellitus (n = 8 active foot infections with evidence of osteomyelitis; n = 2 successfully-treated osteomyelitis; n = 1 cellulitis of the thumb).

Interpretation and Analysis: Focal accumulation of [^{131}I]-rhIL-8 can be seen in a high percentage of cases with active foot infection (e.g., n = 8/8). In other affected appendages, the image profile may appear diffuse (e.g., n = 1/1 thumb cellulitis). In cases successfully treated for osteomyelitis, multiphase [^{99m}Tc]-hydroxyethylene diphosphonate bone scans may be negative early, but late-phase (> 3 hours) uptake can detect degenerative lesions that are not initially detected by imaging with [^{131}I]-rhIL-8 (e.g., n = 2/2 cases). [^{131}I]-rhIL-8 accumulates rapidly within infected foci of osteomyelitis conditions and cellulitis but not in successfully treated infections or degenerative joint disease.

Imaging of human infection with [^{131}I]-labeled recombinant human interleukin-8. Gross MD, Shapiro B, Fig LM, Steventon R, Skinner RW, Hay RV. J Nucl Med 2001 Nov; 42 (11), pp. 1656–9.

Bone/Osteomyelitis Septic Inflammatory Responses/*Staphylococcus Aureus*–Induced *[^{99m}Technetium] ([^{99m}Tc])-PEG Liposomes/ [^{99m}Tc]-HYNIC-IgG/[^{99m}Tc]-MDP/[^{111}Indium] ([^{111}In])-Granulocytes/Gallium-67 ([^{67}Ga])-Citrate*

Background Information: Assessment of disease activity and disease extent in chronic osteomyelitis remains a difficult diagnostic problem. Radiography is not particularly sensitive. Scintigraphic techniques can be more helpful, but routinely available agents lack specificity (e.g., [^{99m}Tc]-methylene diphosphonate (MDP), [^{67}Ga]-citrate) or are laborious to prepare (e.g., [^{111}In] leukocytes).

Route of Administration: [^{99m}Tc]-PEG liposomes (intravenous); [^{99m}Tc]-HYNIC-IgG (intravenous); [^{99m}Tc]-MDP (intravenous); [^{111}In]-granulocytes (intravenous); or [^{67}Ga]-citrate (intravenous).

Dosage: [^{99m}Tc]-PEG liposomes (37 MBq rabbit); [^{99m}Tc]-HYNIC-IgG (37 MBq rabbit); [^{99m}Tc]-MDP (37 MBq rabbit); [^{111}In]-granulocytes (18 MBq rabbit); or [^{67}Ga]-citrate (18 MBq rabbit).

Implementation: Scintigraphic image analysis of osteomyelitis lesions of the femur is performed 4 weeks after bacterial infusion applying [^{99m}Tc]-PEG liposomes, [^{99m}Tc]-HYNIC-IgG, and [^{99m}Tc]-MDP on 3 consecutive days and imaged up to 4 hours (MDP) or 22 hours (liposomes and IgG) postinjection. On day 4, preparations of [^{111}In]-granulocytes or [^{67}Ga]-citrate are injected and imaged up to 44 hours after injection. Uptake in the septic femur is determined by drawing regions-of-interest (ROIs). Ratios of infected-to-sham-operated femur are calculated. After the last image, rabbits are killed, and the left and right femur scored for microbiologic and histopathologic evidence of osteomyelitis.

Animal Model: Chronic osteomyelitis is induced by infusing *S. aureus* organisms into the right reamed and washed femoral canal (rabbits). The canal is then closed with cement and a sham operation performed on the left femur. Routine radiographs are obtained immediately after surgery and before scintigraphy.

Interpretation and Analysis: [^{99m}Tc]-PEG liposomes and [^{99m}Tc]-HYNIC-IgG can correctly identify lesions of osteomyelitis in a high percentage of cases (e.g., n = 6/6). In a small percentage of cases, [^{111}In]-granulocytes and [^{67}Ga]-citrate can produce equivocal results (e.g., 15% or n = 1/6), and [^{99m}Tc]-MDP may not detect osteomyelitis lesions (e.g., 15% or n = 1/6). The uptake in the affected region does not differ significantly between the imaging agents, although [^{99m}Tc]-MDP tends to have higher values (MDP, 4.75 ± 1.23 percent injected dose per gram [%ID/g]; [^{67}Ga], 2.05 ± 0.54 %ID/g; granulocytes, 1.56 ± 0.83 %ID/g; liposomes, 1.75 ± 0.76 %ID/g; and IgG, 1.96 ± 0.27 %ID/g). The ratios of infected-to-normal femur are also not significantly different for the respective radiopharmaceuticals. Radiography visualizes only severe osteomyelitis conditions. [^{99m}Tc]-PEG liposomes and [^{99m}Tc]-HYNIC-IgG perform at least as well as [^{111}In]-granulocytes and [^{67}Ga]-citrate in the localization of chronic osteomyelitis (e.g., rabbits). The ease of preparation, the better image quality, and the lower radiation dose suggest that [^{99m}Tc]-PEG liposomes and [^{99m}Tc]-HYNIC-IgG might be suitable alternatives for [^{67}Ga]-citrate and [^{111}In]-granulocytes in the scintigraphic evaluation of osteomyelitis.

Scintigraphic evaluation of experimental chronic osteomyelitis. Dams ET, Nijhof MW, Boerman OC, Laverman P, Storm G, Buma P, Lemmens JA, van der Meer JW, Corstens FH, Oyen WJ. J Nucl Med 2000 May; 41 (5), pp. 896–902.

Bone/Osteomyelitis Septic Inflammatory Responses/*Staphylococcus Aureus*–Induced *Gallium-67 ([^{67}Ga])-Citrate/ [^{99m}Technetium] ([^{99m}Tc])-Methylene Diphosphonate (MDP)/[^{99m}Tc]-Interleukin-8 (IL-8)*

Cellular/Molecular Mechanism of Action: [^{99m}Tc]-MDP is believed to be assimilated by active osteoblasts/osteoclasts at sites of dynamic bone growth and destruction.

Background Information: Early and accurate diagnosis of osteomyelitis remains a clinical problem. Acute osteomyelitis often occurs in infants and most often is located in the long bones. Radiologic images show changes only in the advanced stages of disease. Scintigraphic imaging with [^{99m}Tc]-MDP or bone scanning is much more sensitive in detecting acute osteomyelitis but lacks specificity.

Application: Detection and characterization of septic osteomyelitis lesions.

Route of Administration: [^{99m}Tc]-MDP (intravenous), [^{99m}Tc]-IL-8 (intravenous).

Dosage: [^{99m}Tc]-MDP (18.5 MBq), [^{99m}Tc]-IL-8 (18.5 MBq).

Implementation: Scintigraphic characterization of osteomyelitis lesions 10 days following lesion induction (e.g., n = 10 rabbits; n = 5/group) utilizing injections of either 18.5 MBq [^{111}In]-granulocytes or 18.5 MBq [^{67}Ga]-citrate. Images are performed both 24 hours and 48 hours postinjection. On day 12, serial images are acquired at 0, 1, 2, 4, 8, 12, and 24 hours after injection of either 18.5 MBq [^{99m}Tc]-MDP or 18.5 MBq [^{99m}Tc]-IL-8 preparations. Uptake in the infected femur is determined by establishing regions-of-interest (ROIs). Ratios of infected femur (target) to sham-operated femur (background) (T/Bs) are then calculated. After the final images are obtained, the right femur is harvested at postmortem to facilitate dissection and analysis of tissue samples for microbiological and histopathological evidence of osteomyelitis.

Animal Model: Acute pyogenic osteomyelitis can be induced in rabbits (e.g., n = 10) by inserting sodium morrhuate and *S. aureus* into the medullary cavity of the right femur. The cavity is then closed with liquid cement. A sham operation is performed on the left femur. Routine radiographs are obtained just before scintigraphy imaging. Acute osteomyelitis develops in a high percentage of rabbits (e.g., n = 8/10).

Interpretation and Analysis: All imaging agents can correctly detect acute osteomyelitis in a very high percentage of cases (e.g., n = 8/8). The extent of infection can be optimally visualized with [^{67}Ga]-citrate and by delayed bone scanning, whereas diaphyseal photopenia is noted with both [^{99m}Tc]-IL-8 and [^{111}In]-granulocytes. Some false-negative (e.g., n = 1/8) and false-positive (e.g., n = 1/8) image results can be observed with [^{111}In]-granulocytes and [^{99m}Tc]-MDP, respectively. Quantitative analysis of the images reveals that the uptake in the infected region is highest with [^{67}Ga]-citrate (4.9 ± 0.8 percent injected dose [%ID]) and [^{99m}Tc]-MDP (4.7 ± 0.7 %ID), whereas the uptake in the infected area is significantly lower with [^{99m}Tc]-IL-8 (2.2 ± 0.2 %ID) and [^{111}In]-granulocytes (0.8 ± 0.2 %ID) ($p < 0.0042$). In contrast, the T/Bs are significantly higher for [^{99m}Tc]-IL-8 (T/B, 6.2 ± 0.3 at 4 hours after injection) than for [^{67}Ga]-citrate, [^{99m}Tc]-MDP, and [^{111}In]-granulocytes, which have ratios of 1.5 ± 0.4, 1.9 ± 0.2, and 1.4 ± 0.1, respectively ($p < 0.0001$). Radiography correctly reveals acute osteomyelitis in only a relatively small percentage of cases (e.g., n = 2/8). In experimentally-induced osteomyelitis, [^{99m}Tc]-IL-8 clearly detects osteomyelitic lesions. Although the absolute uptake in the osteomyelitic area is significantly lower than that obtained with [^{99m}Tc]-MDP and [^{67}Ga]-citrate, the T/Bs are significantly higher for [^{99m}Tc]-IL-8 because of fast background clearance. The ease of preparation, good image quality, and lower radiation burden suggest that [^{99m}Tc]-IL-8 may be a suitable imaging agent for the scintigraphic evaluation of acute osteomyelitis.

[^{99m}Tc]-interleukin-8 for imaging acute osteomyelitis. Gratz S, Rennen HJ, Boerman OC, Oyen WJ, Burma P, Corstens FH. J Nucl Med 2001 Aug; 42 (8), pp. 1257–64.

Bone/Osteomyelitis/Leukocyte Detection *[^{99m}Technetium] ([^{99m}Tc])-Labeled Antigranulocyte Antibody (IgG) Fragments*

Cellular/Molecular Mechanism of Action: Antigranulocyte antibody possesses binding avidity for membrane-associated antigens that are unique to neutrophil populations. Neutrophils are chemotactically attracted to areas of (septic) inflammation. The Fab′ fragment of IgG has the advantage of being devoid of the Fc fragment so that it minimally binds to membrane-associated Fc receptor complexes expressed by the mononuclear phagocytic system residing within the liver and spleen, thereby experiencing low levels of non-specific binding.

Application: Detection and characterization of septic inflammatory lesions.

Route of Administration: [^{99m}Tc]-labeled antigranulocyte antibody fragment (intravenous).

Dosage: [^{99m}Tc]-labeled antigranulocyte antibody fragment (740 MBq [20 mCi]).

Implementation: Immunoscintigrams performed with [^{99m}Tc]-labeled antigranulocyte antibody fragments for the detection of focal lesions of septic inflammation. Validation of findings can be established by histopathology, magnetic resonance imaging, computed tomography, and monitoring of clinical signs.

Interpretation and Analysis: The percentage of true-positive images obtained with [^{99m}Tc]-labeled antigranulocyte antibody fragments for the detection of septic inflammation is approximately 67% (e.g., n = 20/30). The number of false-positive results is relatively low (e.g., n = 3/30). Approximately 20% of images will be true-negatives (e.g., n = 6/30). Consequently, [^{99m}Tc]-labeled antigranulocyte antibody fragments can achieve a high level of sensitivity (e.g.,

95%), moderately high specificity (e.g., 67%), and high diagnostic accuracy (e.g., 86%). Therefore, [^{99m}Tc]-labeled monoclonal antibody-Fab′ fragments are suitable for the detection of osteomyelitis. Its clinical application is simple, and its use guarantees a reliable and accurate diagnostic result just 1–2 hours after injection, making a late scan unnecessary. False-positive results have been reported with conditions of coxarthrosis or hyperostosis, while false-negative results can occur with perforating ulcers of the foot.

Imaging osteomyelitis with [^{99m}Tc]-labeled antigranulocyte antibody Fab′ fragments. Von Rothenburg T, Schaffstein J, Ludwig J, Vehling D, Koster O, Schmid G. Clin Nucl Med 2003 Aug; 28 (8), pp. 643–7.

Osteomyelitis/Interleukin-8 (IL-8) Receptors *[^{99m}Technetium] ([^{99m}Tc])-Labeled IL-8*

Cellular/Molecular Mechanism of Action: The cytokine IL-8 binds with high affinity to the CXCR1 and CXCR2 receptor complexes on neutrophil populations.

Application: Previous investigations have shown that [^{99m}Tc]-IL-8 can rapidly and effectively delineate foci of infection and inflammation in rabbit models of intramuscular infection, colitis, and osteomyelitis.

Semi-Synthetic Methods: A derivative of hydrazinonicotinamide (HYNIC) can be used as a bifunctional coupling agent to label protein fractions with the [^{99m}Tc] radioisotope.

Implementation: Delineate [^{99m}Tc]-IL-8 pharmacokinetic profiles in conditions of neutropenia compared to states of normal health, and determine the ability of [^{99m}Tc]-IL-8 to detect septic abscesses. Complementary investigations include characterization of the interaction of [^{99m}Tc]-IL-8 with blood cells in circulation in normal rabbits, and the distribution of the radiolabel relative to circulating white and red blood cells and plasma. The *in vivo* kinetics of [^{99m}Tc]-IL-8 is established by quantitative analysis of whole-body images acquired between 0 and 6 hours after injection. The results from such analyses (*in vivo* biodistribution) can be validated by *ex vivo* counting of radioactivity in dissected tissue samples.

Animal Model: Turpentine-induced abscesses in both neutropenic and normal rabbits.

Interpretation and Analysis: The abscess uptake (percentage of injected dose per gram of tissue [%ID/g] ± standard error of measurement [SEM]) in immunocompetent rabbits (0.41 ± 0.05) is 10 times higher than that in neutropenic rabbits (0.038 ± 0.014), demonstrating specificity of the target uptake of [^{99m}Tc]-IL-8. Abscess-to-muscle ratios ± SEM are also 10 times higher (110 ± 10 vs 10 ± 5). Lung and spleen uptake in normal rabbits is 3 times higher than that in neutropenic rabbits. The blood clearance of the radiolabel in neutropenic rabbits is similar to that in normal rabbits. In circulation, most of [^{99m}Tc]-IL-8 (70%) is found within the plasma fraction. Less than one-third is associated with red blood cells, and only a very low percentage (< 2.5%) is associated with white blood cells. Image analysis reveals a gradual increase in abscess uptake over time of up to > 15 %ID, which can be confirmed by *ex vivo* gamma counting of infected muscle tissue. The highest increase in uptake in abscesses is observed after 2 hours following injection, when most of the [^{99m}Tc]-IL-8 is cleared from the blood, suggesting specific neutrophil-mediated accumulation of [^{99m}Tc]-IL-8 within abscesses. Furthermore, region-of-interest (ROI) analysis demonstrates gradual accumulation of [^{99m}Tc]-IL-8 within abscesses accompanied by a simultaneous clearance of activity from the lungs, suggesting that neutrophil-associated [^{99m}Tc]-IL-8 initially trapped in the lungs migrates to abscess at later time points, favoring neutrophil-bound transportation from the lungs to abscesses. Substantial support is given for the hypothesis that [^{99m}Tc]-IL-8 localizes in abscesses, mainly bound to peripheral neutrophils. Accumulation within abscesses is a highly specific, neutrophil-driven process. As assessed by *in vivo* and *ex vivo* analysis, the total fraction that accumulates in inflamed tissue is extremely high (up to > 15 %ID) compared with that of other agents used for imaging infection and inflammation.

Kinetics of [^{99m}Tc]-labeled interleukin-8 in experimental inflammation and infection. Rennen HJ, Boerman OC, Oyen WJ, Corstens FH. J Nucl Med 2003 Sep; 44 (9), pp. 1502–9.

Neutrophil Leukotriene B_4 (LTB_4) Receptors/ Induced Myocardial Ischemia Insult *[^{99m}Technetium] ([^{99m}Tc])-RP517/ [F]-RP517 (Fluorescent Analogue)*

Cellular/Molecular Mechanism of Action: In whole blood, [F]-RP517 (500 nmol/L) preferentially labels neutrophil LTB_4 receptor complexes.

Background Information: [^{99m}Tc]-RP517 is a new LTB_4 receptor antagonist developed for imaging acute septic and non-septic inflammatory reactions. A unique property of [^{99m}Tc]-RP517 is its ability to label white blood cells *in vivo* after intravenous injection.

Route of Administration: [^{99m}Tc]-RP517 (intravenous).

Implementation: Evaluate the relative [^{99m}Tc]-RP517 binding to human leukocyte subtypes and the [^{99m}Tc]-RP517 uptake pattern in canine myocardium within inflammatory lesions induced either by coronary occlusion and reperfusion or tumor necrosis factor-alpha (TNF-α) injection. Initial analysis involves delineation of the potential for RP517 analogues to bind to neutrophil populations *in vitro* within whole blood and *in vivo* within the intravascular compartment. Acquisition of such data can be achieved through the use of fluorescence-activated cell sorter analysis performed on whole human blood samples (n = 2) and isolated neutrophils (n= 4) with a fluorescent analogue of [^{99m}Tc]-RP517 referred to as [F]-RP517. Evaluation *in vivo* can entail administration of [^{99m}Tc]-RP517 to determine its biodistribution within the myocardium before and after coronary occlusion. To facilitate *ex vivo* images of the myocardium, the left ventricle can be divided into 72 segments for flow and [^{99m}Tc]-RP517 uptake analyses.

Animal Model: Canine (n = 9 dogs; anesthetized, open-chest surgical exposure before coronary occlusion [90 minutes] and reperfusion [120 minutes]; or n = 3 dogs before intramyocardial TNF-α administration).

Interpretation and Analysis: In whole blood, [F]-RP517 (500 nmol/L) preferentially labels neutrophils. In isolated neutrophil populations, [F]-RP517 (10 nmol/L) binding is inhibited by 44% in the presence of LTB_4 (400 nmol/L). In the analysis of *ex vivo* cardiac samples, an inverse exponential relationship can be detected between [^{99m}Tc]-RP517 uptake and occlusion flow (r = 0.73). In the same 15 segments, [^{99m}Tc]-RP517 uptake is highly correlated with the neutrophil enzyme myeloperoxidase (r = 0.91). *Ex vivo* images reveal tracer uptake in the reperfused area (ischemic to normal count ratio = 2.7 ± 0.2). Therefore, it can be concluded that RP517 binds to the neutrophil LTB_4 receptor complex after intravenous injection. After reperfusion, [^{99m}Tc]-RP517 uptake correlates with myeloperoxidase content and can be observed on *ex vivo* images, indicating that this tracer may have potential as an inflammation-imaging agent.

Assessment of myocardial inflammation produced by experimental coronary occlusion and reperfusion with [^{99m}Tc]-RP517, a new leukotriene B_4 receptor antagonist that preferentially labels neutrophils *in vivo.* Riou LM, Ruiz M, Sullivan GW, Linden J, Leong-Poi H, Lindner JR, Harris TD, Beller GA, Glover DK. Circulation 2002 Jul 30; 106 (5), pp. 592–8.

Sepsis/Bacterial Infection: Selective Organism Detection

[^{99m}Technetium] ([^{99m}Tc])-Labeled Ciprofloxacin/ [^{99m}Tc]-Hexamethylpropyleneamine Oxime (HMPAO)-Labeled White Blood Cell (WBC)

Cellular/Molecular Mechanism of Action: Ciprofloxacin when applied as an imaging agent localizes in high concentrations within living bacteria.

Application: [^{99m}Tc]-labeled ciprofloxacin (infecton) has been developed for detecting infectious foci.

Route of Administration: [^{99m}Tc]-labeled ciprofloxacin and [^{99m}Tc]-HMPAO-labeled WBC preparations are injected intravenously.

Dosage: [^{99m}Tc]-HMPAO-labeled WBC (185–200 MBq): [^{99m}Tc]-labeled ciprofloxacin (370–400 MBq).

Considerations: Previous reports have described greater specificity of radiolabeled ciprofloxacin for bacterial infections compared to radiolabeled WBC scans.

Implementation: Performance of scintigraphic image analysis in suspected cases of bone or joint sepsis using [^{99m}Tc]-labeled ciprofloxacin and [^{99m}Tc]-WBC preparations (e.g., n = 51; n = 21/51 prosthetic implant materials). Procedures that can complement or validate findings observed in scintigraphic image analyses include biochemical, radiologic, and microbiologic data in addition to assessment of clinical history (e.g., outcomes). Scintigraphic images are performed at 1 and 4 hours postinjection of [^{99m}Tc]-labeled ciprofloxacin or [^{99m}Tc]-HMPAO-WBCs. At least a 2-day and at most a 7-day lag-time period occurs between imaging agent administration and the acquisition of scintigraphic images.

Interpretation and Analysis: Scintigraphic imaging with [^{99m}Tc]-labeled ciprofloxacin and [^{99m}Tc]-HMPAO-labeled WBC populations in cases of bone or joint sepsis produces a variety of image assessments including true-positives (e.g., n = 30/32 vs n = 20/32); false-positives (e.g., n = 4/24 vs n = 1/24); true-negatives (e.g., n = 20/24 vs 23/24); and false-negatives (e.g., n = 2/22 vs 12/22), respectively. Corresponding values for sensitivity, specificity, and accuracy are approximately 94%, 83%, and 89% ([^{99m}Tc]-labeled ciprofloxacin), and 63%, 96%, and 77% ([^{99m}Tc]-HMPAO-labeled WBC), respectively. Differences between the 2 agents are statistically significant ($p < 0.001$). [^{99m}Tc]-labeled ciprofloxacin and WBC scan results are in general concordance for approximately 77% of sites (e.g., n = 43/56). [^{99m}Tc]-HMPAO-labeled WBC results for vertebral infections are the most notable. [^{99m}Tc]-ciprofloxacin scans are positive in a large percentage of cases with vertebral osteomyelitis (e.g., n = 83% or 5/6). WBC scans can show photon-deficient areas in some of these cases (e.g., n = 4/6), but normal distribution in the remaining scenarios (e.g., n = 2/6). [^{99m}Tc]-ciprofloxacin is a useful agent for detecting infectious foci in bones and joints. Moreover, the [^{99m}Tc]-labeled ciprofloxacin scans seem to be a more powerful tool in diagnosing vertebral infections than WBC scintigraphy.

Usefulness of [^{99m}Tc]-ciprofloxacin (infecton) scan in diagnosis of chronic orthopedic infections: Comparative study with [^{99m}Tc]-HMPAO leukocyte scintigraphy. Sonmezoglu K, Sonmezoglu M, Halac M, Akgun I, Turkmen C, Onsel C, Kanmaz B, Solanki K, Britton KE, Uslu I. J Nucl Med. 2001 Apr; 42 (4), pp. 567–74.

Septic Inflammatory Disease/Radiolabeling Efficiency/Radiolabel Stability: *In Vivo*/Kinetic Profile: *In Vivo*/Dosimetry: *In Vivo*

Stabilized [^{99m}Technetium] ([^{99m}Tc])-Exametazime-Labeled Leukocytes

Background Information: Labeling leukocytes with [^{99m}Tc]-exametazime is a validated technique for imaging infection and inflammation. A new radiolabeling technique has recently been described that enables leukocyte labeling with a more stable form of [^{99m}Tc]-exametazime.

Application: Detection and characterization of inflammatory and septic disease states.

Route of Administration: Stabilized [^{99m}Tc]-exametazime-labeled leukocytes (intravascular).

Semi-Synthetic Methods: Labeling of autologous leukocyte populations with [^{99m}Tc] using stabilized exametazime.

Implementation: Evaluation of the *in vivo* radioactive biodistribution, kinetic profile, and dosimetry estimates of stabilized [^{99m}Tc]-exametazime-labeled autologous leukocytes. Serial whole-body imaging and blood sampling are acquired up to 24 hours after injection. Cell-labeling efficiency and *in vivo* viability, organ dosimetry, and clearance calculations are calculated from the blood samples and imaging data as well as samples of urine and stool collected up to 36 hours after initial injection.

Human Model: Normal healthy volunteers (n = 10).

Interpretation and Analysis: Cell-labeling efficiencies of 87.5% ± 5.1% can be achieved, which is similar to or better than that reported with the standard preparation of [^{99m}Tc]-exametazime. *In vivo* stability of the radiolabeled leukocytes is also similar to *in vitro* results with stabilized [^{99m}Tc]-exametazime and better than previously reported for the *in vivo* stability of non-stabilized [^{99m}Tc]-exametazime-labeled leukocytes. Organ dosimetry and radiation absorbed doses are similar with a whole-body absorbed dose of 1.3×10^{-3} mGy/MBq. Urinary and fecal excretion of activity is minimal, and visual assessment of images shows little renal parenchymal activity and no bowel activity for up to 2 hours following injection.

Cell labeling and *in vivo* stability appears to improve compared to leukocytes labeled with non-stabilized [^{99m}Tc]-exametazime preparations. Advantages of the methodology include increased preparation cost-effectiveness of stabilized [^{99m}Tc]-exametazime and an extended window for clinical usage, with good visualization of abdominal structures on early images. No significant increase in specific organ and whole-body dosimetry estimates has been noted compared with previous estimates using non-stabilized [^{99m}Tc]-exametazime-labeled leukocytes.

Biodistribution and radiation dosimetry of stabilized [^{99m}Tc]-exametazine-labeled leukocytes in normal subjects. Robins PD, Salazar I, Forstrom LA, Mullan BP, Hung JC. J Nucl Med 2000 May; 41 (5), pp. 934–40.

Septic or Non-Septic Inflammation/Differentiation

[^{99m}Technetium] ([^{99m}Tc])-UBI 29-41/[^{99m}Tc]-Sc-UBI 29-41

Cellular/Molecular Mechanism of Action: A [^{99m}Tc]-labeled peptide derived from ubiquicidine referred to as [^{99m}Tc]-UBI 29-41 targets bacterial and fungal infections but not sterile inflammatory processes.

Application: Differentiation between septic inflammation due to bacterial pathogens from conditions of non-septic inflammatory responses.

Route of Administration: [^{99m}Tc]-UBI 29-41 and [^{99m}Tc]-Sc-UBI 29-41 (intravenous).

Semi-Synthetic Methods: Radiochemical analyses of [^{99m}Tc]-UBI 29-41 and a radiolabeled scrambled version of this peptide, referred to as [^{99m}Tc]-Sc-UBI 29-41, reveal that both peptides can be (i) labeled rapidly (within 10 minutes); (ii) labeled effectively with little colloid formation (less than 5% of the total radioactivity); and (iii) labeled with very little free pertechnetate (or radioactive intermediates) in the preparations containing radiolabeled peptide.

Implementation: Delineation of the relative capacity of [^{99m}Tc]-UBI 29-41 and [^{99m}Tc]-Sc-UBI 29-41 to differentiate between septic

inflammatory responses and conditions of non-septic inflammation. In this manner, greater insight can be achieved in delineating regions of the amino acid sequence of UBI 29-41 that are the most critical for selective imaging of bacterial infections.

Animal Model: Murine (*Staphylococcus aureus*–infected mice).

Interpretation and Analysis: Association of peptides with bacteria has been shown to be temperature dependent. Based on *in vitro* observations, labeling of peptides with [^{99m}Tc] by a direct method is rapid, efficient, and safe. Scintigraphy demonstrates that radioactivity is rapidly removed from the circulation (the half-life of UBI 29-41 and Sc-UBI 29-41 is 16 and 21 minutes, respectively) and occurs primarily as a function of renal clearance mechanisms. Analysis of murine blood reveals that only a small proportion of the intravenously injected [^{99m}Tc]-peptides is associated with blood cells. Although both types of radiolabeled peptides accumulate rapidly at sites of infection, the values for [^{99m}Tc]-UBI 29-41 are higher ($p < 0.05$) than for [^{99m}Tc]-Sc-UBI 29-41. Moreover, injection of excess unlabeled UBI 29-41, but not Sc-UBI 29-41, in scenarios of *S. aureus* infections prior to injection of [^{99m}Tc]-UBI 29-41 significantly ($p < 0.05$) reduces the accumulation of this radiopharmaceutical at sites of sepsis. In addition, significantly ($p < 0.01$) higher amounts of [^{99m}Tc]-UBI 29-41 can be appreciated at the site of infection (e.g., mice) using a carrier-free formulation of radiolabeled UBI 29-41 peptide in contrast to unpurified preparations containing radiolabeled UBI 29-41 peptide. Such *in vivo* data implies that the radiolabeled amino acid sequence [^{99m}Tc]-UBI 29-41 contributes to its accumulation at sites of infection.

Radiochemical and biological characteristics of [^{99m}Tc]-UBI 29-41 for imaging of bacterial infections. Welling MM, Mongera S, Lupetti A, Balter HS, Bonetto V, Mazzi U, Pauwels EK, Nibbering PH. Nucl Med Biol 2002 May; 29 (4), pp. 413–22.

Septic or Non-Septic Inflammation/Differentiation *[^{99m}Technetium] ([^{99m}Tc])-Labeled Ubiquicidin (UBI)*

Cellular/Molecular Mechanism of Action: Human UBI is an antimicrobial peptide that physically binds to bacterial organisms.

Application: Discrimination between bacterial infections and sterile inflammatory reactions.

Route of Administration: [^{99m}Tc]-labeled UBI (intravascular).

Implementation: Evaluate the *in vitro* binding of various [^{99m}Tc]-labeled natural or synthetic peptides (based on the sequence of the human antimicrobial peptide UBI or human lactoferrin [hLF]) to bacteria and leukocytes populations. Complementary investigations can entail the *in vivo* evaluation of these same radiolabeled peptides injected in animal models (e.g., mice) intraperitoneally infected with *Klebsiella pneumoniae* in order to identify sequences that preferentially bind to bacteria compared to host cell populations. The amount of radioactivity associated with bacteria and leukocytes is then quantitated. Discovery of the ability for candidate [^{99m}Tc]-labeled peptides to discriminate between bacterial infections and sterile inflammatory processes can be established *in vivo* (e.g., mice) utilizing intramuscular injections of various bacterial organisms (e.g., multidrug-resistant *Staphylococcus aureus*) and lipopolysaccharides (LPS) of bacterial origin (sterile inflammatory process). Complementary validation studies can entail determination of [^{99m}Tc]-labeled UBI 29-41 and UBI 18-35 distribution in rabbits having an experimental thigh muscle infection with *K. pneumoniae* and in rabbits injected with LPS fractions.

Animal Model: Murine (mouse sepsis: intraperitoneal injection of *K. pneumoniae*.

Animal Model: Rabbit (intramuscular injection of *K. pneumoniae* (septic foci model) and lipopolysaccharide fractions (sterile LPS inflammatory model).

Interpretation and Analysis: In both *in vitro* and *in vivo* binding assays, the 2 peptides, UBI 29-41 and UBI 18-35, represent 2 candidate platforms that appear to be appropriate for image analysis of infection. The radiolabeled peptides can detect infections due to both gram-positive and gram-negative bacteria in mice as early as 5–30 minutes after injection, with a target-to-non-target (T/NT) ratio between 2 and 3; maximum T/NT ratios can be seen within 1 hour after injection. In rabbits, high T/NT ratios (> 5) for [^{99m}Tc]-labeled UBI 29-41 are observed from 1 hour after injection. No accumulation of candidate [^{99m}Tc]-labeled UBI-derived peptides can be observed in thighs of mice and rabbits previously injected with LPS fractions. Scintigraphic investigations into the biodistribution of [^{99m}Tc]-labeled UBI peptides reveal that they are rapidly removed from circulation by renal excretion. Similar data can be observed for [^{99m}Tc]-labeled defensin 1-3. Data for [^{99m}Tc]-labeled hLF and related peptides indicate that these compounds are less favorable for the detection of infection. Taken together, [^{99m}Tc]-labeled UBI 18-35 and UBI 29-41 enable discrimination between bacterial infections and sterile inflammatory processes in both mice and rabbits. Based on their characteristics and properties, these peptides are candidate platforms for the preferential detection of septic bacterial infections.

[^{99m}Technetium]-labeled antimicrobial peptides discriminate between bacterial infections and sterile inflammations. Welling MM, Paulusma-Annema A, Balter HS, Pauwels EK, Nibbering PH. Eur J Nucl Med 2000 Mar; 27 (3), pp. 292–301.

Septic and Non-Septic Inflammation/ Central Nervous System (CNS) Allergic Encephalitis/ Glucocorticoid Response/Leukocytes: *In Vivo* Labeling of Neutrophil and Macrophage Tuftsin Receptors/Multiple Sclerosis: Potential Applications *[^{99m}Technetium] ([^{99m}Tc])-RP128*

Cellular/Molecular Mechanism of Action: The agent RP128 functions as a chelation agent for [^{99m}Tc], in addition to recognizing and binding to tuftsin receptors expressed by neutrophils and monocyte-macrophages.

Application: The agent [^{99m}Tc]-RP128 can be applied for the *in vivo* labeling of neutrophil and macrophage tuftsin receptor complexes for the purpose of detecting and characterizing focal sites of septic inflammation. Potential applications include the detection and characterization of human multiple sclerosis (MS).

Route of Administration: Intravascular.

Implementation: Administration of [^{99m}Tc]-RP128 for the *in vivo* detection of CNS foci of inflammation (e.g., experimental allergic encephalomyelitis [EAE]).

Animal Model: Mouse (e.g., murine EAE developed as a model for human MS).

Interpretation and Analysis: The radiopharmaceutical [^{99m}Tc]-RP128 can be detected at significantly increased levels within EAE-diseased CNS tissues at 0.5, 1.0, and 3.0 hours postinjection using a dual radioisotope technique to correct for non-extravasated tracer ($p < 0.05$). Moreover, extravascular accumulation of [^{99m}Tc]-RP128 can be clearly demonstrated in inflammatory tissues with minimal loss of sensitivity when the secondary isotopic correction for blood volume is omitted. In addition, [^{99m}Tc]-RP128 can successfully monitor glucocorticoid suppression of inflammation ($p < 0.05$), which is detected as a typical dose response to increasing steroid concentration. Clearly, [^{99m}Tc]-RP128 can quantitatively detect CNS inflammation and assess responses to therapy, indicating potential value as an imaging agent both clinically and as a molecule

probe for investigative research purposes. Furthermore, the rapid *in vivo* labeling by [^{99m}Tc]-RP128 of specific inflammatory cells combined with the ability to monitor the progress of anti-inflammatory therapeutics may validate the use of this cellular radiolabeling agent for detecting a variety of inflammatory conditions.

The detection and quantitation of inflammation in the central nervous system during experimental allergic encephalomyelitis using the radiopharmaceutical [^{99m}Tc]-RP128. Paul C, Peers SH, Woodhouse LE, Thornback JR, Goodbody AE, Bolton C. J Neurosci Methods 2000 May 15; 98 (1), pp. 83–90.

INTEGUMENTARY SYSTEM

See neoplastic disease section within this chapter for topics related to melanoma and metastatic melanoma.

METABOLIC AND METABOLISM

Lipoprotein Metabolism and Distribution *[^{99m}Technetium] [^{99m}Tc])-Very Low-Density Lipoproteins (VLDLs)/[^{99m}Tc]-Peroxynitrite-Modified Beta-VLDL/[^{99m}Tc]-Native Beta-VLDL*

Background Information: Free radicals superoxide (O_2^-) and nitric oxide (*NO) are generated by blood vessels and can rapidly react to produce a peroxynitrite anion ($ONOO^-$), a powerful oxidant that modifies lipoproteins, making them more atherogenic.
Cellular/Molecular Mechanism of Action: Radiolabeled lipoproteins behave and are perceived by the body in essentially the same manner that endogenous lipoprotein fractions are when pertaining to interactions with corresponding receptor complexes, transport, and metabolization.
Application: Trace the binding of VLDLs to cell membrane–associated receptor complexes and processes and characterization of VLDL metabolism.
Route of Administration: Intravenous.
Implementation: Evaluate the effect of peroxynitrite-induced modifications on beta-VLDL as to its biodistribution and plasma clearance rate, as well as uptake (assimilation) by THP-1 cells. Examples of preparations that can be applied for diagnostic purposes includes [^{99m}Tc]-labeled VLDLs either in their natural form or as peroxynitrite-modified beta-VLDL [^{99m}Tc]-per-beta-VLDL.

Animal Model: Rabbit (New Zealand White strain with hypercholesterolemia).
Interpretation and Analysis: Very low-density lipoproteins can be successfully radiolabeled with [^{99m}Tc] in a manner that produces a diagnostic agent capable of assessing selective transport mechanisms and targeted organ-specific biodistribution patterns. Following injection the peroxynitrite-modified beta-VLDL ([^{99m}Tc]-per-beta-VLDL) is cleared from circulation faster than the native beta-VLDL ([^{99m}Tc-nat-beta-VLDL) in both normocholesterolemic rabbits (NC) and in hypercholesterolemic rabbits (HC). In HC rabbits, the fractional clearance of [^{99m}Tc]-labeled beta-VLDL is significantly lower than in NC rabbits. Tissue/organ accumulation, *in vivo* of [^{99m}Tc]-labeled beta-VLDL, expressed per gram of tissue has been observed to be kidney > liver > spleen > adrenal gland ≥ lung > aortic arch > heart > or = abdominal aorta > thoracic aorta > psoas muscle. High accumulations in the kidneys suggest processing of [^{99m}Tc]-labeled apolipoproteins by receptors present in kidney cells. The tissue/organ accumulation of [^{99m}Tc]-nat-beta-VLDL in the whole organ occurs in the following order: liver > kidney > heart > spleen > adrenal gland > aorta in HC and NC rabbits. The uptake of [^{99m}Tc]-per-beta-VLDL by the spleen is greater than the uptake by the heart in both groups. Uptake of [^{99m}Tc]-per-beta-VLDL by THP-1 cells *in vitro* is higher than that of [^{99m}Tc]-nat-beta-VLDL. These results show that peroxynitrite-modified beta-VLDL is rapidly removed from plasma and accumulates in several tissues, mainly in the liver and kidney. This may be particularly important in hypercholesterolemic situations that could favor the accumulation of native and peroxynitrite-modified beta-VLDL in several tissues.

Peroxynitrite-modified [^{99m}Tc]-beta-VLDL: tissue distribution and plasma clearance rate. Silva EL, Meneghetti JC, Coelho IJ, Abdalla DS. Free Radic Biol Med 2001 Aug 15; 31 (4), pp. 440–9.

MUSCULOSKELETAL SYSTEM

Bone Activity: Elevated in Skeletal Disorders *[^{99m}Technetium] ([^{99m}Tc])-Labeled Methylene Diphosphonate (MDP)*

Cellular/Molecular Mechanism of Action: The agent MDP is incorporated into hydroxyapetite crystal by biochemically viable osteoblast cell populations residing within skeletal tissues.
Application: Diagnosis of skeletal fractures, osteomyelitis, primary osteosarcoma, secondary metastasis, and other abnormalities affecting the physical and biochemical integrity of bone.
Route of Administration: [^{99m}Tc]-labeled MDP (intravenous).
Implementation: Patients on long-term hemodialysis suffer from dialysis-associated arthropathy due to the deposition of dialysis amyloid. In most clinically affected joints, with the exception of shoulders and hands, an increased uptake of radioisotope can consistently be appreciated in structures surrounding periarticular bone structures. In addition, intense soft-tissue radioisotope uptake around clinically affected large joints can be detected. Similar scintigraphic patterns are not appreciated in negative reference control subjects. A semi-quantitative scale of uptake analysis reveals a degree of correlation with (i) perception of pain and ankle/feet radioisotope uptake; and (ii) number of radiological lesions and degree of isotope uptake in the wrists and knees. In cases of renal failure that are receiving renal dialysis management, it has been proposed that the uptake of radioisotope can be attributed to its binding in affected joint structures to amyloid deposits, soft-tissue calcification, or areas of increased bone turnover.
Interpretation and Analysis: Represents a scintigraphic scanning technique that cannot make a definite diagnosis of amyloid and, therefore, cannot be expected to supersede histological diagnosis. However, it is a useful adjuvant investigative tool that is of particular importance in those cases that are unable or unwilling to undergo biopsy procedures.
Instrumentation: Scintigraphic gamma camera.

Technetium-99-labelled methylene diphosphonate uptake scans in patients with dialysis arthropathy. Sethi D, Naunton Morgan TC, Brown EA, Jewkes RF, Gower PE. Nephron 1990; 54 (3), pp. 202–7.

Bone Skeletal Structures *[^{99m}Technetium] ([^{99m}Tc])-Labeled Methylene Diphosphate (MDP)*

Cellular/Molecular Mechanism of Action: Incorporated into the hydroxyapetite matrix of bone tissues by functional osteoblast populations.
Background Information: Scintigraphy with technetium MDP gives a positive result in bone tissue with a state of elevated metabolic activity. This can be used in the diagnosis of mechanical stress lesions in bone.

Diagnostic Application: Detect sites of active osteoblastic activity such as that appreciated near septic inflammation and fractures.
Route of Administration and Dosage: Intravenous injection.
Implementation: Soft tissue phase imaging is performed at approximately 1 hour postadministration. Following completion of the soft tissue phase, cases are imaged a 2nd time at approximately 3 hours following intravenous injection.
Interpretation and Analysis: Radiolabeled MDP accumulates in soft tissue structures during the initial 30- to 60-minute period following intravenous administration. Detection is achieved with the aid of a computer-integrated scintigraphy (nuclear medicine) camera. Soft tissue lesions affecting joint, tendon, and ligament structures are detected by an increase in the local accumulation of radiolabeled MDP.

Following completion of soft tissue phase imaging, bone phase images are acquired approximately 3 hours following intravenous injection. Orthopedic lesions can be detected as an increase in the local accumulation of radiolabeled MDP within skeletal tissues.

Scintigraphy with [^{99m}Tc]-MDP in the diagnosis of stress lesions in bone. Motta F, Pietrogrande V. Ital J Orthop Traumatol 1985 Jun; 11 (2), pp. 215–22.

Bone/Osteomyelitis Bone Scanning *[^{99m}Technetium] ([^{99m}Tc])-Labeled Antigranulocyte Antibody Fragments*

Cellular/Molecular Mechanism of Action: Antigranulocyte antibody possesses binding avidity for membrane-associated antigens that are unique to neutrophil populations. Neutrophils are chemotactically attracted to areas of (septic) inflammation. The Fab′ fragment of IgG has the advantage of being devoid of the Fc fragment so that it minimally binds to membrane-associated Fc receptor complexes expressed by the mononuclear phagocytic system residing within the liver and spleen (low level of non-specific binding).
Application: Detection and characterization of septic inflammatory lesions.
Route of Administration: [^{99m}Tc]-labeled antigranulocyte antibody fragment (intravenous).
Dosage: [^{99m}Tc]-labeled antigranulocyte antibody fragment [740 MBq (20 mCi)].
Implementation: Immunoscintigrams performed with [^{99m}Tc]-labeled antigranulocyte antibody fragments for the detection of focal lesions of septic inflammation. Validation of findings can be established by histopathology, magnetic resonance imaging, computed tomography, and monitoring of clinical signs.
Interpretation and Analysis: The percentage of true-positive images obtained with [^{99m}Tc]-labeled antigranulocyte antibody fragments for the detection of septic inflammation is approximately 67% (e.g., n = 20/30). The number of false-positive results is relatively low (e.g., n = 3/30). Approximately 20% of images will be true-negatives (e.g., n = 6/30). Consequently, [^{99m}Tc]-labeled antigranulocyte antibody fragments can achieve a high level of sensitivity (e.g., 95%), moderately high specificity (e.g., 67%), and high diagnostic accuracy (e.g., 86%). Therefore, [^{99m}Tc]-labeled monoclonal antibody-Fab′ fragments are suitable for the detection of osteomyelitis. In a clinical environment, preparations and their applications are simple, while providing a reliable and accurate diagnostic result just 1–2 hours after injection, making a late scan unnecessary. Coxarthrosis or hyperostosis can lead to false-positive results. A perforating ulcer of the foot may result in a false-negative conclusion.

Imaging osteomyelitis with [^{99m}Tc]-labeled antigranulocyte antibody Fab′ fragments. Von Rothenburg T, Schaffstein J, Ludwig J, Vehling D, Koster O, Schmid G. Clin Nucl Med 2003 Aug; 28 (8), pp. 643–7.

Bone/Osteomyelitis Bone Scanning *[^{99m}Technetium] ([^{99m}Tc])-PEG Liposomes/[^{99m}Tc]-HYNIC-IgG/[^{99m}Tc]-Methylene Diphosphonate (MDP)/[^{111}Indium] ([^{111}In])-Granulocytes/Gallium-67 ([^{67}Ga])-Citrate*

Background Information: Assessment of disease activity and disease extent in chronic osteomyelitis remains a difficult diagnostic problem. Radiography is not particularly sensitive. Scintigraphic techniques can be more helpful, but routinely available agents lack specificity (e.g., [^{99m}Tc]-MDP, [^{67}Ga]-citrate) or are relatively laborious to prepare (e.g., [^{111}In] leukocytes).
Route of Administration: [^{99m}Tc]-PEG liposomes (intravenous); [^{99m}Tc]-HYNIC-IgG (intravenous); [^{99m}Tc]-MDP (intravenous); [^{111}In]-granulocytes (intravenous); or [^{67}Ga]-citrate (intravenous).
Dosage: [^{99m}Tc]-PEG liposomes (37 MBq rabbit); [^{99m}Tc]-HYNIC-IgG (37 MBq rabbit); [^{99m}Tc]-MDP (37 MBq rabbit); [^{111}In]-granulocytes (18 MBq rabbit); or [^{67}Ga]-citrate (18 MBq rabbit).
Implementation: Scintigrahic image analysis of osteomyelitis lesions of the femur 4 weeks after bacterial infusion applying [^{99m}Tc]-PEG liposomes, [^{99m}Tc]-HYNIC-IgG, and [^{99m}Tc]-MDP on 3 consecutive days and imaged up to 4 hours (MDP) or 22 hours (liposomes and IgG) postinjection. On day 4, preparations of [^{111}In]-granulocytes or [^{67}Ga]-citrate are administered and then imaged up to 44 hours after injection. Uptake in the septic femur is determined by drawing regions-of-interest (ROIs). Ratios of infected-to-sham-operated femur are calculated. After the last image, the left and right femur are scored for microbiologic and histopathologic evidence of osteomyelitis (research models).

Animal Model: Chronic osteomyelitis is induced by infusing *Staphylococcus aureus* into the right reamed and washed femoral canal (e.g., rabbits). The canal is sealed with cement and a sham operation is performed on the left femur. Routine radiographs are obtained immediately after surgery and before scintigraphic imaging.
Interpretation and Analysis: [^{99m}Tc]-PEG liposomes and [^{99m}Tc]-HYNIC-IgG can correctly identify lesions of osteomyelitis in a high percentage of cases (e.g., n = 6/6). In a small percentage of cases, [^{111}In]-granulocytes and [^{67}Ga]-citrate can produce equivocal results (e.g., 15% or n = 1/6), and [^{99m}Tc]-MDP may miss lesions of osteomyelitis (e.g., 15% or n = 1/6). The uptake in the affected region does not differ significantly between the imaging agents, although [^{99m}Tc]-MDP tends to have higher values (MDP, 4.75 ± 1.23 percent injected dose per gram [%ID/g]; [^{67}Ga], 2.05 ± 0.54 %ID/g; granulocytes, 1.56 ± 0.83 %ID/g; liposomes, 1.75 ± 0.76 %ID/g; and IgG, 1.96 ± 0.27 %ID/g). The ratios of infected-to-normal femur are also not significantly different for the respective radiopharmaceuticals. Radiography can visualize only severe osteomyelitis. [^{99m}Tc]-PEG liposomes and [^{99m}Tc]-HYNIC-IgG perform at least as well as [^{111}In]-granulocytes and [^{67}Ga]-citrate in localizing chronic osteomyelitis (e.g., rabbits). The ease of preparation, the better image quality, and the lower radiation dose suggest that [^{99m}Tc]-PEG liposomes and [^{99m}Tc]-HYNIC-IgG might be suitable alternatives to [^{67}Ga]-citrate and [^{111}In]-granulocytes for the scintigraphic evaluation of osteomyelitis conditions.

Scintigraphic evaluation of experimental chronic osteomyelitis. Dams ET, Nijhof MW, Boerman OC, Laverman P, Storm G, Buma P, Lemmens JA, van der Meer JW, Corstens FH, Oyen WJ. J Nucl Med 2000 May; 41 (5), pp. 896–902.

Bone/Osteomyelitis Bone Scanning
Gallium-67 ([^{67}Ga])-Citrate/[^{99m}Technetium] ([^{99m}Tc])-Methylene Diphosphonate (MDP)/[^{99m}Tc]-Interleukin-8 (IL-8)

Cellular/Molecular Mechanism of Action: [^{99m}Tc]-MDP is believed to be assimilated by active osteoblasts/osteoclasts at sites of dynamic bone growth and destruction.

Background Information: Early and accurate diagnosis of osteomyelitis remains a clinical problem. Acute osteomyelitis often occurs in infants and most often is located in long-bone skeletal structures. Radiologic images show changes only in the advanced stages of disease. Scintigraphic imaging with [^{99m}Tc]-MDP, or bone scanning, is much more sensitive in detecting acute osteomyelitis but lacks specificity.

Application: Detection and characterization of septic osteomyelitis lesions.

Route of Administration: [^{99m}Tc]-MDP (intravenous), [^{99m}Tc]-IL-8 (intravenous).

Dosage: [^{99m}Tc]-MDP (18.5 MBq), [^{99m}Tc]-IL-8 (18.5 MBq).

Implementation: Scintigraphic characterization of osteomyelitis lesions 10 days following induction (e.g., n = 10 rabbits; n = 5/group) utilizing injections of either 18.5 MBq [^{111}In]-granulocytes or 18.5 MBq [^{67}Ga]-citrate. Images are performed both 24 hours and 48 hours postinjection. On day 12, serial images are acquired at 0, 1, 2, 4, 8, 12, and 24 hours after injection of either 18.5 MBq [^{99m}Tc]-MDP or 18.5 MBq [^{99m}Tc]-IL-8 preparations. Uptake in the infected femur is determined by establishing regions-of-interest (ROIs). Ratios of infected femur (target) to sham-operated femur (background) (T/Bs) are then calculated. After the final images are acquired, the right femur is harvested postmortem to facilitate dissection and analysis of tissue samples for microbiological and histopathological evidence of osteomyelitis.

Animal Model: Rabbit. Acute pyogenic osteomyelitis can be induced in rabbits (e.g., n = 10) by inserting sodium morrhuate and *Staphylococcus aureus* into the medullary cavity of the right femur. The cavity is then closed with liquid cement. A sham operation is performed on the left femur. Routine radiographs are obtained just before scintigraphy imaging. Acute osteomyelitis develops in a high percentage of rabbits (e.g., n = 8/10).

Interpretation and Analysis: All imaging agents can correctly detect acute osteomyelitis in a very high percentage of cases (e.g., n = 8/8). The extent of infection can be optimally visualized with [^{67}Ga]-citrate and by delayed bone scanning, whereas diaphyseal photopenia is noted with both [^{99m}Tc]-IL-8 and [^{111}In]-granulocytes. Some false-negative (e.g., n = 1/8) and false-positive (e.g., n = 1/8) image results can be observed with [^{111}In]-granulocytes and [^{99m}Tc]-MDP, respectively. Quantitative analysis of the images reveals that the uptake in the infected region is highest with [^{67}Ga]-citrate (4.9 ± 0.8 percent injected dose [%ID]) and [^{99m}Tc]-MDP (4.7 ± 0.7 %ID), whereas the uptake in the infected area is significantly lower with [^{99m}Tc]-IL-8 (2.2 ± 0.2 %ID) and [^{111}In]-granulocytes (0.8 ± 0.2 %ID) ($p < 0.0042$). Conversely, the T/Bs are significantly higher for [^{99m}Tc]-IL-8 (T/B, 6.2 ± 0.3 at 4 hours after injection) than for [^{67}Ga]-citrate, [^{99m}Tc]-MDP, and [^{111}In]-granulocytes, which have ratios of 1.5 ± 0.4, 1.9 ± 0.2, and 1.4 ± 0.1, respectively ($p < 0.0001$). Radiography correctly reveals acute osteomyelitis in only a relatively small percentage of cases (e.g., n = 2/8). In experimentally-induced osteomyelitis, [^{99m}Tc]-IL-8 clearly detects the osteomyelitic lesion. Although the absolute uptake in the osteomyelitic area is significantly lower than that obtained with [^{99m}Tc]-MDP and [^{67}Ga]-citrate, the T/Bs are significantly higher for [^{99m}Tc]-IL-8 because of fast background clearance. The ease of preparation, good image quality, and lower radiation burden suggest that [^{99m}Tc]-IL-8 may be a suitable imaging agent for the scintigraphic evaluation of acute osteomyelitis.

[^{99m}Tc]-interleukin-8 for imaging acute osteomyelitis. Gratz S, Rennen HJ, Boerman OC, Oyen WJ, Burma P, Corstens FH. J Nucl Med 2001 Aug; 42 (8), pp. 1257–64.

Bone/Osteomyelitis Bone Scanning
[^{99m}Technetium] ([^{99m}Tc])-Labeled Interleukin-8 (IL-8)

Cellular/Molecular Mechanism of Action: The cytokine IL-8 binds with high affinity to the CXCR1 and CXCR2 receptors on neutrophils.

Application: Previous investigations have shown that [^{99m}Tc]-IL-8 can rapidly and effectively delineate foci of infection and inflammation in rabbit models of intramuscular infection, colitis, and osteomyelitis.

Semi-Synthetic Methods: A derivative of hydrazinonicotinamide (HYNIC) can be used as a bifunctional coupling agent to label protein fractions with [^{99m}Tc] preparations.

Implementation: Delineation of [^{99m}Tc]-IL-8 pharmacokinetic profiles in conditions of neutropenia compared to normal states and determination of the ability of [^{99m}Tc]-IL-8 to detect septic abscesses. Delineation of the interaction of [^{99m}Tc]-IL-8 with blood cells circulating in normal rabbits can be established through assessment of the distribution of the radiolabel relative to circulating white and red blood cells and plasma. The *in vivo* kinetics of [^{99m}Tc]-IL-8 is established by quantitative analysis of whole-body images acquired between 0 and 6 hours after injection. Results from such analyses (*in vivo* biodistribution) can be validated by *ex vivo* counting of radioactivity in dissected tissue samples.

Animal Model: Turpentine-induced abscesses in both neutropenic and normal rabbits.

Interpretation and Analysis: The abscess uptake (percentage of injected dose per gram of tissue [%ID/g] ± standard error of measurement [SEM]) in immunocompetent rabbits (0.41 ± 0.05) is 10 times higher than that in neutropenic rabbits (0.038 ± 0.014), demonstrating specificity for target uptake of [^{99m}Tc]-IL-8. Abscess-to-muscle ratios ± SEM are also 10 times higher (110 ± 10 vs 10 ± 5). Lung and spleen uptake in normal rabbits is 3 times higher than that in neutropenic rabbits. The blood clearance of the radiolabel in neutropenic rabbits is similar to that in normal rabbits. In circulation, most of [^{99m}Tc]-IL-8 (70%) is found within the plasma fraction. Less than one-third is associated with red blood cells, and only a very low percentage (< 2.5%) is associated with white blood cells. Image analysis reveals a gradual increase in abscess uptake over time up to > 15 %ID, which can be confirmed by *ex vivo* gamma counting of infected muscle tissue. The highest increase in uptake within abscesses is observed after 2 hours following injection, when most of the [^{99m}Tc]-IL-8 clears from the blood, suggesting specific neutrophil-mediated accumulation of [^{99m}Tc]-IL-8 in abscesses. Furthermore, region-of-interest (ROI) analysis demonstrates gradual accumulation of [^{99m}Tc]-IL-8 in abscesses accompanied by a simultaneous clearance of activity from the lungs, suggesting that neutrophil-associated [^{99m}Tc]-IL-8 initially trapped in the lungs ultimately migrates to abscesses at a later point in time, favoring neutrophil-bound transportation from the lungs to the abscess. Substantial support exists for the hypothesis that [^{99m}Tc]-IL-8 localizes in the abscess and is mainly bound to peripheral neutrophils. Accumulation within abscesses is a highly specific, neutrophil-driven process. As determined by *in vivo* and *ex vivo* analysis, the total fraction that accumulates within inflamed tissues is extremely high (up

to > 15 %ID) compared with that of other agents used for imaging infection and inflammation.

Kinetics of [^{99m}Tc]-labeled interleukin-8 in experimental inflammation and infection. Rennen HJ, Boerman OC, Oyen WJ, Corstens FH. J Nucl Med 2003 Sep; 44 (9), pp. 1502–9.

Collagen Synthesis (Abnormal)/Osteosarcoma/ Pancreatic Accumulation/Renal Uptake/ Hepatic Clearance/Collagen Synthesis: Abnormal *(2S,4R)-4-[^{18}F]Fluoro-L-Proline/ (2S,4S)-4-[^{18}F]Fluoro-L-Proline*

Cellular/Molecular Mechanism of Action: (2S,4R)-4-[^{18}F]fluoro-L-proline and (2S,4S)-4-[^{18}F]fluoro-L-proline are radiofluorinated analogues of proline that are systemically perceived as the amino acid proline by endogenous protein synthesis pathways (e.g., collagen production).

Implementation: Evaluate the diastereomeric effect on uptake and metabolic behavior of (2S,4R)-4-[^{18}F]fluoro-L-proline (*trans*-[^{18}F]FPro) and (2S,4S)-4-[^{18}F]fluoro-L-proline (*cis*-[^{18}F]FPro) in view of their potential suitability as tracers for abnormal collagen synthesis. No-carrier-added 4-[^{18}F]fluoro-L prolines can be prepared in about 150 minutes utilizing previously described methodologies (50–60% radiochemical yield).

Animal Model: Murine (mouse osteosarcoma).

Interpretation and Analysis: The compounds *cis*-[^{18}F]F-Pro and *trans*-[^{18}F]F-Pro both exhibit high *in vivo* stability. The tumor uptake of *cis*-[^{18}F]F-Pro in osteosarcomas is high and at 240 minutes postinjection reaches 11.8 ± 2.2 percent injected dose per gram (%ID)/g compared to 7.07 ± 1.68 %ID/g for *trans*-[^{18}F]F-Pro. In contrast to *trans*-[^{18}F]F-Pro, which shows fast and complete renal clearance, the *cis* isomer is accumulated within the pancreas and shows hepatic clearance and renal reuptake. Speciation studies on tissue homogenates reveal protein incorporation only for *cis*-[^{18}F]F-Pro. However, due to the relatively slow protein incorporation rate of *cis*-[^{18}F]F-Pro, the tumor uptake of both compounds in colon carcinomas, mammary carcinomas, and osteosarcomas 1 hour postinjection predominantly reflects amino acid transport.

Preclinical evaluation of 4-[^{18}F]fluoroprolines: Diastereomeric effect on metabolism and uptake in mice. Wester HJ, Herz M, Senekowitsch-Schmidtke R, Schwaiger M, Stöcklin G, Hamacher K. Nucl Med Biol 1999 Apr; 26 (3), pp. 259–65.

Joints/Rheumatoid Arthritis Inflammation/ Intestinal Lesions: Non-Steroidal Anti-Inflammatory Drug (NSAID)-Associated/Intestinal Lesions: Crohn's Ileitis *[^{111}Indium] ([^{111}In]) Leukocytes/Tauro 23 [^{75}Se]-Selena-25-Homocholic Acid/[^{58}Co]-Labeled Cyanocobalamine*

Cellular/Molecular Mechanism of Action: The agent tauro 23 [^{75}Se]-selena-25-homocholic acid is a bile acid analog, while [^{58}Co]-labeled cyanocobalamine is an analogue of vitamin B_{12}. Radiolabeled [^{111}In] leukocytes behave *in vivo* like endogenous leukocytes of the same cell type.

Application: The agents tauro 23 [^{75}Se]-selena-25-homocholic acid and [^{58}Co]-labeled cyanocobalamine can be applied to evaluate intestinal absorption. Conversely, [^{111}In] leukocytes can be used to detect foci of septic and non-septic inflammation.

Route of Administration: Intravenous.

Implementation: Evaluation of residual inflammatory lesions following discontinuation of NSAIDs using [^{111}In] leukocyte scintigraphy imaging methodologies.

Human Model #1: Cases of rheumatoid arthritis (n = 90) and osteoarthritis (n = 7).

Human Model #2: Cases treated with NSAIDs (n = 19); healthy controls (n = 20); and Crohn's ileitis (n = 13).

Interpretation and Analysis: Using [^{111}In] leukocyte imaging techniques reveals that cases of rheumatoid arthritis and osteoarthritis that are administered NSAIDs frequently develop gastrointestinal lesions. More specifically, approximately two-thirds of all cases evaluated on long-term treatment display inflammatory lesions that may persist for up to 16 months following discontinuation. The prevalence and magnitude of intestinal inflammation is unrelated to the type and dose of non-steroidal drugs and previous or concomitant 2nd-line drug treatment. There is a significant inverse correlation ($r = -0.29$, $p < 0.05$) between fecal [^{111}In] excretion and hemoglobin levels in cases treated with NSAIDs. The kinetics of fecal [^{111}In] excretion in cases treated with NSAIDs is almost identical to that of cases with small bowel Crohn's disease. Small bowel radiological examination of cases on NSAIDs reveals that approximately one-sixth have asymptomatic ileal disease with ulceration and strictures (e.g., n = 3/18 cases). Evaluation of cases on anti-inflammatory agents, normal healthy controls, and cases of Crohn's ileitis with tauro 23 [^{75}Se]-selena-25-homocholic acid, and [^{58}Co]-labeled cyanocobalamine reveals several abnormalities. On day 4, more than half the cases with rheumatoid arthritis have evidence of bile acid malabsorption, but the ileal dysfunction is much milder than seen in patients with Crohn's ileitis.

Non-steroidal anti-inflammatory drug–induced intestinal inflammation in humans. Bjarnason I, Zanelli G, Smith T, Prouse P, Williams P, Smethurst P, Delacey G, Gumpel MJ, Levi AJ. Gastroenterology 1987 Sep; 93 (3), pp. 480–9.

Muscle/Exercise Intolerance (Anaerobic)/Left Ventricular (LV) Dysfunction *^{201}Thallium ([^{201}Tl])*

Cellular/Molecular Mechanism of Action: [^{201}Tl] is a radioactive isotope that emits photons.

Background Information: Decreased blood flow to working muscles makes an important contribution to exercise intolerance in patients with chronic heart failure.

Application: Radioactive marker system that can be utilized to detect alterations in muscle metabolism.

Route of Administration: [^{201}Tl] (intravenous).

Implementation: Evaluate whether maldistribution of skeletal muscle blood flow is closely related to exercise intolerance in conditions of cardiac dysfunction.

One investigative strategy for assessing this consideration involves the acquisition of images from whole-body thallium scintigraphy during 1-leg exercise challenge in cases of LV dysfunction. Blood flow distribution to exercising and resting legs is quantified by expressing regional thallium counts as a percentage of whole-body counts at rest, at the level of anaerobic threshold, and at peak exercise.

Human Model: Left ventricular dysfunction (LV ejection fraction < 45%; n = 11 cases).

Interpretation and Analysis: At anaerobic threshold, thallium activity of exercising muscle increases from 4.2 ± 0.7% to 14.0 ± 2.5% ($p < 0.05$) in the thigh and from 1.7 ± 0.3% to 4.1 ± 0.9% ($p < 0.05$) in the calf, compared to resting values. Consequently, the ratio of thallium activity between exercising and resting legs increases to 2.7 ± 0.7 ($p < 0.05$) in the thigh and to 2.3 ± 0.7 ($p < 0.05$) in the calf. When plotted as a function of anaerobic threshold, thallium activity of the exercising thigh ($r = 0.78$, $p < 0.05$) and the thallium

ratio between exercising and resting thigh ($r = 0.69$, $p < 0.05$) declines with a reduction in exercise tolerance. These correlations are not observed in calves. Whole-body thallium scintigraphy demonstrates a maldistribution of leg blood flow in conditions with reduced aerobic exercise capacity, suggesting that this abnormality could play an important role in exercise intolerance in cases with such forms of cardiac dysfunction.

Quantitative evaluation of blood flow distribution to exercising and resting skeletal muscles in patients with cardiac dysfunction using whole-body thallium-201 scintigraphy. Wada O, Asanoi H, Miyagi K, Ishizaka S, Kameyama T, Ishise H, Seto H, Inoue H. Clin Cardiol 1997 Sep; 20 (9), pp. 785–90.

Muscle/Myopathy: Statin-Induced
Methoxy-Isobutyl-Isonitrile (MIBI)

Background Information: Statin-induced myopathy is the most commonly seen side effect in users of this family of drugs. Different forms present either with or without creatine phosphokinase (CK) elevations, signs of *in vivo* oxidation injury or not, or a combination of both. The pathogenetic background, however, still remains obscure. Besides its effectiveness for myocardial and tumor scintigraphy, MIBI is also useful in detecting muscle metabolic abnormalities, which is recognized as an increase in the level of MIBI uptake in diseased muscular segments.

Implementation: Evaluation of statin-induced myopathy utilizing MIBI whole-body imaging techniques performed immediately during statin exposure.

Human Model: Cases of statin-induced myopathy displaying either elevated CK, isoprostanes, or muscle pains at varying combinations ($n = 7$; $n = 5$ males; $n = 2$ females; age = 36–56 years). Reference controls can include cases suffering from lung or breast cancer that are also exposed to statins preparations ($n = 16$; $n = 6/16$ males, $n = 10$ females).

Interpretation and Analysis: No uptake abnormalities can be appreciated in any muscular segment in either affected cases or reference controls. Therefore, MIBI scintigraphy is not useful, apparently, in diagnosing and eventually localizing statin-induced myopathy. Scintigraphy with MIBI is of no diagnostic benefit for gaining further insight into statin-induced myopathy.

Statin-induced myopathy does not show up in MIBI scintigraphy. Lupattelli G, Palumbo B, Sinzinger H. NuclMed Commun 2001 May; 22 (5), pp. 575–8.

NEOPLASTIC DISEASE

Adrenal Gland: Function and Structure
[^{131}I]-6-β-Iodomethyl-Norcholesterol/[^{75}Se]-Selenomethyl-Norcholesterol/[^{131}I]-, [^{123}I]-, and [^{124}I]-Metaiodobenzylguanidine (MIBG)/[^{18}F]-Metafluoro-Benzyl-Guanidine/[^{123}I]-Tyr-Octreotide/[^{111}In]-Diethylenetriamine Pentaacetic Acid (DTPA)-Octreotide/[^{111}In]-DOTA-Octreotide/[^{18}F]-2-Fluoro-d-Deoxyglucose/Metyrapone/Tyrosine Analogues/Low-Density Lipoproteins (LDL Receptors)/Bombesin/Vasoactive Intestinal Polypeptide/Cholecystokinin/Opiate Peptides/[^{11}C]-Acetate

Background Information: Over the last 30 years nuclear medicine imaging of the adrenal gland and its lesions has been achieved by exploitation of a number of physiological characteristics associated with this organ. By seeking and utilizing features that are quantitatively or qualitatively different from those of the adjacent tissues, it is possible to functionally characterize the adrenal gland and associated disease states. In most instances lesions affecting both the cortex and the medulla retain the basic physiology related to their original tissue type. Diagnostic strategies widely used in clinical practice include assessment of (i) radiolabeled cholesterol analog uptake and storage facilitated by LDL receptors and cholesterol ester storage pools in the adrenal cortex utilizing the agents [^{131}I]-6-β-iodomethyl-norcholesterol or [^{75}Se]-selenomethyl-norcholesterol; (ii) catecholamine Type I presynaptic, uptake mechanisms, and intracellular granule uptake and storage processes in the adrenal medulla and extra-adrenal paraganglia utilizing [^{131}I]-, [^{123}I]-, and [^{124}I]-MIBG and [^{18}F]-metafluoro-benzyl-guanidine; (iii) cell surface receptor binding of peptides/neurotransmitters/modulators such as those for the family of 5 subtypes of somatostatin receptors ([^{123}I]-tyr-octreotide, [^{111}In]-DTPA-octreotide, [^{111}In]-DOTA-octreotide, and many others); (iv) increases in tumor glycolysis, particularly in the most malignant adrenal-associated cell types, utilizing [^{18}F]-2-fluoro-d-deoxyglucose, that can be expected to detect certain neoplastic lesions such as malignant pheochromocytomas (particularly the minority of cases that are not detected with MIBG) and adrenal incidentalomas (particularly with known extra-adrenal malignancies).

There are a variety of adrenal tissue characteristics that have the potential for being exploited for various purposes that are not currently employed for clinical uses but nevertheless, have potential as imaging agents. These include (i) inhibitors of adrenal cortical steroid hormone synthesis enzymes (e.g., radiolabeled analogues of metyrapone); (ii) radiolabeled lipoproteins that bind to adrenocortical LDL receptors; (iii) inhibitors of catecholamine biosynthesis enzymes (e.g., radiolabeled analogues of tyrosine and related amino acids); and (iv) cell surface receptors for various peptides and hormones that may be overexpressed by adrenal cortical or adrenal medullary tumors (e.g., radiolabeled analogues of adenocorticotropic hormone [ACTH] for adrenocortical cells of zona fasciculata or zona glomerulosa origin; neurotransmitter/hormone message peptides binding to cell surface receptors such as bombesin, vasoactive intestinal polypeptide, cholecystokinin, and opiate peptides). The adrenal cortex can also synthesize cholesterol from acetate, and preliminary studies with [^{11}C]-acetate positron emission tomography have shown interesting results.

Application: Detection and characterization of the adrenal gland function and dysfunction.

Functional scintigraphy of the adrenal gland. Rubello D, Bui C, Casara D, Gross MD, Fig LM, Shapiro B. Eur J Endocrinol 2002 Jul; 147 (1), pp. 13–28.

Adrenal Gland/Pheochromocytoma
[^{131}I]-Metaiodobenzylguanidine (MIBG)/Metaclopramide

Background Information: Pheochromocytoma accounts for approximately 25% of incidentally discovered adrenal masses. Certain diagnostic procedures (e.g., adrenal arteriography, needle biopsy of an adrenal mass), anesthesia, and abdominal surgery may cause a sudden release of catecholamines from a pheochromocytoma and induce paroxysmal attacks of hypertension. In addition, pheochromocytoma is well known to cause unsuspected operating room deaths. Therefore, it is important to carefully separate this functioning neoplasm from other types of adrenal gland masses.

Pheochromocytoma cases frequently have elevated plasma concentrations of adrenaline (epinephrine)and noradrenaline (norepinephrine), in addition to increases in urinary vanillylmandelic acid, metanephrine, and/or normetanephrine.

Application: Detection of pheochromocytoma.

Route of Administration: Metaclopramide (IV); [^{131}I]-MIBG (IV).

Considerations: In situations where results from these assays are negative, both the metaclopramide (provocative test) and [^{131}I] or [^{123}I]-MIBG (MIBG scintigraphy) can be performed as an alternative diagnostic strategy.
Implementation: Compare results of non-invasive tests including (i) assay of urinary catecholamines and their metabolites; (ii) a provocative pharmacologic test using metoclopramide (MCP test); and (iii) [^{131}I]-MIBG scintigraphy to screen for pheochromocytoma.

Human Model: Cases with an incidentally discovered adrenal mass (n = 10; n = 6 pheochromocytomas, n = 4 non-functioning adrenocortical adenomas).
Interpretation and Analysis: Urinary excretion of catecholamines, metanephrines, and vanillylmandelic acid may be positive in only 50% of cases (e.g., n = 5/10; n = 4 negative; n = 1 false-negative; sensitivity = 83%, specificity = 100%). The [^{131}I/^{123}I]-MIBG reagent uptake within adrenal lesions is increased to the extent that they can be visualized in diagnostic nuclear medicine studies. The MCP test may be positive in less that 50% of cases (e.g., n = 3/7; n = 3/7 negative; n = 1 false-negative; sensitivity = 75%, specificity = 100%). MIBG scintigraphy may similarly be positive in over 50% of cases (e.g., n = 4/7; n = 1/7 negative; n = 2/7 false-negative; sensitivity = 67%, specificity = 100%). Such observations suggest that all patients with an incidentally discovered adrenal mass should undergo a determination of the 24-hour urinary excretion of catecholamines and their metabolites, including metanephrines. If this urine assay is negative, other non-invasive tests, including the MCP test and MIBG scintigraphy, should be considered in selected patients with radiographic characteristics indicative of pheochromocytoma.

Non-invasive screening for pheochromocytoma in patients with an incidentally discovered adrenal mass: Usefulness of provocative test with metoclopramide and [^{131}I]-metaiodobenzylguanidine scintigraphy. Yokoyama H, Tsuji Y. Hinyokika Kiyo 1999 Oct; 45 (10), pp. 677–80.

Adrenal Gland/Pheochromocytoma (Silent/ Subclinical) *[^{131}I]-Metaiodobenzylguanidine (MIBG)/Glucagon*

Application: Diagnosis of subclinical/silent pheochromocytoma.
Route of Administration: Glucagons (IV) and [^{131}I]-MIBG (IV).
Considerations: Adrenal masses can sometimes be incidentally discovered during abdominal ultrasonography and computed tomography in cases that are normotensive and asymptomatic in addition to having nearly normal plasma catecholamine levels. However, urinary levels of catecholamine metabolites are often slightly elevated in such cases.
Implementation: Evaluation of suspected conditions of pheochromocytoma. Note: A cutoff at 4.0 cm for tumor mass size can be set in order to differentiate between benign and malignant tumors.
Interpretation and Analysis: A glucagon provocative test and [^{131}I]-MIBG scintigram can be useful for diagnosing atypical pheochromocytoma. In cases classified as incidentaloma, 82.5% are benign masses, of which 35.0% (n = 36/85) are non-functional adrenal cortical adenomas, and 11.7% (n = 12/85) are pheochromocytoma. Cases with malignant masses are significantly younger than cases with adenomas ($p < 0.05$), and adenomas are significantly smaller than malignant masses ($p < 0.001$). During the diagnosis of atypical incidentaloma, it's essential to evaluate hormonal activity and assess the risk for malignancy. In instances where the mass size is 4 cm or larger, the risk of malignancy increases. More attention should be paid to subclinical hyperfunctional state.

A clinical analysis of 103 cases of adrenal incidentaloma. Tao H, Lu ZL, Li HZ. Zhongguo Yi Xue Ke Xue Yuan Xue Bao 2003 Apr; 25 (2), pp. 172–5.

Apoptosis/Neoplastic Disease *[^{99m}Technetium] ([^{99m}Tc])-Annexin V/ [Cyclophosphamide]/TUNEL Tissue Analysis/ [^{14}C]-Iodoanitpyrine*

Cellular/Molecular Mechanism of Action: Annexin V is a human protein that possesses a high affinity for phosphatidylserine.
Application: Annexin V can be labeled with [^{99m}Tc] to detect *in vivo* apoptosis.
Route of Administration: [^{99m}Tc]-annexin V (intravenous).
Semi-Synthetic Methods: Radiolabeling of annexin V with [^{99m}Tc] (specific activity, 3.0 MBq/μg protein).
Implementation: Evaluate the effectiveness of [^{99m}Tc]-annexin V to characterize *in vivo* the degree of apoptosis in engrafted hepatoma after the 1st dose of chemotherapy. Investigation can involve determining the biodistribution of [^{99m}Tc]-annexin V within innoculated allogenic hepatoma lesion 20 hours after administration of a cyclophosphamide dose. Radioactivity within specific tissues is then determined 6 hours after [^{99m}Tc]-annexin V administration. Tumor uptake of [^{14}C]-iodoanitpyrine is employed as a marker of tumor blood flow. Terminal deoxynucleotidyl transferase-mediated deoxyuridine triphosphate nick-end labeling (TUNEL) of tissue harvested at necropsy is then performed to detect evidence of apoptosis within tumor tissue specimens.

Animal Model: Rat (inoculated with allogenic hepatoma cells [KDH-8] in the left calf muscle, followed 11 days later by randomized administration of a single dose of cyclophosphamide [150 mg/kg intraperitoneally], while those not receiving the chemotherapeutic serve as a negative reference control).
Interpretation and Analysis: Cyclophosphamide treatment significantly increases tumor uptake (percent activity of injected dose per gram of tissue after normalization to the animal's weight [%ID/g/kg]) of [^{99m}Tc]-annexin V (0.070 ± 0.007 %ID/g/kg for treated rats and 0.046 ± 0.009 %ID/g/kg for controls, $p < 0.001$). [^{14}C]-iodoantipyrine uptake is similar in the treated and untreated groups. The number of TUNEL-positive cells in the tumor is significantly larger in the treated rats (297.70 ± 50.34 cells/mm^2) than in the control rats (168.45 ± 23.60 cells/mm^2, $p < 0.001$). Tumor uptake of [^{99m}Tc]-annexin V correlates with the number of TUNEL-positive cells within tumor specimens ($r = 0.712$; $p < 0.001$). Tumor uptake of [^{99m}Tc]-annexin V is significantly increased by a single dose of cyclophosphamide treatment, and the increase is concordant with the number of TUNEL-positive cells in the tumor. Such observations suggest the utility of [^{99m}Tc]-annexin V as a non-invasive means to assess tumor response, although further testing, including clinical evaluation, is required.

Detection of apoptotic tumor response *in vivo* after a single dose of chemotherapy with [^{99m}Tc]-annexin V. Mochizuki T, Kuge Y, Zhao S, Tsukamoto E, Hosokawa M, Strauss HW, Blankenberg FG, Tait JF, Tamaki N. J Nucl Med 2003 Jan; 44 (1), pp. 92–7.

Carcinomas/Gastrin-Releasing Peptide (GRP) Receptors/[Mammary Carcinoma]/ Prostatic Carcinoma/[Small Cell Lung Cancer]/ [Pancreatic Cancer] *[^{111}Indium] ([^{111}In])-Bombesin (BBN)/[^{111}In]-DOTA-X-BBN[7-14]NH$_2$*/Beta-Ala, 5-Ava Spacer/8-Aoc Spacer

Cellular/Molecular Mechanism of Action: Bombesin has been known to bind to GRP receptors with high affinity and specificity.

Background Information: Gastrin-releasing peptide receptors have been shown to be expressed with high densities on several types of cancer cells, including prostate, breast, small cell lung, and pancreas cancers.

Application: Hydrocarbon spacer chains can effectively improve the specificity of detecting and characterizing human prostatic carcinoma cell types when employing [^{111}In]-DOTA-bombesin as a template molecule for the purpose of recognizing GRP receptor complexes.

Implementation: Evaluation of the relative tumor "uptake" and pharmacokinetic parameters for various [^{111}In]-labeled bombesin analogues as potential candidates for specific targeting of human prostate cancers.

***Ex Vivo* Model:** Human (PC-3 androgen-independent human prostate cancer cells).

Animal Model: Murine (CF-1 mice and PC-3 human prostate cancer-derived xenograft in severe combined immunodeficiency [SCID] mice).

Interpretation and Analysis: *In vitro* competitive binding assays, using PC-3 androgen-independent human prostate cancer cells, reveal values < 2.5 nmol/L for inhibitory concentration of 50% for analogues with β-Ala, 5-Ava, and 8-Aoc spacers. *In vivo* biodistribution studies of the [^{111}In]-DOTA-X-BBN[7-14]NH_2 conjugate performed in CF-1 mice at 1 hour after injection reveal that radioactivity uptake within the pancreas (Note: A GRP receptor expressing tissue) increases as a function of hydrocarbon spacer length (Data: 0.20 ± 0.04 percent injected dose [%ID] per gram for the analogue with no spacer to a maximum of 26.97 ± 3.97 %ID/g for the analogue with 8-Aoc spacer). Radioactivity is cleared efficiently from the blood pool by excretion mainly through the renal/urinary pathway (e.g., 71.6 ± 1.8 %ID at 1 hour postinjection for 8-Aoc spacer analog). *In vivo* pharmacokinetic studies of the [^{111}In]-DOTA-8-Aoc-BBN[7-14]NH_2 conjugate conducted on PC-3 human prostate cancer-derived xenografts in SCID mice show a specific uptake of radioactivity within tumors, with 3.63 ± 1.11 %ID/g observed at 1 hour postinjection. High tumor-to-blood and tumor-to-muscle ratios of approximately 6:1 and 45:1, respectively, can be appreciated at 1 hour after injection. Relative to the radioactivity observed in tumors at 1 hour after injection, 43%, 19%, and 9% of the radioactivity is retained at, respectively, 24, 48, and 72 hours postinjection. Radiometallated DOTA-X-BBN[7-14]NH_2 constructs with hydrocarbon spacers ranging from 5 to 8 carbon atoms therefore appear to be viable candidates for further development as diagnostic and therapeutic radiopharmaceuticals for GRP-positive neoplastic disease states.

Novel series of [^{111}In]-labeled bombesin analogues as potential radiopharmaceuticals for specific targeting of gastrin-releasing peptide receptors expressed on human prostate cancer cells. Hoffman TJ, Gali H, Smith CJ, Sieckman GL, Hayes DL, Owen NK, Volkert WA. J Nucl Med 2003 May; 44 (5), pp. 823–31.

Carcinomas/Mammary Carcinoma/Prostatic Carcinoma/Vascular Endothelium Carcinoma/ Human Carcinoid Bon Cells/Rat Pancreatic Tumor Cells (CA20948)
[^{111}Indium] ([^{111}In])-[c(Arg-Gly-Asp-D-Tyr-Lys)]/ [^{125}I]-[c(Arg-Gly-Asp-D-Tyr-Lys)]

Cellular/Molecular Mechanism of Action: Purified fractions of [c(Arg-Gly-Asp-D-Tyr-Lys)] appear to bind specifically and with high affinity to $\alpha_v\beta_3$ receptors on neovascular blood vessel sections of different major human cancers, like prostate and breast cancer, that express this receptor type.

Background Information: Tumors depend on sufficient blood supply for their growth. They are able to promote new blood vessel formation (neoangiogenesis) via angiogenic factors. Inhibition of this process results in tumor involution or necrosis. RGD (Arg-Gly-Asp) peptides have been described to antagonize neoangiogenesis, for example, by binding to $\alpha_v\beta_3$ receptors on blood vessels.

Implementation: Evaluate the ability to visualize neoangiogenesis in tumors *in vitro* and *in vivo*, with an RGD analogue [c(Arg-Gly-Asp-D-Tyr-Lys)], coupled to the chelator diethyleletriame pentaacetic acid (DTPA) to facilitate [^{111}In] and [^{125}I] radiolabeling.

Interpretation and Analysis: In autoradiography and immunohistochemistry studies, [^{125}I]-labeled [c(Arg-Gly-Asp-D-Tyr-Lys)] appears to bind specifically and with high affinity to $\alpha_v\beta_3$ receptors on neovascular blood vessel sections of different major human cancers, like prostate and breast cancer, that express this receptor type. The radioiodinated pharmaceutical also binds to and becomes internalized within human carcinoid Bon cells and rat pancreatic CA20948 tumor cells. Internalization is receptor specific and appears as well to be time and temperature dependent. Administration of different peptide amounts (0.1, 0.5, and 100 μg) *in vivo* in rats reveals that the optimum amount of radiolabeled analogue appears to be 0.1 μg/rat, because uptake decreases with increasing peptide doses. Receptor-specific accumulation of [^{111}In]-labeled analogue can be appreciated in transplantable CA20948 pancreatic tumors. The introduction of the DTPA group in this peptide results in increased renal clearance of the radiopharmaceutical, in contrast to the non-DTPA-conjugated compound that is cleared predominantly via the liver. [^{111}In] emits auger and conversion electrons besides gamma radiation; therefore, this radiopharmaceutical is suitable not only for tumor scintigraphy but also has potential applicability for radionuclide therapy of major human cancers as well. Moreover, after coupling to the chelator DOTA, the analogue can be radiolabeled in a stable manner with beta-emitters, for example [^{90}Y] and [^{177}Lu], expanding its theoretical potential.

Evaluation of a radiolabeled cyclic DTPA-RGD analogue for tumor imaging and radionuclide therapy. van Hagen PM, Breeman WA, Bernard HF, Schaar M, Mooij CM, Srinivasan A, Schmidt MA, Krenning EP, de Jong M. Int J Cancer (Radiat. Oncol. Invest.) 2000 Aug 20; 90 (4), pp. 186–98.

Carcinomas/Lung Carcinoma: Small Cell Type/ Mammary Carcinoma/Prostatic Cancer (Carcinoma)/Pancreatic Cancer (Carcinoma)
[^{99m}Technetium] ([^{99m}Tc])-MAG3-Coupled Bombesin (BN) Peptide

Background Information: Several human cancers, including small cell lung, prostate, breast, gastric, colon, and pancreatic cancers, express receptors for BN-like peptides. Bombesin peptides that bind specifically to these receptors are useful for the *in vivo* detection of BN receptor expressing cancers.

Application: Detection and characterization of neoplastic disease states, including small cell lung, prostate, breast, gastric, colon, and pancreatic cancers that express receptors for BN-like peptides.

Semi-Synthetic Methods: MAG3-coupled BN peptide (MAG3-BN) can be prepared by solid-phase synthesis and radiolabeled with [^{99m}Tc] by an exchange method.

Implementation: Evaluation of the *in vitro* binding avidity (targeting capacity) of [^{99m}Tc]-MAG3-BN for BN receptor complexes expressed by MDA-MB-231 and MCF-7 human breast cancer cell lines. Complementary investigations can entail determination of *in vivo* radioactivity biodistribution profiles.

Animal Model: Murine (normal and nude mice bearing BN receptor-positive tumors).
Interpretation and Analysis: Radiolabeling of MAG3-BN with [^{99m}Tc] produces a single radioactive species (> 95%). *In vitro* cell-binding analyses validate the affinity and specificity of [^{99m}Tc]-MAG3-BN toward BN receptors. *In vivo* biodistribution in mice reveals that [^{99m}Tc]-MAG3-BN clears rapidly from the blood and most non-targeted tissues, while being excreted mainly via the kidneys. Uptake in BN receptor-positive tissues and in the tumor is low to moderate. [^{99m}Tc]-MAG3-BN displays good radiolabeling together with certain favorable biological characteristics and may be a useful peptide radiopharmaceutical in the detection of BN receptor expressing cancers *in vivo*.

Synthesis, radiolabeling, and biological characteristics of a bombesin peptide analogue as a tumor-imaging agent. Okarvi SM, al-Jammaz I. Anticancer Res 2003 May–Jun; 23 (3B), pp. 2745–50.

Central Nervous System (CNS)/Astrocytoma (Low Grade): CNS/Intra-Axial Brain Tumors *[^{201}Thallium] ([^{201}Tl])-Pentetreotide/ [^{111}Indium] ([^{111}In])-Pentetreotide/[Gd]-Enhanced Magnetic Resonance Imaging (MRI)*

Background Information: Highly undifferentiated glial tumors do not express somatostatin receptors (SSR) in contrast to low-grade astrocytomas that contain SSR. To differentiate a malignant glioma from a low-grade astrocytoma and to distinguish an SSR-positive intra-axial brain tumor from an SSR negative 1, [^{111}In]-pentetreotide brain single photon emission computed tomography (SPECT) can be prospectively undertaken.
Application: Detection and characterization of intra-axial brain tumors.
Implementation: Evaluation of intra-axial brain tumors utilizing [^{201}Tl] and [^{111}In]-pentetreotide brain SPECT performed using a 3-day to 4-day interval before surgery. Results form SPECT analyses are compared with those of [Gd]-enhanced MRI.

Human Model: Cases with intra-axial brain tumors (n = 8; n = 3/8 glioblastoma multiforme, n = 1/8 low-grade astrocytoma, n = 1/8 lymphoma, n = 1/8 medulloblastoma, n = 1/8 neurocytoma, n = 1/8 metastatic tumor).
Interpretation and Analysis: Increased uptake of [^{111}In]-pentetreotide can be appreciated in a high percentage of cases with glioblastoma multiforme (n = 2 grade (−); n = 1 grade (+); positive uptake n = 3/3 or 100% of cases) despite lack of SSR.

Low-grade astrocytomas exhibit minimal uptake of [^{111}In]-pentetreotide (grade +). Remaining tumors have intense uptake of [^{111}In]-pentetreotide. [^{201}Tl] SPECT reveals similar findings to those observed with [^{111}In]-pentetreotide scintigraphy except in some conditions of glioblastoma multiforme (e.g., n = 2). Rare cases that have a negative [^{201}Tl] scan will usually show increases in [^{111}In]-pentetreotide uptake. Similarly, a small percentage of cases that have minimal uptake of [^{111}In]-pentetreotide will usually display increased thallium uptake. The uptake pattern of both [^{201}Tl] and [^{111}In]-pentetreotide appears to correlate with [Gd]-enhanced MRI. [^{111}In]-pentetreotide scintigraphy is sensitive for the detection of intra-axial brain tumors; however, it has no role in assessing the tumor grading and in the definition of receptor profiles.

Indium-111-pentetreotide imaging in intra-axial brain tumors: Comparison with thallium-201 SPECT and MRI. Lee JD, Kim DI, Lee JT, Chang JW, Park CY. J Nucl Med 1995 Apr; 36 (4), pp. 537–41.

Central Nervous System (CNS)/Glioma *[^{123}I]-Iodo-α-Methyl Tyrosine (IMT)*

Application: Scintigraphy using [^{123}I]-IMT is useful in the preoperative characterization of gliomas, in detecting recurrent glioma, and in the biological reevaluation of residual or recurrent tumors. Certain non-parenchymal brain metastatic tumors also appear to be detected utilizing the same imaging agents.
Route of Administration: [^{123}I]-IMT (intravenous).
Implementation: Evaluation of [^{123}I]-IMT SPECT as a modality for the management of intracerebral metastases and lymphomas. [^{123}I]-IMT or [^{123}I]-IMT uptake is quantified as a ratio between maximal tumor accumulation and average uptake in the contralateral hemisphere.

Human Model: Cases with CNS neoplasia (n = 31 patients; n = 28 metastases of extracerebral solid tumors; n = 7 cerebral lymphomas). Note: Histopathological detection of high-grade lymphomas, melanomas, and carcinomas originating from the lung, unknown primary, breast, colon, renal cell, ovary, vagina, frontal sinus.
Interpretation and Analysis: All tumors except renal cell (e.g., n = 2) and small cell lung carcinoma (e.g., n = 1) metastases accumulate [^{123}I]-IMT (91%). The highest IMT uptake can be found in some lung carcinoma metastases. [^{123}I]-IMT uptake is highly variable and is similar in primary and recurrent tumors. Significant accumulation of IMT is seen in the majority of tumors, so that this technique might be helpful for the management of cerebral metastases and lymphomas.

[^{123}I]-iodo-α-methyl tyrosine SPECT in non-parenchymal brain tumors. Matheja P, Weckesser M, Rickert Ch, Franzius Ch, Palkovic S, Riemann B, Schober O. Nuklearmedizin 2002; 41 (4), pp. 191–6.

Central Nervous System (CNS)/Blood-Brain Barrier (BBB): Osmotic Disruption/Glioma *[^{99m}Technetium] ([^{99m}Tc])-Epidermal Growth Factor (EGF)/Intravenous vs Intracarotid Administration/ [Mannitol]*

Cellular/Molecular Mechanism of Action: Mannitol is an osmotic agent that can be applied to disrupt the BBB.
Background Information: Previous reports have described methods for labeling EGF with [^{99m}Tc] and have shown that the product, [^{99m}Tc]-EGF, is retained within EGF receptor-positive intracerebral C6EGFR rat gliomas following intratumoral (i.t.) injection of the radioligand.
Application: Mannitol when administered to the intravascular compartment can reduce the severity of cerebral edema presumably through osmotic draw of free water across the BBB. In addition, agents including [^{99m}Tc]-EGF can potentially be applied to characterize optimum delivery modalities and identify neoplastic lesions that may be susceptible to EGF-bioconjugate based platforms for therapeutic intervention.
Route of Administration: [^{99m}Tc]-EGF (intravenous or intracarotid).
Implementation: Evaluation of the potential use of [^{99m}Tc]-EGF as a tumor targeting agent for gliomas. Radiolocalization is determined following intravenous or intracarotid injection with or without hyperosmotic mannitol-induced disruption of the BBB (BBB-D).

Animal Model: Rat (Fisher strain bearing intracerebral implants of C6EGFR gliomas).

Interpretation and Analysis: As determined by gamma-scintillation counting, 4 hours after intracarotid injection of [^{99m}Tc]-EGF, 0.34% of the injected dose per gram (%ID/g) is localized in C6EGFR tumors that express 10^5–10^6 EGFR sites per cell, compared to 0.07 %ID/g for *in vivo* models bearing C6 wild-type gliomas that do not express EGFR. Corresponding tumor-to-brain ratios are approximately 5.6 and 1.6, respectively. Tumors can be visualized by external gamma scintigraphy with *in vivo* models bearing C6EGFR but not C6 wild-type gliomas, thereby establishing that radiolocalization is dependent upon receptor expression. Intracarotid administration of [^{99m}Tc]-EGF significantly increases tumor uptake compared to intravenous injection (0.34 vs 0.14 %ID/g, $p < 0.04$). Blood-brain barrier hyperosmotic disruption induced with mannitol, followed by intracarotid injection of [^{99m}Tc]-EGF, however, does not significantly enhance tumor uptake compared to intracarotid injection without BBB-D (0.45% vs 0.34 %ID/g, $p > 0.1$). The uptake of [^{99m}Tc]-EGF is approximately 4–9 %ID/g in the liver and 12–20 %ID/g in the kidneys after intracarotid or intravenous administration. External gamma scintigraphy of regions-of-interest (ROIs) over the liver and kidneys reveals that approximately 70–80% of the whole-body radioactivity accumulates in these organs, and only 0.47–0.83% in the tumor following intravenous or intracarotic administration of [^{99m}Tc]-EGF. Therefore, EGF can be used as a specific targeting agent for EGFR (+) brain tumors. However, it is unlikely that systemic injection of EGF-based bioconjugates can deliver sufficient amounts of the ligand to brain tumors for therapeutic purposes, and direct delivery by means of either intratumoral injection or a variant of it such as convection-enhanced delivery will be required.

Evaluation of systemically administered radiolabeled epidermal growth factor as a brain tumor targeting agent. Yang W, Barth RF, Leveille R, Adams DM, Ciesielski M, Fenstermaker RA, Capala J. J Neurooncol 2001 Oct; 55 (1), pp. 19–28.

Central Nervous System (CNS)/Glioma: Luciferase-Transfected *Antisense Nucleotide Radiopharmaceuticals/ [^{125}I]Peptide Nucleic Acid (PNA)/Antitransferrin Receptor/[^{125}I]PNA Avid/Biotin Monoclonal Antibody (MAb)*

Application: Model system for the development of antisense radiobiopharmaceutical imaging agents capable of facilitating the *in vivo* detection and characterization of neoplastic diseases affecting the CNS.

Route of Administration: [^{125}I]PNA antisense conjugates are administered intravenously.

Semi-Synthetic Methods: Antisense radiopharmaceuticals can be used *in vivo* to image gene expression in the brain if these polar molecules could be made transportable through (across) the blood-brain barrier. The present studies describe an antisense imaging agent comprised of an iodinated PNA conjugated to a MAb with affinity for the rat transferrin receptor. The molecular targeting strategy utilizes avidin-biotin technology. The PNA has a 16-mer antisense strand corresponding to the sequence around the methionine initiation codon of the luciferase mRNA.

Implementation: Evaluation of the capacity for [^{125}I]PNA conjugates to recognize and physically interact with glioma neoplastic cell types in a selective manner.

Animal Model: Rat glioma cells (C6 type) are permanently transfected with a luciferase expression plasmid for development of rat experimental brain tumor model. Frozen sections of the brain for film autoradiography are then acquired 2 hours following intravenous injection of [^{125}I]PNA conjugates.

Interpretation and Analysis: The expression of the luciferase transgene in the tumors *in vivo* can be confirmed by measurement of luciferase enzyme activity in tumor cell extracts. No image of luciferase gene expression can be obtained after the administration of either the unconjugated antiluciferase PNA or a PNA conjugate that is an antisense strand to the messenger RNA (mRNA) of a viral transcript. In contrast, tumors can be successfully imaged with [^{125}I]PNA that is an antisense strand to the luciferase sequence and conjugated to the targeting antibody. In conclusion, these studies demonstrate that gene expression in the brain *in vivo* can be imaged with antisense radiobiopharmaceuticals that are conjugated to a brain drug-targeting system.

Antisense imaging of gene expression in the brain *in vivo.* Shi N, Boado RJ, Pardridge WM. Proc Natl Acad Sci U S A 2000 Dec 19; 97 (26), pp. 14709–14.

Central Nervous System (CNS)/Glioma Proliferative Activity/Early-Delayed Retention Ratios *[^{99m}Technetium] ([^{99m}Tc])-Methoxy-Isobutyl-Isonitrile (MIBI)/[^{201}Thallium] ([^{201}Tl])/MI/MIB Index/ [Antiglioma Ki-67 Antigen IgG Validation]*

Background Information: [^{99m}Tc]-MIBI, like [^{201}Tl], is a highly efficient agent for the diagnosis and monitoring of glioma tumors. Although [^{201}Tl] uptake is known to be partly associated with proliferative activity, little is known about the correlation between MIBI uptake and proliferation activity in gliomas.

Application: Detection and characterization of CNS glioma lesions, including estimation of proliferative activity.

Implementation: Evaluate the degree of correlation between MIBI uptake and proliferative activities in gliomas. Validation of results can be estimated utilizing monoclonal antibody with affinity for Ki-67 antigen (MIB-1 staining method). By comparing the results with those of [^{201}Tl], it is possible to determine which tracer is suitable for estimating proliferative activities. In this context, cases are subjected to MIBI and [^{201}Tl] SPECT. Early (10 minutes after injection) and delayed images (3 hours after injection) are then obtained for both MIBI and [^{201}Tl] scintigraphy. Single photon emission computed tomography (SPECT) parameters, early ratio (ER), delayed ratio (DR), and retention index (RI) are obtained with both radiopharmaceuticals. Sample lesions obtained by surgical excision are then immunostained with monoclonal antibody directed against Ki-67 antigen (MIB-1 staining method) in order to facilitate calculation of the MI/MIB index. To evaluate the relationship between proliferative activity and SPECT parameters, correlation analysis can be performed to further interpret experimental findings.

Human Model: Cases of presurgical glioma (n = 24; n = 6 low-grade gliomas, n = 5 anaplastic astrocytomas, n = 13 glioblastomas). Surgical excision performed in all cases following initial evaluation with both MIBI and [^{201}Tl] scintigraphy.

Interpretation and Analysis: Values for MI correlate with calculated MIBI uptake ratios (r = 0.75 for ER and r = 0.7 for DR). Both DR and RI for [^{201}Tl] also correlate with MI, but to a lesser degree (r = 0.6 for DR and r = 0.59 for RI). There appears to be no significant correlation between the MIB-1 index and other parameters. Methoxy-isobutyl-isonitrile-uptake parameters demonstrate a stronger positive correlation with the MIB-1 index than that of [^{201}Tl]. With the use of MIBI SPECT, it is possible to estimate the proliferative activity of CNS gliomas non-invasively.

The correlation between [^{99m}Tc]-MIBI uptake and MIB-1 as a nuclear proliferation marker in glioma: A comparative study with [^{201}Tl]. Nagamachi S,

Jinnouchi S, Nabeshima K, Nishii R, Flores L 2nd, Kodama T, Kawai K, Tamura S, Yokogami K, Samejima T, Wakisaka S. Neuroradiology 2001 Dec; 43 (12), pp. 1023–30.

Central Nervous System (CNS)/Glioma/ Somatostatin Receptor Type 2 Postive Neoplasias *[^{90}Y]-Labeled DOTA0-D-Phe$_1$-Tyr$_3$-Octreotide (DOTATOC)*

Cellular/Molecular Mechanism of Action: The agent DOTATOC competes specifically with somatostatin binding to somatostatin receptor (Type 2). In this context, it functions as a metabolically stable small regulatory peptide.

Background Information: Human gliomas, especially of low-grade type, have been shown to express high-affinity somatostatin Type 2 receptors.

Application: Detection and characterization of glioma neoplastic conditions affecting the CNS. The activity:dose ratio (MBq:Gy) can potentially be utilized as a measure for the stability of peptide retention in receptor-positive tissue and may possibly function as a parameter for predicting clinical course.

Implementation: Evaluation of anaplastic glioma patients in a pilot study using the diffusible peptidic vector [^{90}Y]-labeled DOTATOC for receptor targeting. The radiopharmakon can be locoregionally injected into a stereotactically inserted Port-a-cath.

Human Model: Cases of glioma (n = 7 low-grade; n = 4 anaplastic type).

Interpretation and Analysis: The agent DOTATOC competes specifically with somatostatin binding to somatostatin Type 2 receptors in the low nanomolar range as shown by displacement curves of [^{125}I]-[Tyr$_3$]-octreotide in tumor tissue sections. Diagnostic [^{111}In]-labeled DOTATOC scintigraphy following local injection displays homogeneous to nodular intratumoral vector distribution. The cumulative activity of regionally injected peptide-bound [^{90}Y] amounts to 370–3,300 MBq, which is equivalent to an effective dose range between 60 ± 15 and 550 ± 110 Gy. Activity can be injected in 1 to 4 fractions according to tumor volumes; 1,110 MBq of [^{90}Y]-labeled DOTATOC is the maximum activity per single injection applied in some investigations. Disease stabilization and shrinking of a cystic low-grade astrocytoma can be expected in a certain percentage of cases (e.g., n = 6/7). Signs of toxicity if they are observed include secondary perifocal edema. The activity:dose ratio (MBq:Gy) represents a measure for the stability of peptide retention in receptor-positive tissues and might predict the clinical course. Therefore, somatostatin receptor positive human gliomas, especially of low-grade type, can be successfully targeted by intratumoral injection of DOTATOC peptide.

Locoregional regulatory peptide receptor targeting with the diffusible somatostatin analogue [^{90}Y]-labeled DOTA0-D-Phe$_1$-Tyr$_3$-octreotide (DOTATOC): A pilot study in human gliomas. Merlo A, Hausmann O, Wasner M, Steiner P, Otte A, Jermann E, Freitag P, Reubi JC, Müller-Brand J, Gratzl O, Mäcke HR. Clin Cancer Res 1999 May; 5 (5), pp. 1025–33.

Central Nervous System (CNS)/Neural Crest Tumors/ Neuroblastoma (NB)/Ganglioneuroma (GN)/ Ganglioneuroblastoma *[^{123}I]-Metaiodobenzylguanidine ([^{123}I]-MIBG)*

Application: Detection of neural crest tumors applying nuclear medicine imaging techniques.

Dosage: [^{123}I]-MIBG.

Considerations: Scintigraphy with [^{123}I]-MIBG should be the primary imaging procedure followed by computed tomography (CT) in the investigation of cases suffering from neural crest tumors. Results are compared with bone scans and CT images, as well as surgical pathologic findings.

Implementation: Evaluation of neural crest tumor conditions with serial MIBG scans to determine the impact of imaging results on the clinical treatment of pediatric cases with neural crest tumors.

Human Model: Cases with neural crest tumors (n = 27; n = 25/27 with initial diagnoses of NB; n = 1/27 ganglioneuroblastoma; n = 1/27 GN).

Interpretation and Analysis: At initial diagnosis, when compared with bone and CT scans, MIBG imaging does not identify any unsuspected lesions resulting in changes in staging. In NB conditions, approximately 50% of cases that initially have positive MIBG scans will have serial studies that normalize during therapy (e.g., n = 13/25). However, after completion of therapy, over 50% of cases will have a disease relapse (e.g., n = 8/13). Although areas of active disease may be well delineated by other standard imaging modalities, only 50% (e.g., n = 4/8) have MIBG study results that are positive in sites of relapse. Some cases of GN (e.g., n = 1 at diagnosis and 3 after NB therapy) demonstrate an uptake of MIBG that is similar in appearance to that in NB. Therefore, MIBG imaging does not change the staging or alter treatment during therapy for most cases. Normalization of positive study results is an unreliable indicator of outcome for children with NB. Furthermore, when relapses occur, MIBG scans identify only 50% of those with active NB. The uptake of MIBG in GN is indistinguishable from that in NB. In some clinical scenarios, results of serial MIBG studies do not have a significant impact on patient treatment.

Both [^{123}I]-MIBG scintigraphy and x-ray CT are imaging techniques that are capable of accurately detecting neural crest tumors. Slightly more accurate detection of metastatic disease can be observed with [^{123}I]-MIBG scintigraphy. Computed tomography of tumors is useful in planning appropriate metastatic intervention.

The role of [^{131}iodine]-metaiodobenzylguanidine scanning in the correlative imaging of patients with neuroblastoma. Andrich MP, Shalaby-Rana E, Movassaghi N, Majd M. Pediatrics 1996 Feb; 97 (2), pp. 246–50.

Central Nervous System (CNS)/Neuroblastoma (NB) *[^{123}I]-Metaiodobenzylguanidine ([^{123}I]-MIBG)*

Cellular/Molecular Mechanism of Action: [^{123}I]-MIBG is a radioiodinated analogue of guanidine nucleotide.

Application: Improved specificity and sensitivity in the detection of pediatric NB can be achieved applying [^{123}I]-MIBG as a diagnostic probe for scintigraphy procedures applied in concert with magnetic resonance imaging (MRI) diagnostic modalities.

Route of Administration: [^{123}I]-MIBG (intravascular).

Implementation: Evaluation of the comparative effectiveness of MRI and [^{123}I]-MIBG scintigraphic imaging for detecting and characterizing NB lesions (n = 50 examinations for each diagnostic modality). Separate and combined analyses of MRI and MIBG scintigraphic images are then compared with clinical and histologic findings.

Human Model: Cases of NB (n = 28 with n = 193 neuroblastoma lesions).

Interpretation and Analysis: In the diagnosis of NB lesions, MIBG scintigraphy, MRI, and combined analysis show a sensitivity of 69%, 86%, and 99% and a specificity of 85%, 77%, and 95%, respectively. On MRI, some false-positive images may be recorded (e.g., n = 15/50) that can be associated with posttherapeutic reactive changes (e.g., n = 10/15); benign adrenal tumors (e.g., n = 3/15); or enlarged lymph nodes (e.g., n = 2/15). Scintigraphy with MIBG may also produce false-positive findings (e.g., n = 10) that can be

associated with ganglioneuromas (e.g., n = 2/10); benign liver tumors (e.g., n = 2/10); or physiologic uptake (e.g., n = 6/10). The occurrence of false-negative MRI scans for NB can also occur (e.g., n = 13 NB metastases; n = 2 residual masses managed with chemotherapy). Occasionally, primary or residual NBs and metastasis (orbital) can be misinterpreted on MRI as Wilms' tumor, reactive changes after surgery, or rhabdomyosarcoma. A relatively large number of bone metastases (e.g., n = 32) or other sites of NB metastases (e.g., n = 6) may show MIBG uptake in addition to some adrenal NB lesions.

Combined image interpretation can noticeably improve sensitivity and specificity (e.g., n = 1 false-negative [bone metastasis]; n = 3 false-positive [n = 2/3 ganglioneuromas, n = 1/3 pheochromocytoma]). Therefore, in the assessment of NB lesions in pediatric cases, MRI shows a higher sensitivity and MIBG scintigraphy a higher specificity. However, integrated imaging shows an increase in both sensitivity and specificity.

Integrated imaging using MRI and [^{123}I] metaiodobenzylguanidine scintigraphy to improve sensitivity and specificity in the diagnosis of pediatric neuroblastoma. Pfluger T, Schmied C, Porn U, Leinsinger G, Vollmar C, Dresel S, Schmid I, Hahn K. AJR Am J Roentgenol 2003 Oct; 181 (4), pp. 1115–24.

Central Nervous System (CNS)/Neuroblastoma (NB)/Xenotransplants/Spontaneous Arising Neuroblastoma
[^{131}I]-Metaiodobenzylguanidine ([^{131}I]-MIBG)

Cellular/Molecular Mechanism of Action: [^{131}I]-MIBG is a radioiodinated analogue of guanidine nucleotide.
Application: Detection and characterization of NB lesions within the CNS.
Route of Administration: [^{131}I]-MIBG (intraperitoneal).
Dosage: [^{131}I]-MIBG (18 μCi/g: mouse).
Implementation: Evaluate [^{131}I]-MIBG scintigraphy for image localization of high-risk NB xenotransplanted and spontaneously arising NBs (e.g., murine model). In instances when measured tumor volumes exceed 200 mm^3, each mouse receives an intraperitoneal injection of 18 μCi/g [^{131}I]-MIBG. Pinhole scintigraphy can be applied to evaluate the MIBG biodistribution and visualize individual tumors.

Animal Model: Murine (mouse model of high-risk NB employing xenotransplanted and spontaneously arising NBs). Neuroblastoma xenografts are created by subcutaneous inoculation of human NB cell suspensions into the flanks of athymic nude mice. In addition, spontaneous paraspinal NBs can be detected by direct palpation in MYCN trans-genic mice.
Interpretation and Analysis: Image analysis reveals the absorption of radiolabeled MIBG and visualization of tumors. Analysis of the images allows quantification of relative MIBG uptake and determination of linear and area measurements of tumors. In this context, high-energy pinhole imaging effectively demonstrates uptake of radiolabeled MIBG by human NB tumors in murine experimental models. The technique allows for the *in vivo* assessment of tumor burden. In the future, this method will be used to evaluate its sensitivity for detecting metastatic spread as well as for investigating the therapeutic efficacy of high-dose [^{131}I]-MIBG in combination with radiosensitizing agents.
Instrumentation: Gamma camera equipped with a 3-mm pinhole on 1 head and an HEGP collimator on the other.

Pinhole imaging of [^{131}I]-metaiodobenzylguanidine ([^{131}I]-MIBG) in an animal model of neuroblastoma. Accorsi R, Morowitz MJ, Charron M, Maris JM. Pediatr Radiol 2003 Oct; 33 (10), pp. 688–92.

Central Nervous System (CNS)/Neuroendocrine Neoplasias: Catecholamine-Secreting/ Neuroblastoma/Pheochromocytoma
[^{131}I]-Metaiodobenzylguanidine ([^{131}I]-MIBG)/ [^{123}I]-MIBG

Cellular/Molecular Mechanism of Action: [^{123}I]-MIBG is classified as a norepinephrine analog.
Application: Metaiodobenzylguanidine has been in clinical use for 15 years and has been shown to have high sensitivity (about 85%) and specificity (> 95%) for the location of all types of pheochromocytomas. Similar levels of success have been observed with the diagnostic detection of neuroblastoma. Other neuroendocrine lesions have been imaged at lower levels of sensitivity, including carcinoids, medullary thyroid cancer, and non-secretory paragangliomas.
Interpretation and Analysis: Alternative analogues of radiolabeled somatostatin may have greater utility for improved detection of neuroendocrine lesions, including carcinoids, medullary thyroid cancer, and non-secretory paragangliomas. Metaiodobenzylguanidine scintigraphy may also provide a different *in vivo* diagnostic approach for evaluating the sympathetic autonomic nervous system, particularly with respect to cardiac function.
Instrumentation: Various radiolabels for MIBG and its analogues permit planar scintigraphy, single photon emission computed tomography (SPECT), positron emission tomography (PET), intraoperative probe localization, and radiopharmaceutical therapy.

The current status of metaiodobenzylguanidine and related agents for the diagnosis of neuro-endocrine tumors. Shapiro B, Sisson JC, Shulkin BL, Gross MD, Zempel S. Quart J Nucl Med 1995 Dec; 39 (4 Suppl 1), pp. 3–8.

Central Nervous System (CNS)/Neuroendocrine Neoplasia: Catecholamine-Secreting
[^{131}I]-Metaiodobenzylguanidine ([^{131}I]-MIBG)/ [^{123}I]-MIBG

Cellular/Molecular Mechanism of Action: [^{123}I]-MIBG is classified as a norepinephrine analog.
Application: Radioiodinated MIBG ([^{131}I] or [^{123}I]) is used as a radiopharmaceutical that preferentially accumulates within certain neuroendocrine tumors, especially pheochromocytomas and neuroblastomas.
Route of Administration: [^{131}I]-MIBG and [^{123}I]-MIBG (intravenous).
Dosage: [^{131}I]-MIBG and [^{123}I]-MIBG.
Interpretation and Analysis: [^{131}I]-MIBG and [^{123}I]-MIBG permit non-invasive whole-body scintigraphic screening for benign and malignant, familial and sporadic, intra-adrenal and extra-adrenal pheochromocytomas and primary and metastatic neuroblastomas, with high sensitivity (85–90%) and specificity (> 95%). Metaiodobenzylguanidine also concentrates in presynaptic terminals of adrenergic, autonomically innervated organs such as the heart and may be used as a non-invasive *in vivo* probe for characterizing this segment of the autonomic nervous system. As an additional benefit, large doses of [^{131}I]-MIBG and [^{123}I]-MIBG are also capable of selectively delivering radiotherapeutic doses to malignant pheochromocytomas and advanced stages or refractory forms of neuroblastoma.
Instrumentation: Nuclear medicine imaging with a scintillation camera.

Imaging of catecholamine-secreting tumors: Uses of MIBG in diagnosis and treatment. Shapiro B. Baillieres Clin Endocrinol Metab 1993 Apr; 7 (2), pp. 491–507.

Neuroendocrine: Pheochromocytoma/[Elevated Glucagon-Receptor Expression]
Des-His$_1$[Glu$_9$]Glucagon Amide/[^{125}I-Thyr$_{10}$]Glucagon

Cellular/Molecular Mechanism of Action: [^{125}I-Thyr$_{10}$] glucagon is a radiolabeled analogue of glucagon. Des-His$_1$[Glu$_9$] glucagon amide is a glucagon receptor antagonist.
Background Information: Pheochromocytoma lesion express glucagon receptor complexes at elevated densities on their exterior membranes.
Application: Potential diagnostic probe for detecting conditions of pheochromocytoma. Des-His$_1$[Glu$_9$]glucagon amide (GR-A) abolishes the secretory response to glucagon by pheochromocytomas.
Route of Administration: Experimental (*in vitro*).
Implementation: Evaluation of glucagon messenger RNA (mRNA) expression and glucagon receptor expression in pheochromocytoma lesions.

Human *Ex Vivo* Model: Pheochromocytoma lesions (n = 3 and n = 4 normal adrenal medullas).
Interpretation and Analysis: Glucagon-receptor mRNA can be detected by reverse transcription-polymerase chain reaction in human pheochromocytomas but not in normal adrenal medullas. Quantitative autoradiography demonstrates the presence of abundant [^{125}I-Thyr$_{10}$]glucagon binding sites in pheochromocytomas, which can be displaced by both cold glucagon and the glucagon receptor antagonist Des-His$_1$[Glu$_9$]glucagon amide (GR-A). The adrenal medulla is weakly labeled, and binding is not displaced by GR-A. Glucagon enhances epinephrine and norepinephrine release by pheochromocytoma slices with minimal and maximal effective concentrations being 10^{-8} M and 10^{-6} M, respectively. Adrenomedullary slices display a weak catecholamine response only in the presence of 10^{-5} M glucagon.

GR-A abolishes the secretory response to glucagon by pheochromocytomas but not of adrenal medullas. Collectively, these findings indicate that human pheochromocytomas, but not the adrenal medulla, express glucagon receptors and possess a marked secretory response to glucagon, thereby providing the rationale to explain the specificity of the glucagon provocative test in the diagnosis of pheochromocytoma.

Human pheochromocytomas, but not adrenal medulla, express glucagon-receptor gene and possess an *in vitro* secretory response to glucagon. Albertin G, Aragona F, Gottardo L, Malendowicz LK, Nussdorfer GG. Peptides 2001 Apr; 22 (4), pp. 597–600.

Central Nervous System (CNS)/Neuroendocrine Tumors/Somatostatin Receptor Expression
Octreotide/Somatostatin Analogues

Somatostatin and other neuropeptides are expressed in tumors originating from neuronal precursors and paraganglia, namely medulloblastoma, central primitive neuro-ectodermal tumors (cPNETs), neurocytoma, gangliocytoma, olfactory neuroblastoma, and paraganglioma. In medulloblastoma, the most common malignant tumor in childhood, there is extensive expression of somatostatin in addition to somatostatin receptors (SSTR) Type 2 complexes. Although density of SSTR-2 and intensity of the expression of somatostatin genes have no prognostic significance in medulloblastoma, their presence may bring along important information on oncogenesis and relate medulloblastoma to cPNETs. Radiolabeled octreotide scintigraphy may be useful in the follow-up of such conditions, allowing differentiation between scar and tumoral tissue. Moreover, on the basis of octreotide-induced inhibition of cell proliferation in medulloblastoma, a trial with octreotide in cases with recurrent or high-risk tumor is warranted. Meningiomas and low-grade astrocytic gliomas, even if not displaying a clear neuroendocrine phenotype, have high levels of SSTR-2. In meningiomas, SSTR scintigraphy is not part of the routine preoperative assessment; moreover, a therapeutic trial with somatostatin analogues in cases with recurrent or inoperable meningiomas should be carried out with great caution, because somatostatin and octreotide slightly increase cell proliferation in cultured meningiomatous cells. Low-grade gliomas (World Health Organization grade 2), and a smaller fraction of anaplastic astrocytomas, express SSTR-2, while glioblastomas usually do not. Unfortunately, radiolabeled-octreotide scintigraphy is not useful in the differential diagnosis of gliomas, because the results are altered by the disruption of the blood-brain barrier (BBB). In addition, radionuclide-labeled somatostatin analogues are not useful in the therapy of low-grade gliomas, because an intact BBB prevents them from reaching target SSTR-2 complexes. Recently, a pilot study in gliomas has proposed the use of a radiolabeled somatostatin analogue with a locoregional approach in order to overcome the intact BBB.

Neuroendocrine tumors in the brain. Cavalla P, Schiffer D. Ann Oncol 2001; 12 Suppl 2, pp. S131–4.

Cholecystokinin (CCK-B) Receptor Expression/ Meningiomas/Gastroenteropancreatic Tumors/ Medullary Thyroid Carcinoma/Small Cell Lung Cancer/Astrocytomas/Gastrointestinal Tumors/ Stromal Ovarian Cancer
[^{111}Indium] ([^{111}In])-Labeled MP2288/[^{111}In]-Labeled MP2286

Cellular/Molecular Mechanism of Action: [^{111}In]-labeled MP2288 and [^{111}In]-labeled MP2286 recognize and physically bind to CCK-B receptor complexes.
Background Information: Receptors for regulatory peptides such as somatostatin or vasoactive intestinal polypeptide are expressed by a number of human neoplasms and can be visualized *in vivo* with peptide receptor scintigraphy. Recently, the CCK-B receptor, which binds both gastrin and cholecystokinin with high affinity, has been shown using *in vitro* methods to be overexpressed in a number of human tumor tissues, including medullary thyroid carcinomas, small cell lung cancers, astrocytomas, gastrointestinal tumors, and stromal ovarian cancers.
Semi-Synthetic Methods: Design of a novel, unsulfated CCK octapeptide analogue linked to the diethylenetriamine pentaacetic acid (DTPA) and DOTA metal chelating agents.
Implementation: Evaluation of the binding avidity of unsulfated CCK octapeptide analogues linked to the metal chelating agents DTPA and DOTA for CCK-B receptor-positive tissues from human tumors.

Animal Model: Rat (biodistrubution studies).
Interpretation and Analysis: Assays reveal that the most potent compounds are DTPA-[Nle28, 31]-CCK(26-33) (MP2286) and DTPA-[d-Asp26,Nle28,31]-CCK(26-33) (MP2288) with an IC_{50} of 1.5 nM. For comparison, analogues with C-terminal DTPA, such as [Nle28,31,Aphe33(*p*-NH-DTPA)]-CCK(26-33) and CCK-(26-33)-NH$(CH_2)_2$ NH-DTPA, have an IC_{50} of $>$ 100 nM. DOTA-[D-Asp26, Nle28,31]-CCK(26-33) has an IC_{50} of 3.9 nM. The compounds are selective for CCK-B receptors, as they do not bind with high affinity to CCK-A receptors expressed in human tumors (meningiomas or gastroenteropancreatic tumors). Biodistribution

studies with [^{111}In]-labeled MP2286 and MP2288 show that the primary mode of clearance is renal, and the primary sites of uptake (percent injected dose per gram [%ID/g] 24 hours postinjection) are the kidney (0.270 and 0.262, respectively) and gastrointestinal tract (rat). The CCK-B receptor expressing gastric mucosa shows specific *in vivo* accumulation of [^{111}In]-labeled MP2288 can be blocked in the presence of excess unlabeled MP2288. [^{111}In]-labeled MP2286 and MP2288 are also found to be stable in human plasma, whereas both compounds are degraded in urine (> 40% after 3 hours at 37°C). The affinity, specificity, biodistribution, and stability of these 2 DTPA-CCK analogues indicate that these compounds have substantial promise for use in the *in vivo* visualization of CCK-B receptor expressing tumors.

Unsulfated DTPA- and DOTA-CCK analogues as specific high-affinity ligands for CCK-B receptor expressing human and rat tissues *in vitro* and *in vivo*. Reubi JC, Waser B, Schaer JC, Laederach U, Erion J, Srinivasan A, Schmidt MA, Bugaj JE. Eur J Nucl Med 1998 May; 25 (5), pp. 481–90.

Ehrlich Solid Tumor: Murine Transplant/Sarcoma-180 Solid Tumor: Murine Transplant *[^{75}Se]-Labeled L-Selenomethionine/[^{75}Se]-Labeled D-Selenomethionine*

Cellular/Molecular Mechanism of Action: Semi-synthetic *D*-selenomethionine and *L*-selenomethionine are perceived by cells as analogues of the amino acid methionine.
Route of Administration: Intravascular.
Semi-Synthetic Methods: *D*-SeMet-[^{75}Se] can be enzymatically prepared from commercially available *L*-selenomethionine-[^{75}Se] (*L*-SeMet-[^{75}Se]) by using amino acid racemase and immobilized *L*-amino acid oxidase.
Implementation: Evaluation of the radioactive biodistribution of [^{75}Se]-labeled *D*-selenomethionine (*D*-SeMet-[^{75}Se]) and capacity to recognize solid tumors and sarcoid neoplasias.
Animal Model: Murine (tumor-bearing mice with Ehrlich solid tumors and sarcoma-180 solid tumors).
Interpretation and Analysis: No difference can be appreciated in the excretion rate for *D*-SeMet-[^{75}Se] and *L*-SeMet-[^{75}Se] into the urine and feces in normal mice within 48 hours after administration. The *in vivo* uptake of *D*-SeMet-[^{75}Se] in both Ehrlich solid tumors and sarcoma-180 solid tumors is several times higher than that for *L*-SeMet-[^{75}Se] but the uptake of *D*-SeMet-[^{75}Se] and *L*-SeMet-[^{75}Se] is similar within the pancreas. Such findings indicate that *D*-SeMet-[^{75}Se] might be useful as a tumor-imaging agent. *In vitro* experiments on Ehrlich ascites tumor cells show that *D*-SeMet-[^{75}Se] is incorporated into the tumor cells by an Na^+-dependent active transport system similar to *L*-SeMet-[^{75}Se] and that a transport mechanism specific for *D*-SeMet-[^{75}Se] might be present in tumor cells in addition to a transport system common to both *D*- and *L*-forms.

Tumor accumulation of D-selenomethionine-[^{75}Se] in tumor-bearing mice. Goto R, Unno K, Takeda A, Okada S, Tamemasa O. J Pharmacobiodyn 1987 Sep; 10 (9), pp. 456–61.

Endothelium: Vascular (Carcinoma)/Mammary Carcinoma/Prostatic Carcinoma/Human Carcinoid Bon Cells/Rat Pancreatic Tumor Cells (CA20948)/$\alpha_v\beta_3$ Receptor Complexes *[^{111}Indium] ([^{111}In])-[c(Arg-Gly-Asp-D-Tyr-Lys)]/ [^{125}I]-[c(Arg-Gly-Asp-D-Tyr-Lys)]*

Cellular/Molecular Mechanism of Action: Purified fractions of [c(Arg-Gly-Asp-D-Tyr-Lys)] appear to bind specifically and with high affinity to $\alpha_v\beta_3$ receptors on neovascular blood vessel sections of different major human cancers, like prostate and breast cancer, that express this receptor type.
Background Information: Tumors depend on sufficient blood supply for their growth. They are able to promote new blood vessel formation (neoangiogenesis) via angiogenic factors. Inhibition of this process results in tumor involution or necrosis. RGD (Arg-Gly-Asp) peptides have been described to antagonize neoangiogenesis, for example, by binding to $\alpha_v\beta_3$ receptors on blood vessels.
Implementation: Evaluate the ability to visualise neoangiogenesis in tumors *in vitro* and *in vivo*, with an RGD analogue [c(Arg-Gly-Asp-D-Tyr-Lys)], coupled to the chelator diethyleletriame pentaacetic acid (DTPA) to facilitate [^{111}In] and [^{125}I] radiolabeling.
Interpretation and Analysis: In autoradiography and immunohistochemistry studies, [^{125}I]-labeled [c(Arg-Gly-Asp-D-Tyr-Lys)] appears to bind specifically and with high affinity to $\alpha_v\beta_3$ receptors on neovascular blood vessel sections of different major human cancers, like prostate and breast cancer, that express this receptor type. The radioiodinated pharmaceutical also binds to and becomes internalized within human carcinoid Bon cells and rat pancreatic CA20948 tumor cells. Internalization is receptor-specific and appears as well to be time and temperature dependent. Administration of different peptide amounts (0.1, 0.5, and 100 μg) *in vivo* in rats reveals that the optimum amount of radiolabeled analogue appears to be 0.1 μg/rat, because uptake decreases with increasing peptide doses. Receptor-specific accumulation of [^{111}In]-labeled analogue can be appreciated in transplantable CA20948 pancreatic tumors. The introduction of the DTPA group in this peptide results in increased renal clearance of the radiopharmaceutical, in contrast to the non-DTPA-conjugated compound that is cleared predominantly via the liver. [^{111}In] emits auger and conversion electrons besides gamma radiation; therefore, this radiopharmaceutical is suitable not only for tumor scintigraphy but also has potential applicability for radionuclide therapy of major human cancers as well. Moreover, after coupling to the chelator DOTA, the analogue can be radiolabeled in a stable manner with beta-emitters, for example [^{90}Y] and [^{177}Lu], expanding its theoretical potential.

Evaluation of a radiolabeled cyclic DTPA-RGD analogue for tumor imaging and radionuclide therapy. van Hagen PM, Breeman WA, Bernard HF, Schaar M, Mooij CM, Srinivasan A, Schmidt MA, Krenning EP, de Jong M. Int J Cancer (Radiat. Oncol. Invest.) 2000 Aug 20; 90 (4), pp. 186–98.

Folate Receptors/Neoplastic Disease *Gallium-67 ([^{67}Ga])Folate-DF-Folate-(α)/[^{67}Ga] Folate-DF-Folate-(γ)*

Cellular/Molecular Mechanism of Action: Folate is used as a carrier targeting molecule for the radioisotopes due to its binding avidity for folate receptors expressed at relatively high concentrations by certain tumor cell types compared to normal cell types. Deferoxamine functions as a chelating agent for certain radioisotopes (e.g., [$^{67}Ga^{3+}$]).
Application: Identification of folate receptor positive neoplastic lesions applying nuclear medicine imaging techniques.
Route of Administration: Intravenous.
Semi-Synthetic Methods: The vitamin folic acid can be covalently linked to the chelating agent deferoxamine (DF) via an amide bond using a simple carbodiimide coupling reaction. A mixture of 2 isomers, DF-folate-(α) and DF-folate-(γ), can be generated by producing chemical interactions with a carboxyl group at either the α- or γ- position of folic acid, respectively. Isomer separation is feasible applying anion-exchange chromatography and NH_4HCO_3 gradients.

Experimental Interpretation: Competitive binding studies reveal that only the DF-folate-(γ) is recognized by the folate receptors on KB cells and interacts with an affinity comparable to unconjugated folic acid. The DF-folate conjugates can be radiolabeled with the γ-emitting radionuclide [$^{67}Ga^{3+}$] to test for uptake by cultured KB cells overexpressing the folate receptor.
Interpretation and Analysis: The cellular accumulation of [^{67}Ga]-DF-folate-(γ) tracer exhibits rapid uptake kinetics in cell culture with a $T_{1/2}$ of approximately 3 minutes. The KB cell–associated [^{67}Ga]-DF-folate-(γ) radioactivity is competitively blocked by free folic acid, indicating that uptake of [^{67}Ga]-DF-folate-(γ) is specifically mediated by the folate receptor. Because folate receptors are overexpressed on the surface of many neoplastic cells, these results suggest that [^{67}Ga]-DF-folate-(γ) complex might be useful as a diagnostic agent for the non-invasive imaging of folate receptor-positive tumors.
Instrumentation: Computer-integrated nuclear medicine scintigraphy imaging camera.

Preparation of [^{66}Ga]- and [^{68}Ga]-labeled Ga(III)-deferoxamine-folate as potential folate-receptor-targeted PET radiopharmaceuticals. Mathias CJ, Lewis MR, Reichert DE, Laforest R, Sharp TL, Lewis JS, Yang ZF, Waters DJ, Snyder PW, Low PS, Welch MJ, Green MA. Nucl Med Biol 2003 Oct; 30 (7), pp. 725–31.

Folic Acid Receptor Expression/Neoplastic Disease *[^{99m}Technetium] ([^{99m}Tc])-Labeled Folic Acid*

Cellular/Molecular Mechanism of Action: In the context of diagnostic pharmacology, folic acid binds to folic acid receptor complexes variably expressed on the surface membrane of different cell types.
Background Information: It is known that membrane folic acid receptors are responsible for the cellular accumulation of folate and folate analogues such as methotrexate and overexpressed by various tumor cells. However, these receptors are highly restricted in normal differentiated tissues. Results of limited *in vitro* and *in vivo* animal studies suggest that folate receptors can potentially function as a targeting platform for tumor imaging.
Application: Detection and characterization of neoplastic lesions.
Route of Administration: [^{99m}Tc]-labeled folic acid (intravenous).
Dosage: [^{99m}Tc]-labeled folic acid (370 KBq/rat).
Semi-Synthetic Methods: Use of ethylenedicysteine (EC) as a chelating agent for the production of [^{99m}Tc]-EC-folate.
Implementation: Evaluate the labeling efficiency of [^{99m}Tc]-labeled folic acid and its potential use as a tumor-seeking agent. Tissue distribution of [^{99m}Tc]-EC-folate can be determined by evaluations made at 20 minutes and 1, 2, and 4 hours (n = 3 observations/time interval). Validation of receptor-mediated processes can be established employing blocking studies utilizing the co-administration of "cold folic acid" (50 and 150 μmol/kg) in concert with [^{99m}Tc]-EC-folate in tumor-bearing rats. Planar imaging and whole-body autoradiograms are then performed and findings compared to [^{99m}Tc]-EC (control).
Animal Model: Rats (tumor-bearing).
Interpretation and Analysis: In animal studies, tumor/blood count density ratios at 20 minutes to 4 hours increase from 0.81 ± 0.09 to 1.23 ± 0.13 with [^{99m}Tc]-EC-folate. Conversely, these values show a time-dependent decrease from 0.77 ± 0.32 to 0.65 ± 0.01 with [^{99m}Tc]-EC within the same time period. Tumor/muscle and tumor/blood count density ratios significantly decrease with folic acid co-administration. Planar images and autoradiograms confirm that tumors can be visualized clearly with [^{99m}Tc]-EC-folate.

[^{99m}Tc]-ethylenedicysteine-folate: A new tumor-imaging agent. Synthesis, labeling and evaluation in animals. Ilgan S, Yang DJ, Higuchi T, Zareneyrizi F, Bayhan H, Yu D, Kim EE, Podoloff DA. Cancer Biother Radiopharm 1998 Dec; 13 (6), pp. 427–35.

Folate Receptors (Ovarian Carcinoma) *[^{111}Indium] ([^{111}In])-Diethylenetriamine Pentaacetic Acid (DTPA)-Folate*

Cellular/Molecular Mechanism of Action: [^{111}In]-DTPA-folate is a radioactive chelation analogue of folic acid that recognizes and physically binds to folate receptors expressed at relatively high membrane densities by certain neoplastic cell types.
Application: [^{111}In]-DTPA-folate can be applied as a tumor-selective imaging agent in diagnostic nuclear medicine for the purpose of detecting and monitoring neoplastic disease states (e.g., ovarian malignancies). Based on the biological properties of folate, it could also function as a tumor-specific drug delivery platform.
Background Information: The cell-membrane folate receptor is a potential molecular target for tumor-selective drug delivery, including radiolabeled folate-chelate conjugates for diagnostic imaging.
Route of Administration: [^{111}In]-DTPA-folate (intravenous bolus).
Implementation: Evaluation of the diagnostic potential for [^{111}In]-DTPA-folate to function as a diagnostic agent for malignant ovarian disease or endometrial cancer utilizing [^{111}In]-DTPA-folate as an imaging agent (phase I/II clinical trials). Prior to the administration of [^{111}In]-DTPA-folate, some nuclear medicine facilities prefer to administer unlabeled "free" folic acid followed by whole-body imaging at 30 minutes, 4 hours, and 24 hours postinjection of the folate radiopharmaceutical agent. Imaging with single photon emission computed tomography (SPECT) instrumentation can also be performed at the appropriate time-delayed intervals.
Human Model: Female cases of ovarian cancer (n = 35) enrolled in a phase I/II clinical study (n = 33 completing the surgical follow-up required by the study protocol that serves to define disease status). Individual cases either have a pathologically proven malignancy or are scheduled for surgery to resolve suspected new ovarian cancer growth (n = 26 cases), recurrent ovarian cancer (n = 5 cases), or endometrial cancer (n = 2 cases). In some cases, evaluated (e.g., n = 19/26) unlabeled "free" folic acid is administered followed by whole-body imaging at 30 minutes, 4 hours, and 24 hours postinjection of the folate radiopharmaceutical agent.
Interpretation and Analysis: In cases subjected to surgical intervention (e.g., n = 33), slightly less than half have new or recurrent malignant tumors that can be detected (e.g., n = 14/33). A large percentage of newly diagnosed ovarian carcinomas can be identified blindly by multiple professional readers (e.g., n = 7/7 or 100% sensitivity). Conversely, sensitivity for detecting recurrent ovarian-related malignancies can be significantly less (e.g., n = 7/33) in cases where the interpretation is performed without prior knowledge, compared to the evaluation of images with prior knowledge of disease (e.g., n = 28/33 or 84.5% for unmasked readings). Such findings indicate that a correlation exists between anatomic imaging studies (computed tomography) and the diagnostic detection of such lesions. A number of cases may be determined to have benign masses (e.g., n = 18). In the context of a limited population size, the specificity of [^{111}In]-DTPA-folate scintigraphy is approximately 76% and 82% for masked and unmasked image interpretation, respectively. [^{111}In]-DTPA-folate is safe, and possibly effective, for differentiating between malignant and benign ovarian masses based on interpretation of scintigraphic images.

Evaluation of [^{111}In]-DTPA-folate as a receptor-targeted diagnostic agent for ovarian cancer: Initial clinical results. Siegel BA, Dehdashti F, Mutch DG, Podoloff DA, Wendt R, Sutton GP, Burt RW, Ellis PR, Mathias CJ, Green MA, Gershenson DM. J Nucl Med 2003 May; 44 (5), pp. 700–7.

Gastrin-Releasing Peptide (GRP) Receptors/ Prostatic Carcinoma/[Mammary Carcinoma]/ [Small Cell Lung Cancer]/[Pancreatic Cancer] *[^{111}Indium] ([^{111}In])-Bombesin (BBN)/[^{111}In]-DOTA-X-BBN[7-14]NH_2 / Beta-Ala, 5-Ava Spacer/ 8-Aoc Spacer*

Cellular/Molecular Mechanism of Action: Bombesin has been known to bind to GRP receptors with high affinity and specificity.

Background Information: Gastrin-releasing peptide receptors have been shown to be expressed at relatively high densities on several types of cancer cells, including cancers of the prostate, breast, small cell lung, and pancreas.

Application: Hydrocarbon spacer chains can effectively improve the specificity of detecting and characterizing human prostatic carcinoma cell types when employing [^{111}In]-DOTA-bombesin as a template molecular for the purpose of recognizing GRP receptor complexes.

Implementation: Evaluation of the relative tumor "uptake" and pharmacokinetic parameters for various [^{111}In]-labeled BBN analogues as potential candidates for the specific targeting of human prostate cancers.

***Ex Vivo* Model:** Human (PC-3 androgen-independent human prostate cancer cells).

Animal Model: Murine (CF-1 mice and PC-3 human prostate cancer-derived xenografts in severe combined immunodeficient [SCID] mice).

Interpretation and Analysis: *In vitro* competitive binding assays, using PC-3 androgen-independent human prostate cancer cells, reveal values $<$ 2.5 nmol/L for inhibitory concentrations of 50% for analogues with β-Ala, 5-Ava, and 8-Aoc spacers. *In vivo* biodistribution studies of the [^{111}In]-DOTA-X-BBN[7-14]NH_2 conjugates performed on CF-1 mice 1 hour after injection reveal that uptake of radioactivity within the pancreas (Note: A GRP receptor expressing tissue) increases as a function of hydrocarbon spacer length (Data: 0.20 $\pm$ 0.04 percent injected dose per gram [%ID/g] for the analogue with no spacer to a maximum of 26.97 $\pm$ 3.97 %ID/g for the analogue with 8-Aoc spacer). Radioactivity is cleared efficiently from the blood pool by excretion mainly through the renal/urinary pathway (e.g., 71.6 $\pm$ 1.8 %ID at 1 hour postinjection for the 8-Aoc spacer analog). *In vivo* pharmacokinetic studies of the [^{111}In]-DOTA-8-Aoc-BBN[7-14]NH_2 conjugate conducted on PC-3 human prostate cancer-derived xenografts in SCID mice show a specific uptake of radioactivity within tumors, with 3.63 $\pm$ 1.11 %ID/g observed at 1 hour postinjection. High tumor-to-blood and tumor-to-muscle ratios of approximately 6:1 and 45:1, respectively, can be appreciated at 1 hour after injection. Relative to the radioactivity observed in the tumor at 1 hour after injection, 43%, 19%, and 9% of the radioactivity is retained at, respectively, 24, 48, and 72 hours postinjection.

These studies show that radiometallated DOTA-X-BBN[7-14]NH_2 constructs with hydrocarbon spacers ranging from 5 to 8 carbon atoms are suitable candidates for further development as diagnostic and therapeutic radiopharmaceuticals for patients with GRP-positive cancers.

Novel series of [^{111}In]-labeled bombesin analogues as potential radiopharmaceuticals for specific targeting of gastrin-releasing peptide receptors expressed on human prostate cancer cells. Hoffman TJ, Gali H, Smith CJ, Sieckman GL, Hayes DL, Owen NK, Volkert WA. J Nucl Med 2003 May; 44 (5), pp. 823–31.

Gastrointestinal/Colon Cancer/Guanyl Cyclase-C (GC-C) Receptor (LS-180 Cell Type) *[^{125}I]-Tyr$_5$-6-Ahx-Phe$_{19}$-ST[1-19]/[^{111}Indium] ([^{111}In])-DOTA-NCS-6-Ahx-Phe$_{19}$-ST[1-19]*

Cellular/Molecular Mechanism of Action: [^{111}In]-DOTA-NCS-6-Ahx-Phe$_{19}$-ST[1-19] and [^{125}I]-Tyr$_5$-6-Ahx-Phe$_{19}$-ST [1-19] both recognize and bind to GC-C receptor complexes.

Application: Detection and characterization of human colon cancer (e.g., LS-180 cell strains).

Route of Administration: [^{111}In]-DOTA-NCS-6-Ahx-Phe$_{19}$-ST[1-19] and [^{125}I]-Tyr$_5$-6-Ahx-Phe$_{19}$-ST[1-19] (intravenous).

Implementation: Evaluation of the relative *in vitro* competitive binding of [^{111}In]-DOTA-NCS-6-Ahx-Phe$_{19}$-ST[1-19] for GC-C receptor complexes expressed by human colon cancer LS-180 cells compared to [^{125}I]-Tyr$_5$-6-Ahx-Phe$_{19}$-ST[1-19].

Animal Model: Murine (tumor-bearing severe combined immunodeficient [SCID] mice supporting LS-180 colon cancer lesions).

Interpretation and Analysis: Competitive *in vitro* binding studies of [^{111}In]-DOTA-NCS-6-Ahx-Phe$_{19}$-ST[1-19] and [^{125}I]-Tyr$_5$-6-Ahx-Phe$_{19}$-ST[1-19] for GC-C receptors on human colon cancer cells (type LS-180) reveal an IC_{50} value of 7.7 $\pm$ 0.1.6 nM. *In vitro* cellular residualization studies with [^{111}In]-DOTA-NCS-ST peptide and GC-C receptor mediated stimulated cGMP production with LS-180 cells demonstrate that this peptide selectively binds to LS-180 cells in an agonistic fashion. *In vivo* biodistribution studies in mice bearing LS-180 tumors reveal that the [^{111}In]-DOTA-NCS-ST peptide targets the tumor with a specific uptake of 0.94 $\pm$ 0.31 percent injected dose per gram (%ID/g) at 1 hour postinjection and approximately 23% is retained by the tumor at 4 hours postinjection. Radioactivity clears rapidly from the bloodstream with 84.5 $\pm$ 3.4 %ID found in the urine at 1 hour postinjection. High activity in urine and kidney and minimal activity in liver and intestines demonstrates preferential clearance of the radioactivity through the renal/urinary pathway. The specific *in vitro* and *in vivo* accumulation of the radioactivity within LS-180 human colonic cancer cells highlights the potential of radiometallated-DOTA-ST analogues as diagnostic/therapeutic radiopharmaceuticals.

In vivo evaluation of an [^{111}In]-labeled ST-peptide analogue for specific-targeting of human colon cancers. Gali H, Sieckman GL, Hoffman TJ, Owen NK, Chin DT, Forte LR, Volkert WA. Nucl Med Biol 2001 Nov; 28 (8), pp. 903–9.

Gastrointestinal/Colorectal Cancer *[^{111}Indium] ([^{111}In])-Labeled Carcinoembryonic Antigen (CEA) Monoclonal Antibody (MAb)*

Application: Detection of colorectal cancer applying nuclear medicine imaging techniques following curative resection with the simultaneous expression of elevated carcinoembryonic antigen levels and negative clinical diagnostic parameters.

Dosage: Anti-carcinoembryonic antigen MAb Type ZCE-025 (1 mg) labeled with 5.5 mCi of [^{111}In] co-administered with 9 to 39 mg of unlabeled ZCE-025 antibody.

Implementation: Diagnostic scanning is performed 3–7 days after infusion by planar and emission computed tomography.

Interpretation and Analysis: In clinical trials, ZCE-025 MAb imaging detects tumor recurrence or metastasis in 11 of 13 cases

with tumor sites identified within the pelvis (2 cases), abdominal wall (2), retroperitoneum (1), lymph nodes (3), liver (2), bone (2), and lung (1). The accurate localization of colorectal carcinoma recurrences by means of [^{111}In]-ZCE-025 MAb demonstrates the usefulness of this diagnostic agent in scenarios associated with elevated carcinoembryonic antigen levels and negative results from clinical and radiologic workup evaluations.

Improved tumor localization with increasing dose of indium-111-labeled anti-carcinoembryonic antigen monoclonal antibody ZCE-025 in metastatic colorectal cancer. Patt YZ, Lamki LM, Haynie TP, Unger MW, Rosenblum MG, Shirkhoda A, Murray JL. J Clin Oncol 1988 Aug; 6 (8), pp. 1220–30.

Indium 111 ZCE-025 immunoscintigraphy in occult recurrent colorectal cancer with elevated carcinoembryonic antigen level. Doerr RJ, Abdel-Nabi H, Merchant B. Arch Surg 1990 Feb; 125 (2), pp. 226–9.

Gastrointestinal/Colorectal Carcinoma/ Intraoperative Lesion Localization
[^{125}I]-B72.3 Anticolorectal Carcinoma Monoclonal Antibody (MAb)

Cellular/Molecular Mechanism of Action: [^{125}I]-B72.3 MAb selectively binds to antigenic complexes expressed by colorectal carcinoma.
Application: Intraoperative detection and localization of neoplastic lesions using a handheld gamma probe.
Route of Administration: [^{125}I]-B72.3 MAb (intravenous).
Implementation: Evaluation of an intraoperative approach for tumor localization using radiolabeled MAb B72.3 involving the use of a handheld gamma-detecting probe (GDP). Surgical procedures can be performed between 5 and 35 days postadministration of [^{125}I]-labeled MAb B72.3 IgG preparations. Analysis of resected tumor and normal tissues involves measurement of relative [^{125}I]-labeled MAb B72.3 IgG (e.g., injected dose/gram tissue).
Interpretation and Analysis: Applying a handheld GDP, surgeons intraoperatively can successfully localize lesions 68% of the time (e.g., n = 21/31). Resected tumor radiolocalization indices range from 0.5 to 543 with radiolocalization indices of 3.0 or higher in 71% (e.g., n = 22/31) of tumor specimens. Approximately 68% of carcinoma lesions that can be positively detected intraoperatively with a handheld GDP will also have levels of tumor antigen expression that can be detected with an immunoperoxidase-based assay. Alternatively, approximately 8% of lesions that cannot be detected intraoperatively are also antigen negative. About 24% of carcinoma lesions cannot be localized intraoperatively based on the use of the GDP, but immunohistopathology analysis reveals positive expression of detectable levels of tumor antigen. The [^{125}I]-labeled MAb B72.3 IgG reagent recognizes all histologic grades of colorectal cancer. In most situations, higher *in vivo* probe ratios and radiolocalization indices can be observed when intraoperative handheld gamma scans are performed 20–35 days following injection of MAb and preparations are successful in detecting colorectal carcinoma lesions that have metastasized to mesenteric and periaortic lymph nodes, liver, lung, and perirectal soft tissue. A strong degree of correlation ($p = 0.001$) can be appreciated between the intraoperative detection of tumorous lesions with increased MAb B72.3 localization and the *in vitro* measurement of cpm/gram of tumor tissue compared to normal/healthy tissue samples.

Intraoperative radioimmunolocalization of colorectal carcinoma with a handheld gamma probe and MAb B72.3: Comparison of *in vivo* gamma probe counts with *in vitro* MAb radiolocalization. Tuttle SE, Jewell SD, Mojzisik CM, Hinkle GH, Colcher D, Schlom J, Martin EW. Int J Cancer 1988 Sep 15; 42 (3), pp. 352–8.

Gastrointestinal/Colorectal Carcinoma/Prognosis Prediction of Therapeutic Sensitivity
[^{18}F]-5-Fluorouracil (5-FU)

Application: Radiopharmaceutical biodynamic evaluation of 5-FU chemotherapeutic efficacy.
Considerations: The colon carcinoma cell Type 38 is 5-FU sensitive in contrast to R1-rhabdomyosarcoma, which is 5-FU resistant.
Implementation: Delineation of the relationship between [^{18}F]-5-fluorouracil cellular pharmacodynamics and chemotherapeutic sensitivity to 5-FU chemotherapy in colorectal carcinoma cell types.
Semi-Synthetic Methods: Optimized methods for the synthesis of [^{18}F]-labeled 5-FU have been described.
Interpretation and Analysis: Instead of initial tumor uptake, chemotherapeutic sensitivity to 5-FU correlates best with carcinoma [^{18}F] efflux out of lesion sites.

An optimized synthesis of [^{18}F]-labeled 5-fluorouracil and a reevaluation of its use as a prognostic agent. Visser GW, Gorree GC, Braakhuis BJ, Herscheid JD. Eur J Nucl Med 1989; 15 (5), pp. 225–9.

Gastrointestinal/Colorectal Carcinoma: Recurrent Postresection/Surgical Intervention Decision Making/Nuclear Scan vs Computed Tomography (CT) Scan
[^{111}Indium] ([^{111}In])-CYT-103 Monoclonal Antibody (MAb)

Background Information: Recurrent colorectal cancer is seen in as many as 40% of cases after curative resection. In view of the limitations of endoscopic and cross-sectional imaging, external immunoscintigraphy has been added to follow-up regimens in conditions that are at high risk of recurrent disease.
Application: Detection and characterization of colorectal carcinoma as an aid to deciding the merits of surgical intervention.
Route of Administration: Intravascular.
Considerations: Provocative agents (histamine, glucagon, tyramine) are rarely needed. Preoperative localization of tumor lesions can be done with nephrotomography, intravenous pyelography (IVP), computerized axial tomography, ultrasound, [^{131}I]-19-iodocholesterol scan, arteriography, and venography.
Semi-Synthetic Methods: Labeling of CYT-103 MAb (1.0 mg) with [^{111}In] radioisotope (approximately 4.3 mCi).
Implementation: Evaluation of the utility of immunoscintigraphy in conditions of suspected colorectal carcinoma utilizing MAb (e.g., B72.3 or CYT-103) site-specifically labeled with [^{111}In] conjugate. Planar and single photon emission computed tomography (SPECT) imaging is then performed 2–5 days after infusion of, for example, [^{111}In]-CYT-103).
Human Model: Cases of suspected recurrences of previous "curative" colorectal carcinoma resections.
Interpretation and Analysis: Local or regional recurrences (4 cases) and liver metastasis (6 cases) may be detected by physical examination and computed tomography (CT). Alternatively, some cases (e.g., n = 9) may have occult disease with increasing serum carcinoembryonic antigen (CEA) levels and negative conventional workups. Serum CEA levels are elevated (mean, 22 ng/ml) in the vast majority of cases (e.g., 100%). A final diagnosis of recurrence or metastasis can be established in a number of cases by 2nd-look surgery or biopsy (e.g., n = 18). Tumors may potentially be identified at the following locations: pelvis (e.g., n = 12 cases), abdominal wall (e.g., n = 2 cases), retroperitoneum (e.g., n = 1 case), liver (e.g., n = 5 cases), and omentum (e.g., n = 2 cases). Superiority of MAb scans

is supported by its capacity to detect pelvic and intra-abdominal recurrences (100%) at a higher success rate than CT scan (43%). Liver metastases are identified equally well by both modalities. [^{111}In]-CYT-103 scan findings may influence the management of approximately 55% of affected cases (e.g., n = 10/18). Surgery may be avoided in conditions with scan-detected disseminated metastases. Correct identification of occult local recurrences can be made in some cases (e.g., n = 6). Isolated liver metastasis may be confirmed in instances of equivocal CT scan results. Finally, additional intra-abdominal lesions may also be detected. Such observations suggest an important and beneficial role for [^{111}In]-CYT-103 MAb imaging in conditions of suspected recurrent colorectal carcinomas, particularly in cases with negative cross-sectional imaging results; such imaging may prevent cases from undergoing unnecessary surgical exploration.

In-111 CYT-103 monoclonal antibody imaging in patients with suspected recurrent colorectal cancer. Doerr RJ, Herrera L, Abdel-Nabi H. Cancer]1993 Jun 15; 71 (12 Suppl), pp. 4241–7.

Gastrointestinal/Colorectal Carcinoma/Targeting and Pretargeting with Monoclonal Antibody (MAb) Mediated/Human Colorectal Carcinoma Xenographs (SW1222) in Mice *[^{64}Cu]-DOTA-Biotin/[^{64}Cu]-DOTA-NR-LU-10*

Background Information: Pretargeting involves administration of a tumor-targeting MAb covalently linked to a molecule having a high-affinity binding site for a rapidly distributed radiolabeled effector molecule.

Application: Pretargeted [^{64}Cu]-DOTA-biotin should afford markedly superior positron emission tomography (PET) images and therapeutic efficacy due to its extremely rapid tumor uptake and blood clearance.

Semi-Synthetic Methods: DOTA-biotin (biotinylated 1,4,7,10-tetraazacyclododecane-N,N′,N′′,N′′′-tetraacetic acid) and the intact immunoconjugate DOTA-NR-LU-10 are labeled to high specific activities with [^{64}Cu], and the serum stabilities and target binding capabilities of each agent are then assayed (*in vitro*).

Implementation: Compare different pretargeting strategies employing conventionally labeled antibody for targeting tumors with the intermediate-lived radionuclide [^{64}Cu], which has shown promise for PET imaging and radioimmunotherapy of cancer. One approach to characterizing "pretargeting" strategies can involve the evaluation of preparations for their ability to recognize and preferentially accumulate within colorectal carcinoma xenografts. Semi-synthetic preparations of [^{64}Cu]-DOTA-biotin are administered, with and without MAb-streptavidin conjugate NR-LU-10/SA pretreatement and the synthetic clearing agent biotin-GalNAc(16); or injected with [^{64}Cu]-DOTA-NR-LU-10. Biodistribution of both agents is then established from 5 minutes to 48 hours after injection.

Animal Model: Murine (nude mice bearing SW1222 human colorectal carcinoma xenografts).

Interpretation and Analysis: Both [^{64}Cu]-DOTA-biotin and [^{64}Cu]-DOTA-NR-LU-10 are 100% stable *in vitro* in serum. [^{64}Cu]-DOTA-biotin exhibits > 98% specific binding to immobilized streptavidin, whereas the immunoreactivity of [^{64}Cu]-DOTA-NR-LU-10 averages nearly 80%. Biodistributions in SW1222-bearing mice show that NR-LU-10/SA-pretargeted [^{64}Cu]-DOTA-biotin attains a peak tumor uptake of 18.9% of the injected dose per gram (%ID/g) at 1 hour, with a concomitant rapid disappearance from blood and renal excretion. In the absence of pretargeting, [^{64}Cu]-DOTA-biotin has very similar biodistribution and clearance properties, except with extremely low non-specific tumor uptake. Conversely, [^{64}Cu]-DOTA-NR-LU-10 reaches 80.3 %ID/g in tumor tissue, after 48 hours, whereas blood clearance is considerably slower than pretargeted [^{64}Cu]-DOTA-biotin. Comparison of the time-activity curves for tumor uptake and blood clearance of pretargeted [^{64}Cu] and [^{64}Cu]-labeled antibody reveals that the maximum tumor accumulations of radioactivity are similar for each agent (e.g., 17.9% injected activity per gram [%IA/g] and 20.7 %IA/g, respectively). However, the tumor-to-blood ratio of areas under the curves is 14 times higher for pretargeted [^{64}Cu]-DOTA-biotin because of the substantial increase in blood clearance of the small effector molecule. The extremely rapid tumor uptake and blood clearance of pretargeted [^{64}Cu]-DOTA-biotin should afford markedly superior PET images and therapeutic efficacy, compared with conventionally labeled [^{64}Cu]-DOTA-NR-LU-10. Further comparison of the therapeutic efficacy, toxicity, and dosimetry of these 2 agents is warranted.

In vivo evaluation of pretargeted [^{64}Cu] for tumor imaging and therapy. Lewis MR, Wang M, Axworthy DB, Theodore LJ, Mallet RW, Fritzberg AR, Welch MJ, Anderson CJ. J Nucl Med 2003 Aug; 44 (8), pp. 1284–92.

Head and Neck Neoplastic Disease/Benign vs Malignant *[^{201}Thallium] [(^{201}Tl]) Chloride/Gallium-67 ([^{67}Ga])-Citrate*

Application: Differentiation between malignant tumors and benign tumors of the head and neck by means of [^{201}Tl] chloride scintigraphy.

Route of Administration: Intravenous.

Considerations: [^{201}Tl] chloride scintigraphy and [^{67}Ga] scintigraphy performed in conditions of benign or malignant neoplasia initially entail establishing the blood flow index and the tumor retention index by means of [^{201}Tl] scintigraphy. The blood flow index = the count of tumor/the count of control in the early dynamic scan from 30 to 120 seconds after injection; and the tumor retention index = (the count of tumor/the count of control in the delayed dynamic scan 2.5 hours after injection)/(tumor count/control count in the early dynamic scan from 4 to 5 minutes after injection).

Interpretation and Analysis: Early and delayed scans with [^{201}Tl] demonstrate a very high correlation with the blood flow index. The tumor retention index has a tendency to increase in malignant tumors, especially in poorly differentiated tumors and highly invasive tumors. Likewise, the tumor retention index decreases in benign tumors. Results from such obseverations are statistically significant and reveal that [^{201}Tl] scintigraphy is superior to [^{67}Ga] scintigraphy. Scintigraphy with [^{201}Tl] is also useful in detecting neoplastic lesions of relatively small size/mass. The tumor retention index of [^{201}Tl] is useful for the differentiation of malignant tumors of the head and neck from benign tumors of the same areas.

Hepatic Neoplasia: Metastatic Tumor Imaging *[^{75}Se]-Methionine*

Application: Detection of metastatic hepatic tumors applying nuclear medicine imaging methodologies.

Considerations: Preparations of [^{75}Se]-methionine can function as a valuable diagnostic agent for the detection of malignant lesions affecting hepatic tissues.

Various types of biological activity have been shown to be provided by [^{75}Se]-methionine for the detection of metastatic liver tumors. Concerning the spectrum of imaging agents applied in diagnostic nuclear medicine, hepatic neoplasias manifest themselves

with a great degree of variability (e.g., enhanced to absent incorporation into "cold zones" detected with [^{113m}In]-colloid).

Interpretation and Analysis: Analysis of data from human cancer patients with neoplastic lesions affecting various sites within the liver has revealed that the diagnostic value of [^{75}Se]-methionine when applied in combination with [^{113m}In] colloid approaches 90% approximately.

Insulin-Like Growth Factor (IGF) Binding Proteins/ Neoplastic Disease
[^{125}I]-Labeled-IGF

Cellular/Molecular Mechanism of Action: Insulin-like growth factors recognize and bind to membrane-associated receptor complexes [insulin-like growth factor binding proteins].

Background Information: Insulin-like growth factor binding proteins (IGFBPs) play a critical role in modulating IGF activity.

Application: Detection and characterization of certain neoplastic cell types.

Considerations: [^{125}I]-labeled IGF-I is rapidly degraded within the cytosol of some types of neoplastic cell.

Semi-Synthetic Methods: Production of [^{125}I]-labeled-IGF-I by radioiodination of IGF-I using chloramines-T reagent.

Implementation: Evaluate the biodistribution and tumor targeting ability of radiolabeled IGF-I. Complementary investigations can entail *in vitro* and *in vivo* assessment of binding properties for [^{125}I]-labeled IGF-I for IGFBPs. Validation of the relative specificity of uptake can in part be established by co-administration of unlabeled peptide. Because a large amount of the IGF-I is catabolized *in vivo*, valuable information can also be acquired by delineating the *in vitro* catabolism of IGF-I by tumor cells. *In vitro* and *in vivo* chromatography studies can be performed to evaluate the binding profile to IGFBPs and measure serum/urine catabolite concentrations.

Animal Model: Rat and mouse (tumor-bearing nude mice).

Interpretation and Analysis: Binding of radiolabeled IGF-I to IGFBPs *in vitro* occurs in a dose-dependent manner. However, there is a difference in complex formation between serum and heparinized plasma. In heparinized plasma, radioactivity shifts from a 30–50-kDa complex to a 150-kDa complex and to a free ligand, because the formation of IGFBPs/heparin complexes decreases its binding affinity for IGF-I. In plasma prepared with acid citrate dextrose a binding pattern identical to that of serum is observed. Moreover, there is a binding difference between mouse and rat. The [^{125}I]-labeled IGF-I is catabolized very quickly when incubated at 37°C but not at all at 4°C. In tumor-bearing nude mice, the uptake of radioactivity in normal tissues decreases quickly, particularly in the kidney. In mice co-injected with unlabeled carrier, the radioactivity in most normal tissues is lower and the tumor uptake higher than in mice without carrier. [^{125}I]-labeled IGF-I is avidly bound to IGFBPs, both *in vitro* and *in vivo*. By partially saturating such molecular interactions with unlabeled peptides, a favorable biodistribution can be achieved, including faster clearance from normal tissue and higher tumor uptake, which thereby results in better tumor-to-non-tumor ratios. Nevertheless, the rapid catabolism and release of the radiolabel from tumor tissue results in a suboptimal targeting agent.

Effects of insulin-like growth factor binding proteins on insulin-like growth factor-I biodistribution in tumor-bearing nude mice. Sun BF, Kobayashi H, Le N, Yoo TM, Drumm D, Paik CH, McAfee JG, Carrasquillo JA. J Nucl Med 2000 Feb; 41 (2), pp. 318–26.

Leukemia: Human Jurkat Cell Line
[^{99m}Technetium] ([^{99m}Tc])Tat-Peptide 4/ [Fluorescein-5-Maleimide]-Tat-Peptide

Cellular/Molecular Mechanism of Action: [Tc/Re$_V$]complexes can rapidly translocate across cell membranes into intracellular compartments.

Background Information: Rapid and efficient delivery of radioactive metal complexes to the cell interior would enable novel applications in medical imaging and radiotherapy.

Application: [^{99m}Tc]Tat-peptide 4 can potentially be applied for the diagnostic imaging of certain neoplastic disease types.

Route of Administration: [^{99m}Tc]Tat-peptide 4 (intravenous).

Semi-Synthetic Methods: Membrane permeant peptide conjugates incorporating HIV-1 Tat transactivation protein sequences (GRKKRRQRRR) and an appropriate peptide-based motif (epsilon-KGC) that provides an N_3S donor core for chelating technetium and rhenium can be synthesized. Oxotechnetium$_V$ and oxorhenium$_V$ Tat-peptide complexes can be prepared by facile transchelation reactions with permetalates, [Sn^{+2}]chloride, and sodium glucoheptonate. RP-HPLC reveals 2 major [^{99m}Tc]Tat-peptide species (4) that differ in retention time by approximately 2 minutes corresponding to 2 [Re]Tat-peptide species (7) shown to have identical mass, consistent with the formation of 2 isomers, likely the oxo-metal diastereomers. [^{99m}Tc]Tat-peptides are stable to transchelation *in vitro*. To facilitate analysis using fluorescent microscopy, the C-terminus thiol of the prototypic Tat-peptide can be labeled with fluorescein-5-maleimide (yielding conjugate 8).

Implementation: Evaluation of binding avidity and stability of [^{99m}Tc]Tat-peptide 4 in the presence of human Jurkat cell populations.

Tissue Culture Model: Human Jurkat KB 3-1 and KB 8-5 leukemia cell types.

Animal Model: Murine (*in vivo* investigations).

Interpretation and Analysis: In human Jurkat cells, [^{99m}Tc]Tat-peptide 4 show concentrative cell accumulation (30-fold greater than extracellular concentration) and rapid uptake kinetics ($t_{1/2} < 2$ minutes) in a diastereomeric-comparable manner. Paradoxically, uptake is enhanced in 4°C buffer compared to findings noted at 37°C, while depolarization of membrane potential as well as inhibition of microtubule function and vesicular trafficking show no inhibitory effect. Cells preloaded with "4" show rapid washout kinetics into peptide-free solution. Modification of [^{99m}Tc]Tat-peptide by the deletion of the N-terminus Gly with or without biotinylation minimally impacts net-cell uptake.

Fluorescence microscopy reveals that [fluorescein-5-maleimide]-Tat-peptide (conjugate 8) can directly localize the preparation within the cytosol and nuclei (possibly nucleolus) of human Jurkat, KB 3-1, and KB 8-5 tumor cells. Preliminary *in vivo* imaging studies in mice following intravenous administration of prototypic [^{99m}Tc]Tat-peptide "4" reveals an initial whole-body distribution and rapid clearance by both renal and hepatobiliary excretion. Analysis of murine blood *in vivo* and human serum *ex vivo* reveals $> 95\%$ intact complex, while murine urine *in vivo* contains 65% parent complex. Thus, these novel Tat-peptide chelate conjugates, capable of forming stable [Tc/Re$_V$]complexes, rapidly translocate across cell membranes into intracellular compartments and can be readily derivatized for further targeted applications in molecular imaging and radiotherapy.

Novel Tat-peptide chelates for direct transduction of technetium-^{99m} and rhenium into human cells for imaging and radiotherapy. Polyakov V, Sharma V, Dahlheimer JL, Pica CM, Luker GD, Piwnica-Worms D. Bioconjug Chem 2000 Nov–Dec; 11 (6), pp. 762–71.

Lymph Nodes: Sentinel Lymphadenectomy Guide/ Melanoma
[^{99m}Technetium] ([^{99m}Tc])-Sulfur Colloid (SC)/ [^{99m}Tc]-Human Serum Albumin (HAS)/ Isosulfan Blue Dye

Cellular/Molecular Mechanism of Action: Isosulfan blue dye serves as a pigment-based marker system for biological fluid compartments. [^{99m}Tc]-HSA and [^{99m}Tc]-SC can be phagocytized by reticuloendothelial cell populations residing within peripheral lymph nodes.

Background Information: Radiopharmaceutical agents appear to improve the accuracy of sentinel node (SN) identification in patients with early-stage melanoma, but the optimal radiopharmaceutical agent and its timing from injection to surgery remains controversial.

Application: [^{99m}Tc]-SC and [^{99m}Tc]-HSA can be used intraoperatively as probes for lymphatic mapping in radiopharmaceutical-directed sentinel lymphadenectomy (LM/SL) procedures.

Route of Administration: Isosulfan blue dye, [^{99m}Tc]-SC, and [^{99m}Tc]-HSA can be administered intraoperatively into lymphatic vessels.

Implementation: Cutaneous lymphoscintigraphy can be performed before LM/S utilizing 1 of 3 techniques, including (i) HSA ([^{99m}Tc]-HSA) injected at least 24 hours before LM/SL (n = 124 cases); (ii) filtered sulfur colloid ([^{99m}Tc]-SC) injected no more than 4 hours before LM/SL (same-day SC, n = 95 cases); or (iii) [^{99m}Tc]-SC injected at least 18 hours before LM/SL (prior-day SC, n = 28 cases). At the time of LM/SL, isosulfan blue dye is injected alone (SC groups) or with a 2nd dose of HSA (HSA group). A handheld gamma probe is used to determine the radioactive (hot) counts of blue-stained and non-stained nodes, and the *in vivo* and *ex vivo* node-to-background count ratios of the nodes compared.

Human Model: Melanoma (n = 247; American Joint Committee on Cancer stage I or II).

Interpretation and Analysis: Preoperative LS can identify a large percentage of drainage basins (e.g., n = 299 in 247 cases). Lymphatic mapping with radiopharmaceutical-directed sentinel lymphadenectomy (LM/SL) is capable of identifying at least 1 sentinel lymph node in a large percentage of cases. Specific examples include: (i) lymph node basins using same-day SC (98% or n = 119/121); (ii) lymph node basins using HSA (97% or n = 142/146); and (iii) lymph node basins using prior-day SC (100% or n = 32/32). There is no difference ($p = 0.62$) in the accuracy rate between the 3 techniques in the scenario described for a total of 463 SNs in 247 cases. Same-day SC yields higher intraoperative node-to-background count ratios than do either of the other techniques ($p < 0.0001$). Same-day SC also has the greatest relative change in radioactivity between the blue sentinel node and the postexcision basin ($p < 0.0001$), and the highest rate of SNs that are both blue and hot (*in vivo* or *ex vivo* ratio ≥ 2, $p = 0.05$). Therefore, LS and LM/SL performed on the same day with a single injection of filtered [^{99m}Tc]-SC serves as the most useful method for probe-directed LM/SL. The technique demonstrates the highest *in vivo* and *ex vivo* count ratios, falloff of radioactivity between the excised nodes and postexcision basin, and concordance between blue dye and hot nodes. It should be recommended as the method of choice for probe-directed LM/SL.

Standardized probe-directed sentinel node dissection in melanoma. Essner R, Bostick PJ, Glass EC, Foshag LJ, Haigh PI, Wang HJ, Morton DL. Surgery 2000 Jan; 127 (1), pp. 26–31.

Lymph Nodes: Sentinel Lymph Node Detection
[^{99m}Technetium] ([^{99m}Tc])-Diethylenetriamine Pentaacetic Acid (DTPA)-Mannosyl-Dextran

Application: Sentinel node characterization/detection.

Route of Administration: Foot pads (rabbits: n = 4).

Dosage: [^{99m}Tc]-DTPA-mannosyl-dextran (0.22 nmol) or filtered [^{99m}Tc]-sulfur colloid (3.7 MBq in 0.050 mL).

Considerations: Receptor affinity can be measured by Scatchard assay of rabbit liver. Axillary, popliteal, and iliac lymph nodes and each injection site can be assayed for radioactivity at 1 and 3 hours after injection.

Synthetic Chemistry and Analysis: Synthesis begins with a 2-step process that attaches a high density of amino-terminated leashes to a dextran backbone. Allyl-bromide is reacted with pharmaceutical-grade dextran to yield allyl-dextran. After diafiltration with water, filtration, and lyophilization, the product is reacted with aminoethanethiol and ammonium persulfate. The resulting amino-conjugated dextran is then dialyzed, filtered, and lyophilized. The mixed anhydride method can then be used to covalently link together DTPA, 2-imino-2-methoxyethyl-1-D-mannose and amino-conjugated dextran. The molecular diameter of the product can be measured by dynamic light scattering. Amino, mannose, and DTPA densities are measured by trinitrobenzene sulfonate assay, sulfuric acid/phenol assay, and inductively coupled plasma spectroscopy of [gadolinium]-DTPA-mannosyl-dextran, respectively. DTPA-mannosyl-dextran had a molecular weight of 35,800 g/mol and a molecular diameter of 7.1 nm. The final amine, mannose, and DTPA densities are 23, 55, and 8 mol per dextran. Labeling yields are in excess of 98% and stable for 6 hours. Specific activities of 74 3 106 GBq/mol can be achieved. The equilibrium dissociation constant for binding to the mannose-terminated glycoprotein receptor is 0.12 6 0.07 nmol/L.

Interpretation and Analysis: The popliteal extraction at both 1 and 3 hours is significantly ($p < 0.05$) higher for [^{99m}Tc]-DTPA-mannosyl-dextran (90.1% ± 10.7% and 97.7% ± 2.0%, respectively) than for filtered [^{99m}Tc]-sulfur colloid (78.8 ± 6.5 and 67.4% ± 26.8%, respectively). [^{99m}Tc]-DTPA-mannosyl-dextran exhibits significantly faster injection site clearance than does filtered [^{99m}Tc]-sulfur colloid. The [^{99m}Tc]-DTPA-mannosyl-dextran percent injected dose (%ID) for the front and rear paws is 52.6 ± 10.5 and 52.3 ± 8.0 at 1 hour and 45.7 ± 8.5 and 43.6 ± 8.2 at 3 hours after administration. Filtered [^{99m}Tc]-sulfur colloid %ID for the front and rear paws is 70.4 ± 11.0 and 66.3 ± 15.1 at 1 hour and 55.5 ± 7.8 and 66.9 ± 8.5 at 3 hours. Lymph node accumulation of each agent at either 1 or 3 hours is not significantly different. [^{99m}Tc]-DTPA-mannosyl-dextran is a receptor-based sentinel node radiotracer that exhibits the desired properties of rapid injection site clearance and low distal node accumulation. This molecule is the 1st member of a new class of diagnostic agents based on a macromolecular backbone with a high density of sites for the attachment of substrates and imaging reporters. This molecule is 1 of the 1st members of a relatively new class of diagnostic agents based on a macromolecular backbone with a high density of sites for the attachment of substrates and imaging reporters.

In vivo evaluation of 3 different [^{99m}Tc]-labeled radiopharmaceuticals for sentinel lymph node identification. Edreira MM, Colombo LL, Perez JH, Sajaroff EO, de Castiglia SG. Nucl Med Commun 2001 May; 22 (5), pp. 499–504.

Sentinel lymph node identification and sampling in women with early breast cancer using [^{99m}Tc]-labeled dextran 500 and patent blue V dye. Xavier NL, Amaral BB, Cerski CT, Fuchs SC, Spiro BL, Oliveira OL, Menke CH, Biazús JV, Cavalheiro JA, Schwartsmann G. Nucl Med Commun 2001 Oct; 22 (10), pp. 1109–17.

Lymphoma: Malignant
[^{125}I]-Tyr$_3$-Octreotide/ [^{111}Indium] ([^{111}In])-[Diethylenetriamine Pentaacetic Acid-D-Phe$_1$]-Octreotide

Cellular/Molecular Mechanism of Action: Octreotide is a somatostatin analogue that functions as a ligand that recognizes and physically binds to somatostatin receptor complexes.
Application: Characterization of biopsy specimens utilizing autoradiography techniques, and the detection and monitoring of primary and metastatic (human) malignant lymphoma lesions when applied as a non-invasive *in vivo* imaging agent.
Route of Administration: [^{125}I]-[Tyr$_3$]-octreotide (intravenous) [^{111}In]-[DTPA-D-Phe$_1$]-octreotide (intravenous).
Considerations: Somatostatin receptor complexes are expressed by a wide variety of (human) neoplastic disease states and can serve as valuable pathobiochemical tissue markers (indicators) that can be capitalized upon because of their potential for *in vivo* use as diagnostic tools for (human) malignant lymphomas.
Implementation: Evaluation of immune-based autoradiographs of surgically excised malignant tissue samples applying [^{125}I]-[Tyr$_3$]-octreotide as radioligand (binding affinity KD = 1.2 nM). In cases of B-cell non-Hodgkin's lymphoma classified as low-grade, intermediate-grade, and high-grade malignancy, a very high percentage will positively express somatostatin receptor complexes (e.g., 91%, 100%, 70%, respectively).
Interpretation and Analysis: High-density somatostatin receptor complex expression in low-grade malignancy B-cell non-Hodgkin's lymphoma is largely confined to neoplastic follicles, and most of the somatostatin receptors expressed in cases of high-grade malignancy are present at a very high density. Some T-cell lymphomas and Hodgkin's lymphomas are also positive for the expression of somatostatin receptor complexes.

Lymphoma lesions can also be non-invasively localized *in vivo* with the diagnostic imaging agent [^{111}In]-[DTPA-D-Phe$_1$]-octreotide. Positive accumulation of [^{111}In]-[DTPA-D-Phe$_1$]-octreotide on scintigraphic images closely correlates with surgically excised neoplastic tissues [^{125}I]-[Tyr$_3$]-octreotide positive confirmed by receptor ligand autoradiography analysis.
Instrumentation: Scintigraphic gamma camera.

In vitro and *in vivo* detection of somatostatin receptors in human malignant lymphomas. Reubi JC, Waser B, van Hagen M, Lamberts SW, Krenning EP, Gebbers JO, Laissue JA. Int J Cancer 1992 Apr 1; 50 (6), pp. 895–900.

Lymphoma/Non-Hodgkin's Lymphoma (NHL)/ Hodgkin's Disease (HD)
[Gallium-67] ([^{67}Ga])/[^{18}Flourine]-Fluorodeoxyglucose ([^{18}F]-FDG)

Background Information: Until recently, [^{67}Ga] scintigraphy (GS) has been the best available functional imaging modality for evaluating NHL and HD conditions.
Application: [^{18}F]-FDG and [^{67}Ga] scintigraphy.
Implementation: As [^{67}Ga] is a tumor viability agent, the role of [^{67}Ga] scintigraphy is primarily utilized as a complementary follow-up diagnostic procedure.
Interpretation and Analysis: The diagnostic accuracy of [^{67}Ga] scintigraphy in detecting lymphoma is based on transferring the imaging protocol, knowledge of potential physiological and benign sites of [^{67}Ga] uptake, and the [Ga] avidity characteristics of individual lymphoma cell types. A residual mass that persists on computed tomography (CT) scans after treatment poses a common clinical dilemma that may indicate the presence of viable lymphoma requiring further treatment, or it can be benign, consisting of only fibrotic and necrotic tissues. Scintigraphy with [^{67}Ga] can successfully differentiate between these conditions. Routine follow-up with [^{67}Ga] scintigraphy may allow early diagnosis of recurrence and early initiation of treatment. Reversion of a positive [^{67}Ga] scintigraphy to a negative test, and the rapidity with which this occurs, has a high predictive value for prognosis (morbidity/mortality). Lymphoma lesions that appear normal on [^{67}Ga] scintigraphy early during treatment protocols have a better prognosis than lymphoma with a persistence of pathological findings. Other tumor-seeking single photon emitting agents, such as [^{201}thallium], [^{99m}technetium]-methoxyisobutylisonitrile, and [^{111}indium]- octreotide, have been investigated in lymphoma, primarily as an alternative to [^{67}Ga] scintigraphy in specific clinical settings, but are of limited value. The role of radioimmunoscintigraphy is gaining importance in conjunction with radioimmunotherapy. [^{18}F]-FDG imaging of lymphoma using either dedicated or camera-based positron emission tomography (PET) systems is gradually replacing [^{67}Ga] scintigraphy for assessment of lymphoma. [^{18}F]-FDG overcomes some of the limitations of [^{67}Ga] scintigraphy while sharing its tumor viability characteristics. The extensive clinical knowledge and experience accumulated over 3 decades with [^{67}Ga] scintigraphy in lymphoma provides a solid background as well as a model for the assessment of new functional imaging techniques.

Gallium-67 scintigraphy: A cornerstone in functional imaging of lymphoma. Even-Sapir E, Israel O. Eur J Nucl Med Mol Imaging 2003 Jun; 30 Suppl 1, pp. S65–81. Epub 2003 Mar 18.

Lymphoma: Non-Hodgkin's Type (NHL)/ (Staging of Recurrent or Newly Diagnosed NHL)
[^{99m}Technetium] ([^{99m}Tc])-Labeled Anti-lymphoma IgG Fragment

Application: [^{99m}Tc]-labeled anti-lymphoma IgG fragment can be used to stage recurrent or newly diagnosed NHL and to assess targeting prior to the initiation of radioimmunotherapy (RIT).
Route of Administration: [^{99m}Tc]-labeled anti-lymphoma IgG fragment.
Dosage: [^{99m}Tc]-labeled anti-lymphoma IgG fragment [bectumomab (LymphoScan)].
Interpretation and Analysis: In the evaluation of graded tumors (e.g., low-grade; intermediate-grade; high-grade histiological subtypes), the combined application of computed x-ray tomography, radiogallium imaging, fluorodeoxyglucose (FDG) positron emission tomography (PET), and bone marrow biopsy can detect a relatively large number of lesions. Radiolabeled [^{99m}Tc]-labeled antilymphoma IgG fragment can detect approximately 56% of these total lesions and in some instances detects lesions that cannot be identified by other conventional diagnostic modalities. The anatomical location where radiolabeled [^{99m}Tc]-labeled anti-lymphoma IgG fragment is least valuable as a diagnostic imaging agent is in the central abdomen and thoracic cavity. Conversely, radiolabeled [^{99m}Tc]-labeled antilymphoma IgG fragment demonstrates a superior capability to detect lesions within the head and neck region of the body. Relative to [^{67}Ga]-citrate imaging, the performance of [^{99m}Tc]-

labeled anti-lymphoma IgG fragment would have to be considered variable with no clear relationship to anatomic location. However, it does provide better targeting of low and intermediate grade NHL lesions. By comparison, radiogallium out-performs [^{99m}Tc]-labeled antilymphoma IgG fragment imaging (e.g., at n = 23/117 lesion sites, n = 19/23 = high or intermediate-grade disease). Alternatively, [^{99m}Tc]-labeled antilymphoma IgG fragment is superior to radiogallium at other anatomical sites (e.g., n = 6/117 lesions sites, n = 5/6 = low-grade tumor). In summary, nuclear medicine imaging with [^{99m}Tc]-labeled anti-lymphoma IgG fragment has demonstrated potential value as a pre-RIT probe for targeting of B-cell NHL, and it excels at defining small volume, low-grade disease. Unfortunately, as a purely diagnostic agent, its performance is variable.

Radioimmunoscintigraphy (RIS) with bectumomab (Tc^{99m}-labeled IMMU-LL2, Lymphoscan) in the assessment of recurrent non-Hodgkin's lymphoma (NHL). Lamonica D, Czuczman M, Nabi H, Klippenstein D, Grossman Z. Cancer Biother Radiopharm 2002 Dec; 17 (6), pp. 689–97.

Mammary Carcinoma/Detection and Disease Monitoring
[^{125}I]-Tyr(3)]-Octreotide/[^{125}I]-Vasoactive Intestinal Peptide (VIP)/[^{125}I]-Tyr(4)-Bombesin/[^{125}I]-[Leu(31),Pro(34)]-PYY

Cellular/Molecular Mechanism of Action: Recognizes and physically binds to the exterior surface of human mammary carcinoma cell types.
Application: Detection, characterization, and therapeutic "targeting" of human breast cancer cell types (*in vivo*). Breast cancers can express different types of peptide receptors such as somatostatin, VIP, gastrin-releasing peptide (GRP), and hypothalamic neuropeptide Y Type 1 (NPY-Y1) receptors. Investigations performed *in vitro* strongly suggest that the combination of radiolabeled GRP and Y1 analogues could be used as vehicles in the form of selective *in vivo* peptide receptor scintigraphic imaging and radiotherapeutic delivery relevant to both primary and metastatic mammary carcinoma cell populations.
Route of Administration: Intravenous.
Implementation: Detection and characterization of mammary carcinoma neoplastic disease states.
Interpretation and Analysis: In the *in vitro* analysis of primary and metastatic mammary carcinoma tissue samples, the membrane-associated receptor complexes for somatostatin, VIP, GRP, and NPY-Y1 can be detected by ligand-affinity autoradiography applying [^{125}I]-Tyr(3)-octreotide, [^{125}I]-VIP, [^{125}I]-[Tyr(4)]-bombesin and [^{125}I]-[Leu(31), Pro(34)]-PYY, respectively. Majority of neoplastic tissue samples analyzed in this fashion (88%) express at least 1 of the membrane-associated receptor complexes at a relatively high density (> 2,000 dpm/mg tissue). Based on these findings, the receptor probe reagents could function in a valuable capacity as *in vivo* targeting agents for detecting the existence of mammary carcinoma, characterization and monitoring of disease progression, evaluation of response to therapy, and selective delivery of antineoplastic modalities. A 2nd smaller group of neoplastic tissue samples (12%) can be recognized that express none of the 4 receptor complexes evaluated at relatively high densities (< 2,000 dpm/mg tissue).

Relative receptor density expression analyses of neoplastic tissue samples displaying a high level of expression for at least 1 of the complexes reveals that GRP, NPY-Y1, vasoactive intestinal polypeptide Type 1 (VPAC), and somatostatin receptors are present, respectively, in 74%, 66%, 37%, and 21% of the tissue samples evaluated. Estimated mean density values are 9,819 ± 530 dpm/mg tissue for GRP receptors, 9,135 ± 579 dpm/mg for NPY-Y1 receptors, 4,337 ± 528 dpm/mg for somatostatin receptors, and 3,437 ± 306 dpm/mg for VPAC-1 receptors. Important to these observations is the finding that a very high percentage of cells of this tumor type (93%) express NPY-Y1, GRP receptors, or both NPY-Y1 and GRP complexes (93%). Lymph node metastases have receptor expression profiles that closely correlate with those noted for primary tumor tissues.
Instrumentation: Nuclear medicine scintillation imaging camera with computer-integrated instrumentation.

Co-expressed peptide receptors in breast cancer as a molecular basis for *in vivo* multireceptor tumor targeting. Reubi C, Gugger M, Waser B. Eur J Nucl Med Mol Imaging 2002 Jul; 29 (7), pp. 855–62.

Mammary Carcinoma/Detection and Disease Monitoring
[^{123}I]-Anti–Human Milk Fat Globulin (HMFG1)/[^{99m}Technetium] ([^{99m}Tc])-Anti-Carcinoembryonic Antigen (CEA)

Cellular/Molecular Mechanism of Action: Humoral immune-mediated recognition of neoplastic cell-specific membrane-associated antigens expressed by mammary carcinoma facilitated by simple antigen/antibody complex formation. Examples of unique neoplastic cell antigens associated with the exterior membrane include anti-HMFG1 and anti-CEA.
Application: Detection of primary, residual, multicentric, and recurrent mammary carcinoma.
Route of Administration: Intravenous.
Dosage: Murine-origin anti-CEA monoclonal antibody (MAb) Type CYT 380 (0.5–2.0 mg) labeled with [^{99m}Tc] (13–22 millicurie [mCI]) and anti-HMFG1 MAb (0.25–1.0 mg: Unipath, U.K.) labeled with [^{123}I] (4-17 mCI).
Considerations: Radiolabeled MAbs used in this study are potentially useful diagnostic agents for the evaluation of primary or recurrent breast carcinoma conditions, particularly in the scenarios where conventional methodologies are limited.
Implementation: Investigations have assessed the potential proficiency of radioimmunodetection (RAID) of primary, residual, multicentric, and recurrent breast carcinoma using 2 radiolabeled murine MAbs with binding avidity for (i) anti-HMFG1; and (ii) anti-CEA.

Human Model: Cases with suspicious clinical and/or mammographic evidence of primary or recurrent breast carcinoma (n = 13) in a phase I-II prospective, consecutive, non-randomized, non-controlled study; case subjects receive intravenous infusions of [^{99m}Tc]-anti-CEA monoclonal Type CYT 380 (n = 5 cases) or [^{123}I]-anti-HMFG1 monoclonal antibody (n = 8 cases).
Interpretation and Analysis: Both types of radiolabeled monoclonal antibodies bind specifically to breast cancer lesions, resulting in successful RAID profiles (e.g., n = 10/12 cases [n = 5/5 cases with [^{99m}Tc]-anti-CEA; and n = 5/7 receiving [^{123}I]-anti-HMFG group resulting in 83.3% level of accuracy]). Sensitivity is relatively high (87.5%) based on the correlation of true-positive scans with observations noted at the time of surgical intervention. Monoclonal antibody facilitated scans can accurately diagnose lesions of primary invasive mammary carcinoma confirmed histiologically (e.g., n = 3/4). Detection of the presence of residual carcinoma may be slightly less effective following wide surgical excision (e.g., 1 of 2 cases) or in conditions with soft tissue metastases (e.g., n = 3). Some conditions may display patterns of a true-negative scan (specificity 75%) that may be observed in cases presented with suspicious mammographic recurrence post-lumpectomy (n = 2) or those with questionable soft tissue recurrence (n = 1). Somewhat infrequently, cases with primary breast carcinoma may have a false-negative scan or others may display false-positive scans in the presence of fibrosis

that develops following lumpectomy and/or radiation therapy. Adverse reactions to radiolabeled immunoglobulin injection are not common, but the possibility of a hypersensitivity reaction should be a consideration if serial scintigraphic images are performed over an extended period of time. Radioummunodetection (scintigraphic imaging) can be confirmed by immunohistochemistry in a high percentage of cases (e.g., n = 6/9).

Diagnosis of breast carcinoma with radiolabeled monoclonal antibodies (MAbs) to carcinoembryonic antigen (CEA) and human milk fat globulin (HMFG). Rosner D, Nabi H, Wild L, Ortman-Nabi J, Hreshchyshyn MM. Cancer Invest 1995; 13 (6), pp. 573–82.

Mammary Carcinoma/Detection and Disease Monitoring
N-(N-Benzylpiperidin-4-yl)-2-[^{18}F]-Fluorobenzamide

Cellular/Molecular Mechanism of Action: Selectively assimilated by human mammary carcinoma.
Application: Detection and characterization of human mammary carcinoma populations that express sigma receptor complexes. In this context, the agent can potentially function as a positron emission tomography (PET) imaging agent for breast cancer.
Route of Administration: N-(N-benzylpiperidin-4-yl)-2-[^{18}F]-fluorobenzamide.
Implementation: Detection of mammary carcinoma neoplastic lesions *in vivo* applying PET imaging modalities.
Animal Model: Mice (severe combined immunodeficient [SCID] mice bearing MDA-MB231 tumor and native explants of human mammary carcinoma).
Interpretation and Analysis: Investigations performed *in vivo* in SCID mice bearing MDA-MB231 tumors reveal (i) a high uptake of compound #2 in neoplastic lesions (3.8%/g); and (ii) ratios of tumor/muscle and tumor/blood of approximately 6.2 and 7.0, respectively, at 1 hour postinjection. Pretreatment of SCID mice with haldol increases the uptake of compound "2" in blood, muscle, and other well-perfused organs, while decreasing its uptake by tumors. The ratios of tumor/muscle and tumor/blood decrease from 6.2 and 7.0 to 1.3 and 1.1, respectively, at 1 hour postinjection. At 2 hours postinjection, the ratios of tumor/muscle and tumor/blood decrease from 4.9 and 7.8 to 1.4 and 1.4, respectively. The tumor uptake of compound #2 in SCID mice bearing primary tumor explants from human cases of breast cancer can be lower than observed with MDA-MB231 tumors (1.66%/g vs 3.78%/g), and the ratios of tumor/muscle and tumor/blood are 3.5 and 3.7, respectively, at 1 hour postinjection. Such findings suggest that compound "2" may be a potential ligand for (PET) imaging of breast cancer.

N-(*N*-Benzylpiperidin-4-yl)-2-[^{18}F]fluorobenzamide: A potential ligand for PET imaging of breast cancer. Shiue C, Shiue GG, Benard F, Visonneau S, Santoli D, Alavi AA. Nucl Med Biol 2000 Nov; 27 (8), pp. 763–7.

Mammary Carcinoma/Estrogen Receptor Alpha (ERα)
4-Para-Phenylvinyl Estradiol Analogues

Cellular/Molecular Mechanism of Action: Synthetic 17α-E-(4-substituted phenyl)vinyl estradiol represents a class of ligands that retain significant binding avidity for the ERα-HBD.
Application: Detection and characterization of estradiol receptor alpha (ERα-HBD) or imaging the distribution and expression density of estradiol receptor alpha complexes.
Semi-Synthetic Methods: An array of 4-*para*-substituted phenylvinyl estradiol derivatives can be fabricated using a combination of reagent formulations in combination with solid-phase Pd(0)-catalyzed methods.
Interpretation and Analysis: The compounds (e.g., 5a through 5j) are evaluated for binding affinity using the estrogen receptor alpha hormone binding domain (HDB) isolated from transfected BL21 cell lines. Although these compounds are somewhat lower in relative binding affinity (RBA at 25°C is 1–60%) than estradiol (100%), most have higher affinity than the unsubstituted parent phenylvinyl estradiol (RBA = 9%).

Because the substituents did not generate a structure-activity relationship directly based on physicochemical properties, evaluations are performed using molecular modeling and molecular dynamics to establish key interactions between the ligand (e.g., *para* substituent especially) and the protein molecule. The observed relative binding affinities are directly related to the calculated binding energies. Amino acids juxtaposed to the *para* position play a significant but not dominant role in binding. In particular, 4-substitution tends to increase receptor binding affinity compared to the unsubstituted analogue, as exemplified by product 5e (4-$COCH_3$), which has the highest RBA value (60%) of the series. Palladium(0)-catalyzes coupling reactions on solid support or in solution using suitably substituted iodo arenes and 17α-E-tributylstannylvinyl estradiols offer a flexible approach to their preparation.

Molecular modeling studies of the receptor suggest that there exists additional ligand accessible regions within the ERα-HBD to generate interactions that may enhance receptor affinity or modify efficacy in developing new therapeutic agents. Studies to undertake modification in the properties and/or position of the aryl substituents in subsequent series to further define that role are in progress.

Synthesis and evaluation of 17alpha-20E-21-(4-substituted phenyl)-19-norpregna-1,3,5(10),20-tetraene-3,17beta-diols as probes for the estrogen receptor alpha hormone binding domain. Hanson RN, Lee CY, Friel CJ, Dilis R, Hughes A, DeSombre ER. J Med Chem 2003 Jul 3; 46 (14), pp. 2865–76.

Mammary Carcinoma: Estrogen Receptor Expression
[^{99m}Technetium] ([^{99m}Tc)-N_2S_2]-Z-Aminotamoxifen/ [^{99m}Tc-N_2S_2]-E-Aminotamoxifen/[Rhenium-N_2S_2]-Z-Aminotamoxifen/[Rhenium- N_2S_2]-E-Aminotamoxifen

Cellular/Molecular Mechanism of Action: Aminotamoxifen recognizes and binds to membrane-associated estrogen receptor complexes.
Application: Imaging agent for the detection and characterization of breast cancer.
Route of Administration: Intravascular.
Semi-Synthetic Methods: The bifunctional chelator agent N_2S_2 is conjugated to Z- and E-aminotamoxifens through an amide linkage. Both [^{99m}Tc] and rhenium can be complexed with N_2S_2 employing mechanisms of simple chelation.
Implementation: Detection and characterization of mammary carcinoma lesions (*in vivo*).
Interpretation and Analysis: For the Z-isomer, chelation with rhenium in the presence of sodium acetate yields a mixture of 2 isomers, anti and syn, in a 1:1 ratio and in the presence of hydroxide results in only the anti isomer. Both the Z- and E-tamoxifen conjugates can be chelated with the [^{99m}Tc] radioisotope at the tracer level, yielding a single isomer product. Such preparations can be designated as antibase on chromatographic comparison to rhenium complexes. Radiochemical yields are consistently greater than 80%, with Sep-Pak column purification yielding a final product with > 99% radiochemical purity and no residual starting material. Both *in*

vitro and *in vivo* biological evaluation of the tamoxifen chelates indicate very limited estrogen receptor binding.

Single isomer technetium-^{99m} tamoxifen conjugates. Hunter DH, Luyt LG. Bioconjug Chem 2000 Mar–Apr; 11 (2), pp. 175–81.

Mammary Carcinoma/Estrogen Receptor Expression
[^{123}I]-Labeled Estradiol Derivatives

Background Information: Radiolabeled estrogen receptor ligands are tracers that can be used for functional receptor diagnosis. Their specificity toward receptors, together with the fact that only 50–70% of mammary carcinomas are receptor positive, renders them unsuitable for detection of primary tumors or metastases, and this means that estrogen receptor scintigraphy can be used neither for tumor screening nor for staging. However, both [^{18}F]-labeled and [^{123}I]-labeled estradiol derivatives are suitable for *in vivo* imaging of estrogen receptors.
Application: Detection and characterization of mammary carcinoma lesions that express estrogen receptor complexes.
Route of Administration: [^{123}I]-labeled estradiol derivatives (intravascular).
Interpretation and Analysis: The high specificity of both [^{18}F]-labeled and [^{123}I]-labeled estradiol derivatives *in vivo* in animal experiments and related *in vitro* studies have been reproduced *in vivo* in humans.

Tracers with positron radiation emitters are, however, hardly suitable for broad application, owing to the short half-life of [^{18}F], which means that users need to be situated close to a cyclotron and a correspondingly equipped radiochemical laboratory. The number of available positron emission tomography (PET) scanners, on the other hand, has increased over the last few years, especially in Germany, so that this, at least, does not present a limiting factor. All the same, [^{123}I]-labeled estradiol derivatives will find more widespread application, because the number of gamma cameras incorporating modern multihead systems is several times greater. The results of studies with [^{123}I]-E2 scintigraphy published to date are very promising, even given the initial technical problems just mentioned. As a method of examination, it could be enhanced by using improved tracers with a higher tumor contrast and less disturbance from overlapping in diagnostically relevant locations, for instance, by selecting tracers with higher activities whose excretion is more renal than hepatobiliary. The use of modern multihead camera systems can also be expected to improve the photon yield.

Estrogen receptor scintigraphy. Scheidhauer K, Scharl A, Schicha H. Q J Nucl Med 1998 Mar; 42 (1), pp. 26–32.

Mammary Carcinoma/*N*-Nitrosomethylurea (NMU)-Induced/Glioma: Central Nervous System
[^{99m}Technetium] ([^{99m}Tc])-T3,4BCPC/ Potential Delivery Platform

Cellular/Molecular Mechanism of Action: The exact mechanism that facilitates the selective uptake of T3,4BCPC by certain neoplastic cell types has not been precisely established.
Application: Potential application as a detectable delivery modality that selectively recognizes certain neoplastic cell types (e.g., glioma, mammary carcinoma).
Route of Administration: T3,4BCPC (intravenous).
Dosage: T3,4BCPC (5.0 mg/kg body weight; murine fibrosarcoma model).
Semi-Synthetic Methods: The new water-soluble photosensitizer 5,10,15,20-tetrakis[3,4-*bis*(carboxymethyleneoxy)-phenyl] chlorin (T3,4BCPC) has been prepared, characterized, and methods developed for radiolabeling with [^{99m}Tc] preparations.
Implementation: Determination of biodistribution profiles in tumor models in order to establish the comparative properties of the tumor-seeking radiopharmaceuticals [^{99m}Tc^{V}]-dimercaptosuccinic acid (DMSA), [^{201}Thallous]-chloride ([^{201}Tl]Cl), and [^{99m}Tc]-citrate using a gamma camera imaging systems. In the 2nd phase of evaluation, *in vivo* efficacy of the compound is determined by establishing its potential as a photodynamic therapeutic agent achieved by the conduction of a preclinical photodynamic therapy (PDT) study performed in fibrosarcoma-bearing mice (postinjection of T3,4BCPC).
Animal Model: Murine (C_3H/J virus-induced spontaneous mammary tumors).
Animal Model: Murine (fibrosarcoma-bearing).
Animal Model: Rats (Wistar strain).
Animal Model: Rat (NMU-induced mammary tumors).
Animal Model: Rat (transplanted C_6-glioma).
Interpretation and Analysis: Accumulation of activities within the liver, kidney, bladder, and large intestine at 4 hours postinjection indicates that the labeled ligand is largely eliminated through renal excretion and partly through the hepatobiliary system. In NMU-induced rat mammary tumors, the labeled ligand shows a 5-fold tumor-to-muscle (T/M) ratio compared to [^{99m}Tc^{V}]-DMSA (3-fold) and [^{201}Tl]Cl (3-fold). In the case of C_3H/J virus-induced spontaneous mammary tumors, differences are not marked. However, in transplanted rat C_6-glioma, the T/M ratio of the labeled compound is appreciably higher (4-fold) than that noted with [^{99m}Tc^{V}]-DMSA (2-fold), [^{201}Tl]Cl (3-fold), and [^{99m}Tc]-citrate (more than 3-fold). Therefore, radiolabeled T3,4BCPC may have potential utility for detecting neoplastic lesions. Photodynamic therapy applications of T3,4BCPC in fibrosarcoma-bearing mice evaluated following delivery of a laser dose of 20 mW for 60 seconds reveals an 80% destruction of tumor mass. The molecule may therefore be useful for PDT of cancer. The labeled agent could also be useful in monitoring the progression/regression of tumors before, during, and after chemotherapy, radiation therapy, or PDT.

Preparation and biological evaluation of the new chlorin photosensitizer T3,4BCPC for detection and treatment of tumors. Murugesan S, Shetty SJ, Srivastava TS, Samuel AM, Noronha OP. J Photochem Photobiol B 2002 Aug; 68 (1), pp. 33–8.

Mammary Carcinoma/Vasoactive Intestinal Peptide Receptor (VIP-R) Complexes
[^{99m}Technetium] ([^{99m}Tc])-Hexamethylpropyleneamine Oxime (HMPAO)-[SSL-VIP] Liposomes

Cellular/Molecular Mechanism of Action: Vasoactive intestinal peptide recognizes and physically binds to its respective receptor complex.
Background Information: Targeted delivery of radionuclides and therapeutic agents to specific biomarkers of breast cancer has important implications for the diagnosis and therapy of breast cancer. Vasoactive intestinal peptide receptors have approximately a greater expression density in human breast cancer compared to normal breast tissue.
Semi-Synthetic Methods: Incorporation of VIP (28 amino acid mammalian neuropeptide), as a breast cancer targeting moiety for selectively imaging of breast cancer. Vasoactive intestinal peptide is covalently attached to the surface of sterically stabilized liposomes (SSL) containing encapsulated [^{99m}Tc]-HMPAO radionuclide.

Implementation: Evaluation of liposome preparations as a potential delivery platform/imaging agent for mammary carcinoma. Complementary investigations can delineate the pharmacokinetics and biodistribution of [^{99m}Tc]-HMPAO encapsulating SSL with and without VIP.

Animal Model: Rats with *n*-methyl nitrosourea (MNU)-induced *in situ* breast cancers.

Interpretation and Analysis: The presence of VIP does not alter the size, and [^{99m}Tc]-HMPAO encapsulation ability of SSL. It also does not alter the pharmacokinetic profile of SSL. Long-circulating liposomes with and without VIP on their surface accumulate at significantly higher quantities in breast cancer compared to normal breast, indicating passive targeting of these constructs to cancer tissues. Importantly, in breast cancer, [^{99m}Tc]-HMPAO encapsulating SSL with VIP shows significantly more accumulation than SSL without VIP. The tumor-to-non-tumor ratio is also significantly higher for [^{99m}Tc]-HMPAO encapsulating VIP-SSL than [^{99m}Tc]-HMPAO encapsulating SSL without VIP, suggesting active targeting of VIP-SSL to breast cancer. Collectively, these data showed that [^{99m}Tc]-HMPAO encapsulating VIP-SSL can be successfully used for targeted imaging of breast cancer lesions.

VIP grafted sterically stabilized liposomes for targeted imaging of breast cancer: *In vivo* studies. Dagar S, Krishnadas A, Rubinstein I, Blend MJ, Onyuksel H. J Control Release 2003 Aug 28; 91 (1–2), pp. 123–33.

Mammary Carcinoma/Ineffective Diagnostic Imaging Agent for Neoplasia
[^{99m}Technetium] ([^{99m}Tc])-Medronate/[Methylene Diphosphate]

Background Information: Breast scintigraphy (BS) with the bone-seeking agent [^{99m}Tc]-medronate (MDP) can be usefully combined with mammography to diagnose and characterize questionable breast lumps. However, this radiotracer does not seem to provide any further prognostic information about breast cancer.

Application: Detection and characterization of mammary carcinoma lesions.

Implementation: Delineate the prognostic yield of MDP-BS in an effort to search for correlations that exist between scintigraphic findings and major biological and histologic parameters. Cases of mammary carcinoma are subjected to scintigraphic imaging with [^{99m}Tc]-MDP bone scan for the purpose of preoperative staging, as well as conventional breast imaging. Cancer/background ratio (c/b index) with lesion histotype, diameter, grading, and the tissue concentrations of steroid receptors, cathepsin D, Type 1 tymidine kinase, pS2, and p53 proteins are then statistically compared.

Interpretation and Analysis: The agent MDP-BS fails to detect a rather large percentage of mammary neoplastic lesions in the small to medium size range (n = 11/44 false-negative with a size range = 0.5–2.0 cm). Similary, the agents detected a relatively small percentage of mammographically questional lesions (e.g., n = 7/16), but can correctly visualize some multifocal cases (e.g., n = 2). Unfortunately, MDP-BS depicts no metastatic axillary lymph nodes. There is no statistically significant correlation between the c/b index and prognostic markers.

Different from evaluating BS with [^{99m}Tc]-methoxy-isobutyl-isonitrile, [^{201}T1], [^{18}F]-FDG, [^{111}In]-OCT, and radiolabeled estrogens, MDP-BS (despite its good overall accuracy) appears to have no prognostic role. In fact, despite the well-known capability of soft tissue lesions to take up the tracer, MDP tumor trapping seems to depend mainly on the increased permeability of neovessels and on interstitial space enlargement. Few reports are available in the literature about correlations between *in vivo* MDP uptake by the breast cancer and prognostic parameters. The lack of any statistical significance is in agreement with the theory and confirms the little prognostic value of MDP-BS. Nevertheless, further trials are warranted on larger series of cases to validate the referenced study's findings.

Human Model: Cases of primary breast cancer (n = 44).

The prognostic significance of [^{99m}Tc]-MDP breast scintigraphy. A comparison with histological and molecular parameters. Dimonte M, Leo G, Marsigliante S, Manca C. Radiol Med (Torino) 1999 Nov; 98 (5), pp. 352–5.

Melanoma
[^{99m}Technetium] ([^{99m}Tc])Oxotechnetium^{V}-Complexes of Amine-Amide-Dithiol (AADT)

Cellular/Molecular Mechanism of Action: [^{99m}Tc]Oxotechnetium(V) complexes of AADT chelates containing tertiary amine substituents possess binding affinity for melanoma cell types.

Application: Diagnostic imaging agent for the non-invasive *in vivo* detection of melanoma and associated metastases.

Route of Administration: Intravenous.

Semi-Synthetic Methods: Complexation is achieved by mixing the AADT-$CH_2[CH_2]$nNR2 (n = 1, 2; R = Et, n-Bu) ligand with a [^{99m}Tc]oxotechnetium^{V}-glucoheptonate precursor to make AADT-[^{99m}Tc]oxotechnetium^{V} complexes in nearly quantitative yield.

Implementation: Evaluation of the binding affinity of [^{99m}Tc] oxotechnetium^{V}-complexes of amine-amide-dithiol for sigma receptor complexes.

Interpretation and Analysis: Evaluation of the binding affinity for sigma receptor complexes reveals that preparations possess values in the low μM range with K_i values in the 7.8–26.1 and 0.18–2.3 μM range for $sigma_1$ and $sigma_2$ receptors, respectively. Cellular *in vitro* uptake of [^{99m}Tc] complexes by intact B16 murine melanoma cells at 37°C after a 60-minute incubation varies between 12% for complex 2 (n = 1, R = n-Bu) to 68% for complex 4 (n = 2, R = n-Bu). Complexes 1-Tc–4-Tc *in vitro* in the C57Bl/B16 mouse melanoma model significantly localize within tumor lesions. Complex 1-Tc (n = 1, R = Et) provide *in vivo* tumor uptake of 7.6 percent injected dose per gram (%ID/g) at 1 hour postadministration with values of > 4 that can be observed for initial melanoma/blood (M/B), melanoma/spleen (M/S), and melanoma/lung (M/L) ratios. At a time period of 6 hours postadministration, the observed measurements for these same ratios substantially increase (e.g., 10.8, 10.1, 7.3, respectively). While complex 3-Tc (n = 3, R = Et) can have an initial tumor uptake level of 3.7 %ID/g at 1 hour postadministration (M/B, M/S, M/L ratios > 2), a greater tumor retention and slightly faster clearance from non-tumor-containing organs results in 6-hour M/B, M/S, and M/L ratios of 19.1, 19.1, and 12.7, respectively.

[^{99m}Tc]oxotechnetium(V) complexes amine-amide-dithiol chelates with dialkylaminoalkyl substituents as potential diagnostic probes for malignant melanoma. Friebe M, Mahmood A, Bolzati C, Drews A, Johannsen B, Eisenhut M, Kraemer D, Davison A, Jones AG. J Med Chem 2001 Sep 13; 44 (19), pp. 3132–40.

Melanoma/Melanocyte-Stimulating Hormone (MSH) Receptor
[^{111}Indium] ([^{111}In])-DOTA-ReCCMSH/[^{111}In]-DOTA-CCMSH/[^{111}In]-DOTA-CMSH/[^{111}In]-DOTA-NDP

Cellular/Molecular Mechanism of Action: Possesses binding avidity for MSH receptor complexes.

Application: Detection and characterization of neoplastic cell types (melanoma) that express MSH receptor complexes.

Semi-Synthetic Methods: Production of (i) DOTA-ReC-CMSH; (ii) its reduced non-metalated linear homolog, DOTA-CCMSH; and (iii) an analogue in which rhenium cyclization is replaced by disulfide bond cyclization → DOTA-[$Cys_{4,10}$,D-Phe_7]α-MSH_{4-13} (CMSH). DOTA can also be conjugated to the amino terminus of 1 of the highest-affinity α-MSH receptor-binding peptides, [Nle_4,D-Phe_7]α-MSH (NDP), as a linear peptide standard. The DOTA-conjugated α-MSH analogues can subsequently be [^{111}In] radiolabeled.

Implementation: Evaluation of the effect of rhenium-mediated peptide cyclization on melanoma targeting, biodistribution, and clearance kinetics of the α-MSH analogue 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) coupled ReO-cyclized [$Cys_{3,4,10}$,D-Phe_7]α-MSH_{3-13} (DOTA-ReCCMSH). One approach to achieving such an objective can entail assessment of the *in vitro* receptor-binding affinity of (i) [^{111}In]-DOTA-ReCCMSH; (ii) [^{111}In]-DOTA-CCMSH; (iii) [^{111}In]-DOTA-[$Cys_{4,10}$,D-Phe_7]α-MSH_{4-13} (CMSH); and (iv) [^{111}In]-DOTA [Nle_4,D-Phe_7]α-MSH (NDP) for B16/F1 murine melanoma cell types in addition to determing their relative *in vivo* biodistribution properties in tumor-bearing and non-tumor-bearing mice.

Animal Model: Murine (C57 and melanoma tumor-bearing C57 mice).

Interpretation and Analysis: The tumor uptake values of [^{111}In]-DOTA-ReCCMSH are significantly higher than those of the other closely related [^{111}In]-DOTA-α-MSH conjugates. Even at 24 hours after injection, a comparison of the tumor uptake values for [^{111}In]-DOTA-coupled ReCCMSH (4.86 ± 1.52 percent injected dose [%ID]/g), CCMSH (1.91 ± 0.56 %ID/g), CMSH (3.09 ± 0.32 %ID/g), and NDP (2.47 ± 0.79 %ID/g) highlight the high tumor retention property of ReCCMSH. Rhenium-coordinated cyclization results in less renal radioactivity accumulation of [^{111}In]-DOTA-ReCCMSH (8.98 ± 0.82 %ID/g) than of [^{111}In]-DOTA-CCMSH (63.2 ± 15.6 %ID/g), [^{111}In]-DOTA-CMSH (38.4 ± 3.6 %ID/g), and [^{111}In]-DOTA-NDP (12.0 ± 1.96 %ID/g) at 2 hours after injection and its urinary clearance significantly increases (92 %ID at 2 hours postinjection). A high radioactivity uptake ratio of tumor-to-normal tissue can be observed for [^{111}In]-DOTA-ReCCMSH (e.g., 489, 159, 100, and 49 for blood, muscle, lung, and liver, respectively, at 4 hours after injection). The novel ReO-coordinated cyclic structure of DOTA-ReCCMSH contributes significantly to its enhanced tumor-targeting and renal clearance properties. Such characteristics make DOTA-ReCCMSH an excellent candidate for melanoma radiodetection and radiotherapy.

Evaluation of a [^{111}In]-DOTA-rhenium cyclized α-MSH analog: A novel cyclic-peptide analogue with improved tumor-targeting properties. Chen J, Cheng Z, Owen NK, Hoffman TJ, Miao Y, Jurisson SS, Quinn TP. J Nucl Med 2001 Dec; 42 (12), pp. 1847–55.

Melanoma/Melanocyte-Stimulating Hormone (MSH) Receptor Complexes
[^{111}Indium] ([^{111}In])-DOTA-MSH(OCT)/[^{111}In]-DOTA-NDP-MSH

Cellular/Molecular Mechanism of Action: The octapeptide [βAla$_3$, Nle_4, Asp_5, D-Phe_7, Lys_{10}]-α-MSH_{3-10} referred to as MSH (OCT) is an analogue of α-MSH.

Background Information: Scintigraphic imaging of metastatic melanoma lesions requires highly tumor-specific radiopharmaceuticals. Because both melanotic and amelanotic melanomas overexpress melanocortin-1 receptors (MC1R), radiolabeled analogues of α-MSH are potential candidates for development as melanoma diagnostic imaging agents.

Application: Detection and characterization of malignant melanoma lesions.

Route of Administration: [^{111}In]-DOTA-MSH(OCT) and [^{111}In]-DOTA-NDP-MSH (intravenous).

Semi-Synthetic Methods: Molecular design of the octapeptide analogue MSH(OCT) utilizes conjugation reactions involving its *N*-terminal amino group to the metal chelator in the form of 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) to enable incorporation of radiometals (e.g., [^{111}In]) into the peptide.

Implementation: Evaluation of the *in vitro* ligand binding avidity of non-radioactive DOTA-MSH(OCT) for MC1R. Complementary investigations can involve determining the *in vivo* biodistribution of [^{111}In]-DOTA-MSH(OCT) in normal reference control and tumor-bearing models.

Animal Model: Murine (B16-F1 melanoma tumor-bearing mice).

Interpretation and Analysis: The non-radioactive ligand DOTA-MSH(OCT) possesses a relatively high level of *in vitro* binding avidity for MC1R complexes (IC_{50} 9.21 nM). *In vivo* [^{111}In]-DOTA-MSH(OCT) exhibits a favorable biodistribution profile after injection into tumor-bearing *in vivo* models. The radiopeptide is rapidly cleared from blood through the kidneys and, most importantly, accumulates preferentially within melanoma lesions. Lung and liver melanoma metastases can be clearly imaged on tissue section autoradiographs 4 hours after injection of [^{111}In]-DOTA-MSH(OCT). A comparative study of [^{111}In]-DOTA-MSH(OCT) with [^{111}In]-DOTA-[Nle_4, D-Phe_7]-α-MSH ([^{111}In]-DOTA-NDP-MSH) demonstrates that DOTA-MSH(OCT) peptide is a superior ligand reagent, particularly with regard to the amount of radioactivity taken up by non-malignant organs, including bone, the most radiosensitive tissue. Therefore, [^{111}In]-DOTA-MSH(OCT) is a promising melanoma imaging agent.

DOTA α-melanocyte-stimulating hormone analogues for imaging metastatic melanoma lesions. Froidevaux S, Calame-Christe M, Sumanovski L, Tanner H, Eberle AN. Ann N Y Acad Sci 2003 Jun; 994, pp. 378–83.

Melanoma/Melanocyte Stimulating Hormone (MSH) Receptor Expression/Non-Specific Renal Uptake Inhibition Strategies
Melanocyte-Stimulating Hormone (MSH) Analogues/[^{99m}Technetium] ([^{99m}Tc])-CCMSH/Lys_{11} Replacement/Lysine Co-Administration

Cellular/Molecular Mechanism of Action: Melanocyte-stimulating hormone and related analogues physically bind to receptor complexes associated with the exterior surface membrane of melanoma cell types.

Physiological Mechanism of Action: Preliminary reports have demonstrated that [^{99m}Tc]-labeled cyclic [$Cys_{3,4,10}$, D-Phe_7]α-MSH_{3-13} (CCMSH) exhibits high tumor uptake and retention values in a murine melanoma tumor model.

Application: Detection and characterization of primary or metastatic melanoma lesions.

Route of Administration: Intravascular.

Implementation: Evaluation of the tumor targeting capacity of [^{99m}Tc]-CCMSH for comparision with radiolabeled α-MSH peptide analogues including [^{125}I]-(Tyr_2)-[Nle_4, D-Phe_7]α-MSH [^{125}I]-(Tyr_2)-NDP]; [^{99m}Tc]-CGCG-NDP; [^{99m}Tc]-Gly_{11}-CCMSH; and [^{99m}Tc]-Nle_{11}-CCMSH. Initial delineation of *in vitro* receptor binding, internalization, and cellular retention of radiolabeled α-MSH analogues can be performed using B16/F1 murine cell lines. Further characterization of the *in vivo* properties of these radiobiopharmaceutical agents can be determined in mouse melanoma models.

Complementary investigations can be performed to establish molecular strategies for reducing non-specific renal uptake of imaging agents. Examples of 2 strategies that can be employed to decrease non-specific kidney uptake of [^{99m}Tc]-CCMSH include (i) substitution of Lys_{11} in CCMSH with Gly_{11} or Nle_{11}; and (ii) lysine co-injection.

Animal Model: Murine (C57 strain mice and severe combined immunodeficient [SCID] mice, inoculated subcutaneously with B16/F1 murine and TXM-13 human melanoma cell populations).

Interpretation and Analysis: The *in vitro* receptor binding, internalization, and cellular retention of radiolabeled α-MSH analogues in B16/F1 murine cell line reveals that > 70% of the receptor-bound radiolabeled analogues are internalized together with the receptor. Ninety percent of the internalized [^{125}I]-(Tyr_2)-NDP, whereas only 36% of internalized [^{99m}Tc]-CCMSH, is released from the cells into the medium during a 4-hour incubation period (37°C).

In an *in vivo* environment, tumor uptake values of 11.32 and 2.39 [percent injected dose (%ID)/g] can be observed for [^{99m}Tc]-CCMSH at 4 hours post-injection, resulting in tumor:blood uptake ratios of approximately 39.0 and 11.5 in murine melanoma-C57 and human melanoma-SCID mouse models, respectively. Biodistribution data for the modified peptides reveals that Lys_{11} replacement dramatically decreases kidney uptake, whereas the tumor uptakes of [^{99m}Tc]-Nle_{11}- and [^{99m}Tc]-Gly_{11}-CCMSH are significantly lower than that of [^{99m}Tc]-CCMSH. Lysine coinjection significantly decreases kidney uptake (e.g., from 14.6 %ID/g to 4.5 %ID/g at 4 hours after injection in murine melanoma-C57 mice) without creating significant changes in value for tumor uptake of [^{99m}Tc]-CCMSH. Therefore, the compact cyclic structure of [^{99m}Tc]-CCMSH, its resistance to degradation, and its enhanced intracellular retention are the major contributing factors to the superior *in vivo* tumor targeting properties of [^{99m}Tc]-CCMSH. The Lys_{11} residue in [^{99m}Tc]-CCMSH is critical to *in vivo* tumor targeting, and lysine co-injection rather than lysine replacement can significantly decrease non-specific renal radioactivity accumulation without impeding the high melanoma-targeting properties of [^{99m}Tc]-CCMSH. The metal-cyclized CCMSH molecule displays excellent potential for development as a melanoma-specific diagnostic and therapeutic agent.

Melanoma-targeting properties of [^{99m}technetium]-labeled cyclic α-melanocyte-stimulating hormone peptide analogues. Chen J, Cheng Z, Hoffman TJ, Jurisson SS, Quinn TP. Cancer Res 2000 Oct 15; 60 (20), pp. 5649–58.

Melanoma (Metastatic)/Melanocyte-Stimulating Hormone (MSH) Receptor Expression *[^{111}Indium] ([^{111}In])-DOTA-NDP-MSH/ [^{111}In]-DOTA-MSH(OCT)*

Cellular/Molecular Mechanism of Action: The peptide [Nle_4, D-Phe_7]-α-MSH is a very potent α-MSH analogue that recognizes and physically binds to MSH receptor complexes. Similarly, [βAla_3, Nle_4, Asp_5, D-Phe_7, Lys_{10}]-α-MSH_{3-10} is an α-MSH octapeptide analog.

Application: Scintigraphic imaging of metastatic melanoma lesions requires highly tumor-specific radiolabeled compounds. Because both melanotic and amelanotic melanomas overexpress receptors for α-MSH (receptor name: melanocortin Type 1 receptor, or MC1R), radiolabeled α-MSH analogues are potential candidates for development as diagnostic imaging agents for melanoma conditions.

Route of Administration: [^{111}In]-DOTA-NDP-MSH and [^{111}In]-DOTA-MSH(OCT) are presumably administered intravenously.

Semi-Synthetic Methods: Covalent conjugation of [Nle_4, D-Phe_7]-α-MSH (NDP-MSH) and a newly designed α-MSH octapeptide analog, [βAla_3, Nle_4, Asp_5, D-Phe_7, Lys_{10}]-α-MSH_{3-10} (MSH(OCT)) to the metal chelator 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA), thereby enabling radiometal incorporation into the complex.

Implementation: Evaluation of the (i) potential *in vitro* binding avidity of [^{111}In]-DOTA-NDP-MSH and [^{111}In]-DOTA-MSH(OCT) for MC1R; (ii) melanogenic activity of [^{111}In]-DOTA-NDP-MSH and [^{111}In]-DOTA-MSH(OCT) in isolated mouse B16F1 cells; and (iii) *in vivo* biodistribution of the hormone receptor ligands in mouse models of primary and metastatic melanoma.

Animal Model: Murine (melanoma B16F1-bearing mice).

Interpretation and Analysis: DOTA-MSH(OCT) binds with high affinity (inhibitory concentration of 50% IC_{50} = 9.21 nmol/L) to the MC1R, although with a lower potency than does DOTA-NDP-MSH (IC_{50} = 0.25 nmol/L). In B16F1 melanoma-bearing mice, both [^{111}In]-DOTA-NDP-MSH and [^{111}In]-DOTA-MSH(OCT) exhibit high MC1R-mediated uptake by melanoma, which differs by a factor of only 1.5 at 4 hours postadministration. The main route of excretion for both radioconjugates is the kidneys, whereby [^{111}In]-DOTA-MSH(OCT) produces somewhat higher kidney values than does [^{111}In]-DOTA-NDP-MSH. Conversely, the latter conjugate is much more poorly cleared from other non-malignant tissues, including bone, the most radiosensitive organ. Therefore, [^{111}In]-DOTA-MSH(OCT) displays higher uptake ratios of tumor-to-non-target tissue (e.g., tumor-to-bone ratio at 4 hours post-administration is approximately 4.9 for [^{111}In]-DOTA-NDP-MSH and 53.9 for [^{111}In]-DOTA-MSH(OCT)). Lung and liver melanoma metastases can easily be visualized on tissue section autoradiographs after injection of [^{111}In]-DOTA-MSH(OCT). Radio-reversed-phase high-performance liquid chromatography analysis of urine samples reveals that most [^{111}In]-DOTA-MSH(OCT) is excreted intact 4 hours after injection, indicating good *in vivo* stability. Therefore, [^{111}In]-DOTA-MSH(OCT) appears to exhibit more favorable overall performance than does [^{111}In]-DOTA-NDP-MSH in murine models of primary and metastatic melanoma, making it a promising melanoma imaging agent.

A novel DOTA-α-melanocyte-stimulating hormone analogue for metastatic melanoma diagnosis. Froidevaux S, Calame-Christe M, Tanner H, Sumanovski L, Eberle AN. J Nucl Med. 2002 Dec; 43 (12), pp. 1699–706.

Metastatic Neoplastic Disease/Carcinoma Metastasis to Bone/Recurrent Tumor and Postradiotherapy Change/Paget's Disease *[^{111}Indium] ([^{111}In])-Labeled Bleomycin*

Cellular/Molecular Mechanism of Action: Preferential uptake by cancer cells, including neoplastic conditions located within the thorax, abdomen, or pelvis.

Route of Administration: Intravenous.

Dosage: [^{111}In] (2 mCi) chelated to 2 mg bleomycin.

Considerations: The optimum time to perform scintigraphy examinations is 72 hours after intravenous injection.

Implementation: Establish the optimum time to visualize tumor [^{111}In]-labeled bleomycin uptake.

Interpretation and Analysis: A relatively high percentage of the injected dose of [^{111}In]-labeled bleomycin accumulates within tumors to the extent that it is sufficient for acquiring positive visual images (e.g., n = 53/62 cancer cases). Extent of tumor involvement can occasionally be underestimated (n = 7/62) or overestimated (n = 5/62; usually with 2° infection). Related investigations have suggested that indium provides the most clinically relevant information

when distinguishing between recurrent tumor and postradiotherapy changes in the thorax and pelvis, the diagnosis of recurrent carcinoma within the pelvis, and the distinction between bony metastases from carcinoma of the prostate and Paget's disease. Further clinical trials are necessary to assess these situations.

Indium 111-A-bleomycin—A new tracer for imaging orofacial neoplasms. Kment G, Matejka M, Porteder H, Sinzinger H. J Oral Maxillofac Surg 1988 Sep; 46 (9), pp. 742–5.

Kinetics of [^{111}In]-labeled bleomycin in patients with brain tumors: Compartmental vs non-compartmental models. Ryynänen PM, Savolainen SE, Aronen HJ, Korppi-Tommola ET, Huhmar HM, Kallio ME, Hiltunen JV. Ann Nucl Med 1998 Dec; 12 (6), pp. 313–21.

Multidrug-Resistance-1 (MDR1) Phenotype *[^{99m}Technetium] ([^{99m}Tc])-SestaMIBI/XR9576/ Vinorelbine (Navelbine)*

Cellular/Molecular Mechanism of Action: [^{99m}Tc]-sestaMIBI is a substrate of the multidrug transporter complex P-glycoprotein (Pgp).
Background Information: *In vitro*, retention of [^{99m}Tc]-sestaMIBI by cells that overexpress Pgp can be enhanced by the addition of Pgp inhibitors. XR9576 (Tariquidar) is a potent and selective non-competitive inhibitor of Pgp that is active at 25–80 nM.
Application: Functional imaging agent for the MDR1 neoplastic cell phenotype.
Implementation: A phase I trial employing XR9576 in combination with vinorelbine (Navelbine) to assess conditions of metastatic cancer using a [^{99m}Tc]-sestaMIBI scan (baseline and at 48–96 hours later by a 2nd scan 1–3 hours after the administration of XR9576). Time activity curves and areas-under-the-curves (AUCs) are obtained for tumor, liver, lung, and heart, and tissue:heart AUC ratios are calculated.

Human Model: Phase I trial (n = 26 metastatic neoplasia cases).
Interpretation and Analysis: XR9576 enhances [^{99m}Tc]-sestaMIBI accumulation and retention in the liver of all but 2 cases with a mean change of +128%. Furthermore, in cases with tumor masses visible with [^{99m}Tc]-sestaMIBI (e.g., n = 13/17), the tumor:heart [^{99m}Tc]-sestaMIBI AUC (0–3 hours) increases after XR9576 administration, with increases of 36 to 263% detected in certain instances (e.g., n = 8 cases). Therefore, the *in vivo* administration of XR9576 inhibits [^{99m}Tc]-sestaMIBI efflux in both the normal liver and in drug-resistant tumors. Such findings provide convincing evidence of the existence of XR9576-inhibitable [^{99m}Tc]-sestaMIBI efflux in a large fraction of drug-resistant tumors. One can predict that efflux of Pgp substrates also occurs in these tumors. XR9576 provides an efficient way to inhibit this efflux and offers the potential to increase drug exposure in human cancer.

Increased [^{99m}Tc]-sestaMIBI accumulation in normal liver and drug-resistant tumors after the administration of the glycoprotein inhibitor XR9576. Agrawal M, Abraham J, Balis FM, Edgerly M, Stein WD, Bates S, Fojo T, Chen CC. Clin Cancer Res 2003 Feb; 9 (2), pp. 650–6.

Multidrug-Resistance-Associated Protein (MRP)/ [Leukemia] *[^{99m}Technetium] ([^{99m}Tc])-Tetrofosmin ([^{99m}Tc]-TF)/ Verapamil*

Cellular/Molecular Mechanism of Action: Tetrofosmin is a substrate molecule for MRP expressed by certain neoplastic cell types.
Application: Detection and characterization of neoplastic cell types (e.g., leukemia) that possess resistance to chemotherapeutic intervention due to the expression of MRP. Such knowledge can provide prognostic information and the basis for the design of alternative strategies for therapeutic intervention.
Route of Administration: [^{99m}Tc]-TF (intravenous).
Implementation: Evaluation of the kinetics of cellular accumulation and retention of [^{99m}Tc]-TF in leukemia wild-type cell lines and its corresponding chemotherapeutic-resistant cell line to determine if [^{99m}Tc]-TF is a substrate for MRP with and without the presence of verapamil.

Tissue Culture Model: Leukemia wild-type HL60/WT cell line and a corresponding doxorubicin-resistant HL60/DOX cell line that expresses the MRP but without P-glycoprotein (Pgp) overexpression (37°C).
Interpretation and Analysis: [^{99m}Tc]-TF net accumulation is significantly lower in HL60/DOX (1.35 ± 0.23%) than in HL60/WT (12.79 ± 0.47%) at 60 minutes ($p < 0.001$). Three minutes after exchanging the incubation solution with the tracer-free medium, only 18.20 ± 0.34% of [^{99m}Tc]-TF remains in HL60/DOX, whereas 84.74 ± 0.65% is retained in HL60/WT ($p < 0.001$). In the presence of 10 μM verapamil, [^{99m}Tc]-TF net accumulation in HL60/DOX is 302% of the control and washout is significantly delayed. [^{99m}Tc]-TF would be a substrate for MRP and [^{99m}Tc]-TF may be used as a functional *in vivo* imaging agent of MRP.

Technetium-^{99m}-tetrofosmin would be a substrate for multidrug-resistance-associated protein (MRP): Comparison between a leukemia cell line with high MRP gene expression and its parental cell line. Li XF, Kinuya S, Yokoyama K, Konishi S, Ma YY, Watanabe N, Shuke N, Bunko H, Michigishi T, Tonami N. Cancer Biother Radiopharm 2001 Feb; 16 (1), pp. 17–23.

Multidrug-Resistance (MDR) Protein/Predicted Chemotherapeutic Response Rate/Osteosarcoma *[^{99m}Technetium] ([^{99m}Tc])-Methoxy-Isobutyl-Isonitrile (MIBI)/[^{99m}Tc]-MIBI Washout Rate*

Cellular/Molecular Mechanism of Action: [^{99m}Tc]-MIBI is a pharmaceutical substrate transported by the MDR-related proteins.
Background Information: *In vitro* studies have demonstrated that [^{99m}Tc]-MIBI is a transport substrate of MDR-related proteins. Minimal knowledge is available about the potential of [^{99m}Tc]-MIBI scintigraphy as a functional imaging tool for the *in vivo* detection of MDR-associated protein (MRP) expression in osteosarcoma. Little research has been devoted to characterizing the potential role of MRP and [^{99m}Tc]-MIBI imaging in schemes for the prediction of clinical outcome.
Application: Detection and characterization of MDR protein expression in neoplastic tissues (e.g., osteosarcoma) in a manner that can assist in predicting response to therapeutic intervention.
Implementation: Evaluation of osteosarcoma conditions before and after initiation of chemotherapy. Tumor-to-background ratios of both early (10 minutes) and delayed (1 hour) images and the percentage washout rate (WR%) of [^{99m}Tc]-MIBI are calculated. Immunohistochemical analysis of MRP and P-glycoprotein (Pgp) can be performed on biopsy specimens, and the response to preoperative chemotherapy assessed by histopathologic examination. In this manner, it will be possible to examine if scintigraphic parameters are of any benefit in distinguishing the functional capacity of Pgp and MRP.

Human Model: Cases of osteosarcoma (n = 24).
Interpretation and Analysis: Approximately 62.5% of osteosarcomas display significant MRP expression levels (e.g., n = 15/24).

The level of MRP expression significantly correlates with WR% of [^{99m}Tc]-MIBI ($r = 0.58$, $p = 0.003$), and the WR% of [^{99m}Tc]-MIBI is significantly faster in cases with higher MRP expression than in those with a low MRP score ($p = 0.007$). The clearance rate of [^{99m}Tc]-MIBI is significantly slower in tumor samples with negative or low expression of both Pgp and multidrug-resistance protein ($16\% \pm 6.2\%$) when compared with osteosarcomas that express high levels of both proteins ($31.7\% \pm 8.7\%$) ($p = 0.001$). There appears not to be a significant difference between the WR% of [^{99m}Tc]-MIBI in tumors with co-expression of both proteins and in tumors with high expression of either Pgp or MRP. Both the rate of MRP expression and the WR% of [^{99m}Tc]-MIBI significantly correlate with response rate. Therefore, the WR% of [^{99m}Tc]-MIBI correlates with MRP expression levels. Both the WR% of [^{99m}Tc]-MIBI and MRP expression correlate with response to therapeutic intervention. [^{99m}Tc]-MIBI can therefore be used as a general probe for functional imaging of both Pgp and MRP; however, it is not capable of differentiating the functional status of either MDR-related glycoprotein.

[^{99m}Tc]-MIBI imaging as a predictor of therapy response in osteosarcoma compared with multidrug-resistance-associated protein and P-glycoprotein expression. Burak Z, Moretti JL, Ersoy O, Sanli U, Kantar M, Tamgac F, Basdemir G. J Nucl Med 2003 Sep; 44 (9), pp. 1394–401.

Multidrug-Resistance (MDR) Protein/ P-Glycoprotein (Pgp) Transport Activity/ [Mammary Carcinoma]/[Lung Tumor]
[^{99m}Technetium] ([^{99m}Tc])$(CO)_3$(Methoxy-Isobutyl-Isonitrile [MIBI])$_3$] + (Tc-CO-MIBI)

Cellular/Molecular Mechanism of Action: [^{99m}Tc$(CO)_3$ $(MIBI)_3$] + (Tc-CO-MIBI) can function as a transport substrate for MDR protein 1 (Pgp).

Background Information: Multidrug resistance mediated by the overexpression of MDR1 Pgp is 1 of the best characterized obstacles to successful chemotherapy in conditions of neoplastic disease. Furthermore, the protective function of Pgp-mediated efflux of xenobiotics in various organs has a profound effect on the bioavailability of drugs in general. Thus, there is an expanding requirement to non-invasively interrogate Pgp transport activity *in vivo*.

Application: Detection and characterization of MDR protein/Pgp transport function and genetic expression. Secondary applicability includes the capacity to facilitate evaluation of the efficacy of inhibitors of MDR protein/Pgp transport function and genetic expression.

Implementation: Evaluation of the recognition properties (binding avidity) of [^{99m}Tc](I)-tricarbonyl complexes in the form of [^{99m}Tc$(CO)_3(MIBI)_3$]+ (Tc-CO-MIBI) for Pgp.

***Ex Vivo* Model:** Drug-sensitive KB 3-1 cell lines; colchicine-selected drug-resistant KB 8-5 cell types; chemotherapeutic-sensitive MCF-7 mammary carcinoma cell lines; H69 lung tumor cell lines.

Animal Model: Murine (MDR1a/1b(−/−)-gene-deleted mice and wild-type mice.

Interpretation and Analysis: Tc-CO-MIBI has a 60-fold higher accumulation in drug-sensitive KB 3-1 cells compared to colchicine-selected drug-resistant KB 8-5 cells. In KB 8-5 cells, tracer enhancement can be achieved with the potent MDR modulator LY335979 (EC50 = 62 nM). Similar behavior can be observed using drug-sensitive MCF-7 breast adenocarcinoma cells and MCF-7/MDR1 stable transfectants, thereby confirming that Tc-CO-MIBI is specifically excluded by MDR1 Pgp overexpression. By comparison, net accumulation in control H69 lung tumor cells is 9-fold higher than in MDR-associated protein (MRP1)-expressing H69AR cells, indicating only modest transport by MRP1. Biodistribution analysis following tail vein injection of Tc-CO-MIBI shows delayed liver clearance as well as enhanced brain uptake and retention in MDR-gene-deleted mice vs wild-type mice, directly demonstrating that Tc-CO-MIBI is a functional *in vivo* probe for detecting Pgp transport activity.

Characterization of a novel [^{99m}Tc]-carbonyl complex as a functional probe of MDR1 P-glycoprotein transport activity. Dyszlewski M, Blake HM, Dahlheimer JL, Pica CM, Piwnica-Worms D. Mol Imaging 2002 Jan–Mar; 1 (1), pp. 24–35.

Neoplastic Disease
Cobalt-57-Bleomycin ([^{57}Co]-BLM)

Cellular/Molecular Mechanism of Action: Isomerism of bleomycin affects its affinity for neoplastic cell types. Bleomycin Type I isomer is superior with respect to this particular property.

Background Information: [^{57}Co]-BLM has proven to be the most stable and useful tumor-diagnostic agent among several radiolabeled BLMs. However, the considerably long half-life of [^{57}Co] causes logistical difficulties in handling and precludes its extensive use. In previous studies, it has been demonstrated that BLM produces 2 geometrical isomers when forming a cobalt chelation complex.

Application: Detection of neoplastic lesions by nuclear medicine imaging methodologies.

Interpretation and Analysis: Both tumor accumulation in tumor-bearing mice and stability of DNA binding of Type I isomer are higher than those for Type II.

Instrumentation: Computer-integrated nuclear medicine imaging methodologies.

Planar cobalt-57 bleomycin scintigraphy compared with CT-scan in the diagnosis and staging of lung cancer. Verhoeven GT, Kho GS, Ausema L, Krenning EP, Hilvering C. Neth J Med 1994 Apr; 44 (4), pp. 116–21.

Neoplastic Disease
3′-([^{82}Br], [^{36}Cl], or [^{123}I]) "Arabino" Pyrimidine Nucleosides

Application: Detection of neoplastic lesions.

Dosage: 3′-radiohalogenated ([^{36}Cl], [^{82}Br], or [^{123}I]) "arabino" pyrimidine nucleosides.

Interpretation and Analysis: No preferential tissue uptake can be observed. The compounds are excreted mainly unchanged in the urine. The 3′-[$^{3\ 6}$Cl]- and 3′-[^{82}Br]-3′-deoxyarabino nucleosides exhibit biliary uptake. The low uptake of injected radioactivity by the tumor is probably due to the combined effects of the lack of a C-3′ hydroxyl group in the "ribo" configuration, the presence of a halogen group related to chemical properties, the structural rigidity imposed by the physical presence of a halogen group, and the short biological half-lives of the compounds.

Tumor uptake of radiolabeled pyrimidine bases and pyrimidine nucleosides in animal models: VI. 1-(3′-[^{36}Cl]-chloro-, 1-(3′-[^{82}Br]-bromo-, and 1-(3′-[^{123}I]-iodo-3′-deoxy-beta-D-arabinofuranosyl)uracil. Lee YW, Mercer JR, Wiebe LI, Knaus EE. Int J Appl Radiat Isot 1984 Nov; 35 (11), pp. 1057–61.

Neoplastic Disease
[^{131}I]-1-(2-Phenoxy-Ethyl)-2-Nitroimidazole

Cellular/Molecular Mechanism of Action: The highly lipophilic and protein-bound derivatives of 1-(2-phenoxy-ethyl)-2-nitroimidazole (PENI; RGW-609) are known radiosensitizers.

Background Information: IPENI and DIPENI are radiosensitizers by inference only; that is, they have not been tested for radiosensitizer properties. However, PENI, the parent compound, has been shown to be active as a radiosensitizer, and the peak potentials (polarographic) for both IPENI and DIPENI fall near those of MISO, PENI, and most other 2-nitroimidazole sensitizers.
Application: The low concentration levels in target tissues achieved by [^{131}I]-PENI mitigate against its use as a diagnostic imaging agent in nuclear medicine scintigraphy.
Semi-Synthetic Methods: The agents can be prepared by introducing 1 (IPENI) and 2 (DIPENI) iodine atoms into the phenyl ring via electrophilic substitution. The electron affinity of all 3 compounds, as determined by differential pulse polarography, is similar to that for MISO, a radiosensitizer that has undergone clinical trials, but protective (P) values are 2–3 orders of magnitude greater than for MISO, and percent protein binding (%PB) values are as high as 30% *in vitro* compared to less than 1% for MISO. [^{131}I]-PENI is prepared by catalyzed halogen exchange with Na[^{131}I] facilitating a greater than 90% yield, and a product that is chemically and radiochemically stable in solution for at least 2 weeks.
Implementation: Evaluation of the biodistribution profiles for [^{131}I]-PENI in conditions of neoplastic disease.

Animal Model: Murine (BDF/1 strain mice bearing EMT-6 tumors).
Interpretation and Analysis: Whole-body studies show rapid hepatic extraction and biliary elimination with little or no accumulation in any other tissue, (including tumor and fat), indicating that P and %PB values have little impact on *in vivo* distribution and disposition. [^{131}I]-PENI is not measurably deiodinated *in vivo*.

Electron-affinic compounds for labeling hypoxic cells: The synthesis and characterization of 1-[2-(2-iodophenoxy)-ethyl]-2-nitroimidazole. Wiebe LI, Jette DC, Chapman JD. Nuklearmedizin 1984 Apr; 23 (2), pp. 63–7.

Neoplastic Disease and Inflammation
Gallium-67 ([^{67}Ga])

Cellular/Molecular Mechanism of Action: Although many hypotheses concerning the mechanism of uptake of [^{67}Ga] into tumors and inflammation have been proposed, a unified consensus has not been established.
Application: [^{67}Ga] has been used in nuclear medicine as an imaging agent for neoplastic disease and inflammation.
Implementation: The uptake of [^{67}Ga] by hepatic tissues in carbon tetrachloride (CCl_4)-treated rats is slightly enhanced by the administration of $FeCl_3$ 5 minutes before the injection of the radioimaging agent.

Animal Model: Rat (CCl_4-induced hepatic injury).
Route of Administration: Intravascular.
Considerations: Previously, it was unknown if transferrin (Tf) was involved in [^{67}Ga] uptake by hepatic tissues. However, it is well known that [Fe^{+3}] can inhibit the binding of [^{67}Ga] to transferrin. If the mechanism of [^{67}Ga] uptake is clarified, the sensitivity of diagnostic imaging with [^{67}Ga] could be improved.
Interpretation and Analysis: The entering of [^{67}Ga] into hepatocytes in livers exposed to CCl_4 is similar to the uptake by liver tissue. In addition, the administration of [$FeCl_3$] slightly increases the entry of [^{67}Ga] in to hepatocytes. These results suggest that free [^{67}Ga] ion (not [^{67}Ga]-transferrin complexes) enters hepatocytes in the livers of CCl_4-treated rats.

Free [^{67}Ga] enters into the hepatocytes of carbon tetrachloride-treated rats. Abe S, Hasegawa S, Nirasawa M, Sato N, Ohkubo Y. Hepatol Res 2003 Mar; 25 (3), pp. 306–11.

Neoplastic Disease/Interleukin-2 (IL-2) Receptor Expression
Gallium-67 ([^{67}Ga]) Ga-2-(p-SCN-Bz)-NOTA Anti-IL-2 IgG

Cellular/Molecular Mechanism of Action: Immunoglobulin-based recognition and binding to IL-2 receptor.
Application: The low molecular weight protein (LMWP) has been proposed as a diagnostic agent for the detection of neoplastic disease states.
Semi-Synthetic Methods: The disulfide-linked fragment (dsFv) of the antibody to the alpha subunit of the IL-2 receptor can be radiolabeled with a [^{67}Ga] Ga-2-(*p*-SCN-Bz)-NOTA derivative linked through an isothiocyanato group to either the epsilon-amino group of lysine or the alpha-amino group of the N-terminal amino acids.
Considerations: Because different amino acids in the dsFv are radiolabeled applying the method described, it is possible to study the relative residence times of the various catabolites.
Implementation: Evaluation of the residence time for methionine and lysine conjugates within the same kidney.
Interpretation and Analysis: Approximately $>$ 60% of the injected dose localizes in the mouse kidney. The major catabolites ($>$ 95%) in the kidney can be identified as the Ga-2-(p-SCN-Bz)-NOTA conjugated with either lysine or methionine, with no evidence of [^{67}Ga] transchelation. The methionine conjugate has a significantly shorter residence time than the lysine conjugate in the same kidney. Labeling the appropriate amino acid in a LMWP may lead to reduced residence times and increased diagnostic or therapeutic ratios. Appropriately synthesized radiobiological agents of this design can preferentially accumulate within neoplastic tissues, producing a high "target-to-background" ratio on nuclear medicine scintigraphic images.
Instrumentation: Computer-integrated nuclear medicine scintigraphy instrumentation.

Biodistribution and catabolism of Ga-67-labeled anti-Tac dsFv fragment. Wu C, Jagoda E, Brechbiel M, Webber KO, Pastan I, Gansow O, Eckelman WC. Bioconjug Chem 1997 May–Jun; 8 (3), pp. 365–9.

Neoplastic Disease/Oxytocin Receptor Complex Expression/Endothelial Carcinoma/Mammary Carcinoma/Glioblastoma/Neuroblastoma/Vascular Expression
[^{111}Indium] ([^{111}In])-DOTA-Lys$_8$-Vasotocin

Cellular/Molecular Mechanism of Action: Lys_8-vasotocin (LVT) is an analogue of oxytocin that possesses high binding affinity for oxytoxin receptor complexes.
Semi-Synthetic Methods: Covalent cross-linking the chelating agent 1,4,7,10-tetraazacyclododecane-N,N′,N′′,N′′′-tetraacetic acid (DOTA) to LVT.
Implementation: Evaluation of the ability for the radioactive ligand [^{111}In]-DOTA-Lys_8-vasotocin to recognize and physically bind to oxytocin receptor complexes expressed by mammary carcinoma and glioblastoma cell types.

***Ex Vivo* Model:** MCF-7 (mammary carcinoma); MOG-U-V-W (glioblastoma) and transiently transfected COS7 cell lines.

Animal Model: Murine (TS/A mouse mammary tumor).
Interpretation and Analysis: The agent DOTA-LVT retains high *in vitro* binding affinity for human oxytoxin receptor complexes endogenously expressed by cell lines such as MCF-7 breast carcinoma and MOG-U-V-W glioblastoma cells lines, as well as to tran-

siently transfected COS7 cells. In investigations performed *in vivo*, [^{111}In]-DOTA-LVT specifically binds to oxytoxin receptor-positive TS/A mouse mammary tumors. Based on the nature of these laboratory findings, DOTA-LVT could potentially function as a platform for imaging and possibly the therapeutic management of oxytoxin receptor-positive human tumors such as breast and endometrial carcinomas, neuroblastomas, and glioblastomas.

[^{111}In]-labeled 1,4,7,10-tetraazacyclododecane-N,N′,N′′,N′′′-tetraacetic acid-lys$_8$-vasotocin: A new powerful radioligand for oxytocin receptor expressing tumors. Bussolati G, Chinol M, Chini B, Nacca A, Cassoni P, Paganelli G. Cancer Res 2001 Jun 1; 61 (11), pp. 4393–7.

Neoplastic Disease/Membrane-Associated Cancer Antigens/[^{99m}Technetium] ([^{99m}Tc]) Anti-Carcinoembryonic Antigen (CEA) Monoclonal Antibody (MAb)/Colorectal Cancer/Bladder Cancer/Thyroid Cancer
[^{99m}Tc]- CEA MAb

Cellular/Molecular Mechanism of Action: Monoclonal antibody is used as a targeting modality for unique antigens expressed on the external surface membrane of neoplastic cell types.

Background Information: Monoclonal antibody can be produced with binding avidity for almost any protein, glycoprotein, or lipoprotein antigen greater than 10 kDA in mass.

Examples of preparations other than radiolabled anti-CEA include (i) [^{111}In]-labeled anti-MUC1 mucin for invasive bladder cancer; and (ii) [^{131}I]-MN-14 F(ab)$_2$ anti-CEA MAb for medullary thyroid cancer.

Although this allows flexibility in the design of new agents, binding avidities and specificity of binding can vary between different monoclonal antibody preparations.

Diagnostic Application: Detection of neoplastic disease states that express membrane-associated CEA at relatively high densities.

Route of Administration: Intravascular.

Dosage: [^{99m}Tc]-anti-CEA monoclonal antibody (925 MBq)

Considerations: Intact radiolabeled IgG immunoglobulin will accumulate within the spleen and liver due to binding to Fc-receptor sites expressed on the exterior surface membrane of cell populations comprising the reticuloendothelial (RE) or mononuclear phagocytic system. Enzymatic cleavage of the Fc fragment with either pepsin or papain results in the generation of Fab′ or Fab′$_2$. Such IgG molecular fragments display a significantly higher target-to-background ratio than intact IgG. Examples of radiolabeled MAbs applied for either diagnostic or therapeutic purposes include those targeted against p57 protein fractions expressed by malignant melanoma cell types.

Implementation: Evaluate the usefulness of immunoscintigraphy with an anti-CEA MAb fragment labeled with [^{99m}Tc] for early detection of colorectal cancer recurrence in patients with rising serum CEA levels. Cases are then subjected to immunoscintigraphy imaging studies (e.g., n = 8 cases; n = 59 acquired images). Immunoscintigraphy is performed after injection of anti-CEA MAb. Planar images of the thorax, abdomen, and pelvis, as well as single photon emission computed tomography (SPECT) of the abdomen and pelvis are obtained 4 and 24 hours after injection. Abdominal computed tomography (CT) scans can additionally be performed prior to scintigraphic imaging. Findings are subsequently validated by histopathological analysis (e.g., n = 28 cases) or by imaging and clinical follow-up of at least 6 months following the immunoscintigraphy (e.g., n = 31 cases).

Human Model: Cases of colorectal cancer (e.g., n = 51 consecutive patients; n = 27 women, n = 24 men; population mean age 68.9 ± 10.2 years) with rising CEA levels (e.g., 16.2 ± 18.2 ng/ml).

Interpretation and Analysis: A considerable number of cases will not show recurrence during the follow-up period (e.g., n = 41). Conversely, slightly less than two-fifths of all cases will have a confirmed diagnosis of extrahepatic abdominal or pelvic disease (e.g., n = 18/51); approximately one-fifth of cases will have liver metastases (e.g., n = 11/51); slightly less than one-fifth of cases will have thoracic involvement (e.g., n = 9/51); while a relatively small number will have bone metastasis (e.g., n = 2/51). In cases with pelvic and extrahepatic abdominal disease, immunoscintigraphy will be true-positive in most instances (e.g., n = 14/18 true-positive and n = 4/18 false-positive). Of the cases classified as true-positive, only about half are detectable by CT imaging (e.g., n = 7/14).

In the remaining cases with no detectable lesions on immunoscintigraphy images, most of these results can be classified as true-negatives (e.g., n = 37/41 true-negative, n = 4/41 false-negative). Therefore, the sensitivity and specificity for immunoscintigraphy in extrahepatic abdominal and pelvic disease is approximately 78% and 90%, respectively. CT results show a lower sensitivity of 61% ($p < 0.05$) and specificity of 83%. Liver metastases may not be detected by CT (e.g., n = 9 cases), but such lesions may alternatively only be detected in a small number of cases utilizing immunoscintigraphy (e.g., n = 2/9). Therefore, scintigraphy with anti-CEA MAb fragment labeled with [^{99m}Tc] is superior to CT for the detection of pelvic and extrahepatic abdominal recurrence of colorectal cancer, while CT is more sensitive in the detection of liver and lung metastases. Immunoscintigraphy has a limited usefulness in the detection of distant metastases, but it may be helpful in the diagnosis of suspected colorectal recurrence in patients with non-conclusive CT findings, when FDG-PET is not available.

Is there a role for [^{99m}Tc]-anti-CEA monoclonal antibody imaging in the diagnosis of recurrent colorectal carcinoma? Fuster D, Maurel J, Muxí A, Setoain X, Ayuso C, Martín F, Ortega ML, Fuertes S, Pons F. Q J Nucl Med 2003 Jun; 47 (2), pp. 109–15.

Neoplastic Disease Imaging/[Cardiac Pool and Bone Distribution]/[*In Vivo* Stability]
[^{57}Co]-Bleomycin/[^{111}Indium] ([^{111}In])-Bleomycin/[^{99m}Technetium] ([^{99m}Tc])-Bleomycin/[^{197}Hg]-Bleomycin

Investigations with bleomycin labeled with radionuclides other than [^{57}Co] in human cases suffering from cancer and in tumor-bearing animals have been described. In human cases, [^{57}Co]-bleo appears to be a better tumor-seeking radiopharmaceutical than [^{111}In]-bleo, [^{99m}Tc]-bleo, or [^{197}Hg]-bleo. This can be explained by a higher stability *in vivo* and better tumor-seeking property of [^{57}Co]-bleo, in addition to less disturbing activity in the cardiac pool and in bone or other normal tissues when assessing scintigraphic images. Results with [^{111}In]-bleo labeled in acidic solution are essentially no different from those with [^{111}In]-bleo labeled in neutral solution. Results of [^{197}Hg]-bleo are almost identical with those of [^{197}Hg]Cl$_2$ regarding the tumor-seeking properties as well as distribution profiles in normal tissues and organs. Probably the complex of [^{197}Hg] to bleomycin is not stable *in vivo*. The superiority of [^{57}Co]-bleo over [^{99m}Tc]-bleo and [^{197}Hg]-bleo, and also over [^{67}Cu]-bleo, has been confirmed in tumor-bearing animals. Such findings indicate that the use of bleomycin as a tumor-seeking pharmaceutical labeled with [^{111}In], [^{99m}Tc], [^{197}Hg], or [^{67}Cu] seems to be very limited.

Clinical evaluation of radiolabeled bleomycin for tumor detection. Rasker JJ, Beekhuis H, van de Poll MA, Versluis A, Jurjens H, Woldring MG. Nuklearmedizin 1978 Dec; 17 (6), pp. 238–48.

Neoplastic Disease States/Glioma/ Mammary Tumors (Carcinogen-Induced) *[^{99m}Technetium] ([^{99m}Tc])-Field Bean Protease Inhibitor (FBPI)/[$^{99m}Tc^{V}$]-Dimercaptosuccinic Acid (DMSA)/[^{201}Thallous] Chloride (TlCl)/ [$^{99m}TcO_4^-$]-Citrate*

Application: Detection and characterization of gliomas of the central nervous system and possibly other types of neoplastic disease.

Route of Administration: [$^{99m}TcO_4^-$]-FBPI (intravenous)

Semi-Synthetic Methods: Purified FBPI can be labeled with [$^{99m}TcO_4^-$] functioning as a tracer molecule. Labeling is done in the presence of Sn^{2+} serving as a reducing agent and the resulting yield is approximately 95%. At room temperature, the product is stable for at least a 2-hour incubation period.

Implementation: Evaluation of the biodistribution for [^{99m}Tc]-labeled FBPI to ascertain its ability to locate within tumor lesions. Biodistribution analysis is determined at various time intervals following administration.

Animal Model: Rat (Wistar strain bearing carcinogen-induced mammary tumors or transplanted C6 glioma).

Interpretation and Analysis: Biodistribution analysis of [^{99m}Tc]-FBPI reveals that it undergoes rapid blood clearance from the systemic circulation (approximately 5 hours). The complex is predominantly eliminated through renal and hepatobiliary excretory mechanisms. The tumor-to-muscle (T/M) ratios obtained with [^{99m}Tc]-FBPI in C6 glioma explants are nearly 2- to 5-fold higher than observed with several conventional tumor-seeking radiopharmaceuticals such as [^{99m}Tc]-DMSA, [^{201}Thallous] chloride ([^{201}Tl]Cl]), and [^{99m}Tc]-citrate. Similarly, the T/M ratio obtained with [^{99m}Tc]-FBPI in a mammary tumor model, on the other hand, appears to be 2–3-fold higher than observed with [^{99m}Tc]-DMSA and [^{201}Tl]Cl]. The ratio is, however, comparable with that obtained with [^{99m}Tc]-citrate. Therefore, [^{99m}Tc]-FBPI has the specific potentials for imaging gliomas and possibly other tumors as well.

[^{99m}Tc]-labeled field bean protease inhibitor can function as an efficient tumor detecting agent. Murugesan S, Banerji AP, Noronha OP, Samuel AM, Fernandes AO. Indian J Exp Biol 2001 Aug; 39 (8), pp. 742–7.

Neoplastic Disease/Insulin-Like Growth Factor (IGF) Binding Proteins *[^{125}I]-Labeled-IGF*

Cellular/Molecular Mechanism of Action: Insulin-like growth factor recognizes and binds to membrane-associated receptor complexes (IGF binding proteins [IGFBPs]).

Background Information: IGFBPs play a critical role in modulating IGF activity.

Application: Detection and characterization of certain neoplastic disease types.

Considerations: [^{125}I]-labeled IGF-I is degraded quite rapidly within the cytosol of some neoplastic cell types.

Semi-Synthetic Methods: Production of [^{125}I]-labeled-IGF-I by the radioiodination of IGF-I using chloramines-T reagent.

Implementation: Evaluate the biodistribution and tumor targeting ability of radiolabeled IGF (e.g., [^{125}I]-IGF-I). Because IGFBPs play a critical role in modulating IGF activity, the binding properties of [^{125}I]-labeled IGF-I to IGFBPs can be investigated under both *in vitro* and *in vivo* conditions. Complementary investigations can be initiated to study the *in vitro* catabolism of IGF-I by tumor cells. Validation of the relative specificity of uptake can in part be established by co-administration of unlabeled peptide. *In vitro* and *in vivo* chromatography studies are performed to evaluate the binding profile to IGFBPs and measure serum/urine catabolite concentrations.

Animal Model: Rat and mouse (tumor-bearing nude mice).

Interpretation and Analysis: Binding of radiolabeled IGF-I to IGFBPs *in vitro* occurs in a dose-dependent manner. However, there is a difference in complex formation between serum and heparinized plasma. In heparinized plasma, radioactivity shifts from a 30- to 50-kDa complex to a 150-kDa complex and to a free ligand, because the binding of heparin with IGFBPs decreases its affinity for IGF-I. In plasma prepared with acid citrate dextrose a binding pattern identical to that of serum is observed. Moreover, there is a binding difference between mouse and rat. The [^{125}I]-labeled IGF-I is catabolized very quickly when incubated at 37°C but not at all at 4°C. In tumor-bearing nude mice, the uptake of radioactivity in normal tissues decreases quickly, particularly in the kidneys. In mice co-injected with unlabeled carrier, the radioactivity in most normal tissues is lower and the tumor uptake higher than in the mice without carrier. [^{125}I]-labeled IGF-I is avidly bound to IGFBPs, both *in vitro* and *in vivo*. By partially saturating this binding with unlabeled peptides, a favorable biodistribution can be achieved, including faster clearance from normal tissue and higher tumor uptake, which results in better tumor-to-non-tumor ratios. Nevertheless, the rapid *in vivo* catabolism and release of the radiolabel from tumor tissue result in a suboptimal targeting agent.

Effects of insulin-like growth factor binding proteins on insulin-like growth factor-I biodistribution in tumor-bearing nude mice. Sun BF, Kobayashi H, Le N, Yoo TM, Drumm D, Paik CH, McAfee JG, Carrasquillo JA. J Nucl Med 2000 Feb; 41 (2), pp. 318–26.

Neoplastic Disease: Topoisomerase I and II/ Adenocarcinoma (HT29)/Gliobastoma (U87MG)/ Melanoma (A375M Antigen Positive) *[^{11}C]-9-Methoxyphenazine-1-Carboxamide/ [^{11}C]2-(4-Pyridyl)Quinoline-8-Carboxamide/ [^{11}C]DACA/[Topoisomerases I and II]*

Cellular/Molecular Mechanism of Action: The tricyclic carboxamide N-[2-(dimethylamino)ethyl]acridine-4-carboxamide (DACA) is a DNA-intercalating agent capable of inhibiting both topoisomerases I and II enzyme fractions.

Background Information: The tricyclic carboxamide DACA is currently in phase II clinical trial. Many related analogues have been developed, but despite their potent *in vitro* cytotoxicities, they exhibit poor extravascular distribution.

Application: Delineation of rational drug selection.

Semi-Synthetic Methods: Each candidate compound shares a common structural feature, *N*-dimethyl side chain, which is radiolabeled with carbon-11 (positron-emitting radioisotope).

Implementation: Evaluate the biodistribution and metabolite profiles of the prototype compound, DACA, with 3 analogues to aid rational drug selection in order to identify agents that are "minimal intercalators" with lower DNA association constants. In this fashion, promising candidates can be identified in emerging preclinical studies in animals that can ultimately be evaluated in humans using positron emission tomography (PET) or nuclear medicine.

Animal Model: Murine (mice bearing human tumor xenografts).

Interpretation and Analysis: Acridine DACA, phenazine SN 23490, pyridoquinoline SN 23719, and dibenzodioxin SN 23935 are cytotoxic when evaluated with *in vitro* assays utilizing HT29, U87MG, and A375M cell lines (IC_{50} of 1.4 to 1.8 μM, 0.4 to 0.6 μM, 1.3 to 1.6 μM, and 24 to 36 μM, respectively). *Ex vivo* biodistribution studies with carbon-11 radiolabeled compounds in mice

bearing human tumor xenografts show rapid clearance of [^{11}C]-radioactivity (parent drug and metabolites) from blood and major organs. Rapid hepatobiliary clearance and renal excretion can also be observed. There is low (< 5% of injected dose/gram [%ID/g]) and variable uptake of [^{11}C]-radioactivity in 3 tumor types for all of the compounds. Tumor (U87MG) to blood [^{11}C]-radioactivity for [^{11}C]DACA, [^{11}C]-9-methoxyphenazine-1-carboxamide (SN 23490), [^{11}C]2-(4-pyridyl)quinoline-8-carboxamide (SN 23719), and [^{11}C]dibenzo[1,4]dioxin-1-carboxamide (SN 23935) at 30 minutes are approximately 2.9 ± 1.1, 2.3 ± 0.6, 2.6 ± 0.6, and 0.7 ± 0.2, respectively. For SN 23719, the distribution of [^{11}C]-radioactivity in normal tissues and tumors determined *ex vivo* is in broad agreement with that determined *in vivo* by whole-body PET scanning. [^{11}C]DACA is rapidly and extensively metabolized to several plasma metabolites and a major tumor metabolite. Conversely, [^{11}C]SN 23935, [^{11}C]SN 23490, and [^{11}C]SN 23719 shows less extensive metabolism. In tumor samples, parent [^{11}C]DACA and [^{11}C]SN 23935 is present between 0.3 and 1.5 %ID/g, whereas [^{11}C]SN 23490 and [^{11}C]SN 23719 is present between 1.5 and 2.8 %ID/g. Therefore, by using a strategy employing [^{11}C]-labeling, it is possible to determine the tissue distribution and metabolic stability of novel tricyclic carboxamides.

Given the objective directed at identifying analogues with potentially improved *in vivo* activity against solid tumors, the agents SN 23490 and SN 23719 have more favorable distribution and metabolic stability compared with DACA and SN 23935. Such observations suggest that further development and evaluation are warranted. The radiolabeling strategy used allows *ex vivo* and *in vivo* evaluation of promising anticancer agents in animals and offers the potential of rapid translation to studies in humans using PET. Because of their mechanism of action, this class of agents also has the potential of being developed into diagnostic biopharmaceutical probes.

Comparative biodistribution and metabolism of carbon-11-labeled N-[2-(dimethylamino)ethyl]acridine-4-carboxamide and DNA-intercalating analogues. Osman S, Rowlinson-Busza G, Luthra SK, Aboagye EO, Brown GD, Brady F, Myers R, Gamage SA, Denny WA, Baguley BC, Price PM. Cancer Res 2001 Apr 1; 61 (7), pp. 2935–44.

Neurotensin-Positive Tumors/Adenocarcinomas/ Pancreatic Cancer
[^{111}Indium] ([^{111}In])-Diethylenetriamine Pentaacetic Acid (DTPA)-Neurotensin [Arg$_8$, Arg$_9$, and Ile$_{12}$]/ Fluorescein-Neurotensin [Arg$_8$, Arg$_9$, and Ile$_{12}$]

Cellular/Molecular Mechanism of Action: Native neurotensin (NT) is a tridecapeptide that binds to neurotensin receptor (NTR) and induces tumor growth.

Background Information: The prevalence of NTR in several human tumors makes it an attractive target for the delivery of cytotoxic drugs and design of cancer imaging agents. Unfortunately, NT has a short plasma half-life, which hinders its use for *in vivo* biomedical applications. Numerous reports suggest that Arg$_8$-Arg$_9$ and Tyr$_{11}$-Ile$_{12}$ amide bonds are particularly susceptible to degradation by proteolytic enzymes.

Semi-Synthetic Methods: Substitution of Arg$_8$, Arg$_9$, and Ile$_{12}$ amino acids with the corresponding commercially available mimics. Preparations can be conjugated to DTPA for subsequent radiolabeling to produce [^{111}In]-DTPA or conjugated with fluorescein.

Animal Model: Mouse (severe combined immunodeficient [SCID] bearing NTR-positive human adenocarcinoma [HT29] xenografts).

Interpretation and Analysis: The surrogate amino acids are amenable to standard Fmoc peptide synthesis strategies, and the resulting compounds are stable in biological media for > 4 hours and bind to NTR with high affinity. Conjugation of DTPA to the synthetic peptides and subsequent labeling with [^{111}In]-DTPA for nuclear imaging or fluorescein for optical imaging does not diminish NTR binding avidity. Evaluation of the *in vivo* biodistribution of a representative [^{111}In]-DTPA-NT peptide analogue in HT29-bearing SCID mice reveals that the compound is primarily retained in tumor tissue (2.2 %ID/g) and the kidneys (4.8 %ID/g) at 4 hours post-injection. Co-injection of cold NT and the radiolabeled NT peptide analogue inhibits tumor but not kidney uptake, and demonstrates that retention of the radiolabeled compound in tumor tissue is mediated by NTR specific uptake while it accumulates in the kidneys by a non-specific mechanism. These findings show that NT peptide analogues are robust and can deliver imaging agents to NTR-positive tumors such as pancreatic cancer.

Novel bioactive and stable neurotensin peptide analogues capable of delivering radiopharmaceuticals and molecular beacons to tumors. Achilefu S, Srinivasan A, Schmidt MA, Jimenez HN, Bugaj JE, Erion JL. J Med Chem 2003 Jul 17; 46 (15), pp. 3403–11.

Otolaryngological Conditions/Thyrotoxicosis and Solitary Thyroid Nodules/Thyrotoxicosis/ Solitary Thyroid Nodules/Parathyroid Adenoma/ Salivary and Lacrimal Gland/Bone
[^{99m}TcO^{-4}]/[^{123}I]/[^{99m}TcO^{-4}]/[^{201}Tl]/[^{99m}TcO^{-4}]/ [^{99m}TcO^{-4}]-MDP

Background Information: Nuclear medicine has a distinct role to play in otolaryngological practice. Accurate diagnosis of endocrine conditions is now possible using precise *in vitro* hormone measurements. Specific clinical questions can be answered using *in vivo* investigations. [^{99m}TcO^{-4}]/[^{123}I] scintigraphy is used to evaluate thyrotoxicosis and solitary thyroid nodules. [^{99m}TcO^{-4}]/[^{201}T1] subtraction scanning is of value in the preoperative localization of parathyroid adenomas and [^{99m}TcO^{-4}] is particularly useful in assessing salivary and lacrimal gland function and drainage. [^{99m}TcO^{-4}]-MDP bone scanning is useful in the evaluation of osteomyelitis, temporomandibular joint dysfunction, bone graft viability, and some facial fractures. The role of radioisotopes in the management of differentiated and medullary carcinoma of the thyroid is now well established.

Application: Detection of thyrotoxicosis and solitary thyroid nodules by scintigraphic imaging.

Interpretation and Analysis: Although there are many other agents available to image head and neck cancer, few can actually achieve the required diagnostic sensitivity and specificity. The introduction of monoclonal antibodies into routine imaging has been hampered by distinct practical problems and a search is now on for more sensitive non-specific diagnostic agents. It is now possible to evaluate new [^{99m}Tc]-labeled tumor-imaging agents using animal tumor model systems, and the use of radioactivity in all aspects of otolaryngological research adds an extra quantitive dimension. Together with single photon emission computed tomography (SPECT), and the introduction of positron emission tomography (PET) to image the physiology of normal tissues and tumors, the use of radionuclide investigations can lead only to an increase in ear, nose, and throat (ENT) diagnostic sensitivity and specificity and, subsequently, to an overall improvement in the diagnosis, staging, and treatment of cancer affecting the head and neck.

Nuclear medicine in otolaryngology. Watkinson JC. Clin Otolaryngol 1990 Oct; 15 (5), pp. 457–69.

Ovarian Carcinoma: Imaging *[^{111}Indium] ([^{111}In])-(hCTMO1) Monoclonal Antibody*

Cellular/Molecular Mechanism of Action: Immunoglobulins designed to recognize and physically bind to ovarian carcinoma antigens.
Application: Detection and characterization of ovarian carcinoma cell types.
Route of Administration: Intravenous.
Dosage: (D1) 0.1 mg per kg body weight of radiolabeled antibody; (D2) 1 mg per kg body weight; and (D3) 1 mg per kg body weight of unlabeled antibody followed 1 hour later by 0.1 mg per kg body weight of radiolabeled antibody. Images are acquired using a gamma camera at 1 hour and up to 96 hours after injection.
Implementation: Evaluation of suspected cases of primary ovarian carcinoma. Images are acquired using a gamma camera at 1 hour and up to 96 hours after injection.

Human Model: Cases with a high suspicion of primary ovarian carcinoma on the basis of ultrasound or computed tomography (CT) imaging and serum CA125 concentrations, and those in whom there is a suspicion of recurrent ovarian carcinoma after being treated for histologically confirmed carcinoma.
Interpretation and Analysis: At the low dose of antibody the sensitivity for detection of ovarian carcinoma is 70%. After increasing the dose of antibody, and also after predosing with unlabeled antibody, the sensitivity increases to 100%, but there is a large number of false-positive results observed at the higher dose, and therefore the specificity is lower. The liver and bone marrow are the organs with the highest activities due to the binding of labeled antibody to the Fc receptor expressed by cells of the mononuclear phagocytic system. An increased accumulation of radiolabeled immunoglobulin within a specific anatomical location or organ system implies the presence of ovarian carcinoma.

An immunoscintigraphic evaluation of the engineered human monoclonal antibody (hCTMO1) for use in the treatment of ovarian carcinoma. Davies Q, Perkins AC, Roos JC, Molthoff CF, Verheijen RH, Frier M, Kenemans P, Broadhead T, Sopwith M, Symonds EM. Br J Obstet Gynaecol 1999 Jan; 106 (1), pp. 31–7.

Ovarian Cancer: Carcinoma/Sensitivity and Specificity/Folate Receptor Expression *[^{111}Indium] ([^{111}In])-Diethylenetriamine Pentaacetic Acid (DTPA)-Folate*

Cellular/Molecular Mechanism of Action: [^{111}In]-DTPA-folate is a radioactive chelation analogue of folic acid that recognizes and physically binds to folate receptors expressed at relatively high membrane densities by certain neoplastic cell types.
Application: [^{111}In]-DTPA-folate can be applied as a tumor-selective imaging agent in diagnostic nuclear medicine for the purpose of detecting and monitoring neoplastic disease states (e.g., ovarian malignancies). Based on the biological properties of folate, it can also function as a tumor-specific drug delivery platform.
Background Information: The cell-membrane folate receptor is a potential molecular target for tumor-selective drug delivery, including radiolabeled folate-chelate conjugates for diagnostic imaging.
Route of Administration: [^{111}In]-DTPA-folate (intravenous bolus).
Implementation: Evaluation of the diagnostic potential for [^{111}In]-DTPA-folate to function as a diagnostic agent for malignant ovarian disease or endometrial cancer utilizing [^{111}In]-DTPA-folate as an imaging agent (phase I/II clinical trials). Prior to the administration of [^{111}In]-DTPA-folate, some nuclear medicine facilities prefer to administer unlabeled "free" folic acid followed by whole-body imaging at 30 minutes, 4 hours, and 24 hours postinjection of the folate radiopharmaceutical agent. Imaging with single photon emission computed tomography (SPECT) instrumentation can also be performed at the appropriate time-delayed intervals.

Human Model: Female cases of ovarian cancer (n = 35) enrolled in a phase I/II clinical study (n = 33 completing the surgical follow-up required by the study protocol that serves to define disease status). Individual cases either have a pathologically proven malignancy or are scheduled for surgery to resolve suspected new ovarian cancer growth (n = 26 cases), recurrent ovarian cancer (n = 5 cases), or endometrial cancer (n = 2 cases). In the first 19 of 26 cases, evaluated unlabeled "free" folic acid has been administered followed by whole-body imaging at 30 minutes, 4 hours, and 24 hours postinjection of the folate radiopharmaceutical agent.
Interpretation and Analysis: In cases subjected to surgical intervention (e.g., n = 33), slightly less than half have new or recurrent malignant tumors that can be detected (e.g., n = 14/33). A large percentage of newly diagnosed ovarian carcinomas can be identified blindly by multiple professional readers (e.g., n = 7/7 or 100% sensitivity). Conversely, sensitivity for detecting recurrent ovarian-related malignancies can be significantly less (e.g., n = 7/33) in cases where the interpretation is performed without prior knowledge, compared to the evaluation of images with prior knowledge of disease (e.g., n = 28/33 or 84.5% for unmasked readings). Such findings indicate that a correlation exists between anatomic imaging studies (computed tomography [CT]) and the diagnostic detection of such lesions. A number of cases may be determined to have benign masses (e.g., n = 18). In the context of a limited population size, the specificity of [^{111}In]-DTPA-folate scintigraphy is approximately 76% and 82% for masked and unmasked image interpretation, respectively. [^{111}In]-DTPA-folate is safe, and possibly effective, for differentiating between malignant and benign ovarian masses based on interpretation of scintigraphic images.

Evaluation of [^{111}In]-DTPA-folate as a receptor-targeted diagnostic agent for ovarian cancer: Initial clinical results. Siegel BA, Dehdashti F, Mutch DG, Podoloff DA, Wendt R, Sutton GP, Burt RW, Ellis PR, Mathias CJ, Green MA, Gershenson DM. J Nucl Med 2003 May; 44 (5), pp. 700–7.

Pancreatic/Pituitary/Adrenal/Somatostatin Receptors: Subtype 2 (sst2) *[^{111}Indium] ([^{111}In])-(DTPA0,Tyr$_3$)-Octreotide/[^{111}In]-(DOTA0,Tyr$_3$)-Octreotide/[^{111}In]-(DTPA0)-Octreotide*

Cellular/Molecular Mechanism of Action: Possesses physical binding avidity for subtype 2 somatostatin receptor (sst2) complexes.
Application: Detection and characterization of pituitary, pancreatic, and adrenal neoplastic lesions that express an overabundance of sst2 complexes.
Implementation: Evaluate the potential usefulness of radiolabeled [DTPA0,Tyr$_3$]octreotide and [DOTA0,Tyr$_3$]octreotide as radiopharmaceuticals for somatostatin receptor-targeted scintigraphy and radiotherapy. Analysis can involve the characterization of *in vitro* somatostatin receptor binding complemented by the determination of the *in vivo* pattern of metabolism of agents compared to [^{111}In]-DTPA0-octreotide.

Animal Model: Rats (CA20948 tumor-bearing Lewis rats).
Interpretation and Analysis: Comparing different peptide-chelator constructs, [DTPA0,Tyr$_3$]octreotide and [DOTA0,Tyr$_3$] octreotide have been found to have a higher affinity than [DTPA0] octreotide for subtype 2 somatostatin receptors (sst2) in mouse

AtT20 pituitary tumor cell membranes (all IC_{50} values obtained are in the low nanomolar range). Studies *in vivo* in CA20948 tumor-bearing Lewis rats reveal a significantly higher uptake of both [^{111}In]-labeled [DOTA0,Tyr_3]octreotide and [DTPA0,Tyr_3]octreotide in sst2-expressing tissues than after injection of [^{111}In]-(DTPA0)octreotide, showing that substitution of Tyr for Phe at position 3 in octreotide results in increased affinity for its receptor and in a higher target tissue uptake. Uptake of [^{111}In]-labeled [DTPA0] octreotide, [DTPA0,Tyr_3]octreotide, and [DOTA0,Tyr_3]octreotide in pituitary, pancreas, adrenals, and tumors is decreased to $<$ 7% of control by pretreatment with unlabeled octreotide (e.g., 0.5 mg/rat), indicating specific binding to sst2 complexes. Comparing different radionuclides, [^{90}Y]-(DOTA0,Tyr_3)-octreotide has the highest uptake in sst2-positive organs, followed by the [^{111}In]-(DOTA0,Tyr_3)-octreotide, whereas (DOTA0,[^{125}I]-Try_3)-octreotide uptake is low compared to that of other radiopharmaceuticals, when measured 24 hours after injection. Renal uptake of [^{111}In]-labeled (DTPA0)-octreotide, (DTPA0,Tyr_3)-octreotide, and (DOTA0,Tyr_3)-octreotide is reduced over 50% by intravenous injection of D-lysine (400 mg/kg), whereas radioactivity in blood, pancreas, and adrenals is not affected.

Preclinical comparison of [DTPA0] octreotide, [DTPA0,Tyr_3] octreotide, and [DOTA0,Tyr_3] octreotide as carriers for somatostatin receptor-targeted scintigraphy and radionuclide therapy. De Jong M, Bakker WH, Breeman WA, Bernard BF, Hofland LJ, Visser TJ, Srinivasan A, Schmidt M, Béhé M, Mäcke HR, Krenning EP. Int J Cancer 1998 Jan 30; 75 (3), pp. 406–11.

Pancreatic/Pituitary/Adrenal/Somatostatin Receptor-Positive Organs/Octreotide Receptor-Positive Organ Systems
[^{111}Indium] ([^{111}In])-(DOTA0,D-Phe$_1$,Tyr$_3$)-Octreotide/ D-Lysine

Cellular/Molecular Mechanism of Action: [^{111}In]-(DOTA0, D-Phe_1,Tyr_3)-octreotide recognizes and physically binds to somatostatin receptor-positive lesions.

Background Information: Indium-111-diethylenetriamine pentaacetic acid (DTPA)-octreotide or [^{111}In]-DTPAOC is used successfully for imaging somatostatin receptor-positive lesions. A new and promising application is its use in peptide-receptor radionuclide therapy (PRRT). For the latter purpose, [DOTA0,D-Phe_1,Tyr_3] octreotide (DOTATOC), which is suitable for stable radiolabeling with [^{90}Y], is probably even more promising. Significant renal uptake of these octreotide analogues exists, however, reducing the scintigraphic sensitivity for detection of small tumors in the perirenal region and limiting the possibilities for PRRT. Renal uptake of [^{111}In]-DTPAOC can be reduced to about 50% of control by L-lysine administration *in vivo* in rats.

Application: Different forms of lysine could potentially be applied to diminish non-specific renal tissue binding of [^{111}In]-(DOTA0,D-Phe_1,Tyr_3)-octreotide. The agent [^{111}In]-(DOTA0,D-Phe_1,Tyr_3)-octreotide can be applied for the detection and characterization of certain disease states associated with the expression of somatostatin receptor-positive lesions. The delivery platform DTPA-octreotide can be non-specifically associated with renal tissues during scintigraphic imaging studies. Different forms of lysine could potentially be applied to diminish non-specific renal tissue binding.

Route of Administration: [^{111}In]-DTPAOC (intravenously, intraperitoneally, or orally); [^{90}Y]-DOTATOC (intravenous).

Dosage: [^{111}In]-DTPAOC (0.2 MBq, 0.5 μg–0.5 mg); [^{90}Y]-DOTATOC (1 MBq, 0.5 μg).

Implementation: Evaluation of the renal uptake of [^{111}In]-DTPAOC in the presence or absence of D-lysine or L-lysine. At 1, 4, or 24 hours, organs are harvested and their corresponding radioactivity counted for comparision. Complementary investigations involve determination of similar differential organ uptake profiles applying [^{90}Y]-DOTATOC in the presence or absence of D-lysine.

Animal Model: Rat (male Wistar rats [200–250 g]).

Interpretation and Analysis: Administration of D-lysine or L-lysine in a single intravenous dose of 400 mg/kg results in more than 50% inhibition of kidney uptake of [^{111}In]-DTPAOC at all time points tested, independent of the mass of [^{111}In]-DTPAOC administered. Higher or repeated doses of lysine do not give a significantly higher percentage inhibition. D-lysine, given orally at a dose of 400 mg/kg at 30 or 15 minutes before [^{111}In]-DTPAOC injection, results in 30% and 20% inhibition of kidney uptake, respectively. L-lysine, given orally 30 minutes before [^{111}In]-DTPAOC administration, results in a 30% inhibition as well. Inhibition of kidney [^{111}In]-DTPAOC uptake by L-lysine after intraperitoneal administration is 40%. After L-lysine administration, [^{111}In]-DTPAOC is decreased in the kidneys and in somatostatin receptor-positive organs such as the pancreas and adrenal glands. Conversely, D-lysine does not have a significant effect on uptake in octreotide receptor-positive organs. Renal uptake of [^{90}Y]-DOTATOC is reduced by 65% with intravenous D-lysine, whereas radioactivity in blood, pancreas, and adrenal glands is not affected. D-lysine may be preferred to L-lysine for reduction of renal uptake of radioactivity during scintigraphy and PRRT because of its lower toxicity and because it should not interfere with the natural amino acid metabolic balance.

D-lysine reduction of indium-111 octreotide and yttrium-90 octreotide renal uptake. Bernard BF, Krenning EP, Breeman WA, Rolleman EJ, Bakker WH, Visser TJ, Mäcke H, de Jong M. J Nucl Med 1997 Dec; 38 (12), pp. 1929–33.

Parathyroid Adenomas
[^{99m}Technetium] ([^{99m}Tc])/ [^{201}Thallium] ([^{201}T1]) Subtraction Scanning

Application: Preoperative localization of parathyroid adenomas by scintigraphic imaging.

Considerations: Although there are many other agents available to image head and neck cancer, few can actually achieve the required diagnostic sensitivity and specificity. The introduction of monoclonal antibodies into routine imaging has been hampered by distinct practical problems and the search is now on for more sensitive non-specific diagnostic agents. It is now possible to evaluate new [^{99m}Tc]-labeled tumor-imaging agents using animal tumor models and the use of radioactivity in all aspects of otolaryngological research adds an extra quantitative dimension.

Together with single photon emission computed tomography (SPECT) and the introduction of positron emission tomography (PET) to image the physiology of normal tissues and tumors, the use of radionuclide investigations can lead only to an increase in ear, nose, and throat (ENT) diagnostic sensitivity and specificity and, subsequently, to an overall improvement in the diagnosis, staging, and treatment of cancer involving the head and neck.

Parathyroid Adenomas: Ectopic
[^{99m}Technetium] ([^{99m}Tc])-SestaMIBI/[^{201}Thallium] ([^{201}Tl])

Background Information: [^{99m}Tc]-sestaMIBI has been introduced for the preoperative localization of abnormal parathyroid glands in conditions of primary hyperparathyroidism with promising results. However, the sensitivity of sestaMIBI and thallium to detect abnormal parathyroid glands is partly dependent on gland size.

Implementation: Evaluate and compare the sensitivity of sestaMIBI subtraction scintigraphy with thallium subtraction scintigraphy in conditions of primary hyperparathyroidism with predominantly mild increases in serum calcium level utilizing [^{201}Tl] and [^{99m}Tc]-sestaMIBI scintigraphy.

Human Model: Cases with primary hyperparathyroidism (n = 39). The mean (± standard deviation) serum level of calcium is approximately 2.75 ± 0.17 mmol/L. In about 72% of cases (e.g., n = 28/39) serum levels of calcium are less than 2.85 mmol/L. These cases are classified as having mild abnormalities in serum calcium. The other cases are evaluated before surgery with both sestaMIBI and thallium subtraction scintigraphy. Note: Autonomous thyroid adenomas may preclude performing subtraction scintigraphy.

Interpretation and Analysis: SestaMIBI subtraction scintigraphy correctly localizes about 86% (n = 31/36) of parathyroid adenomas compared with only 47% (n = 17/36) by thallium subtraction scintigraphy ($p < 0.001$). Occurrence of false-positive results with sestaMIBI is low (may be seen with thyroid adenoma), while other scans may appear negative. Both the sestaMIBI and the thallium subtraction scintigraphy may localize 1 single enlarged gland in cases with multiple gland involvement (n = 3 cases). Prediction accuracy of multiglandular disease is very low. SestaMIBI subtraction scintigraphy is superior to thallium subtraction scintigraphy and has a high sensitivity for localizing a solitary parathyroid adenoma in cases with mild increase in serum calcium level. The sensitivity decreases in cases with multiglandular parathyroid disease and concomitant thyroid nodular abnormalities.

SestaMIBI vs thallium subtraction scintigraphy in parathyroid localization: A prospective comparative study in patients with predominantly mild primary hyperparathyroidism. Bergenfelz A, Tennvall J, Valdermarsson S, Lindblom P, Tibblin S. Surgery 1997 Jun; 121 (6), pp. 601–5.

Parathyroid Adenoma/Radio-Guided Resection *[^{99m}Technetium] ([^{99m}Tc])-SestaMIBI*

Background Information: Radio-guided resection of hyperfunctioning parathyroid glands has been shown to be technically feasible in cases of parathyroid adenomas. Radio-guided excision may obviate the need for intraoperative frozen sections because excised parathyroid adenomas uniformly have radionuclide *ex vivo* counts > 20% of background. The feasibility and applicability of radio-guided techniques for patients with parathyroid hyperplasia are unclear.

Application: Image analysis of the parathyroid gland.

Route of Administration: [^{99m}Tc]-sestaMIBI (intravascular).

Dosage: [^{99m}Tc]-sestaMIBI (10 mCi).

Implementation: Evaluate the ability of [^{99m}Tc]-sestaMIBI to image the parathyroid gland in a manner suitable to guide "same-day" exploratory (radio-guided) parathyroidectomy in conditions of hyperparathyroidism. Using a gamma probe, intraoperative scanning is performed, looking for *in vivo* radionuclide counts > background to localize abnormal parathyroid glands. After excision, radionuclide counts of each *ex vivo* parathyroid gland are determined and expressed as a percentage of background counts.

Human Model: Cases of hyperparathyoridism subjected to neck exploration (n = 77 primary; n = 25 secondary/tertiary).

***Ex Vivo* Model:** Parathyroid glands (n = 180 resected hyperfunctioning parathyroid glands).

Interpretation and Analysis: In conditions of hyperparathyroidism, radio-guided surgery is a sensitive adjunct for the intraoperative localization of both adenomatous and hyperplastic glands. Some clinical investigations have reported essentially a 100% success rate in localizing enlarged parathyroid glands with a gamma probe (e.g., n = 180/180). It has also been shown that the "> 20% rule" for *ex vivo* counts not only applies to parathyroid adenomas but also to hyperplastic glands. Therefore, radio-guided resection is equally effective and informative for both adenomatous and hyperplastic glands.

Radio-guided parathyroidectomy is equally effective for both adenomatous and hyperplastic glands. Chen H, Mack E, Starling JR. Ann Surg 2003 Sep; 238 (3), pp. 332–7; discussion 337–8.

Pituitary Adenoma/Radio-Guided Resection *[^{99m}Technetium] ([^{99m}Tc])-SestaMIBI/ [Ultrasonography]*

Background Information: Clinical or subclinical hyperparathyroidism is 1 of the most common endocrine disorders. Excessive secretion of parathyroid hormone is most frequently caused by an adenoma of the parathyroid gland. Unsuccessful surgery with persistent hyperparathyroidism, due to inadequate preoperative or intraoperative localization, may be observed in about 10% of patients. The conventional surgical approach for resolution of parathyroid adenoma is bilateral neck exploration. Imaging-based-localization techniques include ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI), and scintigraphy.

Application: [^{99m}Tc]-sestaMIBI scintigraphy can be used to preoperatively localize parathyroid adenomas in a manner that greatly facilitates performing minimally-invasive parathyroidectomy (MIP) procedures. In MIP, the incision is small, dissection is minimal, postoperative pain is less, and hospital stays are shorter.

Route of Administration: [^{99m}Tc]-sestaMIBI (intravascular).

Implementation: Detection and characterization of parathyroid adenoma conditions.

Interpretation and Analysis: Parathyroid scintigraphy with [^{99m}Tc]-sestaMIBI is based on the principle that this radioactive tracer molecule has a relatively long radioactive retention time within the parathyroid compared to thyroid tissue. Because of the frequent association of parathyroid adenomas with nodular goiter, the optimal imaging combination is [^{99m}Tc]-sestaMIBI scintigraphy and ultrasonography. Different protocols have been used for [^{99m}Tc]-sestaMIBI parathyroid scintigraphy, depending on the institutional logistics and experience (classical dual-phase scintigraphy, various subtraction techniques in combination with radioiodine, or [^{99m}Tc]-pertechnetate).

Performing a minimally-invasive parathyroidectomy procedure is greatly aided by the use of a gamma probe to facilitate intraoperative guidance based on the *in vivo* detection of regional radioactivity counts detected after the injection of [^{99m}Tc]-sestaMIBI. Different protocols used for gamma-probe-guided MIP are designed as a function of different timing intervals for administration and doses of injected tracer. Gamma-probe-guided MIP is a very effective surgical approach for treating conditions of primary hyperparathyroidism due to a solitary parathyroid adenoma. The procedure is technically easy, safe with a low morbidity rate, and has better cosmetic results and lower overall cost than conventional bilateral neck exploration. Specific guidelines should be followed when selecting cases for gamma-probe-guided MIP.

Preoperative localization and radio-guided parathyroid surgery. Mariani G, Gulec SA, Rubello D, Boni G, Puccini M, Pelizzo MR, Manca G, Casara D, Sotti G, Erba P, Volterrani D, Giuliano AE. J Nucl Med 2003 Sep; 44 (9), pp. 1443–58.

Proliferation of Neoplastic Cells/DNA Synthesis/ Thymidine Kinase Expression
5-Iodo-4′-Thio-2′-Deoxyuridine (ITdU)

Cellular/Molecular Mechanism of Action: 5-iodo-4′-thio-2′-deoxyuridine is a metabolically stable nucleoside that can function as a substrate for cellular thymidine kinase biochemical activity.
Application: Radioiodinated forms of ITdU and 5-iodo-2′-deoxyuridine (IUdR) can be applied to detect elevations in DNA synthesis in cell populations that positively express thymidine kinase activity. In this capacity, both ITdU and IUdR can serve as indicator molecules for measuring alterations in cellular proliferation especially relevant to the characterization of neoplastic disease states.
Route of Administration: Usually ITdU or IUdR would most frequently be administered intravenously/intravascularly. Theoretically, it may be possible to effectively image lesions if the agents are administered intrathecally for central nervous system (CNS) tumors, by direct injection into tumors, or into the arterial network supplying a suspected neoplastic lesion.
Semi-Synthetic Methods: Radiolabeling of ITdU and 5-iodo-1-(4-thio-beta-D-arabinofuranosyl)uracil (ITAU) with [^{125}I] utilizing a destannylation reaction of the trimethylstannyl precursor for each nucleoside. The products can be isolated in high yields and with a $>$ 99% level of radiochemical purity.
Implementation: Evaluation of ITdU and ITAU for their ability to be synthetically incorporated into nuclear DNA and serve as a marker for cellular mitosis/proliferation.

***Ex Vivo* Model:** Thymidine kinase-expressing L-M cells and thymidine kinase-deficient mutant L-M (TK$^-$) cells.
Interpretation and Analysis: [^{125}I]-ITdU is effectively phosphorylated by cytosolic nucleoside kinases and specifically incorporated into a thymidine kinase-expressing L-M cell rather than a thymidine kinase-deficient mutant L-M (TK$^-$) cell. In addition, *in vitro* cell metabolism studies employing [^{125}I]-ITdU reveal that [^{125}I]-ITdU is effectively and specifically incorporated into a DNA fraction ($>$ 90% at 60 minutes). Therefore, [^{125}I]-ITdU appears to be an effective DNA synthesis marker. In contrast, [^{125}I]-ITAU is neither remarkably phosphorylated by cytosolic nucleoside kinases nor notably incorporated into an L-M cell compared to L-M (TK$^-$) cell. [^{125}I]-ITdU and [^{125}I]-ITAU show a higher resistance to phosphorolytic cleavage by recombinant thymidine phosphorylase than does [^{125}I]-IUdR. Furthermore, biodistribution of [^{125}I]-ITdU and [^{125}I]-ITAU display better *in vivo* stability of radioiodination than do [^{125}I]-IudR preparations. [^{125}I]-ITdU also displays a significantly higher uptake in proliferating organs (thymus, spleen, small intestine, and bone) than in non-proliferating organs (brain, muscle, liver, and lung), as does [^{125}I]-IUdR, at 18 hours postinjection. As indicated by *in vitro* studies, [^{125}I]-ITAU does not show any significant uptake in proliferating organs. Therefore, radioiodinated ITdU is potentially useful as a proliferation-imaging agent, and further studies should clarify the usefulness of this compound as a SPECT tumor-imaging agent.

Rationale of 5-[^{125}I]-iodo-4′-thio-2′-deoxyuridine as a potential iodinated proliferation marker. Toyohara J, Hayashi A, Sato M, Tanaka H, Haraguchi K, Yoshimura Y, Yonekura Y, Fujibayashi Y. J Nucl Med 2002 Sep; 43 (9), pp. 1218–26.

Prostatic Carcinoma/"Enhanced Permeability and Retention" (EPR) Effect/Human Prostatic Carcinoma Transplants (Rat): Tumor-Specific Delivery Modality
[^{131}I]-[(N-2-(Hydroxypropyl)Methacrylamide] (HPMA)

Route of Administration: Intravenous.
Dosage: Equimolar concentrations of radioiodinated copolymers of HPMA with small amounts of methacryloyltyrosinamide (pHPMA) differing in molecular weight (23.4-kD, 27.3-kD, 30.5-kD, 44-kD, 58.4-kD, 60.1-kD).
Implementation: Investigations have described the optimal design of polymers intended for tumor detection and drug delivery based on the initial delineation of the fate and total body distribution of soluble synthetic macromolecules derived from copolymers of HPMA. Evaluations can be performed by monitoring scintigraphic images acquired following radiolabeling of the product with [^{131}I] during a 7-day time window. Scintigraphic data can be validated by determining absolute amounts of [^{131}I]-pHPMA in both tumor tissue and normal organs after sacrificing animals.

Animal Model: Detection of Dunning prostate carcinomas (subline R3327-AT1) transplanted into Copenhagen rats.
Interpretation and Analysis: Copolymers are cleared from the intravascular compartment in a molecular-weight dependent manner, either via excretion or by extravasation into normal and neoplastic tissues. While distribution patterns for pHPMAs in normal organs are quite similar, absolute amounts of copolymer uptake differ. The higher the molecular weight, the more radioactivity is taken up by the organs. Highest amounts of radioactivity are seen in the lung, liver, and spleen. In solid tumors, the kinetics of pHPMA accumulation is clearly dependent on molecular weight. pHPMAs below the renal threshold peaks at 24 hours postinjection and then remains constant. In contrast, copolymers above the renal clearance threshold display a continuous accumulation, reaching a significantly higher tumor uptake, presumably due to the very small or non-existent polymer release from tumor tissue. Absolute amounts of tumor uptake determined by dissection analysis are 0.5 $\pm$ 0.1% of injected dose/g tissue for the 27.3-kD pHPMA and 1.2 $\pm$ 0.1% for the 60.1-kD pHPMA, respectively.

In conclusion, laboratory results have demonstrated the influence of the molecular weight of the synthetic polymer pHPMA on plasma circulation time, excretion, and organ clearance. While pHPMAs are cleared from all normal tissues except the spleen quite effectively, these polymers accumulate in solid tumors in a size-dependent manner, due to the well-known EPR effect. Such information is of fundamental interest for ongoing studies on the pharmacokinetics of synthetic polymers, especially when these molecules are conjugated with targeting moieties and therapeutic or diagnostic agents.

Synthetic macromolecular drug carriers: Biodistribution of poly[(N-2-hydroxypropyl)methacrylamide] copolymers and their accumulation in solid rat tumors. Kissel M, Peschke P, Subr V, Ulbrich K, Schuhmacher J, Debus J, Friedrich E. PDA J Pharm Sci Technol 2001 May–Jun; 55 (3), pp. 191–201.

Prostatic Carcinoma/Gene Expression Imaging
[Gd]-Anti-Messenger RNA (mRNA) Oligonucleotide Strand/Trans-Membrane Carrier Peptide

Cellular/Molecular Mechanism of Action: The spatial orientation of gadolinium changes when placed within a magnetic field. Trans-membrane carrier proteins are transported across cell membrane structures by specific membrane-associated complexes. Oligonucleotides can be designed as complementary sequences to specific mRNA strands and the resulting cDNA/mRNA double strand complexes thereby effectively preventing translation of the mRNA strand. Diagnostically, complementary cDNA strands would theoretically accumulate intracellularly within cells that are actively transcribing the corresponding mRNA sequences that cDNA strands have been designed to recognize and physically bind to.

Background Information: The term "molecular imaging" can be broadly defined as the *in vivo* characterization and measurement of biological processes at the cellular and molecular level.
Application: Extrapolation of the concept and methodologies for the design of strategies for the diagnostic detection of *in vivo* gene expression. Example: Specific oncogene expression within neoplastic cell types.
Route of Administration: Theoretically intravenous would be the preferred method of delivery.
Semi-Synthetic Methods: Development of a novel intravital and intracellular contrast agent that is composed of a detection molecule, an oligonucleotide sequence (peptide nucleic acid [PNA]), and a trans-membrane carrier peptide that is composed of a peptide sequence similar to that of the homeodomain of the Antennapedia protein.
Implementation: Determine if a (i) labeled oligonucleotide complex can accumulate in tumor cells *in vitro* and *in vivo*; and (ii) whether the specificity of a PNA for the upregulated c-myc mRNA in the cell's cytoplasm has an effect on contrast agent retention within tumor cells.
Tissue Culture Model: HeLa cell lines.
Animal Model: Rat (Dunning R3327 AT1 rat prostate adenocarcinoma).
Interpretation and Analysis: Using the c-myc-specific and a c-myc-non-specific control PNA, an increase in signal intensity in the tumor cells can be observed after 10 minutes *in vitro* and *in vivo* (maximum reached *in vitro* in HeLa within 60 minutes compared to Dunning R3327 AT1 rat prostate adenocarcinoma cells *in vivo* within 30 minutes). Such increases of signal intensity can be maintained *in vitro* in HeLa cells for only 4 hours and in Dunning R3327 AT1 rat prostate adenocarcinoma cells *in vivo* at least for 5 hours by using the c-myc mRNA-specific PNA as a "retention" agent.

Intracellular visualization of prostate cancer using magnetic resonance imaging. Heckl S, Pipkorn R, Waldeck W, Spring H, Jenne J, von der Lieth CW, Corban-Wilhelm H, Debus J, Braun K. Cancer Res 2003 Aug 15; 63 (16), pp. 4766–72.

Pulmonary Carcinoma
N-[2-(Hydroxyethoxy)Methyl]-5-[^{3}H]Methyluracil (^{3}H-1)

Application: Unsuitable for diagnostic imaging of neoplastic disease states.
Semi-Synthetic Methods: The production of tritium-labeled acyclonucleoside N-[2-(hydroxyethoxy)methyl]-5-[^{3}H]methyluracil ([^{3}H]-3) can be synthesized from the precursor, 5-[^{3}H]-methyluracil, [^{3}H]-1, which is subsequently converted to a 2,4-bis-trimethylsilyl intermediate, which is then coupled with 2-acetoxyethoxymethyl bromide to yield 1-[(2-acetoxyethoxy)methyl-5-[^{3}H]methyluracil ([^{3}H]-2). Treatment of [^{3}H]-2 with sodium methoxide in methanol produces [^{3}H]-3 (specific activity 188 MBq mmol^{-1}).
Implementation: Evaluation of the tissue distribution of ^{3}H-3.
Animal Model: Murine (male BDF1 mice bearing Lewis lung carcinomas).
Interpretation and Analysis: The tissue distribution of [^{3}H]-3 reveals that long bones exhibit the highest tumor:tissue ratios. The kidney contains the highest radioactivity level relative to the tumor, suggesting a major urinary route of excretion. The primary radioactive blood component (89.21%) has a biological half-life of approximately 0.19 minutes. The candidate compound is unsuitable for use as a diagnostic agent for Lewis lung carcinoma because of low tumor uptake and rapid urinary elimination of injected radioactivity from the body.

Tumor uptake of radiolabelled pyrimidine bases and pyrimidine nucleosides in animal models-VIII. Synthesis and tissue distribution of N-[2-(hydroxyethoxy) methyl]-5-[3H]methyluracil. Lee YW, Iwashina T, Gati WP, Knaus EE, Wiebe LI. Int J Appl Radiat Isot 1985 May; 36 (5), pp. 395–8.

Renal Carcinoma/Associated Unique Antigen
[^{99m}Technetium] ([^{99m}Tc])-G250/Antigen-Specific Immunoglobulin

Cellular/Molecular Mechanism of Action: Immunoglobulins specifically designed to selectively interact with and bind to unique membrane-associated antigens expressed by renal carcinoma cell types.
Route of Administration: Most frequently given by intravenous infusion.
Considerations: Not all monoclonal antibody preparations are effective in their ability to selectively detect neoplastic lesions, and therefore their efficacy has to be predetermined (prescreened) prior to their application.
Interpretation and Analysis: Perfusion of tumor-bearing kidneys with [^{99m}Tc]-labeled G250 and RC38 antibody can be used to effectively visualize lesions of renal cell carcinoma following formation of Ag/Ab complexes with renal cell carcinoma-associated antigens. Superior preparations display minimal uptake in normal renal tissues (e.g., tumor-to-kidney ratios after perfusion = 2.2 to 2.7). Following rinsing for 3 hours with unlabeled perfusion fluid the tumor-to-kidney tissue ratios can increase from 2.7 to 8.6. Based on observations from preliminary investigations, it has been concluded that perfusion of tumor-bearing human kidneys with radiolabeled monoclonal antibodies is a relatively simple way to evaluate renal cell carcinoma-associated monoclonal antibodies as *in vivo* diagnostic agents.

Perfusion of tumor-bearing kidneys as a model for scintigraphic screening of monoclonal antibodies. van Dijk J, Oosterwijk E, van Kroonenburgh MJ, Jonas U, Fleuren GJ, Pauwels EK, Warnaar SO. J Nucl Med 1988 Jun; 29 (6), pp. 1078–82.

Renal Cell Carcinoma (RCC)/Associated Unique Antigens
Radiolabeled G250 Monoclonal Antibody (MAb)

Cellular/Molecular Mechanism of Action: Monoclonal antibodies can be designed to recognize and physically bind to membrane-associated antigens uniquely expressed by RCC.
Background Information: Excellent visualization of tumor lesions can be achieved with [^{131}I]-labeled MAb G250 in cases with RCC. In several cases, [^{131}I]-cG250 immunoscintigraphy can detect tumor lesions that cannot be visualized by radiography or computed tomography (CT).
Application: Improved detection and characterization of RCC lesions through the development of [^{99m}Tc]-labeled MAb G250 preparation and the acquisition of scintigraphic images with increased sensitivity and specificity.
Semi-Synthetic Methods: The G250 MAb can be labeled with [^{99m}Tc] according to 3 methods using (i) S-hydrazinonicotinamide (HYNIC); (ii) S-benzoylmercaptoacetyltriglycine (MAG3); and (iii) a direct labeling method (Schwarz method).
Implementation: Evaluation of the *in vitro* stability, biodistribution, and imaging potential of 3 [^{99m}Tc]-labeled G250 preparations to detect *in vivo* xenographs of RCC. [^{125}I]-G250 and the non-specific MAb [^{131}I]-MN14 can be used as reference control antibodies. Stability of radiolabeled monoclonal antibody preparations can be tested in serum at 37°C over the course of a 48-hour incubation peri-

od. In addition, diethylenetriamine pentaacetic acid, cysteine, and glutathione challenge assays can be performed to acquire supplemental information.

Animal Model: Murine (nude mice with subcutaneous RCC xenografts).

Interpretation and Analysis: All preparations show good stability in serum during 48-hour incubation periods. [^{99m}Tc]-G250 (Schwarz) displays release of the radiolabel at a 100-fold or higher molar excess of cysteine and at a 10,000-fold or higher molar excess of glutathione. [^{99m}Tc]-MAG3-G250 shows release of the radiolabel at a 10,000-fold molar excess of cysteine. [^{99m}Tc]-HYNIC-G250 is stable under all conditions. Tumors can be clearly visualized with all preparations. [^{99m}Tc]-G250 (Schwarz) shows significantly lower blood levels (3.8 % injected dose per gram [%ID/g]) compared with all other preparations (11.2, 13.4, and 13.4 %ID/g for [^{99m}Tc]-HYNIC-G250, [^{99m}Tc]-MAG3-G250, and [^{125}I]-G250, respectively, 48 hours postinjection). At 48 hours postinjection, mean tumor uptake is very high with all G250 MAb preparations: (92.4 = [^{99m}Tc]-HYNIC-G250; 125.9 = [^{99m}Tc]-MAG3-G250; 29.4 = [^{99m}Tc]-G250 Schwarz; and 75.4 = [^{125}I]-G250 %ID/g). Mean tumor uptake of the non-specific [^{131}I]-MN14 MAb is 6.6 %ID/g. Therefore, [^{99m}Tc]-HYNIC-G250 shows excellent *in vitro* stability and tumor targeting. Moreover, this preparation can be labeled with high efficiency (> 95%) at room temperature within 15 minutes. [^{99m}Tc]-HYNIC-G250 seems to be an ideal candidate for radioimmunodetection of RCC.

In vivo and *in vitro* characterizations of 3 [^{99m}Tc]-labeled monoclonal antibody G250 preparations. Steffens MG, Oosterwijk E, Kranenborg MH, Manders JM, Debruyne FM, Corstens FH, Boerman OC. J Nucl Med 1999 May; 40 (5), pp. 829–36.

Renal Cell Carcinoma (RCC)/Metastatic *[^{111}Indium] ([^{111}In])-Labeled Octreotide*

Cellular/Molecular Mechanism of Action: [^{111}In]-labeled octreotide is a radioactive somatostatin analogue that recognizes and binds to its corresponding receptor complex.

Application: Detection and characterization of RCC.

Route of Administration: [^{111}In]-labeled octreotide (intravascular).

Implementation: Evaluation of the biodistribution of labeled octreotide radioactivity in scintigraphic scans (n = 11) and images correlates with diagnostic compted tomography (CT) and/or x-ray images.

Interpretation and Analysis: Positive tumor uptake can be observed in a number of cases (e.g., n = 9/68). Approximately 60% of known tumor lesions can be visualized with octreotide scan (e.g., n = 40/68). Acquisition of a 2nd scan can be applied to detect progression of disease and/or lack of response to therapeutic intervention characterized by scintigraphic images that display intensified lesion octreotide uptake. False-positive lesions (e.g., n = 4) can be observed in a relatively large number of octreotide scintigraphic images. Renal cell carcinoma expresses somatostatin receptors and can be visualized by radiolabeled octreotide scintigraphy. The scintigraphic technique can be used as an instrument for *in vivo* characterization of the disease. Such diagnostic methodologies could function as the basis for future investigations regarding the possible therapeutic effect of octreotide in the management of renal cell cancer.

[^{111}In-DTPA-D-Phe$_1$]-octreotide scintigraphy in the management of patients with advanced renal cell carcinoma. Edgren M, Westlin JE, Kälkner KM, Sundin A, Nilsson S. Cancer Biother Radiopharm 1999 Feb; 14 (1), pp. 59–64.

Sigma$_2$ Receptor Complexes (Sigma$_2$-Opioid)/ Mammary Adenocarcinoma *[^{99m}Technetium] ([^{99m}Tc])-Sigma$_2$ Receptor Ligand (Racemic Formulations) / Rehnium-2 (Re-2)/ Pentazocine/Haloperidol*

Cellular/Molecular Mechanism of Action: [^{99m}Tc]-labeled [(N-[2-((3′-N′-propyl-[3,3,1]aza-bicyclononan-3α yl)(2′′-methoxy-5-methyl-phenylcarbamate)(2-mercaptoethyl)amino)acetyl]-2-aminoethanethiolato] technetium$_V$ oxide), [^{99m}Tc]$_2$, displays specific binding avidity toward sigma$_2$ receptor complexes (sigma-opioid). Note: Pentazocine is an agonist at κ-opioid receptors and a weak agonist at μ-opioid receptors. In this context, it is classified as a mixed opioid because it functions as an agonist at some opioid receptors and an antagonist at others.

Application: Detection and characterization of neoplastic disease states associated with the expression of sigma$_2$-opioid receptor complexes (e.g., human mammary carcinoma).

Route of Administration: Intravenous.

Semi-Synthetic Methods: Preparation of [^{99m}Tc]$_2$ can be achieved by heating the S-protected starting material, 1, in the presence of acid, a reducing agent (stannous glucoheptonate) and sodium [^{99m}Tc]pertechnetate. The lipophilic racemic mixture can be successfully prepared at a 10–50% yield and a radiochemical purity of approximately 98%. Separation of the isomers, peak A and peak B, can be successfully achieved by using a chiralpak AD column eluted with an isocratic solvent (n-hexane/isopropanol; 3:1; v/v). The peak A and peak B appear to co-elute with the isomers of the surrogate, Re-2, under the same high-performance liquid chromatography (HPLC) condition.

Implementation: Evaluate the *in vitro* binding avidity and selectivity of [^{99m}Tc]$_2$ and Re-2 for sigma$_2$ receptors. Further delineation of the potential diagnostic efficacy of the molecular probes can be determined by performing biodistribution studies utilizing *in vivo* tumor-bearing models.

Animal Model: Murine (mouse mammary adenocarcinoma, cell line 66 known to overexpress sigma$_2$ receptor complexes).

Interpretation and Analysis: *In vitro* binding assays show that Re-2 displays excellent binding affinity and selectivity toward sigma$_2$ receptors (K_i = 2,723 and 22 nM for sigma$_1$ and sigma$_2$ receptor, respectively). Biodistribution studies in tumor-bearing mice (mammary adenocarcinoma) reveal that racemic [^{99m}Tc]$_2$ localizes within tumors. Uptake in the tumor is 2.11, 1.30, and 1.11% dose/gram at 1, 4, and 8 hours postinjection, respectively, suggesting good uptake and retention within tumor cells. Tumor uptake is significantly, but incompletely, blocked (about 25–30% blockage) by co-injection of "cold" (+)pentazocine or haloperidol (1 mg/kg). A majority of the radioactivity localized within the tumor tissue can be extracted (> 60%), and HPLC analysis reveals that it is the original compound (racemic [^{99m}Tc]$_2$ purity ≥ 98%). Distribution of purified HPLC peak A and HPLC peak B can be detected in the same tumor-bearing mice at 4 hours postinjection. Tumor uptake is similar for both isomers, but the blood and peripheral tissue content for the isomer in peak B is higher than that for the isomer in peak A. It is evident that the isomer in peak A possesses significantly better tumor/blood and tumor/muscle ratios. The higher rate of *in vivo* metabolism can be confirmed by the higher thyroid uptake values for the peak B isomer when compared to the peak A isomer. Therefore, the [^{99m}Tc]-labeled sigma receptor imaging agent [^{99m}Tc]$_2$ has demonstrated the feasibility of using [^{99m}Tc]-labeled agents for imaging tumor cell expression of sigma receptor complexes.

Development of a [^{99m}Tc]-labeled sigma$_2$ receptor-specific ligand as a potential breast tumor-imaging agent. Choi SR, Yang B, Plossl K, Chumpradit S,

Wey SP, Acton PD, Wheeler K, Mach RH, Kung HF. Nucl Med Biol 2001 Aug; 28 (6), pp. 657–66.

Somatostatin Receptor Complexes/Neuroendocrine Cancers/Gliomas/Mammary Carcinoma/Melanoma/Small Cell Lung Cancer

[^{99m}Technetium] ([^{99m}Tc])-Tricine-(HYNIC-TOC)/[^{99m}Tc]-Ethylenediaminediacetic Acid-(HYNIC-TOC)/[^{99m}Tc]-Tricine-Nicotinic Acid-(HYNIC-TOC)/[^{111}Indium] ([^{111}In])-Diethylenetriamine Pentaacetic Acid (DTPA)-Octreotide/[^{111}In]-DTPA-D-Phe$_1$-Octreotide

Cellular/Molecular Mechanism of Action: Recognizes and physically binds to somatostatin receptor complexes.

Background Information: Indium-111-labeled DTPA-D-Phe$_1$-octreotide ([^{111}In]-DTPA-OC, OctreoScan) has been introduced into clinical routine for the detection of somatostatin receptor (SSTR)-positive tumors, which are predominantly of neuroendocrine origin. Other potential applications in other SSTR-positive cancers (e.g., small cell lung cancer, breast cancer, melanoma) have been limited mainly due to restricted availability and high cost of suitable radionuclides. Previous attempts to introduce [^{99m}Tc]-labeled analogues of octreotide have not been very successful in terms of labeling technique, *in vivo* biodistribution, and/or tumor detection capabilities.

Application: Early, rapid image-based diagnosis of somatostatin receptor positive neoplastic lesions.

Route of Administration: [^{99m}Tc]-HYNIC-D-Phe$_1$-Tyr$_3$-octreotide and [^{111}In]-DTPA-octreotide (intravascular).

Semi-Synthetic Methods: Production of high-specific activity [^{99m}Tc] radiolabeled hydrazinonicotinyl-Tyr$_3$-octreotide (HYNIC-TOC) using tricine, ethylenediaminediacetic acid (EDDA), and tricine-nicotinic acid as coligand systems.

Implementation: Evaluation of the *in vitro* properties and *in vivo* biodistribution of [^{99m}Tc]-tricine-HYNIC-TOC, [^{99m}Tc]-EDDA-HYNIC-TOC, and [^{99m}Tc]-tricine-nicotinic acid-HYNIC-TOC compared to [^{111}In]-DTPA-octreotide. Receptor binding analyses can be performed using AR42J rat pancreatic tumor cell membranes. Complementary investigations can involve the characterization of internalization processes and protein binding studies performed, in addition to establishing *in vivo* biodistribution profiles within pancreatic tumors.

***Ex Vivo* Model:** Rat AR42J pancreatic tumor cell membrane receptor binding analyses.

Animal Model: Murine (AR42J pancreatic tumor-bearing nude mice).

Interpretation and Analysis: The [^{99m}Tc]-labeled HYNIC peptides possess retained somatostatin receptor binding affinities (Kd $<$ 2.65 nM). Protein binding and internalization rates are dependent on the coligand used. Specific tumor uptake between 5.8% and 9.6% of the injected dose per gram (%ID/g) can be appreciated for the [^{99m}Tc]-labeled peptides, compared with 4.3 %ID/g for [^{111}In]-DTPA-octreotide. Tricine applied as a coligand shows higher activity levels in muscle, blood, and liver, whereas tricine-nicotinic acid produces significant levels of activity in the gastrointestinal tract. EDDA displays the most promising overall biodistribution profile, with tumor-to-liver and tumor-to-gastrointestinal tract ratios similar to those obtained with [^{111}In]-DTPA-octreotide, lower ratios in blood and muscle, but considerably higher tumor-to-kidney ratios. Molecular TOC can be radiolabeled to high specific activities using HYNIC as a bifunctional chelator. The high specific tumor uptake, rapid blood clearance, and predominantly renal excretion make [^{99m}Tc]-EDDA-HYNIC-TOC a promising candidate as an alternative to [^{111}In]-DTPA-octreotide for tumor imaging.

[^{99m}Tc]-HYNIC-[Tyr$_3$]-octreotide for imaging somatostatin-receptor-positive tumors: Preclinical evaluation and comparison with [^{111}In]-octreotide. Decristoforo C, Melendez-Alafort L, Sosabowski JK, Mather SJ. J Nucl Med 2000 Jun; 41 (6), pp. 1114–9.

Somatostatin Receptor Complexes/Neuroendocrine Tumors/Gliomas/Mammary Carcinoma/Melanoma/Small Cell Lung Cancer

[^{99m}Technetium] ([^{99m}Tc])-Tricine-HYNIC-TOC/[^{111}Indium] ([^{111}In])-Diethylenetriamine Pentaacetic Acid (DTPA)-D-Phe$_1$-Octreotide

Cellular/Molecular Mechanism of Action: [^{99m}Tc]-tricine-HYNIC-TOC detects and physically binds to somatostatin receptor complexes in a manner highly analogous to [^{111}In]-DTPA-D-Phe$_1$-octreotide.

Background Information: [^{111}In]-labeled DTPA-D-Phe$_1$-octreotide (DTPA-OC, OctreoScan) has been introduced into clinical routine for the detection of somatostatin receptor (SSTR)-positive tumors, which are predominantly of neuroendocrine origin. Other potential applications in other SSTR-positive cancers (e.g., small cell lung cancer, breast cancer, melanoma) have been limited mainly by restricted availability and high cost of suitable radionuclides. Previous attempts to introduce [^{99m}Tc]-labeled analogues of octreotide have not been very successful in terms of the labeling procedure, *in vivo* biodistribution, and/or tumor detection capabilities.

Application: The agent [^{99m}Tc]-HYNIC-D-Phe$_1$-Tyr$_3$-octreotide or [^{99m}Tc]-tricine-HYNIC-TOC can be utilized to detect and characterize neoplastic cell types that express elevated membrane densities of somatostatin receptor complexes (similar to [^{111}In]-DTPA-OC). [^{99m}Tc]-HYNIC-D-Phe$_1$-Tyr$_3$-octreotide appears to provide more rapid (early) image acquisition of SSTR-positive neoplastic lesions.

Route of Administration: [^{99m}Tc]-HYNIC-D-Phe$_1$-Tyr$_3$-octreotide and [^{111}In]-DTPA-octreotide (intravascular).

Implementation: Evaluation of neoplastic lesions proven to be positive for SSTR expression utilizing both the [^{99m}Tc]-labeled analogue HYNIC-D-Phe$_1$-Tyr$_3$-octreotide (HYNIC-TOC = tricine as a coligand) and [^{111}In]-DTPA-octreotide. Serial whole-body scans, spot views, and/or single photon emission tomography studies are then performed and images qualitatively and semi-quantitatively evaluated (e.g., selective regions-of-interest [ROI]).

Human Model: Cases with proven SSTR-positive neoplastic lesions (n = 13 patient scans; n = 12 SSTR-positive tumors; n = 9/13 scanned with both [^{99m}Tc]-tricine-HYNIC-TOC and [^{111}In]-DTPA-OC).

Interpretation and Analysis: Delineation of the biodistribution of [^{99m}Tc]-tricine-HYNIC-TOC reveals high physiological uptake within the kidney, moderate uptake in the liver and spleen, and little uptake within the gastrointestinal system. The tracer shows predominantly renal and negligible hepatobiliary excretion. Known SSTR-positive tumor sites show rapid and intense tracer accumulation. [^{99m}Tc]-tricine-HYNIC-TOC is rapidly taken up by tissues within the 1st hour after injection and has basically no significant clearance ($<$ 20%) from normal or tumor tissue thereafter. Alternatively, [^{111}In]-DTPA-OC shows continuous clearance from normal tissues as well as renal and very little hepatobiliary excretion. Nevertheless, patterns of accumulation of [^{99m}Tc]-tricine-HYNIC-TOC in tumors and normal organs are comparable to those for [^{111}In]-DTPA-OC. Comparison on a lesion-by-lesion basis reveals similar tumor detection capabilities in intrahepatic tumor sites and superior capabilities

of [^{99m}Tc]-tricine-HYNIC-TOC with respect to extrahepatic lesions. In conclusion, [^{99m}Tc]-tricine-HYNIC-TOC shows promise as a tracer for SSTR imaging, given its favorable clinical characteristics (specific and high receptor affinity, good biodistribution, renal excretion, low radiation exposure, high imaging quality), on-demand availability, and cost-effectiveness. [^{99m}Tc]-tricine-HYNIC-TOC allows earlier diagnosis (10 minutes–4 hours) compared with [^{111}In]-DTPA-OC (4–24 hours).

Detection of somatostatin receptor-positive tumors using the new [^{99m}Tc]-tricine-HYNIC-D-Phe$_1$-Tyr$_3$-octreotide: First results in patients and comparison with [^{111}In]-DTPA-D-Phe$_1$-octreotide. Bangard M, Béhé M, Guhlke S, Otte R, Bender H, Maecke HR, Biersack HJ. Eur J Nucl Med 2000 Jun; 27 (6), pp. 628–37.

Somatostatin Receptors/Renal Clearance: Strategies for Modification
[^{111}Indium] ([^{111}In])-Diethylenetriamine Pentaacetic Acid (DTPA)-Met(1)-Octreotide/[^{111}In]-DTPA-Phe$_1$-Octreotide

Cellular/Molecular Mechanism of Action: Octreotide and lanreotide are somatostatin derivatives that specifically bind to somatostatin receptors.
Background Information: Metabolic studies employing [^{111}In]-DTPA-labeled peptides and polypeptides show that the radiolabeled (poly)peptides generate [^{111}In]-DTPA adducts of amino acid that possess long residence times in the lysosomal compartment of tissues where (poly)peptides accumulate. However, some investigations have suggested that metal-chelate-methionine (Met) might possess *in vivo* behaviors different from metal-chelate adducts of other amino acids.
Application: Octreotide or lanreotide are the most frequently used radiopharmaceuticals for detection and characterization of certain neoplastic cell types that express relatively high membrane densities of somatostatin receptors. Different molecular components can be used to modify the rate of renal clearance for biopharmaceutical conjugates containing octreotide or lanreotide.
Semi-Synthetic Methods: [^{111}In]-DTPA-Met(1)-octreotide.
Implementation: Elucidate some of the biological characteristics of Met to determine if they may accelerate the renal elimination rate of [^{111}In]-DTPA-Met into the urine (when using [^{111}In]-DTPA-Met(1)-octreotide as an imaging agent) and compare findings to [^{111}In]-DTPA-L-Phe$_1$-octreotide functioning as a reference control.
Interpretation and Analysis: Both [^{111}In]-DTPA-conjugated octreotide analogues are stable during 3-hour incubation periods in murine serum (37°C). Both [^{111}In]-DTPA-octreotide analogues show rapid radioactive clearance from the blood and similar accumulation of radioactivity in the kidney. No significant differences can be observed between the 2 agents pertaining to renal radioactivity levels from 10 minutes to 24 hours postinjection. Metabolic studies indicate that [^{111}In]-DTPA-Met(1)-octreotide and [^{111}In]-L-Phe$_1$-octreotide generate [^{111}In]-DTPA adducts of Met and Phe, respectively, as the final radiometabolites at similar rates. These findings suggest that the long residence times of tissue radioactivity after administration of [^{111}In]-DTPA-labeled peptides and polypeptides can be attributed to the inherent characteristics of the [^{111}In]-DTPA chelation group.

Significance of [^{111}In]-DTPA chelate in renal radioactivity levels of [^{111}In]-DTPA-conjugated peptides. Akizawa H, Arano Y, Mifune M, Iwado A, Saito Y, Uehara T, Ono M, Fujioka Y, Ogawa K, Kiso Y, Saji H. Nucl Med Biol 2001 May; 28 (4), pp. 459–68.

Somatostatin Receptors/Staging of Malignancy/Predictive Response to Somatostatin-Based Therapeutics/Prognostic/Differential Diagnostic Marker
[^{123}I]-Tyr$_3$-Octreotide/[^{111}Indium] ([^{111}In])-Diethylenetriamine Pentaacetic Acid (DTPA)-D-Phe$_1$-Octreotide

Cellular/Molecular Mechanism of Action: Octreotide functions as a peptide analogue of somatostatin.
Background Information: Octreotides plays an important role in neoplasia because their physiological properties are mediated through specific somatostatin receptor complexes expressed by neoplastic cell populations. Analysis of somatostatin receptors *in vitro* reveals that they are expressed at relatively high densities by various type of human neoplasias and serves as the experimental basis for the development of somatostatin analogues as non-invasive *in vivo* imaging agents. Relevant examples in this regard include the development of [^{123}I]-Tyr$_3$-octreotide and [^{111}In]-DTPA-D-Phe$_1$-octreotide to facilitate gamma camera scintigraphic imaging masses suspected of being tumors that express somatostatin receptor complexes at relatively high membrane densities.
Application: Non-invasive *in vivo* detection and imaging of neoplastic disease states.
Route of Administration: [^{123}I]-Tyr$_3$-octreotide (intravenous) and [^{111}In]-DTPA-D-Phe$_1$-octreotide (intravenous).
Interpretation and Analysis: Lesion uptake of imaging agent above background levels for normal healthy tissue represents a possible positive detection of a neoplastic lesion. The somatostatin receptor imaging strategy may help localize primary tumors and metastases, sufficient for staging certain tumors types, to predict the probability of success with somatostatin-based therapies and as a prognostic or differential diagnostic disease marker. It may also be of use in other pathological disease states for localization of selected inflammatory processes and to monitor anti-inflammatory therapy. Somatostatin receptor imaging represents an example of the clinical use of a small peptide as an efficient *in vivo* diagnostic tool.
Instrumentation: Gamma camera scintigraphic imaging modalities.

Receptor imaging of human diseases using radiolabeled peptides. Reubi JC, Lamberts SJ, Krenning EP. J Recept Signal Transduct Res 1995 Jan–Mar; 15 (1–4), pp. 379–92.

Somatostatin Receptors: Subtype 2 (sst2)/Pituitary Neoplasia/Pancreatic Neoplasia/Adrenal Neoplasia
[^{111}Indium] ([^{111}In])-(DTPA0,Tyr$_3$)-Octreotide/[^{111}In]-(DOTA0,Tyr$_3$)-Octreotide/[^{111}In]-(DTPA0)-Octreotide

Cellular/Molecular Mechanism of Action: Possess physical binding avidity for sst2 complexes.
Application: Detection and characterization of pituitary, pancreatic, and adrenal neoplastic lesions that express an overabundance of sst2 complexes.
Implementation: Evaluate the potential usefulness of radiolabeled (DTPA0,Tyr$_3$)-octreotide and (DOTA0,Tyr$_3$)-octreotide as radiobiopharmaceuticals for somatostatin receptor-targeted scintigraphy and radiotherapy. Detailed analysis can entail the characterization of *in vitro* somatostatin receptor binding complemented by determination of the *in vivo* patterns of metabolism of agents compared to [^{111}In]-DTPA0-octreotide.
Animal Model: Rats (CA20948 tumor-bearing Lewis rats).

Interpretation and Analysis: Comparisons made between different peptide-chelator constructs reveal that (DTPA0,Tyr_3)-octreotide and (DOTA0,Tyr_3)-octreotide have a higher affinity than (DTPA0)-octreotide for sst2 (e.g., mouse AtT20 pituitary tumor cell membranes with all IC_{50} values obtained in the low nanomolar range). Studies *in vivo* in CA20948 tumor-bearing Lewis rats reveal a significantly higher uptake of both [^{111}In]-labeled (DOTA0,Tyr_3)-octreotide and (DTPA0,Tyr_3)-octreotide in sst2-expressing tissues than after the injection of [^{111}In]-(DTPA0)-octreotide, showing that substitution of Tyr for Phe at position 3 in octreotide results in increased affinity for its receptor and in a higher target tissue uptake. Uptake of [^{111}In]-labeled (DTPA0)-octreotide, (DTPA0,Tyr_3)-octreotide, and (DOTA0,Tyr_3)-octreotide in pituitary, pancreas, adrenals, and tumor is decreased to less than 7% of control by pretreatment with unlabeled octreotide/rat (0.5 mg), reflecting specific binding to sst2 complexes. Comparing different radionuclides, [^{90}Y]-(DOTA0,Tyr_3)-octreotide has the highest uptake in sst2-positive organs, followed by the [^{111}In]-(DOTA0,Tyr_3)-octreotide, whereas (DOTA0,[^{125}I]-Try_3)-octreotide uptake is low compared to that of the other radiopharmaceuticals, when measured 24 hours after injection. Renal uptake of [^{111}In]-labeled (DTPA0)-octreotide, (DTPA0,Tyr_3)-octreotide and (DOTA0,Tyr_3)-octreotide is reduced over 50% by the intravenous injection of D-lysine (400 mg/kg), whereas radioactivity in blood, pancreas, and adrenals is not affected.

Preclinical comparison of (DTPA0)-octreotide, (DTPA0,Tyr_3)-octreotide, and (DOTA0,Tyr_3)-octreotide as carriers for somatostatin receptor-targeted scintigraphy and radionuclide therapy. De Jong M, Bakker WH, Breeman WA, Bernard BF, Hofland LJ, Visser TJ, Srinivasan A, Schmidt M, Béhé M, Mäcke HR, Krenning EP. Int J Cancer 1998 Jan 30; 75 (3), pp. 406–11.

Thyroid Cancer
[^{99m}Technetium] ([^{99m}Tc])-Methoxy-Isobutyl-Isonitrile (MIBI)

Background Information: [^{99m}Tc]-MIBI scintigraphy has recently been utilized in clinical scenarios for detecting thyroid cancer metastases. In this capacity, its role has been considered supplementary to serum thyroglobulin (Tg) measurements and radioactive iodine [^{131}I] whole-body scans (WBS).

Implementation: Evaluate the sensitivity and specificity of [^{99m}Tc]-MIBI scans to localize metastatic lesions in conditions of thyroidectomized thyroid cancer. Presence or absence of thyroid cancer can be determined in concert with other diagnostic modes, including serum Tg measurements, [^{131}I] WBS, bone scans, chest x-rays, computed tomography (CT), ultrasonography, histopathology, and evolution of disease assessed during follow-up examinations. All scans are evaluated on a lesion-to-lesion basis for the purpose of detecting neck, lung, and bone metastases and also on a region basis, namely head-neck, chest, and abdomen-pelvis-extremities (ab-p-ex) areas.

Human Model: Cases of thyroidectomized thyroid cancer (n = 68).

Interpretation and Analysis: Sensitivity of detection with [^{99m}Tc]-MIBI is approximately 94.4% (e.g., n = 17/18) for neck, 78.4% (e.g., n = 40/51) for lung, and 92.8% (e.g., n = 64/69) for skeletal lesions. Positive predictive values (PPV) and negative predictive values (NPV) are approximately 96.3% (e.g., n = 26/27) and 97.7% (e.g., n = 43/44) for head-neck; 94.7% (e.g., n = 71/75) and 50.0% (e.g., n = 12/24) for chest; and 100.0% (e.g., n = 25/25) and 93.1% (e.g., n = 54/58) for ab-p-ex regions, respectively. For all scan sites taken together, PPV and NPV are approximately 96.1% (e.g., n = 122/127) and 86.5% (e.g., n = 109/126), respectively. Therefore, [^{99m}Tc]-MIBI can be proposed as a 1st-line diagnostic agent for the follow-up protocol of thyroid cancer patients, although the ability to detect small lung metastases is somewhat limited.

Diagnostic value of [^{99m}technetium]-methoxyisobutyl isonitrile ([^{99m}Tc]-MIBI) scintigraphy in detecting thyroid cancer metastases: A critical evaluation. Alam MS, Kasagi K, Misaki T, Miyamoto S, Iwata M, Iida Y, Konishi J. Thyroid 1998 Dec; 8 (12), pp. 1091–100.

Thyroid Cancer: Differentiated
[^{123}Iodine] ([^{123}I])/[^{131}Iodine] ([^{131}I])

Cellular/Molecular Mechanism of Action: The radioisotopes [^{131}I] and [^{123}I] are recognized as atomic iodine by the thyroid gland.

Application: Detection and characterization of abnormalities affecting the thyroid gland (e.g., differentiated thyroid cancer, hyperthyroidism).

Dosage: Iodine [^{131}I] at 120 MBq/dose (ablation level of activity of [^{131}I] = 4,000 MBq) compared to [^{123}I] at 200 MBq/dose applied as a diagnostic agent.

Considerations: For measurements taken posttherapy, the gamma camera is operated in the high-count rate mode with appropriate correction factors to compensate for any count loss. The resultant radiation dose to the thyroid remnant, as the therapeutic radioiodine is being taken up, may be sufficient to inhibit the uptake process, thus leading to a reduction in maximum uptake when compared with that of the diagnostic activity of radioiodine.

Implementation: Evaluation of radioiodine [^{131}I] administration for diagnostic purposes following recent surgery as a measure of thyroid bed at 3 days. Subsequent thyroid ablation using [^{131}I] is administered 3–38 days later (median 14) and uptake in the thyroid bed measured once or twice, 1–3 days posttherapy. Affected cases can alternatively be given [^{123}I] as the diagnostic agent with the uptake measured at 24 hours. Ablation dosages of radioiodine can then be administered 5–47 (median 19) days later and uptake again measured at 24 hours.

Human Model: Cases that have undergone recent surgery for differentiated thyroid cancer (n = 26 with [^{131}I] and n = 16 with [^{123}I]).

Interpretation and Analysis: Reduced uptake of therapeutically administered [^{131}I] can be observed in the vast majority of cases (n = 26/26 or 100% at $p < 0.001$) that display a median value of 32.8% (range 6–93%) of the uptake in the diagnostic study. In cases given diagnostic [^{123}I], reduced uptake of the ablative radioiodine can be observed in 94% of cases (n = 15/16 at $p < 0.001$), and overall the median value is 58.8% (range 17–130%) of the diagnostic uptake. In a small number of cases, uptake posttherapy is increased (e.g., n = 1/16). The "stunning" observed in case group types given [^{123}I] is significantly less ($p < 0.001$) than in case group types given [^{131}I].

In cases given diagnostic [^{131}I], "stunning" appears to increase in severity the longer the time interval between the diagnostic and therapeutic radionuclides, for intervals up to 25 days. Thereafter, there seemed to be some recovery of uptake capability. Overall there is no evidence of a large rapid loss of radionuclide from the thyroid bed 1–3 days posttherapy. The "stunning" observed using [^{123}I] cannot be explained by errors in the estimation of relative uptake due to different tissue absorption of the [^{131}I] and [^{123}I] photons, nor by the radiation dose delivered by [^{123}I]. However, ablative [^{131}I] itself may cause "stunning" because the cumulated activity, over the 1st few hours of uptake, is not insignificant when compared with all the cumulated activity from a diagnostic administration of [^{131}I]. The resultant radiation dose delivered to the thyroid remnant, as the therapeutic radioiodine is being taken up, may be sufficient to inhibit the uptake process, thus leading to a reduction in maximum uptake when compared with that of the diagnostic activity of radioiodine.

Instrumentation: Computer-integrated nuclear medicine scintigraphic imaging instrumentation (dual-head gamma camera).

Self-stunning in thyroid ablation: Evidence from comparative studies of diagnostic [^{131}I] and [^{123}I]. Hilditch TE, Dempsey MF, Bolster AA, McMenemin RM, Reed NS. Eur J Nucl Med Mol Imaging 2002 Jun; 29 (6), pp. 783–8.

Thyroid Cancer: Differentiated Thyroid Cancer *[^{123}I] Compared to [^{131}I] Posttherapy Radioactive Imaging*

Cellular/Molecular Mechanism of Action: [^{123}I] and [^{131}I] are radioactive analogues of iodine and are physiologically recognized as molecular iodine by the thyroid gland.

Application: Nuclear medicine imaging for detection and characterization of differentiated thyroid cancer.

Route of Administration: Oral.

Dosage: [^{123}I] (185–555 MBq).

Background Information: Radioactive iodine [^{131}I] plays a major role in the diagnosis and management of differentiated thyroid cancer (DTC); however, data on the use of the [^{123}I] isotope in DTC are limited.

Implementation: Evaluation of thyroid cancer conditions utilizing [^{123}I] and comparison with results obtained following posttherapeutic [^{131}I] doses. Scans are evaluated in 3 clinical scenarios including (i) after the 1st [^{131}I] therapy dose; (ii) following the 2nd [^{131}I] therapy dose; and (iii) in cases of elevated Tg and negative diagnostic scan findings.

Human Model: Cases of thyroid cancer (n = 238 diagnostic whole-body scans performed 24 hours postadministration of radioiodine (images acquired with [^{123}I] at 24 hours and 4–5 days post-[^{131}I] therapy).

Interpretation and Analysis: Comparison of whole-body scans performed 24 hours after oral ingestion of [^{123}I] with their corresponding [^{131}I] posttherapy whole-body scans obtained 4–5 days after [^{131}I] therapy reveals a high level of concordance (concordance rate, 93.8%; n = 166 pairs). Some posttreatment scans (e.g., n = 6/166) can show more foci in the thyroid bed than pretreatment scans but display no evidence of uptake in new areas. A small fraction of posttreatment scans (e.g., n = 5/166) will show foci in new locations (e.g., n = 3/166 cervical lymph nodes (CLN); n = 1/166 lung; and n = 1/166 bone metastasis). Following secondary [^{131}I] therapy, a relatively large number of pairs will demonstrate complete concordance (e.g., n = 28/34 pairs; concordance rate, 82.4%). Some discordant pairs show additional foci in areas that have already detected a positive signal on pretreatment scans (e.g., n = 5). A relatively small number of cases may show posttreatment scans with new bone metastasis in a different site from the bone metastases identified on the corresponding pretreatment scan (e.g., n = 1). In pairs of scans in cases with elevated Tg and negative pretreatment scans, a relatively large percentage will remain negative on posttreatment scans (e.g., n = 15/27) while a little more than 1/5 may have posttreatment scans that reveal uptake in the thyroid bed (e.g., n = 6/27) and slightly more than 1/10 posttreatment scans show lung uptake (e.g., n = 3/27) in cases that have computed tomography scans of the chest with evidence of only bronchiectasis (n = 2/3 cases) and lung scarring (n = 1/3 cases) without evidence of lung metastases. A small number of posttreatment scans (e.g., n = 3) may show definite uptake (in thyroid bed, thyroid bed and lung, and CLN) compared with their corresponding pretreatment scans, originally described as being negative but retrospectively thought to have faint uptake. In pretreatment scans (e.g., n = 56), the [^{123}I] diagnostic activity level can be effectively achieved with 185 MBq, and the results show complete concordance in the vast majority of scan-pairs (e.g., n = 54/56). A small number of posttreatment scans will show additional uptake (e.g., n = 2; n = 1 bone; n = 1 CLN). Such observations suggest that pretreatment scanning using [^{123}I] is highly comparable to [^{131}I] posttreatment scans and that [^{123}I]is an excellent diagnostic agent in DTC.

[^{123}I] isotope as a diagnostic agent in the follow-up of patients with differentiated thyroid cancer**:** Comparison with post-[^{131}I] therapy whole body scanning. Alzahrani AS, Bakheet S, Al Mandil M, Al-Hajjaj A, Almahfouz A, Al Haj A. J Clin Endocrinol Metab 2001 Nov; 86 (11), pp. 5294–300.

Thyroid Cancer: Metastatic *[^{99m}Technetium] ([^{99m}Tc]) Furifosmin/[^{99m}Tc]-Methoxy-Isobutyl-Isonitrile (MIBI)/[^{99m}Tc]-SestaMIBI/ [^{99m}Tc] Tetrofosmin/[^{18}F]FDG-PET/[^{201}Thallium] ([^{201}Tl])/[^{131}I]/[^{123}I]*

Many isotopes are available for imaging cases with suspected thyroid cancer recurrence and metastases. Thyroid-stimulating hormone (TSH)-stimulated low-dose [^{131}I] whole-body scanning with serum thyroglobulin either by standard LT4 withdrawal or rhTSH stimulation is the preferred test for monitoring cases without palpable disease or elevated serum thyroglobulin on LT4 therapy. This approach has the advantage of detecting disease states that may be amenable to [^{131}I] therapy, although low-dose [^{131}I] scans are less sensitive than are scans with other imaging agents. [^{123}I] has better imaging characteristics than [^{131}I] and has been shown to be equivalent or superior to low-dose [^{131}I] in recent studies. As the availability of [^{123}I] increases and the cost decreases, this agent may replace [^{131}I] in imaging for recurrent or metastatic thyroid cancer. Other imaging procedures to find suspect disease states may be required when low-dose [^{131}I] imaging procedures are negative in conditions such as those associated with elevated serum thyroglobulin during LT4 therapy or after TSH stimulation. Many diagnostic imaging services perform a sensitive neck ultrasound to look for surgically remediable disease and consider a non-contrast computed tomography (CT) scan of the chest to look for small pulmonary metastases that poorly concentrate low doses of [^{131}I]. Fluoro-18-deoxyglucose positron emission tomography (PET), [^{99m}Tc]-MIBI, [^{201}Tl], and [^{99m}Tc] tetrofosmin are primarily useful in the setting of a negative whole-body [^{131}I] scan and elevated serum thyroglobulin. [^{18}F]FDG-PET seems to have the highest sensitivity in this setting and would be the preferred imaging agent, but availability and cost are major issues. Although some researchers have advocated these radiopharmaceuticals as 1st-line agents replacing [^{131}I], there is little support for this position. This approach to imaging is not cost-effective because positive scans in these cases would most likely require [^{131}I] scintigraphy to determine whether the lesions are amenable to radioiodine therapy. [^{99m}Tc] pertechnetate, [^{99m}Tc] furifosmin, and somatostatin receptor scintigraphy have a limited role in imaging for recurrent or metastatic differentiated thyroid carcinoma. In choosing among [^{99m}Tc]-MIBI, [^{201}Tl], and [^{99m}Tc] tetrofosmin, the technetium label of sestaMIBI and tetrofosmin results in better image quality and faster imaging than [^{201}Tl]. Although [^{99m}Tc]-sestaMIBI and [^{99m}Tc]tetrofosmin have not been compared in a large clinical series, the higher tumor-to-background ratio and consistently high sensitivities of [^{99m}Tc] tetrofosmin suggest that it could potentially have additional value over [^{99m}Tc]-sestaMIBI, but there is still limited experience with [^{99m}Tc] tetrofosmin.

Isotope imaging for metastatic thyroid cancer. Haugen BR, Lin EC. Endocrinol Metab Clin North Am 2001 Jun; 30 (2), pp. 469–92.

Thyroid Carcinoma: Metastatic Medullary Thyroid Carcinoma (MTC)/Lung Carcinoma: Small Cell Type/Cholecystokinin B (CCK-B) Receptor Expression *[^{131}I]-Labeled Gastrin-I (Heptadecapeptide)*

Cellular/Molecular Mechanism of Action: Radiolabeled [^{131}I]-labeled heptadecapeptide gastrin-I functions as a CCK-B receptor binding ligand.

Background Information: The outstanding sensitivity of pentagastrin in detecting the presence of primary, recurrent, or metastatic MTC suggests widespread expression of the corresponding receptor type in human MTC. Indeed, recent autoradiographic studies have demonstrated the presence of cholecystokinin (CCK-B or gastrin) receptors not only in more than 90% of MTCs but also in a high percentage of small cell lung cancers, stromal ovarian cancers, astrocytomas, and several other tumor types.
Application: Detection and characterization of metastatic thyroid carcinoma lesions.
Route of Administration: [^{131}I]-labeled gastrin-I (intravenous).
Dosage: [^{131}I]-labeled gastrin-I (1 μg).
Implementation: Evaluate the potential of radiolabeled gastrin to target CCK-B receptor expressing tumors by determinging the *in vivo* biodistribution of radioiodinated human heptadecapeptide gastrin-I. In this context, both the diagnostic and therapeutic capabilities of radiolabeled CCK-B preparations can be evaluated utilizing [^{131}I]-labeled gastrin-I to investigate their behavior in conditions of metastatic MTC.

Animal Model: Murine (nude mice bearing subcutaneous xenografts of the human MTC cell line, TT).

Human Model: Cases of metastatic MTC.
Interpretation and Analysis: Peptide in amounts of approximately 1 μg produces maximum tumor uptake (8.9 ± 2.9 %ID/g) and can be observed *in vivo* in animal models at 1 hour postinjection, with tumor-to-blood ratios as high as 6.3 ± 1.9. Physiological CCK-B receptors in the stomach, gallbladder, and pancreas are targeted as well (e.g., murine). The major route of excretion is the kidney, but strong evidence for a biliary excretion pathway also exists. Pilot therapy studies with [^{131}I]-labeled gastrin show significant antitumor efficacy compared to untreated reference controls. In accordance with preclinical data, good receptor targeting is observed at tumor sites within the stomach, gallbladder, and pancreas of cases with metastatic MTC. Such observations suggest that gastrin and its analogues may represent a useful new class of receptor binding peptides for the diagnosis and therapy of a variety of tumor types, including MTC and small cell lung cancer. Future preclinical and clinical studies will address in more detail the molecular features that render CCK-B receptor binding agents potentially useful candidates for *in vivo* scintigraphy and radionuclide therapy.

Targeting of cholecystokinin-B/gastrin receptors *in vivo*: Preclinical and initial clinical evaluation of the diagnostic and therapeutic potential of radiolabeled gastrin. Behr TM, Jenner N, Radetzky S, Béhe M, Gratz S, Yücekent S, Raue F, Becker W. Eur J Nucl Med 1998 Apr; 25 (4), pp. 424–30.

Thyroid Carcinoma/Metastatic Medullary Thyroid Cancer (MTC)/Cholecystokinin-B (CCK-B) and Gastrin Receptor Expressing Neoplasias

[^{111}Indium] ([^{111}In])-Diethylenetriamine Pentaacetic Acid (DTPA)-Octreotide/Pentagastrin Stimulation/ CCK [-Trp-Met-Asp-PheNH$_2$]/[^{111}In]-DTPA-D-Glu(1)-Minigastrin

Background Information: Nuclear medicine is engaged with the detection of pathological processes with the help of radionuclides. An interesting approach is to target antigens, symporters, or receptors with diagnostic and therapeutic radionuclides. Different peptide receptors like somatostatin, bombesin/gastrin-releasing peptide (GRP), or vasoactive intestinal peptide (VIP) are (over) expressed on cancer cells, and are therefore an ideal target for diagnosis and therapy with radiolabeled peptides. The somatostatin analogue OctreoScan (octreotide coupled with DTPA) can be labeled with [^{111}In] and is widely used in nuclear oncology for the staging of different tumors (e.g., carcinoids). Other peptides like neurotensin, bombesin/GRP, and VIP have been employed in (pre)clinical investigations. The staging of metastatic MTC with the conventional radiological procedures is sometimes difficult. The high sensitivity of the pentagastrin stimulation test in detecting primary or metastatic MTC indicates the presence of tumor, but its localization is often not possible. This reaction of the tumor cells to the pentagastrin stimulation test suggests a widespread expression of the corresponding receptor type on human MTC. Indeed, autoradiographic studies demonstrated CCK-B/gastrin receptors not only in > 90% of MTCs but in a high percentage of small cell lung cancers, stromal ovarian, and potentially a variety of other tumors, including gastrointestinal adenocarcinomas, neuroendocrine tumors, and malignant glioma.
Considerations: Candidate ligands of interest include a variety of CCK/gastrin-related peptides, all having in common the C-terminal CCK receptor binding tetrapeptide sequence-Trp-Met-Asp-PheNH$_2$ or derivatives thereof. They were members of the gastrin or cholecystokinin families, or possessed characteristics of both, which differ by the intramolecular position of a tyrosyl moiety. Stability of these agents and their affinity has been studied and optimized *in vitro* and *in vivo* along with the determination of their biodistribution and therapeutic efficacy tested in preclinical models.
Implementation: Develop and systematically optimize suitable radioligands for targeting CCK-B receptors *in vivo* and investigate their role in the staging and therapy of MTC and other CCK-B receptor expressing malignancies. Candidate ligands of interest include a variety of CCK/gastrin-related peptides, all having in common the C-terminal CCK receptor binding tetrapeptide sequence-Trp-Met-Asp-PheNH$_2$ or derivatives thereof.

Effectiveness of minigastrin targeting properties can futher be demonstrated in conditions of advanced metastatic disease (e.g., n = 8 cases) involving the injection of a dose-escalation administration protocol with potentially therapeutic activities of [^{90}Y]-labeled minigastrin derivative at 4- to 6-week intervals (30–50 mCi/m^2 per injection for a maximum of 4 injections).
Interpretation and Analysis: Best tumor uptake and tumor-to-non-tumor ratios are obtained with members of the gastrin family, due to their superior selectivity and affinity for the CCK-B receptor subtype. Radiometal-labeled derivatives of minigastrin show excellent targeting of CCK-B receptor expressing tissues in animals and healthy human volunteers. Preclinical therapy experiments in MTC-bearing animals show significant antitumor efficacy. In a related clinical study of 75 MTC cases with metastatic MTC, n = 43/75 suffered of known, and n = 32/75 had occult disease. Scintigraphy for CCK-B receptor expression performed with [^{111}In]-DTPA-D-Glu(1)-minigastrin in such instances reveals normal organ uptake essentially confined to the stomach (and to a lesser extent the gallbladder and, in premenopausal women, to normal breast tissue) as a result of CCK-B receptor specific binding, and to the kidneys as excretory organs. All tumor manifestations known from conventional imaging can be visualized as early as 1 hour postinjection, with increasing tumor-to-background ratios over time; frequently at least 1 lesion will be detected in cases with occult disease (e.g., n = 29/32 cases; patient-based sensitivity 91%). The lesions detected can include local recurrences, lymph node, pulmonary, hepatic, splenic, and bone (marrow) metastases.

In conditions of advanced metastatic disease injected with [^{90}Y]-labeled minigastrin derivative, using a dose-escalating protocol is associated with the development of hematologic and renal abnormalities. Such side effects appear to reflect a dose-limiting toxicity between 40 and 50 mCi/m^2. Some cases will experience partial remission (e.g., n = 2), some cases will stabilize a previously rapidly-progressing disease state (e.g., n = 4). Such findings suggest that

CCK-B receptor ligands may be a useful new class of receptor binding peptides for diagnosis and therapy of a variety of (CCK-B receptor expressing) tumor types. They allow for a sensitive and reliable staging of patients with metastatic MTC. Initial therapeutic results are promising, but nephrotoxicity is a major concern to be solved.

Cholecystokinin-B (CCK-B)/gastrin receptor targeting peptides for staging and therapy of medullary thyroid cancer and other CCK-B receptor expressing malignancies. Béhé M, Behr TM. Biopolymers 2002; 66 (6), pp. 399–418.

Thyroid (Cancer) Metastasis
[^{99m}Technetium] ([^{99m}Tc])-Methoxy-Isobutyl-Isonitrile (MIBI)

Application: Detection of thyroid cancer metastases that can serve as a supplemental diagnostic procedure to the measurement of serum thyroglobulin and radioiodine [^{131}I] whole-body scans in thyroidectomized cases of thyroid cancer.
Route of Administration: Intravenous.
Considerations: The imaging agent [^{99m}Tc]-MIBI has been proposed as a 1st-line diagnostic agent for the follow-up protocol of thyroid cancer, although the ability to detect small lung metastases is somewhat limited.
Implementation: Presence or absence of thyroid cancer can be judged applying several other diagnostic modalities, including serum thyroglobulin measurements, [^{131}I]-whole-body scan, bone scans, chest x-rays, computed tomography (CT), ultrasonography, histopathology, and monitoring the evolution of disease during follow-up periods. All scans are read on a lesion basis for detecting neck, lung, and bone metastases and also on a regional basis, namely head-neck, chest, and abdomen-pelvis-extremities (ab-p-ex) areas.
Interpretation and Analysis: Sensitivity of detection has been reported to be 94.4% (n = 17/18) for neck, 78.4% (n = 40/51) for lung, and 92.8% (n = 64/69) for skeletal lesions. Positive predictive value (PPV) and negative predictive value (NPV) were 96.3% (n = 26/27) and 97.7% (n = 43/44) for head-neck; 94.7% (n = 71/75) and 50.0% (n = 12/24) for chest; and 100.0% (n = 25/25) and 93.1% (n = 54/58) for ab-p-ex regions, respectively. For all scan sites taken together, PPV and NPV are 96.1% (n = 122/127) and 86.5% (n = 109/126), respectively.
Instrumentation: Computer-integrated nuclear medicine scintigraphic camera imaging.

Whole-body scintigraphy with [^{99m}Tc]-MIBI, [^{18}F]-FDG, and [^{131}I] in patients with metastatic thyroid carcinoma. Fridrich L, Messa C, Landoni C, Lucignani G, Moncayo R, Kendler D, Riccabona G, Fazio F. Nucl Med Commun 1997 Jan; 18 (1), pp. 3–9.

Thyroid Remnant and Thyroid Carcinoma Metastasis/Pre- and Postthyroid Abalation Diagnostics
[^{123}Iodine] ([^{123}I])/[^{131}Iodine] ([^{131}I])

Cellular/Molecular Mechanism of Action: Iodine is preferentially assimilated by the thyroid gland.
Application: Postoperative detection of thyroid remnants and/or thyroid carcinoma metastases. The uptakes of thyroablative doses of [^{123}I] by postoperative thyroid remnants and/or thyroid carcinoma metastases following diagnostic surveys with [^{131}I] or [^{123}I] can be compared by visual inspection.
Dosage: [^{131}I] (3–10 mCi) and [^{123}I] (300 μCi).
Implementation: Evaluation of [^{123}I] and [^{131}I] as diagnostic and therapeutic radiopharmaceutical agents (e.g., n = 26 survey cases receiving [^{131}I] at a diagnostic dose level of 3 to 10 mCi; and n = 14 cases receiving [^{123}I] at the usual diagnostic dose of 300 μCi). The age, sex, and tumor type of the 2 groups are not statistically different.
Human Model: Cases with a diagnostic scan demonstrating functioning tissue, remnant, and/or metastasis, following thyroidectomy for differentiated thyroid carcinoma. The age, sex, and tumor type in the 2 groups receiving either [^{123}I] or [^{131}I] are not statistically different.
Interpretation and Analysis: The uptake of the ensuing thyroablative dose of [^{131}I] appears, by visual inspection, to be impaired in slightly less than 80% of cases receiving [^{131}I] group (e.g., n = 20/26) and in none of the [^{123}I] group (e.g., n = 0/14: $p < 0.00003$). In [^{131}I] group cases, there is a suggestion of a dose response (e.g., the higher the administered activity of [^{131}I] for the diagnostic scan, the greater the decline in the subsequent uptake of the thyroablative dose [$p = 0.0007$]). Thyroid remnants or cervical lymph node metastases appear to be affected more frequently than are distant (pulmonary or skeletal) metastases ($p = 0.004$). Therefore, iodine uptake function may be suppressed by the absorbed radiation from the 3–10 mCi "diagnostic" scanning dose of [^{131}I]. In this regard, [^{123}I] may be a better initial diagnostic agent to be used prior to radioablation therapy.
Instrumentation: Computer-integrated nuclear medicine scintigraphic imaging instrumentation.

Superiority of iodine-123 compared with iodine-131 scanning for thyroid remnants in patients with differentiated thyroid cancer. Mandel SJ, Shankar LK, Benard F, Yamamoto A, Alavi A. Clin Nucl Med 2001 Jan; 26 (1), pp. 6–9.

Treatment Response (Radiation Therapy)/Glucose Metabolism/Amino Acid Metabolism/Nucleic Acid Metabolism
[^{18}F]-5-Fluorodeoxyuridine/L-Methyl-[^{14}C]Methionine/6-[^{3}H]Thymidine/2′-Deoxy-5-[^{18}F]Fluorouridine

Cellular/Molecular Mechanism of Action: Reflects neoplastic cell nucleic acid metabolism.
Application: Diagnostic imaging of neoplastic lesions.
Route of Administration: [^{18}F]-5-fluorodeoxyuridine (usually intravascular).
Implementation: Evaluation of metabolic tracers for glucose, amino acid, and nucleic acid metabolisms. 2-deoxy-2-[^{18}F]fluoro-D-glucose (^{18}FDG), L-methyl-[^{14}C]methionine (^{14}C-Met), [6-^{3}H] thymidine (^{3}H-Thd), 2′-deoxy-5-[^{18}F]fluorouridine (^{18}FdUrd), and the conventional radionuclide [^{67}Ga]-citrate can be used to assess the feasibility of monitoring the effectiveness of tumor radiotherapy using a quadruple tracer technique. In this context, 2 combinations of 4 tracers (^{18}FDG or ^{18}FdUrd, ^{14}C-Met, ^{3}H-Thd, and [^{67}Ga]) can be compared in a time-course study after single-dose irradiation (20 Gy) and also used in a dose-dependency study performed 6 days after 5, 10, 15, or 20 Gy of irradiation.
Animal Model: Rat AH109A tumor model.
Interpretation and Analysis: [^{18}F]-FDG shows a large change in uptake and a steady response to radiotherapy. Fluorodeoxyuridine shows a rapid decrease after radiotherapy, but the range of change in uptake is narrow. [^{67}Ga] cannot detect tumor response early after treatment but shows a marked change in uptake later. 6-^{3}H-Thd and [^{14}C]-Met show a rapid response to irradiation and a high sensitivity for monitoring radiotherapy, suggesting that they may be applicable for PET studies.

Tracer feasibility for monitoring tumor radiotherapy: A quadruple tracer study with fluorine-18-fluorodeoxyglucose or fluorine-18-fluorodeoxyuridine, L-[methyl-14C]methionine, [6-^{3}H]thymidine, and gallium-67. Kubota K, Ishiwata K, Kubota R, Yamada S, Tada M, Sato T, Ido T. J Nucl Med 1991 Nov; 32 (11), pp. 2118–23.

PANCREAS

See neoplastic disease section within this chapter for malignant and benign conditions affecting the pancreas.

Pancreas: Normal/Pancreatitis (Potential Application)
[^{99m}Technetium] ([^{99m}Tc])-Hexamethylpropyleneamine Oxime (HMPAO) Neutrophils

Cellular/Molecular Mechanism of Action: Granulocytes are capable of migration activity in response to chemotactic factors (stimuli).
Route of Administration: [^{99m}Tc]-HMPAO-labeled granulocytes (intravenous).
Dosage: [^{99m}Tc]-HMPAO-labeled granulocytes (mean = 5.42×10^7 cells in a 2 mL volume/cat).
Semi-Synthetic Methods: Autologous granulocytes are labeled *in vitro* with [^{99m}Tc]-HMPAO. Feline granulocytes can be successfully labeled with [^{99m}Tc]-HMPAO at a labeling efficiency of 15 to 42% (average of 27%).
Implementation: Evaluate the biodistribution of autologous [^{99m}Tc]-HMPAO-labeled granulocytes. In this context, autologous-origin [^{99m}Tc]-HMPAO-labeled granulocytes are injected intravenously, followed by the acquisition of whole-body scintigraphic images at 1, 5, 15, and 30 minutes and 1, 2, and 4 hours postadministration. At 12 to 24 hours, computed tomomgraphy (CT) images of the abdomen are taken both precontrast and postcontrast. Following CT imaging, a surgical pancreatic biopsy sample is collected for analysis. Less than 1 minute is often necessary to acquire a 500,000-count image.
Animal Model: Feline (anesthetized for the acquisition of CT images).
Interpretation and Analysis: Granulocytes distribute predominantly to the lung, spleen, and liver in order of decreasing activity. Only background activity can be identified in the region of the pancreas. The pancreas is easily identified on CT images of the abdomen. The pancreas is hypoattenuated relative to both the spleen and liver. Contrast image-enhancing media can improve the visualization of the pancreas with peak efficacy appreciated immediately, then gradually clearing over a 30-minute test period. Following contrast medium administration the pancreas remains hypoattenuated relative to the spleen. Analysis of biopsy specimens using the animal model described usually confirms the absence of pancreatic inflammation and appreciation of no adverse effects as a result of pancreatic biopsy. Both CT and radiolabeled granulocytes appear to hold promise as imaging procedures for the detection of feline pancreatitis. Normal parameters may be altered in the face of inflammation, facilitating the detection of feline pancreatitis. Data from cases of suspect feline pancreatitis are needed to evaluate these methods for clinical utility.

Evaluation of the feline pancreas using computed tomography and radiolabeled leukocytes. Head LL, Daniel GB, Tobias K, Morandi F, DeNovo RC, Donnell R. Vet Radiol Ultrasound 2003 Jul–Aug; 44 (4), pp. 420–8.$eref

RENAL SYSTEM

Glomerular Filtration Function
[^{99m}Technetium] ([^{99m}Tc])-Mercaptoacetyltriglycine (MAG3)/[^{123}I]-Ortho-Iodohippuric Acid (OIH)

Cellular/Molecular Mechanism of Action: Mercaptoacetyltriglycine and OIH are passively excreted into the urine by mechanisms of plasma filtration at the level of the renal glomerulus.
Application: Evaluation of renal glomerular function/perfusion.
Route of Administration: [^{99m}Tc]-MAG3 and [^{123}I]-OIH (intravascular).
Implementation: Evaluation of renal function based on analysis of scintigraphic clearance of [^{99m}Tc]-MAG3 and [^{123}I]-OIH.
Human Model: Cases of impaired renal function (n = 12 patients).
Interpretation and Analysis: MAG3 renal scintigraphy provides better quality and functional information compared to OIH. The MAG3 and OIH renograms show identical relative kidney uptake and T_{max}, but $T_{1/2}$ of MAG3 is longer ($p < 0.001$). The plasma clearance of MAG3 is lower than that of OIH, but they correlate significantly ($r = 0.87$, $p < 0.005$). Also, the plasma clearances of MAG3 and *para*-aminohippuric acid (calculated by the standard clearance technique) show good correlation ($r = 0.77$, $p < 0.05$). Urinary excretion during the 1st 60 minutes after injection is the same for the 2 radiopharmaceuticals. Therefore, [^{99m}Tc]-MAG3 can function as a suitable alternative to [^{123}I]-OIH for renal scintigraphic imaging.

Clinical assessment of [^{99m}Tc]-MAG3 scintigraphy for impaired renal function. Sato M, Hirayama K, Ishikawa N, Takeda T, Wu J, Itai Y, Kobayashi M, Koyama A. Kaku Igaku 1994 Jan; 31 (1), pp. 75–84.

Glomerular Filtration/Glomerular Injury/(Minimal Change Glomerulonephritis)
[^{99m}Technetium] ([^{99m}Tc])- or [^{111}Indium] ([^{111}In])-Diethylenetriamine Pentaacetic Acid (DTPA)/[^{131}I]-Hippuran Alternative/[^{99m}Tc]-Glucoheptonate (GHA) Alternative/[^{99m}Tc]-Dimercaptosuccinate (DMS) Alternative

Cellular/Molecular Mechanism of Action: The agents [^{131}I]-hippuran, [^{99m}Tc]-GHA, [^{99m}Tc]-DMS, and [^{99m}Tc]- and [^{111}In]-DTPA are retained within the intravascular compartment and passively eliminated in the urine by glomerular filtration.
Application: Renal diagnostic agents.
Route of Administration: Intravenous.
Animal Model: Glomerular lesions can be induced by intravenous injection of puromycin aminonucleoside (PA) 9 days before radionuclide studies (model of spontaneous "minimal change" glomerulonephritis in humans).
Interpretation and Analysis: Computer-generated early renal uptake of [^{99m}Tc]-DTPA or GHA correlates with the glomerular filtration rate (GFR) quantitated by biexponential plasma clearance of DTPA administered by single intravenous injection. The early renal uptake of hippuran and DMS correlates poorly with GFR as assessed by DTPA clearance. However, the 2-hour renal retention of DMS correlates well with the DTPA clearance. None of the parameters measured with [^{131}I]-hippuran correlate well with DTPA clearance, probably because of decreases in protein plasma binding of hippuran secondary to hypoproteinemia. None of the agents are superior to labeled DTPA for the detection of glomerular damage in this experimental model.

Detection of diffuse glomerular lesions in rats: I. Comparisons of conventional radioactive agents. McAfee JG, Thomas FD, Subramanian G, Lyons B, Roskopf M. J Nucl Med 1986 Apr; 27 (4), pp. 502–12.

Nephro-Urology Imaging Agent
[^{99m}Technetium] ([^{99m}Tc])-Malic Acid/[^{99m}Tc]-Dimercaptopropionic Acid

Implementation: Evaluation of the fates of thalidomide and norphenylephrine and safety evaluation of some xenobiotics includ-

ing food additives, plasticizers, and domestic chemical products performed in animals using synthesized [^{14}C]- or [^{3}H]-labeled compounds.

Interpretation and Analysis: Of several agents examined, 2 new radiopharmaceuticals, [^{99m}Tc]-malic acid and [^{99m}Tc]-dimercaptopropionic acid, have displayed effectiveness as renal imaging agents when administered at adequate concentrations in animal models and humans. Useful information can be obtained for the diagnosis of renal diseases using both radiopharmaceutical agents.

Application of radionuclides in pharmaceutical fields. Tanaka A. Yakugaku Zasshi 2000 Jun; 120 (6), pp. 506–19.

Renal Artery Stenosis (RAS): Vascular Hypertension/ Renal Ischemia/[RAS > 50%] *[^{99m}Technetium] ([^{99m}Tc])-Mercaptoacetyltriglycine (MAG3)/Captopril Test*

Cellular/Molecular Mechanism of Action: Captopril inhibits the biochemical activity of angiotensin-converting enzyme (ACE inhibitor).

Physiological Mechanism of Action: Angiotensin in its most active form promotes increased vascular tone.

Route of Administration: Captopril (oral).

Dosage: Captopril (50 mg).

Implementation: Evaluation of vascular hypertension utilizing renal scintigraphic imaging facilitated by the application of [^{99m}Tc]-MAG3 1 hour after captopril premedication. Baseline studies are obtained only for those cases showing abnormal findings in provocative studies and after having undergone previous renal arteriography analysis.

Human Model: Cases with vascular hypertension (e.g., n = 82).

Interpretation and Analysis: Sensitivity and specificity for the detection of RAS > 50% is approximately 89% and 91%, respectively. After captopril administration, tracer parenchymal transit time increases significantly in ischemic kidneys (334 ± 93 seconds in baseline conditions vs 468 ± 96 seconds after captopril, $p < 0.001$) but not in kidneys without RAS or RAS < 50% (243 ± 46 seconds vs 271 ± 95 seconds, p = non-significant). False-positive responses are mostly bilateral and associated with marked decreases in blood pressure. [^{99m}Tc]-MAG3 is an effective compound for detecting RAS ≥ 50% with captopril renal scintigraphy. Performing the provocative test as a 1st step considerably reduces the number of scintigraphic studies required.

Use of technetium-^{99m}-MAG3 for renal scintigraphy after angiotensin-converting enzyme inhibition. Dondi M, Monetti N, Fanti S, Marchetta F, Corbelli C, Zagni P, De Fabritis A, Losinno F, Levorato M, Zuccalá. J Nucl Med 1991 Mar; 32 (3), pp. 424–8.

Renal Failure: Acute/Cardiac Failure: Congestive/ Endothelin Receptor Expression: Antagonist Receptor Occupancy/Individualization of Endothelin Receptor Antagonist Dosage *[^{125}I]ET-1/BQ-123/BQ-788/L-749,329*

Cellular/Molecular Mechanism of Action: The agents BQ-123 and BQ-788 bind to and block ETA and ETB type endothelin receptor complexes (receptor antagonists). Conversely, L-749,329 (non-peptide antagonist) has a relatively balanced affinity for each of the 2 endothelin receptor subtypes.

Physiological Mechanism of Action: Endothelin is 1 of the most potent vasoconstrictors known. As a point of reference, prostacycline (PGI_2) is 1 of the most potent vasodilatory agents identified to date and thromboxane TXA2 is a potent vasocontrictive agent.

Background Information: Endothelin has been implicated in various diseases, including acute renal failure and congestive heart failure. Such observations imply that these disease states can possibly be managed with endothelin receptor antagonists. However, establishing the dosages for these antagonists may be difficult because no convenient physiologic indicator of action exists and because of complexities in receptor function. Two receptor subtypes have been identified for which selective antagonists have been reported (e.g., BQ-123 for the ETA receptor and BQ-788 for the ETB receptor). Of the 3 natural peptide hormones (ET-1, ET-2, and ET-3), ET-1 exhibits high affinity for both subtypes of receptor.

Application: Characterization of the relative expression of 2 endothelium receptor subtypes in a manner that provides information for establishing individualized dosage schedules for endothelin receptor antagonists pertaining to the management of various disease states, including acute renal failure and congestive heart failure.

Implementation: Evaluation of the *in vivo* biodistribution of [^{125}I]ET-1 with and without the presence of selective peptide antagonists, and a non-peptide antagonist (L-749,329). The agent [^{125}I]ET-1 possesses binding avidity for endothelin receptor complexes.

Animal Model: Rat.

Animal Model: Primate (rhesus monkey).

Interpretation and Analysis: The agents BQ-123, BQ-788, and L-749,329 inhibit binding consistent with physical interaction with a single receptor site. However, the sum of inhibition by the selective antagonist is greater than 100% (as defined by inhibition with L-749,329), which suggests (i) lower *in vivo* selectivity than determined *in vitro*, and/or (ii) receptor subtype interactions. The latter explanation is supported, in part, by *in vitro* autoradiographic studies as well as investigations in isolated tissues and cell preparations. Synthetic ET-1 radiolabeled with [^{123}I] facilitates the acquisition of images that reflect receptor distribution in 2 *in vivo* animal models. Utilizing planar, non-invasive imaging, it is possible to visualize the occupancy of endothelin receptor by antagonists in both the kidney and lung. [^{123}I]ET-1 can therefore be used to determine appropriate clinical dosages of antagonist needed for receptor saturation.

Radioiodinated endothelin-1: A radiotracer for imaging endothelin receptor distribution and occupancy. Gibson RE, Fioravanti C, Francis B, Burns HD. Nucl Med Biol 1999 Feb; 26 (2), pp. 193–9.

Renal Function: Measurement and Quantification *[^{99m}Technetium] ([^{99m}Tc])-Mercaptoacetyltriglycine*

Background Information: Pharmacokinetic modeling based on compartmentalization has provided a valuable tool to assess the clearance patterns of various glomerular and tubular agents. However, no models have been proposed thus far that combine vascular data and imaging data in order to gain a deeper knowledge about renal pathophysiology and to obtain more diagnostic information of clinical relevance. To this aim, investigations have utilized a 4-pool model for the evaluation of separate renal functions.

Application: Evaluation of renal function in cases of renal disease and in the screening of potential renal transplant donors.

Implementation: Evaluation of a 4-pool model based on the identification of the 2 kidneys as 2 distinct pools. Such an approach makes it possible to integrate the separate kidney contributions derived from *in vivo* imaging data, and allows quantitative measurement of many parameters specific to each kidney.

Human Model: Cases without evidence of disease (n = 10 volunteers) compared to conditions of various types of renal disease (n = 20).

Interpretation and Analysis: The parameters TERR, TERL, MRTR, MRTL, vR, vL, k3R-1, K3L-1 permit the differentiation of normal from abnormal states of renal function, as well as being able to distinguish between monolateral and bilateral renal disease in cases known to have abnormal renal function. The diagnostic approach applied combines the advantages of plasma clearance methods with those derived by gamma camera imaging, while also making it possible to quantitate differential parameteters of renal function. Such features may be clinically relevant in renal transplant donors, where full knowledge of renal pathophysiology could guide the procedure.

A theoretical 4-compartment model to evaluate separate kidney technetium-^{99m}-MAG3 kinetics in humans. Curti G, DeMartini D, Santaniello B, Taddei G, Fresco GF. Kidney Int 1998 Dec; 54 (6), pp. 2029–36.

Renal Glomerular Filtration Rate
[^{99m}Technetium] ([^{99m}Tc])-Diethylenetriamine Pentaacetic Acid (DTPA)/[Creatinine Clearance Test]/ Captopril Test Enhancement

Cellular/Molecular Mechanism of Action: Creatinine and DTPA per se do not exert a molecular or cellular or biological effect. Instead, they function as marker molecules because they are passively excreted into the urinary filtrate from the plasma.
Application: Evaluation of renal glomerular filtration rate especially in scenarios where urine cannot be collected for analysis by conventional analysis procedures (creatinine clearance test [CCT]).
Route of Administration: [^{99m}Tc]-DTPA (intravascular).
Implementation: Computer validation for implementing the Gates' method for calculating parameters associated with radionuclide glomerular filtration rate (RGFR). Accuracy of the original method can be improved by replacing the Tonnesen's formula that estimates renal depth with direct measurement from lateral views to calculate tissue attenuation correction.

Evaluation of renal glomerular filtration rate can be achieved applying both the CCT and dynamic [^{99m}Tc]-DTPA renal scintigraphy (DRS). Radionuclide glomerular filtration rate is quantified from the attenuation-corrected absolute DTPA uptake of the kidneys on DRS between 120 and 180 seconds after injection. Attenuation correction is estimated using the lateral views of the kidneys taking into account the distance from the computed geometric center of the kidneys to the posterior body surface along a line vertical to the collimator surface. CCT and glomerular filtration rate estimates from DRS are then compared by linear regression.

Human Model: Chronic renal failure (n = 38 cases).
Interpretation and Analysis: Radionuclide glomerular filtration rate estimates agree well with CCT, yielding a correlation coefficient of approximately 0.92 (e.g., n = 38 cases) and 0.90 in cases suffering from chronic renal failure (e.g., n = 11). The proposed modifications improve RGFR accuracy to the precision range of blood sample–based methods. The modified method requires little additional work and no extra cost in cases undergoing DRS. Radionuclide glomerular filtration rate calculation may be advantageous in cases when 24-hour urine collection for CCT cannot be obtained, and it should improve the accuracy of the captopril test.

Renal depth estimates to improve the accuracy of glomerular filtration rate. Steinmetz AP, Zwas ST, Macadziob S, Rotemberg G, Shrem Y. J Nucl Med 1998 Oct; 39 (10), pp. 1822–9.

Renal Glomerular Function/Renal Allograft/ Transplant Rejection
[^{99m}Technetium] ([^{99m}Tc])-Acidic Fibroblast Growth Factor 1 (FGF-1)/[^{99m}Tc]-Mercaptoacetyltriglycine (MAG3)

Background Information: Acidic fibroblast growth factor functions as a potent hormonal inducer of *in vivo* wound repair. In addition, involvement of FGF-1 in a number of pathophysiological conditions, including chronic human renal allograft rejection, has been described. Consequently, there is an increasing need to monitor FGF-1 pharmacokinetics and distribution for both therapeutic and diagnostic purposes.
Route of Administration: [^{99m}Tc]-MAG3 and [^{99m}Tc]-labeled FGF-1 (intravenous).
Implementation: Evaluation of renal function facilitated by the application of dynamic [^{99m}Tc]-MAG3 imaging, and subsequent image analysis of [^{99m}Tc]-labeled FGF-1 ([^{99m}Tc]-FGF-1) biodistrubution profiles. Complementary validation investigations entail performing microautoradiography of harvested kidneys to facilitate determination of [^{99m}Tc]-FGF-1 compartmental localization.

Animal Model: Rat (sham-operated, syngeneic renal transplanted, and allogeneic renal transplanted rats).
Interpretation and Analysis: Allogeneic renal transplants appear grossly abnormal on [^{99m}Tc]-MAG3 renal scans. In scenarios of this type, a significant reduction in [^{99m}Tc]-FGF-1 renal binding can be detected by imaging analyses, in contrast to renal binding in sham-operated and syngeneic renal transplanted scenarios, which are not significantly different. Both groups of renal transplants show a redistribution of FGF-1 to the glomerular compartment. Therefore, [^{99m}Tc]-FGF-1 serves as a new radiotracer that can effectively measure *in vivo* targeting of growth factor. Reduced renal binding of [^{99m}Tc]-FGF-1 in the allogeneic transplanted kidney is consistent or correlates with decreases in blood flow. Unique glomerular targeting of [^{99m}Tc]-FGF-1 in the transplanted kidney provides additional evidence supporting a role for this growth factor in the pathogenesis of chronic rejection.
Instrumentation: Anger gamma camera.

Glomerular targeting of acidic fibroblast growth factor-1 in renal transplanted rats. Zinn KR, Kelpke S, Akhi K, Viera L, Chaudhuri TR, Thompson JA. Transplantation 2002 May 15; 73 (9), pp. 1447–54.

Renal Tubular Function/Renal Plasma Flow
[^{99m}Technetium] ([^{99m}Tc])-Labeled Hippurate Analogues

Cellular/Molecular Mechanism of Action: Radiolabled hippurate analogues are rapidly cleared from the blood (rat) by the kidney. Due to their extensive elimination by the kidney, they can serve as imaging agents during periods of peak removal from the plasma.
Application: The 7 [^{99m}Tc]-labeled hippurate analogues: [^{99m}Tc]-hippurate, [^{99m}Tc]-alpha-hydroxyhippurate, [^{99m}Tc]-*m*-hydroxyhippurate, [^{99m}Tc]-*o*-hydroxyhippurate [^{99m}Tc]-salicylglycine ([^{99m}Tc]-SG)], [^{99m}Tc]-*p*-hydroxyhippurate, [^{99m}Tc]-salicylglycylglycine, and [^{99m}Tc]-salicylglycylglycylglycine can all be applied for imaging the kidney.
Route of Administration: Intravenous.
Considerations: The imaging agent [^{99m}Tc]-SG has the same desirable biological properties of the 2 diagnostic agents, [^{99m}Tc]-mercaptoacetyltriglycine ([^{99m}Tc]-MAG3) and [^{99m}Tc]-dimercaptosuccinate ([^{99m}Tc]-DMSA).

Interpretation and Analysis: A fraction of [^{99m}Tc]-SG administered systemically displays a definite transit time within the kidney and is excreted rapidly into the urine, being similar to [^{99m}Tc]-MAG3. The binding ratio to the plasma proteins is 96.0% (91.1% associated with albumin), being higher than that for [^{99m}Tc]-DMSA, at 30 minutes. Lipophilicity analysis reveals far less pH-dependent changes in a range between pH 4.0–7.4. [^{99m}Tc]-SG distributes about 91% into the renal cortex, being similar to that of [^{99m}Tc]-DMSA. The biological properties of [^{99m}Tc]-SG suggest that it is a promising agent for measuring renal plasma flow and renal morphology.

Synthesis and preclinical evaluation of technetium-^{99m}-labeled hippurate analogues. Fukuoka M, Kiyohara T, Kobayashi T, Kojima S, Tanaka A, Kubodera A. Nucl Med Biol 1995 Feb; 22 (2), pp. 181–91.

RESPIRATORY SYSTEM

Adult Respiratory Distress Syndrome (ARDS) *[^{111}Indium] ([^{111}In])-Labeled (aICAM-1)*

Cellular/Molecular Mechanism of Action: Possesses binding avidity for leukocyte cell populations.
Application: Detection of foci associated with sepsis and inflammation.
Considerations: Previous studies utilizing the bleomycin-induced lung injury model suggest that [^{111}In]-labeled anti-intercellular adhesion molecule-1 (e.g., rat aICAM-1) might be a useful ARDS diagnostic agent. Lung inflammation can be detected with [^{111}In]-aICAM-1 very early in the course of the disease. These results support the suggestion that [^{111}In]-aICAM-1 could be a very early, highly specific ARDS diagnostic agent and may be useful to detect a wide range of inflammatory conditions.
Implementation: Evaluation of lung injury as a function of the biodistribution, scintigraphic images, and lung ICAM-1 upregulation following the administration of [^{111}In]-labeled polymorphonuclear leukocytes (rat PMNs), [^{111}In]-aICAM-1, [^{111}In]-labeled normal IgG (murine nmIgG), and [^{111}In]-labeled serum albumin (rat RSA) injected 18–24 hours before animal model termination.

Animal Model: Rat (control and post–oleic acid–induced injury).

Interpretation and Analysis: [^{111}In]-RSA and [^{111}In]-nmIgG localize in inflamed lung by 5 minutes postinjury (PI). [^{111}In]-PMN uptake increases significantly only at 24 hours PI. [^{111}In]-aICAM-1 localization increases significantly (30–60%) at 1 hour PI and remains elevated up to 24 hours PI. Lung/blood ratios (L/B) at 1 and 4 hours PI are very low (< 0.6) for [^{111}In]-nmIgG and [^{111}In]-PMN; however, for [^{111}In]-aICAM-1, they are > 1 and 25–60% higher than those for control samples. A low L/B suggests poor inflammation detection on the images. Images and region-of-interest (ROI) analysis confirm that only [^{111}In]-aICAM-1 can distinguish inflamed lungs at 4 hours PI. ICAM-1 is upregulated at 4 and 24 hours PI.

Early detection of oleic acid–induced lung injury in rats using [^{111}In]-labeled anti-rat intercellular adhesion molecule-1. Weiner RE, Sasso DE, Gionfriddo MA, Thrall RS, Syrbu S, Smilowitz HM, Vento J. J Nucl Med 2001 Jul; 42 (7), pp. 1109–15.

Adult Respiratory Distress Syndrome (ARDS)/ Respiratory Distress Syndrome of Newborns (RDS) *[^{99m}Technetium] ([^{99m}Tc])-Exogenous Natural Surfactant (ENS)*

Cellular/Molecular Mechanism of Action: Pulmonary surfactant is a lipoproteic biological fluid secreted by alveolar Type II cells that prevents collapse of respiratory alveoli by reducing the surface tension imposed on these structures.
Application: Detection of RDS and ARDS.
Dosage: [^{99m}Tc]-ENS (900–1,110 MBq).
Considerations: Surfactant deficiency is the major factor responsible for RDS and ARDS. Since 1980, the exogenous administration of surfactant has been studied for the treatment of these syndromes.
Semi-Synthetic Methods: Exogenous natural surfactant (ENS) applied as a radiopharmaceutical precursor following radiolabeling with [^{99m}Tc] to produce [^{99m}Tc]-ENS.
Implementation: Evaluation of [^{99m}Tc]-ENS for aerial/ventilation lung scintigraphy (3 minute nebulization) compared to [^{99m}Tc]-diethylenetriamine pentaacetic acid (DTPA).

Human Model: Volunteers ($n = 5$; some of whom smoke).

Interpretation and Analysis: [^{99m}Tc]-ENS images are of at least the same quality as [^{99m}Tc]-DTPA images. However, in some smoking volunteers, the [^{99m}Tc]-DTPA images show some regions that seemed to be not well ventilated, although these areas appear well ventilated in [^{99m}Tc]-ENS imaging. Such observations suggest that [^{99m}Tc]-ENS can be used for ventilation scintigraphy to allow the observation of some areas that cannot be visualized using [^{99m}Tc]-DTPA as a ventilation agent.

[^{99m}Tc]-ENS ventilation scintigraphy: Preliminary study in human volunteers. Calmanovici G, Boccio J, Goldman C, Hager A, De Paoli T, Alak M, Degrossi O, García del Río H, Nicolini J, Caro R, Zubillaga M. Nucl Med Biol 2000 Feb; 27 (2), pp. 215–8.

The pulmonary surfactant system: Physiology, pathologies associated with its alteration, and exogenous administration as therapeutic and diagnostic agent. Calmanovici G, Boccio J, Lysionek A, Salgueiro M, Caro R, Hager A, de Paoli T, Zubillaga M. Acta Physiol Pharmacol Ther Latinoam 1998; 48 (4), pp. 175–90.

Amiodarone-Induced Pulmonary Toxicity (AIPT) *[^{99m}Technetium] ([^{99m}Tc])-Diethylenetriamine Pentaacetic Acid (DTPA)/Gallium-67 [^{67}Ga]*

Application: Amiodarone hydrochloride, which is used in life-threatening cardiac tachyarrhythmia, has been known to cause AIPT as a complication.
Route of Administration: Inhalation of aerosolized preparations.
Implementation: Investigate the clinical value of [^{99m}Tc]-DTPA scintigraphy in cases with AIPT in comparison with [^{67}Ga] scan imaging. Both [^{67}Ga] and [^{99m}Tc]-DTPA are delivered as an aerosol prior to scintigraphy imaging, in addition to performing various laboratory tests.

Human Model: Cases of AIPT ($n = 7$; Type A); cases receiving AIPT without pulmomary toxicity ($n = 8$; Type B); and reference control subjects ($n = 11$).

Interpretation and Analysis: [^{67}Ga] scintigraphy is positive in a modest percentage of cases of AIPT (e.g., $n = 4/7$), but no abnormalities may be detected in any Type B cases (e.g., $n = 0/8$). A positive correlation can be found ($r = 0.52$, $p < 0.05$) between k_{ep} values determined by [^{99m}Tc]-DTPA aerosol scintigraphy and the cumulative dose of amiodarone. The mean k_{ep} values are approximately 2.04% ± 0.85%/min, 1.30% ± 0.42%/min, and 0.86% ± 0.19%/min for groups A, B and C, respectively. The mean clearance rate of Type A case is significantly faster than that of normal reference controls ($p < 0.0005$) and Type B cases ($p = 0.028$). In addition, there is a significant difference between Type B and Type C cases ($p = 0.015$). In conclusion, [^{67}Ga] lung scintigraphy is a useful method for the detection of AIPT, but [^{99m}Tc]-DTPA aerosol scintigraphy offers better results

than [^{67}Ga] scintigraphy. Early changes in [^{99m}Tc]-DTPA clearance may be observed in cases receiving amiodarone. The k_{ep} value in cases with AIPT is noticeably increased with respect to normal reference controls. Given its favorable physical properties, low cost, lower radiation burden, and ability to be used as an objective measure for the pulmonary clearance rate, [^{99m}Tc]-DTPA aerosol scintigraphy appears to be promising in cases receiving amiodarone therapy.

Technetium-^{99m}-DTPA aerosol scintigraphy in amiodarone-induced pulmonary toxicity in comparison with Ga-67 scintigraphy. Dirlik A, Erinc R, Ozcan Z, Atasever A, Bacakoglu F, Nalbantgil S, Ozhan M, Burak Z. Ann Nucl Med 2002 Nov; 16 (7), pp. 477–81.

Deposition Estimation/Respiratory Nebulization (Inhalation)
[^{99m}Technetium] ([^{99m}Tc])-Tobramycin-Serum Albumin

Cellular/Molecular Mechanism of Action: The albumin component of [^{99m}Tc]-serum albumin serves to increase the molecular weight of the agent complex in a manner that hinders the rate of diffusion across biological membranes and under certain circumstances encourages uptake by the mononuclear phagocytic system.

Background Information: The ability to predict drug deposition of inhaled drugs used in cystic fibrosis (CF) is important if there is a need to target specific doses of drug to the lungs of individual cases. The gold standard of measuring pulmonary deposition is the quantification of an aerosolized radiolabel either mixed with the drug solution or tagged directly to the compound of interest. Accuracy of the quantification can be assured if there is agreement between the amount of radioactivity before and after administration. Before administration, the radiolabel is concentrated in the well of the nebulizer, whereas after administration, it is distributed throughout the nebulizer, the expiratory filter and connectors, and the upper airway, stomach, trachea, and lung. Not only is the geometry of the distribution that is presented to the gamma camera different, but there are different attenuation factors for the various body tissues.

Application: Preparations of [^{99m}Tc]-tobramycin-serum albumin can be used to evaluate the accuracy of the quantification of pulmonary deposition and compare *in vitro* nebulizer performance with that measured *in vivo* during the deposition study.

Route of Administration: [^{99m}Tc]-tobramycin-serum albumin (nebulized inhalation).

Dosage: [^{99m}Tc]-tobramycin-serum albumin (80 milligrams).

Implementation: Delivery of 80 milligrams of tobramycin and [^{99m}Tc] bound to human serum albumin using a Pari LC Jet Plus (Pari Respiratory Equipment, Inc., Richmond, VA) breath-enhanced nebulizer.

Human Model: Normal (n = 10).

Interpretation and Analysis: Approximately 99 ± 2% of the initial radioactivity can be accounted for *in vivo* postdelivery. The fraction of [rate of lung deposition/total body deposition] is the *in vivo* respirable fraction (0.62 ± 0.07), which closely agrees with *in vitro* measurements of respirable fraction (0.62 ± 0.04). Drug output measured by the change in weight and concentration in the nebulizer systematically overestimates drug output measured by deposition studies. The results indicate that 11.8 of the initial 80 mg is deposited in the lungs. This technique could be adapted to accurately quantify the amount of deposition on any inhaled therapeutic agent, but caution must be used when extrapolating performance of a nebulizer on the bench to expected deposition in clinical cases.

Accounting for radioactivity before and after nebulization of tobramycin to insure accuracy of quantification of lung deposition. Coates AL, Dinh L, MacNeish CF, Rollin T, Gagnon S, Ho SL, Lands LC. J Aerosol Med 2000 Fall; 13 (3), pp. 169–78.

Inflammation of Endothelium: Acute Pulmonary/Bleomycin-Induced Pulmonary Injury
[^{111}Indium] ([^{111}In])-Anti-ICAM-1 Monoclonal Antibody

Cellular/Molecular Mechanism of Action: The antibody component of [^{111}In]-anti-ICAM-1 monoclonal IgG antibody recognizes and physically binds to intracellular adhesion molecule-1 complexes expressed on the exterior surface membrane of "activated" endothelial cells.

Application: Detection of endothelial injury and acute vascular inflammatory responses, including alterations associated with bleomycin-induced pulmonary injury.

Route of Administration: [^{111}In]-anti-ICAM-1 monoclonal IgG antibody (intravenous).

Implementation: Evaluation of alterations in endothelial intracellular adhesion molecule expression following bleomycin-induced pulmonary injury employing [^{111}In]-anti-ICAM-1 monoclonal IgG antibody (e.g., [^{111}In*]-aICAM-1) with findings compared to [^{111}In]-labeled normal mouse IgG (e.g., [^{111}In*]-nmIgG). Tissue samples are harvested 24 hours following image acquisition and their radioactivity measured. Lung tissue can be cryostat-sectioned to detect the presence of ICAM-1 by immunofluorescence, and the upregulation of LFA-1α identified in blood polymorphonuclear leukocytes (PMNs) using fluorescence-activated cell-sorter (FACS) analysis.

Animal Model: Rat (lung injury induced by intratracheal bleomycin injection 4 or 24 hours before humane sacrifice).

Interpretation and Analysis: Evaluation of bleomycin-induced lung injury utilizing [^{111}In]-anti-ICAM-1 monoclonal IgG antibody reveals that the percent injected dose/organ in lungs both at 4 and 24 hours postbleomycin increases significantly in contrast to values observed in either uninjured reference controls or with the administration of [^{111}In]*nmIgG. At 4 and 24 hours postinjury, the target-to-blood (T/B) ratio is 8/1 and 6/1, respectively. For [^{111}In]*nmIgG, the T/B ratio at 4 hours is 0.5/1 and 0.4/1 at 24 hours. [^{111}In]-anti-ICAM-1 monoclonal IgG antibody preparations administered post-bleomycin-induced pulmonary injury produce 4- and 24-hour images that can easily be distinguished from uninjured reference controls. All images with [^{111}In]*nmIgG show only cardiac blood-pool and liver activity with little lung activity. Lung ICAM-1 immunofluorescence intensity increases in the bleomycin-treated pulmonary samples compared to uninjured lungs. Expression of LFA-1α on PMNs increases 19% and 210% at 4 hours and 24 hours postinjury, respectively, compared to control values. Biodistribution and imaging data therefore demonstrate that [^{111}In]-anti-ICAM-1 monoclonal IgG antibody is capable of detecting early acute bleomycin-induced lung injury. Immunofluorescence and FACS data suggest that [^{111}In]-anti-ICAM-1 monoclonal IgG antibody uptake is a specific process. Monoclonal antibody preparations possessing such attributes have potential as an early radionuclide detector of acute inflammations.

Early detection of bleomycin-induced lung injury in rat using indium-111-labeled antibody directed against intercellular adhesion molecule-1. Weiner RE, Sasso DE, Gionfriddo MA, Syrbu SI, Smilowitz HM, Vento J, Thrall RS. J Nucl Med 1998 Apr; 39 (4), pp. 723–8.

Inflammatory Pulmonary Disease/Acute Respiratory Distress Syndrome (ARDS)
[^{111}Indium] ([^{111}In])-Labeled Neutrophils/[^{111}In]-aICAM-1/[^{111}In]-Labeled Normal Mouse IgG (nmIgG)/[^{111}In]-Labeled Rat Serum Albumin (RSA)

Cellular/Molecular Mechanism of Action: The monoclonal immunoglobulin aICAM-1 recognizes and physically binds to ICAM-1 complexes (intracellular adhesion molecule-1). Neutrophils

through mechanisms of chemotactic activity migrate to anatomical regions of inflammation and sepsis.

Background Information: Previous study of the bleomycin-induced lung injury models has revealed that [^{111}In]-labeled anti-rat intercellular adhesion molecule-1 (aICAM-1) might be a useful ARDS diagnostic agent.

Application: Detection and characterization of conditions of inflammation within the lung similar to that associated with ARDS.

Implementation: Evaluation of the biodistribution, scintigraphic imaging profiles, and lung ICAM-1 upregulation utilizing [^{111}In]-labeled polymorphonuclear leukocytes (PMNs), [^{111}In]-aICAM-1, [^{111}In]-labeled nmIgG, and [^{111}In]-labeled RSA injected 18–24 hours before euthanasia.

Animal Model: Rat neutrophils (polymorphonuclear leukocytes or PMNs) and rat *in vivo* radioactive distribution studies following induced injury with oleic acid.

Interpretation and Analysis: [^{111}In]-RSA and [^{111}In]-nmIgG localize in inflamed lung at 5 minutes postinjury (PI). [^{111}In]-PMN uptake increases significantly only at 24 hours PI. [^{111}In]-aICAM-1 localization increases significantly (30–60%) at 1 hour PI and remains elevated up to 24 hours PI. Lung/blood ratios (L/B) at 1 and 4 hours PI are very low (< 0.6) for [^{111}In]-nmIgG and [^{111}In]-PMN; however, for [^{111}In]-aICAM-1, values are > 1 and 25–60% higher than those observed for reference controls. A low L/B suggests poor detection of inflammation on acquired images. Images and region-of-interest (ROI) analysis confirm that only [^{111}In]-aICAM-1 can distinguish inflamed lungs at 4 hours PI. ICAM-1 is upregulated at 4 and 24 hours PI. Under certain circumstances, [^{111}In]-aICAM-1 can detect lung inflammation very early in the course of the disease, which suggests that [^{111}In]-aICAM-1 could be a very early, highly specific ARDS diagnostic agent and may be useful to detect a wide range of inflammations.

Early detection of oleic acid–induced lung injury in rats using [^{111}In]-labeled anti-rat intercellular adhesion molecule-1. Weiner RE, Sasso DE, Gionfriddo MA, Thrall RS, Syrbu S, Smilowitz HM, Vento J. J Nucl Med 2001 Jul; 42 (7), pp. 1109–15.

Pulmonary Metabolism: FMO-II
[^{11}C]-Octylamine

Cellular/Molecular Mechanism of Action: Preferentially sequesters within pulmonary tissues.

Physiological Mechanism of Action: Substantial levels of flavin-containing monooxygenase Type II (FMO-II) can be found associated with microsomal enzyme fractions; it possesses considerably high activities for primary amines like octylamine.

Application: Characterization of metabolizing schemes and as an investigative platform for evaluating candidate pharmaceutical agents.

Route of Administration: [^{11}C]-octylamine.

Dosage: [^{11}C]-octylamine.

Interpretation and Analysis: The initial lung uptake during the 1st minute is $70 \pm 6\%$ of the administered dose, and 40% of the injected dose remains after 15 minutes. Approximately 12% of the administered radioactivity is exhaled as [$^{11}CO_2$] during the 1st 30 minutes.

Metabolism of fluperlapine by cytochrome P450-dependent and flavin-dependent monooxygenases in continuous cultures of rat and human cells. Fischer V, Wiebel FJ. Biochem Pharmacol 1990 Apr 15; 39 (8), pp. 1327–33.

Ventilation Imaging/Pulmonary Embolism/ Ventilation/Perfusion Dual Imaging Evaluation
Xenon ([^{133}Xe])/[^{99m}Technetium] ([^{99m}Tc])-Macroaggregated Serum Albumin

Cellular/Molecular Mechanism of Action: Diffusible radioactive gas, which is inhaled down to the level of the alveolus.

Application: Detection of altered or abnormal ventilation patterns within the pulmonary tree. Examples include neoplastic lesions and septic pulmonary disease.

Route of Administration: Inhalation.

Dosage: Respiratory system inhalation.

Implementation: Evaluation of pulmonary embolism cases as a function of [^{133}Xe] ventilation images in 2 posterior oblique views; [^{99m}Tc]-macroaggregated serum albumin perfusion scans; and angiograms in cases subsequently discharged on anticoagulant therapy. On review, angiograms are considered embolism positive if intraluminal filling defects, a trailing embolus, or a branch occlusion $\geq$ than a segmental branch are detected (n = 29; 73%); and uncertain if reinterpreted as either equivocal or negative or in the presence of a single, small subsegmental filling defect of questionable clinical significance. The ventilation-perfusion scans are read as high (n = 18; 45%), intermediate (n = 10; 25%), or low (n = 12; 30%) probability.

Human Model: Cases that have undergone both nuclear imaging and invasive selective pulmonary angiography (n = 160; n = 40 embolism cases discharged on anticoagulant therapy; average age 57 years; n = 25/40 female).

Interpretation and Analysis: The proportion of cases with diagnostic certainty on angiography in the high-, intermediate-, and low-probability scintigraphic subgroups is, respectively, 100% (n = 18/18), 70% (n = 7/10), and 33% (n = 4/12) (p = 0.004). In patients diagnosed with pulmonary embolism based on selective angiography, a lower probability of pulmonary embolism on ventilation-perfusion scintigraphy correlates with a lesser degree of diagnostic certainty on angiography and a higher incidence of single subsegmental emboli.

Scintigraphic probability and angiographic diagnostic certainty in acute pulmonary embolism. Lette J, Cerino M, Barrette G, Dufresne MP, De Maria S, Eybalin MC, Levasseur A. Clin Nucl Med 2003 Nov; 28 (11), pp. 897–904.

Ventilation Perfusion/Mismatch Profiles/Reverse Ventilation Perfusion Mismatch
[^{99m}Technetium] ([^{99m}Tc])-Diethylenetriamine Pentaacetic Acid (DTPA) Aerosol/[^{99m}Tc]-Macroaggregated Albumin (MAA)

Cellular/Molecular Mechanism of Action: [^{99m}Tc]-DTPA aerosol simply permeates the air inhaled during the ventilation cycle and the radioactive vapor subsequently enters functional alveolei. [^{99m}Tc]-MAA, due to its size, remains primarily within the intravascular compartment following direct infusion.

Background Information: The phenomenon of reverse mismatched ventilation-perfusion on pulmonary scintigraphy is a fairly common occurrence.

Application: [^{99m}Tc]-DTPA aerosol can be applied to detect regional alterations in pulmonary ventilation. Conversely, [^{99m}Tc]-MAA can be utilized to map regional changes in pulmonary vascular perfusion.

Route of Administration: [^{99m}Tc]-DTPA aerosol (inhalation); [^{99m}Tc]-MAA (intravenous).

Implementation: Evaluation of scenarios characterized by alteration in pulmonary ventilation and vascular perfusion.

Interpretation and Analysis: Affected cases can display evidence of declining oxygen saturation and reverse mismatched ventilation-perfusion imaging patterns associated with radiotracer retention in a main bronchus. In such situations, [^{99m}Tc]-DTPA aerosol intake within the lung can reveal tracer retention in the trachea and right main bronchus and absent ventilation in the right or left lung. Alternatively, [^{99m}Tc]-MAA lung images reflect patterns of pulmonary vascular perfusion within either the left or right lung. In this fashion, it is possible to detect regions within the lung that may be perfused but not ventilating, or segments that are ventilating but not being perfused adequately (e.g., ventilation-perfusion mismatch). In contrast, reverse mismatched ventilation-perfusion, or totally absent ventilation with preservation of some perfusion in the right lung, results in functional intrapulmonary shunting, which can explain decreasing oxygen saturation observed in some pulmonary conditions. A concurrent portable thoracic radiograph may show elevations of the right hemidiaphragm, a shift of the mediastinum to the right, deviation of the endotracheal tube, narrowing of the intercostal space of the right thorax, and collapse of the right lower lobe. Radiographic findings of underventilation of the right lung with atelectasis of the right lower lobe can be due to a variety of causes, including mucous obstruction of the right main bronchus.

Reverse mismatched ventilation-perfusion pulmonary imaging with accumulation of technetium-^{99m}-DTPA in a mucous plug in a main bronchus: A case report. Shih WJ, Bognar B. J Nucl Med Technol 1999 Dec; 27 (4), pp. 303–5.

Ventilation Perfusion/[Strategies for Improved Imaging]
[^{133}Xe] Aerosol/[^{99m}Technetium] ([^{99m}Tc]) Intravascular Marker

Background Information: In nuclear medicine, the match and mismatch between the images of lung perfusion and ventilation provide an important criterion for the diagnosis of pulmonary embolism. Usually, for imaging clarity, ventilation scans using [^{133}Xe] are performed before the perfusion scan using [^{99m}Tc]. But the inverse order is preferred clinically, because (i) if the perfusion image is normal, there is no need to do the ventilation scan, and (ii) if the perfusion image is abnormal, the ventilation image can be obtained by focusing on the perfusion abnormalities. However, the quality of the ventilation image is reduced if the ventilation scan is performed after perfusion scans, because the 140 keV photons emitted from [^{99m}Tc] will scatter into the acquisition window of [^{133}Xe] (81 keV).
Implementation: Evaluation of image processing techniques for the purpose of discovering strategies that provide reduced scattering effect from [^{99m}Tc] in a manner that facilitates acquisition of better [^{133}Xe] ventilation images.
Interpretation and Analysis: First, an image sequence in the preferred inverse order is simulated using the images acquired in the normal order. Image processing techniques are used to find an optimized way to reduce the scattering background in the ventilation image. Second, a real image sequence is acquired in the inverse order. An improved ventilation image is then obtained by applying image processing techniques to this image sequence.

Enhancement of Xe-133 ventilation lung scan image acquired after [^{99m}Tc] perfusion scan. Lu H, Farison JB, Dennis MJ. Biomed Sci Instrum 1997; 33, pp. 118–25.

Ventilation Perfusion
[^{99m}Technetium] ([^{99m}Tc])-C and [^{81m}Kr] Aerosol Inhalation/[^{99m}Tc]-Macroaggregated Albumin (MAA)

Background Information: A method of producing aerosols (technegas) that been described, in which [^{99m}Tc] is bound to carbon atoms ([^{99m}Tc]-C), has been evaluated by comparing [^{99m}Tc]-C images with those obtained with [^{81m}Kr] in the same patients.
Route of Administration: [^{99m}Tc]-MAA (intravenously).
Dosage: [^{99m}Tc]-C and [^{81m}Kr] (200 kcounts inhaled) and [^{99m}Tc]-MAA injection (4–7 mCi injected, and 400 kcounts inhaled).
Implementation: Evaluation of ventilation/perfusion patterns. Immediately after the last [^{99m}Tc]-C view, a supine position is maintained and [^{81m}Kr] is inhaled at tidal volume. Immediately after [^{81m}Kr] ventilation views are recorded, MAA preparations are injected (4–7 mCi). The same 4 views (ant, lop, rop, post) are recorded after inhalation of [^{99m}Tc]-C and [^{81m}Kr] and injection of [^{99m}Tc]-MAA (400 kcounts).

Human Model: Cases suffering from 23-fold pulmonary embolism (PE; n = 25).
Interpretation and Analysis: The mean penetration index of [^{99m}Tc]-C (0.91) is lower than that of [^{81m}Kr] (1.04) ($P < 0.03$). The apex to base lung distribution of [^{99m}Tc]-C and [^{81m}Kr] appear to be similar. The mean heterogeneity of [^{99m}Tc] distribution is 23 fold greater than that of [^{81m}Kr] (14) ($p = 10^{-4}$). The [^{99m}Tc]-C ventilation image quality is considered very good (e.g., n = 16/25) or good (e.g., n = 6/25). Significant foci of high bronchial uptake are infrequent. Interpretation of the examinations performed after inhalation of [^{99m}Tc]-C and [^{81m}Kr] is usually concordant (e.g., n = 25/25 or 100%). Usually no cases have an [^{81m}Kr]/[^{99m}Tc]-MAA examination suggestive of PE when [^{99m}Tc]-C/[^{99m}Tc]-MAA indicates a low probability of PE, and vice versa. [^{99m}Tc]-C aerosols enable good quality ventilation images to be obtained in nearly all cases. Thus [^{99m}Tc]-C aerosols could be used in preference to [^{81m}Kr] in ventilation studies for the diagnosis of PE.

Comparison of technetium-^{99m} aerosol and krypton-81m in ventilation studies for the diagnosis of pulmonary embolism. Peltier P, De Faucal P, Chetanneau A, Chatal JF. Nucl Med Commun 1990 Sep; 11 (9), pp. 631–8.

Ventilation/Perfusion (V/Q)
[^{99m}Technetium] ([^{99m}Tc])-Pertechnegas/[^{99m}Tc]-Macroaggregated Albumin (MAA)

Cellular/Molecular Mechanism of Action: [^{99m}Tc]-Pertechnegas is inhaled into the deepest reaches of the respiratory tract similar to gaseous air. [^{99m}Tc]-MAA, due to its large size (molecular mass), largely remains within the intravascular compartment after injection.
Background Information: [^{99m}Tc]-Pertechnegas is a micro-aerosol carbon particle labeled with [^{99m}Tc] radioisotope.
Route of Administration: [^{99m}Tc]-Pertechnegas (inhaled).
Dosage: [^{99m}Tc]-Pertechnegas (1 mCi or 37 MBq); [^{99m}Tc]-MAA (4 mCi or 148 MBq).
Implementation: Evaluation of suspected pulmonary emboli lesions applying ventilation imaging facilitated by the inhalation of [^{99m}Tc]-Pertechnegas in 5 breaths or less. Planar images in multiple projections are recorded for preset counts. A final posterior image can be acquired to evaluate residual lung background activity. Immediately following ventilation imaging, perfusion imaging in the identical projections is performed using [^{99m}Tc]-MAA.

Human Model: Cases suspected of suffering from pulmonary emboli (n = 4).
Interpretation and Analysis: A number of cases may demonstrate matched uniform ventilation and perfusion (e.g., n = 2/4) or segmental ventilation-perfusion "mismatch" defects (e.g., n = 2/4) consistent with pulmonary emboli. In each case, residual Pertechnegas background lung activity (count rate) at the end of the last ventilation image is less than 10% of the initial [^{99m}Tc]-MAA counts (count rate). The advantages of Pertechnegas, in comparison to

aerosolized diethylenetriamine pentaacetic acid (DTPA), include (i) less residual ventilation image activity superimposed on the MAA perfusion images; (ii) reduced demand for patient cooperation due to fewer required breaths (5 or less); and (iii) lack of deposition of activity in the central airways. Therefore, Pertechnegas has properties that make it ideally suited for routine lung ventilation imaging.

Technetium-^{99m} labeled microaerosol "Pertechnegas." A new agent for ventilation imaging in suspected pulmonary emboli. Ashburn WL, Belezzuoli EV, Dillon WA, Mensh BD, Hoogland D, Yeung DW, Coade GE. Clin Nucl Med 1993 Dec; 18 (12), pp. 1045–52.

Ventilation/Perfusion (V/Q)/[High Spatial Resolution]
Xenon ([^{133}Xe])

Cellular/Molecular Mechanism of Action: Xenon is radioactive gas that can be inhaled into the lower respiratory tract.
Route of Administration: Xenon is inhaled as an aerosol so that regions of the lung can be profiled according to their degree of ventilation or lack thereof.
Implementation: Evaluation of pulmonary function by measuring both regional ventilation (V) and perfusion (Q) in which the regional radiodensity (RD) in the lung during [^{133}Xe] wash-in is a function of regional V (increasing RD) and Q (decreasing RD). Four 2.5-mm-thick computed tomography (CT) images are simultaneously acquired immediately cephalad to the diaphragm at end inspiration for each breath during 3 minutes of [^{133}Xe] breathing. Observed changes in RD during [^{133}Xe] wash-in are used to determine regional V and Q.

Animal Model: Sheep (5 anesthetized, pharmacologically paralyzed, mechanically ventilated, supine).
Interpretation and Analysis: For 16 mm^3, Q displays more variance than V: the coefficient of variance of Q (CV_Q) = 1.58 ± 0.23, the CV of V (CV_V = 0.46 ± 0.07, and the ratio of CV_Q to CV_V = 3.5 ± 1.1. CV_Q (1.21 ± 0.37) and the ratio of CV_Q to CV_V (2.4 ± 1.2) is smaller at 1,000-mm^3 scale, but CV_V (0.53 ± 0.09) is not. V/Q distributions also display scale dependence: log SD of V and log SD of Q are 0.79 ± 0.05 and 0.85 ± 0.10 for 16-mm^3 and 0.69 ± 0.20 and 0.67 ± 0.10 for 1,000-mm^3 regions of lung, respectively. V and Q measurements made with CT and [^{133}Xe] also demonstrate vertical orientation and isogravitational heterogeneity as described using other methodologies. Sequential images acquired by CT during [^{133}Xe] breathing can be used to determine both regional V and Q non-invasively with high spatial resolution.

Determination of regional ventilation and perfusion in the lung using xenon and computed tomography. Kreck TC, Krueger MA, Altemeier WA, Sinclair SE, Robertson HT, Shade ED, Hildebrandt J, Lamm WJ, Frazer DA, Polissar NL, Hlastala MP. J Appl Physiol 2001 Oct; 91 (4), pp. 1741–9.

RESPIRATORY BREATH TESTS: PULMONARY AND HEPATIC FUNCTION ASSESSMENT

Asthma Bronchiale/Inhalation Diagnostic Agent
L-[guanidino-[^{15}N]$_2$-Arginine Monohydrochloride/ Spirometry and Oscillometry Alternative

Application: Inhalation breath test.
Route of Administration: Inhalation.
Dosage: Aqueous solution, 20 atom % [^{15}N].
Considerations: Inhalation of a chemical diagnostic agent should provide novel ways of establishing a more specific diagnosis, for instance of inflammatory states of the bronchial and lung mucosa. The amino acid, L-[guanidino-[$^{15}N_2$]arginine monohydrochloride is resorbed and partly metabolized to [^{15}NO].
Implementation: Exhaled air is collected under defined conditions in 10-L breath bags and analyzed for NO using chemiluminescence.
Interpretation and Analysis: Under standardized test conditions, healthy persons (e.g., n = 6) exhale 0.97 ± 0.08 μmol NO/m^3 compared to conditions of asthma (e.g., n = 7) with 1.17 ± 0.14 μmol NO/m^3. A better distinction is expected comparing the [^{15}NO] exhalation. The [^{15}N] abundance of NO is determined using Cryotrap gas chromatography–mass spectrometry instrumentation. Between 30 and 80 minutes after inhaling 700 mg [^{15}N]arginine, a maximum with a plateau of the [^{15}NO] abundance is found in the exhaled air. At this time, healthy and asthmatic subjects exhibit clear differences in their exhaled [^{15}NO] amounts. Under standardized test conditions, healthy cases (n = 6) exhale 102.3 ± 6.7 nmol [^{15}NO]/m^3, whereas asthmatic cases (n = 7) exhale only 76.1 ± 10.9 nmol [^{15}NO]/m^3. The yield of [^{15}NO] after the inhalation of [^{15}N]-labeled arginine could potentially serve as a marker for demonstrating pathophysiological changes in lung epithelium.

[$^{15}N]_2$-arginine as a 1st potential inhaled diagnostic agent to characterize respiratory diseases. Krumbiegel P, Denk E, Russow R, Rolle-Kampczyk U, Metzner G, Herbarth O. Exp Lung Res 2002 Oct–Nov; 28 (7), pp. 535–42.

Hepatic Function: Breath Test
[^{13}C]-Methacetin/[^{15}N]-Methacetin/[^{14}C]-Methacetin

Application: Detection of conditions associated with hepatic disease.
Considerations: Stable isotopes, such as [^{13}C], should be substituted for the long-lived radionuclide [^{14}C] in the [^{14}C] breath test when doing liver function tests in children and pregnant women.
Implementation: Synthesize, evaluate, and compare the capacity of [^{13}C], [^{15}N]-methacetin, and [^{14}C]-methacetin to function as suitable diagnostic agents. Methods have been described for the measurement of [^{14}C] and [^{13}C] in the breath.
Interpretation and Analysis: Following oral administration of radio carbon-labeled methacetin to cases with liver disease and healthy reference controls, a good degree of correlation can be appreciated between [^{13}C]- and [^{14}C]-measurements in the same subject, which is complemented by an effective level of discrimination between controls and affected cases. Measurements of [^{14}C] in the urine support the presumed advantage of [^{13}C]-methacetin over [^{14}C]-methacetin when applied for such purposes.

[^{13}C]-methacetin breath test for monitoring hepatic function in cirrhotic patients before and after liver transplantation. Petrolati A, Festi D, De Berardinis G, Colaiocco-Ferrante L, Di Paolo D, Tisone G, Angelico M. Aliment Pharmacol Ther 2003 Oct 15; 18 (8), pp. 785–90.

Hepatic Metabolic Capacity Breath Test
[^{13}C]-Methacetin/[^{14}C]-Methacetin/[^{15}N]-Methacetin

Background Information: To grade liver damage, the Child-Pugh classification can be used, but these tests do not quantitatively reflect the functional hepatic reserve.
Application: Detection of conditions associated with hepatic disease.
Considerations: Stable isotopes, such as [^{3}C], should be substituted for the long-lived radionuclide [^{14}C] in the [^{14}C] breath test when doing liver function tests in children and pregnant women. For comparison, [^{13}C]-methacetin, [^{15}N]-methacetin, and [^{14}C]-methacetin have been synthesized as suitable diagnostic agents.

Implementation: Evaluation of liver function through assessement of hepatic metabolization of biochemical substrates detected by measurement of [^{14}C] and [^{13}C] in exhaled CO_2 air.

Diagnostic Interpretation and Implications: Following oral administration of radio carbon-labeled methacetin, a good degree of correlation can be appreciated between [^{13}C]- and [^{14}C]-measurements in the same subject, which is complemented by an effective level of discrimination between controls and cases with hepatic disease. Measurements of [^{14}C] in urine support the presumed advantage of [^{13}C]-methacetin over [^{14}C]-methacetin when applied for this particular purpose.

[^{13}C]-methacetin metabolism in patients with cirrhosis: Relation to disease severity, hemoglobin content, and oxygen supply. Zipprich A, Meiss F, Steudel N, Sziegoleit U, Fleig WE, Kleber G. Aliment Pharmacol Ther 2003 Jun 15; 17 (12), pp. 1559–62.

Hepatic Metabolism/Dysfunction and Biochemical Capacity/[Breath Test]
[^{13}C]-Methacetin/[^{13}C]-Phenylalanine

Cellular/Molecular Mechanism of Action: [^{13}C]-methacetin and [^{13}C]-phenylalanine are radioactive analogues of methacetin and the amino acid phenylalanine. Each of these agents is metabolized in the liver and radioactive [$^{13}CO_2$] is ultimately excreted in exhaled air.

Background Information: To grade liver damage, the Child-Pugh classification can be used, but these tests do not quantitatively reflect the functional hepatic reserve.

Considerations: Advantages of the [^{13}C]-phenylalanine breath test and [^{13}C]-methacetin breath test include their large margin of safety and convenient utilization for quantifying functional hepatic reserve.

Application: [^{13}C]-phenylalanine breath test and [^{13}C]-methacetin breath tests can potentially be utilized to quantify functional hepatic reserve in conditions of chronic liver disease.

Dosage: [^{13}C]-phenylalanine (100 mg) and [^{13}C]-methacetin (75 mg).

Implementation: Evaluation of [^{13}C]-phenylalanine and [^{13}C]-methacetin as possible molecular/biochemical probes in breath test protocols for assessing liver function in the form of functional hepatic reserve in conditions of chronic hepatic disease. In this context, breath samples are collected after the administration of [^{13}C]-phenylalanine and [^{13}C]-methacetin. Mass spectrometry analysis is utilized to measure [$^{13}CO_2$] enrichment.

Human Model: Both tests performed in 48 healthy volunteers and 48 chronic liver disease patients.

Interpretation and Analysis: Both tests discriminate between normal and abnormal hepatic function, decreasing results of the [$^{13}CO_2$] enrichment agreeing with the increasing severity in cases of hepatic disease ([^{13}C]-phenylalanine breath test multiple correlation coefficient: 0.72, global $p < 0.001$; [^{13}C]-methacetin breath test: 0.73, $p < 0.001$). Correlation between the [^{13}C]-phenylalanine breath test and [^{13}C]-methacetin breath test is 0.63, $p < 0.001$. In cases where both tests detect pathological changes, the sensitivity for detecting hepatic dysfunction is high (98%), although specificity decreases to 60%. Best results are obtained at 30 minutes with the [^{13}C]-phenylalanine breath test and at 10 minutes with methacetin breath test. Therefore, both [^{13}C]-phenylalanine breath test and methacetin breath test are safe and easy tests to perform and both are able to discriminate the hepatic functional capacity between the different groups studied.

[^{13}C]-phenylalanine and [^{13}C]-methacetin breath test to evaluate functional capacity of hepatocyte in chronic liver disease. Lara Baruque S, Razquin M, Jimenez I, Vazquez A, Gisbert JP, Pajares JM. Dig Liver Dis 2000 Apr; 32 (3), pp. 226–32.

Intestinal Malabsorption and Compromised Mucosal Integrity/[Hydrogen Breath Test]
D-Xylose Absorption

Application: Malabsorptive evaluation in renal failure is difficult because most absorptive testing requires urinary collections. Kinetic analysis of D-xylose absorption and D-xylose breath testing are performed in an effort to establish an effective absorption test in cases that are functionally anephric.

Route of Administration: D-xylose (oral and intravenously).

Dosage: D-xylose 15-g (oral) and 10-g (intravenous) dosage schemes.

Considerations: Serum samples have been used to calculate the kinetic rate constants and extent of D-xylose absorption. After the oral D-xylose, end expiratory breaths are collected every 15 minutes for 3 hours and analyzed for H_2 (e.g., measured by gas chromatography analysis).

Implementation: Evaluation of fasting renal failure cases without diarrhea or symptoms of malabsorption on 2 separate non-dialysis days after receiving D-xylose on day 1 (oral) and day 2 (IV). Serum samples are used to calculate the kinetic rate constants and extent of D-xylose absorption.

Interpretation and Analysis: The mean absorption rate constant (Ka) and bioavailability (F) are similar to published values for normal subjects using the 15-g dose (0.936 min^{-1}; range, 0.227–1.96; and 74%, range 46–99, respectively). Some cases ($n = 12$) have normal 1-hour serum D-xylose concentrations (> 20 mg/dL). There are no clear inverse correlations between the rate constant for absorption or bioavailability and peak breath hydrogen or the area-under-the-curve for breath H_2 vs time. Using 15-g oral D-xylose, mean bioavailability and absorption rate constants are normal in functionally anephric patients with no clinical evidence of malabsorption. Some cases ($n = 3$) have elevated breath peak H_2 concentrations, but there are no clear inverse correlations between bioavailability and breath H_2 values. A 1-hour serum D-xylose concentration > 20 mg/dL may be considered normal in such case groups, similar to patients with normal renal function.

Instrumentation: Gas chromatography (hydrogen gas measurement).

D-xylose kinetics and hydrogen breath tests in functionally anephric patients using the 15-gram dose. Craig RM, Carlson S, Ehrenpreis ED. J Clin Gastroenterol 2000 Jul; 31 (1), pp. 55–9.

Pulmonary Cell Decompensation/Pulmonary Inflammation
[$^{1\text{-}13}$C]-Glucose/([$^{13}CO_2$] Breath Tests)

Cellular/Molecular Mechanism of Action: Following inhalation, agents are absorbed into the systemic circulation where they are subsequently metabolized by the liver and then exhaled as a radiolabeled metabolite (e.g., CO_2).

Application: Breath test (CO_2-based).

Route of Administration: An aerosolized aqueous solution (25%) is inhaled with the aid of an aerosol provocation system (APS).

Dosage: Optimum inhalation dose for [^{13}C]-glucose has been determined to be 205 mg.

Considerations: Many tests designed to evaluate pathophysiological alterations of the gastrointestinal tract involve the oral intake of a biochemical substrate that is metabolized and subsequently measured in exhaled air samples. (e.g., CO_2-based breath test, [^{15}N]-based urine test). Despite this traditional methodology, it seems logical that the study of pathophysiological changes of the bronchial and lung epithelium can be more appropriately evaluated through the inhaled administration of a stable isotope-labeled agent.

Investigators have suggested that the inhalation of suitable [^{13}C]-labeled substrates will pave the way for a new group of [$^{13}CO_2$] breath tests aiding investigations of specific pathophysiological changes in the pulmonary tract, such as inflammations of certain sections and decompensations of cell functions.

Implementation: Evaluation of suitable [^{13}C]-labeled substrates for the detection and quantitative measurement of [$^{13}CO_2$] in exhaled air. Breath samples are collected at 15-minute intervals and analyzed for [$^{13}CO_2$] 75–120 minutes after the end of inhalation.

Interpretation and Analysis: Breath samples collected at 15-minute intervals and analyzed for [$^{13}CO_2$] 75–120 minutes after the end of inhalation demonstrate a well-reproducible maximum delta [^{13}C] value of 6% over baseline (DOB). Speculating that the pulmonary resorption of the [^{13}C]-glucose is the rate-limiting step of elimination, decompensations in the epithelium ought to be reflected as changes in 1-[^{13}C]-glucose resorption rates and altered [$^{13}CO_2$] output.

Instrumentation: Nebulizer (“Medic Aid”; Erich Jaeger Würzburg).

Towards an inhalative [^{13}C] breath test method. Krumbiegel P, Rolle-Kampczyk U, Liebergeld P, Herbarth O, Köbrich R. Isotopes Environ Health Stud 2002 Jun; 38 (2), pp. 65–70.

19 Positron Emission Tomography (PET) and Single Photon Emission Computed Tomography (SPECT)

General/Artifacts in Positron Emission Tomography (PET)/Computed Tomography (CT) Imaging
Iodinated Contrast Imaging Agents

Implementation: Intravenous and oral iodinated contrast agent administered to oncology cases (e.g., n = 30) combined with whole-body PET/CT. Computed tomography images acquired in the presence of intravenous and oral iodinated contrast agent are used for PET attenuation correction. Positron emission tomography images have been assessed for the presence of artifacts that are defined as a region of high count rate on attenuation-corrected images in accurate co-registration with a contrast-enhanced blood vessel. Intravascular enhancement of thoracic veins is quantified by the application of regions-of-interest (ROI) analyses, and quantities in cases with artifact (Group 1) and without artifact (Group 2) correlated. Body surface area is calculated for all cases.

Interpretation and Analysis: Contrast-induced PET artifact can be appreciated in approximately 13% of cases (e.g., n = 4/30 cases). Mean differences in density within enhanced intravascular images are highly significant ($p < 0.001$) compared to case groups with artifact (2,262 ± 304 Hounsfield units [HU]) and without artifact (1,058 ± 209 HU). Body surface area is significantly lower ($p = 0.035$) in cases with artifact (1.67 ± 0.11 m^2) than in cases without artifact (2.01 ± 0.18 m^2). Contrast-enhanced dual-modality PET/CT examinations may result in a PET artifact that is due to the transient bolus passage of undiluted intravenous contrast agent.

Focal tracer uptake: A potential artifact in contrast-enhanced dual-modality PET/CT scans. Antoch G, Freudenberg LS, Egelhof T, Stattaus J, Jentzen W, Debatin JF, Bockisch A. J Nucl Med 2002 Oct; 43 (10), pp. 1339–42.

Adrenal Gland: Function and Structure
[^{131}I]-6-β-Iodomethyl-Norcholesterol/[^{75}Se]-Selenomethyl-Norcholesterol/[^{131}I]-, [^{123}I]-, and [^{124}I]-Metaiodobenzylguanidine (MIBG)/[^{18}F]-Metafluoro-Benzyl-Guanidine/[^{123}I]-Tyr-Octreotide/[^{111}In]-Diethylenetriamine Pentaacetic Acid (DTPA)-Octreotide/[^{111}In]-DOTA-Octreotide/[^{18}F]-2-Fluoro-d-Deoxyglucose/Metyrapone/Tyrosine Analogs/Low-Density Lipoproteins (LDL Receptors)/Bombesin/Vasoactive Intestinal Polypeptide/Cholecystokinin/Opiate Peptides/[^{11}C]-Acetate

Background Information: Over the past 30 years nuclear medicine imaging of the adrenal gland and its lesions has been achieved by exploitation of a number of physiological characteristics associated with this organ. By seeking and utilizing features that are quantitatively or qualitatively different from those of the adjacent tissues, it is possible to functionally characterize the adrenal gland and associated disease states. In most instances lesions affecting both the cortex and the medulla retain the basic physiology related to their tissue of origin. Agents widely used in clinical practice include (i) uptake and storage of radiolabeled cholesterol analogues via the LDL receptors and cholesterol ester storage pools in the adrenal cortex utilizing [^{131}I]-6-β-iodomethyl-norcholesterol and [^{75}Se]-selenomethyl-norcholesterol; (ii) catecholamine type I, (presynaptic, uptake mechanism and intracellular granule uptake and storage mechanism in the adrenal medulla and extra-adrenal paraganglia utilizing [^{131}I]-, [^{123}I]-, and [^{124}I]-MIBG and [^{18}F]-meta-fluoro-benzyl-guanidine); (iii) cell surface receptor binding of peptides/neurotransmitters/modulators such as those for the family of 5 subtypes of somatostatin receptors ([^{123}I]-tyr-octreotide, [^{111}In]-DTPA-octreotide, [^{111}In]-DOTA-octreotide, and many others); (iv) although not specific for the adrenal gland, increased tumor glycolysis, particularly in the most malignant adrenal-associated cell types, the [^{18}F]-2-fluoro-d-deoxyglucose can be expected to detect certain neoplastic lesions such as malignant pheochromocytomas (particularly the minority of cases that cannot be detected by MIBG) and adrenal incidentalomas (particularly when they occur with known extra-adrenal malignancies).

There is a variety of adrenal tissue characteristics that have the potential for being exploited for various purposes that are not currently employed for clinical uses, but nevertheless have potential as imaging agents. These include (i) inhibitors of adrenal cortical steroid hormone synthesis enzymes (e.g., radiolabeled analogues of metyrapone); (ii) radiolabeled lipoproteins that bind to adrenocortical LDL receptors; (iii) inhibitors of catecholamine biosynthesis enzymes (e.g., radiolabeled analogues of tyrosine and related amino acids); and (iv) cell surface receptors for various peptides and hormones that may be overexpressed by adrenal cortical or adrenal medullary tumors (e.g., radiolabeled analogues of adenocorticotropic hormone (ACTH) for adrenocortical cells of zona fasciculata or zona glomerulosa origin; neurotransmitter/hormone message peptides binding to cell surface receptors such as bombesin, vasoactive intestinal polypeptide, cholecystokinin, and opiate peptides). The adrenal cortex can also synthesize cholesterol from acetate, and preliminary studies with [^{11}C]-acetate positron emission tomography have shown interesting results.

Application: Detection and characterization of the adrenal gland function and dysfunction.

Functional scintigraphy of the adrenal gland. Rubello D, Bui C, Casara D, Gross MD, Fig LM, Shapiro B. Eur J Endocrinol 2002 Jul; 147 (1), pp. 13–28.

CARDIOVASCULAR SYSTEM

Acetylcholine Receptors: Muscarinic/Cardiac Muscarinic Acetylcholinergic Receptors/Central Nervous System (CNS) Muscarinic Acetylcholinergic Receptors/Carcinoma of the Colon
[^{123}I]-PIP/[^{125}I]-PIP

Cellular/Molecular Mechanism of Action: The agent IPIP functions as a ligand for muscarinic acetylcholinergic complexes (mAChR).

Background Information: Prior to approval for *in vivo* use in humans, organ doses for radioiodinated IPIP ligands must 1st be evaluated.

Application: Radioiodinated IPIP ligands can be applied *in vivo* for imaging mAChR using modalities like single photon emission computed tomography (SPECT).

Implementation: Identify the most optimum mAChR ligand-binding properties of 4 different IPIP sterioisomers through the evaluation of their biodistribution pattern. A biokinetic model can be developed for the Z-(S)-IPIP stereoisomer for estimating the internal absorbed dose in humans based on extrapolation from an appropriate rat model.

Animal Model: Rat (IPIP biokinetic model).

Interpretation and Analysis: The thyroid is the critical organ for this radiopharmaceutical, with an absorbed dose estimate of 2.4 mGy/MBq for both males and females, when labeled with [^{123}I]. Even when blocked, the thyroid is still the critical organ, yet it receives a 90% reduction in dose. The heart and brain receive the next highest doses in both males and females. Effective dose estimates for the use of pure [^{123}I]-PIP in humans are 0.16 mSv/MBq for males and 0.14 mSv/MBq for females. The biodistribution studies of the Z-(S)-IPIP stereoisomer show the most promise as a successful agent for imaging muscarinic receptor sites in the heart and brain. IPIP can potentially be applied as a therapeutic radiopharmaceutical for certain colon carcinomas where muscarinic receptor sites are expressed in the tumor cells. These results provide preliminary data for use of IPIP in clinical studies on humans.

In vivo biodistribution of [^{125}I]-PIP and internal dosimetry of [^{123}I]-PIP radioiodinated agents selective to the muscarinic acetylcholinergic receptor complex. Breeden WK 3rd, Hamby DM, Carey JE Jr, Eckerman KF, McPherson DW, Knapp FF Jr. Med Phys 2000 Apr; 27 (4), pp. 778–86.

Acetylcholinesterase
[^{11}C]-Edrophonium

Semi-Synthetic Methods: Tracers can be prepared by N-[^{11}C]-methylation of precursors using [^{11}C]-methyl triflate and isolated by solid-phase extraction (SPE) purification procedure that provides a 50–65% radiochemical yield.

Implementation: Evaluation of [^{11}C]-edrophonium and its analogues as potential positron emission tomography (PET) imaging agents for the detection and characterization of cardiac acetylcholinesterase.

Facile synthesis of [^{11}C]-edrophonium and its analogues as new potential PET imaging agents for heart acetylcholinesterase. Zheng QH, Liu X, Fei X, Wang JQ, Mock BH, Glick-Wilson BE, Sullivan ML, Hutchins GD. Bioorg Med Chem Lett. 2003 May 19; 13 (10), pp. 1787–90.

Angiography/Coronary Artery: Angina Pectoris (Vasospastic)/Presynaptic Myocardial Sympathetic Abnormality
[^{123}I]-Labeled Metaiodobenzylguanidine (MIBG)/ Ergonovine

Cellular/Molecular Mechanism of Action: Ergonovine promotes arterial wall smooth muscle contraction.

Application: Assess the presence and location of presynaptic myocardial sympathetic abnormality in conditions of vasospastic angina.

Route of Administration: [^{123}I]-labeled MIBG given IV. Ergonovine is administered by intracoronary infusion (ICA).

Dosage: [^{123}I]-labeled MIBG (111 mBq).

Considerations: Single photo emission computed tomography (SPECT) with MIBG can permit the non-invasive detection and evaluation of suspected vasospastic angina.

Interpretation and Analysis: In cases of vasospastic angina pectoris (n = 50) previously evaluated by coronary artery angiography following intracoronary artery ergonovine infusion, a 99–100% obstructive spasm is defined as a positive response. Images aquired 20 minutes and 3 hours following the administration of [^{123}I]-MIBG SPECT (111 mBq) can reveal mild reductions in tissue uptake (e.g., n = 5/25). In contrast, images at 3 hours often demonstrate [^{123}I]-MIBG SPECT abnormalities (e.g., n = 20/25). The location of [^{123}I]-MIBG abnormalities can be completely or partially consistent with the spastic coronary regions (e.g., n = 18/25). Alternatively, reduced [^{123}I]-MIBG uptake may be noted in cases with a negative ergonovine provocative test (e.g., n = 4/25). Accordingly, positive and negative predictive values of MIBG SPECT for the provocative test have been estimated to be 83% (e.g., n = 20/24) and 81% (e.g., n = 21/26), respectively.

Instrumentation: Single photon emission computed tomography.

Value of iodine-123 metaiodobenzylguanidine scintigraphy in patients with vasospastic angina. Taki J, Yasuhara S, Takamatsu T, Nakajima K, Tatami R, Ishise S, Matsunari I, Takayama T, Tonami N. Eur J Nucl Med 1998 Mar; 25 (3), pp. 229–34.

Angiography: Coronary Artery/Epicardial Vasculature
[^{99m}Technetium] ([^{99m}Tc])-SestaMIBI/ [^{99m}Tc]-Tetrofosmin/Dipyridamole

Cellular/Molecular Mechanism of Action: SestaMIBI and tetrofosmin function as intravascular carrier molecules for [^{99m}Tc].

Application: Imaging of vascular structures, including the coronary artery and epicardial arteries, utilizing various modalities including nuclear medicine techniques.

Implementation: Evaluation of the anatomical integrity of cardiac vascular structures in conditions of 50 to 90% stenosis of 1 to 2 major epicardial vessels without previous evidence of myocardial infarction (e.g., n = 81 cases) applying dipyridamole single photon emission computed tomography (SPECT) imaging facilitated by the application of either [^{99m}Tc]-sestaMIBI or [^{99m}Tc]-tetrofosmin.

Interpretation and Analysis: [^{99m}Tc]-sestaMIBI can detect reversible perfusion defects in a greater number of segments than is possible with [^{99m}Tc]-tetrofosmin (total 363 and 285, $p < 0.001$, and mean ± standard deviation [SD], 2.2 ± 3.0 and 1.8 ± 2.5 per patient, $p = 0.008$, respectively), it demonstrates a larger extent of perfusion defect than [^{99m}Tc]-tetrofosmin (mean ± SD, 15.8% ± 12.3% and 12.0% ± 11.4%, $p < 0.03$, respectively), and more often correctly identifies disease in more than 1 coronary artery ($p = 0.02$). There is better defect contrast with [^{99m}Tc]-sestaMIBI (defect/normal wall count ratios are 0.60 ± 0.15 vs 0.73 ± 0.14 for [^{99m}Tc]-sestaMIBI and [^{99m}Tc]-tetrofosmin, respectively, $p = 0.01$, for reversible defects in identical segments with both agents; and 0.73 ± 0.16 vs 0.79 ± 0.17, respectively, $p < 0.01$, for reversible defects detected with either agent alone). There is no significant difference in diagnostic sensitivity or image quality. Such differences between 2 commonly used tracers may have significant diagnostic and prognostic implications.

Enhanced detection of reversible perfusion defects by Tc-99m sestaMIBI compared to Tc-99m tetrofosmin during vasodilator stress SPECT imaging in mild-to-moderate coronary artery disease. Soman P, Taillefer R, DePuey EG, Udelson JE, Lahiri A. J Am Coll Cardiol 2001 Feb; 37 (2), pp. 458–62.

Angiography/Cardiac: Myocardial Ischemia/ Coronary Artery Stenosis
[^{99m}Technetium] ([^{99m}Tc])-SestaMIBI/Dipyridamole Stress Test/Levovist (Ultrasound Contrast Media)

Background Information: Power Doppler imaging is a method that can be adapted for myocardial contrast echocardiography

(MCE). It can selectively evaluate the signal coming from an ultrasound contrast agent, thereby facilitating the conduction of myocardial perfusion studies.

Application: Detection and characterization of coronary artery stenosis, myocardial ischemia/perfusion.

Implementation: Evaluation of the relative accuracy of the noninvasive imaging modalities of power Doppler MCE; stress echo wall motion; and nuclear scan imaging (single photon emission computed tomography [SPECT]) to assess coronary artery stenosis and myocardial ischemia/perfusion without and during pharmacological stress testing using coronary angiography as a reference standard. Power Doppler MCE is acquired using continuous intravenous infusion of Levovist contrast agent. Echo wall motion images can also be acquired for application in comparative analyses. At peak stress, [^{99m}Tc]-sestaMIBI is injected and stress SPECT images acquired 30 minutes after injection.

Human Model: Dipyridamole stress test (e.g., n = 25).

Interpretation and Analysis: Power Doppler MCE and SPECT show an 84% concordance (e.g., n = 21/25 cases; kappa = 0.67) for the detection of ischemia. Concordance based on coronary artery territories for normal perfusion vs fixed defects vs reversible defects is 92% (69% of 75; kappa = 0.81), with 100% for left anterior descending, 92% for right coronary artery, and 84% for circumflex artery structures. Power Doppler MCE has a lower sensitivity than SPECT (89% vs 100%) but higher specificity (100% vs 88%) for identification of stenotic (≥ 70%) coronary arteries as assessed by angiography. Echo wall motion analysis displays the lowest sensitivity (68%) with 100% specificity. Accuracy is 94% for both power Doppler MCE and SPECT, and 83% for wall motion analysis. Power Doppler MCE is a sensitive and specific method for identifying myocardial perfusion during pharmacological stress. Accuracy of power Doppler MCE for stenotic coronary arteries appears to be slightly higher than stress echo wall motion and similar to SPECT.

Non-invasive detection of coronary artery stenosis: A comparison among power Doppler contrast echo, [^{99m}Tc]-sestaMIBI SPECT, and echo wall motion analysis. Rocchi G, Fallani F, Bracchetti G, Rapezzi C, Ferlito M, Levorato M, Reggiani LB, Branzi A. Coron Artery Dis 2003 May; 14 (3), pp. 239–45.

Brugada Syndrome (Arryhythmia)/ Presynaptic Sympathetic Innervation Dysfunction *[^{123}I]-Metaiodobenzylguanidine (MIBG)*

Cellular/Molecular Mechanism of Action: [^{123}I]-MIBG is an analogue of the adrenergic neurotransmitter norepinephrine.

Background Information: Patients with Brugada syndrome present with characteristic electrocardiogram (ECG) abnormalities (atypical right bundle-branch block and ST-segment elevation) and life-threatening ventricular tachyarrhythmias despite structurally normal hearts. Involvement of the autonomic nervous system is suggested by the occurrence of ventricular tachyarrhythmias and sudden death at rest or during sleep and by changes of typical ECG signs under pharmacological modulation of the myocardial autonomic tone.

Application: Characterization of presynaptic sympathetic innervation to the heart in conditions of Brugada syndrome.

Route of Administration: [^{123}I]-MIBG (intravenous).

Implementation: Evaluation of the presynaptic cardiac neuronal reuptake of norepinephrine (uptake 1) in cases of Brugada syndrome and age-matched control subjects using the norepinephrine analogue [^{123}I]-MIBG in concert with single photon emission computed tomography (SPECT) and quantitative 33-segment bull's-eye analysis.

Human Model: Brugada syndrome (n = 17; n = 10 age-matched controls).

Interpretation and Analysis: Regionally reduced [^{123}I]-MIBG uptake is present in almost half of all cases with Brugada syndrome (e.g., n = 8/17 or 47%) but not in reference controls. Quantitative analysis shows segmental reduction of [^{123}I]-MIBG uptake in the inferior and septal left ventricular wall in patients with Brugada syndrome compared with control subjects ($p < 0.05$). No correlation can be appreciated between findings with [^{123}I]-MIBG SPECT and clinical characteristics of study patients. Abnormal [^{123}I]-MIBG uptake in Brugada syndrome cases indicates presynaptic sympathetic dysfunction exists within the heart. These findings may have a potential impact on the pathophysiology and arrhythmogenesis in cases with Brugada syndrome. Future quantitative investigations of the presynaptic and postsynaptic sympathetic and parasympathetic branches of the cardiac autonomic nervous system may clarify whether these observations represent a primary adrenergic dysfunction or an imbalance between sympathetic and parasympathetic innervation of the heart.

Cardiac autonomic dysfunction in Brugada syndrome. Wichter T, Matheja P, Eckardt L, Kies P, Schäfers K, Schulze-Bahr E, Haverkamp W, Borggrefe M, Schober O, Breithardt G, Schäfers M. Circulation 2002 Feb 12; 105 (6), pp. 702–6.

Cardiac Death: Predictive Outcome Parameters/ Hemodynamic Responses: Heart Rate and Systolic Blood Pressure *Adenosine/[Adjunct Single Photon Emission Computed Tomography (SPECT) Agent]*

Physiological Mechanism of Action: Adenosine phosphate promotes relaxation of vascular smooth muscle and a negative chronotropic effect on cardiac function.

Application: Detection of hemodynamic responses to adenosine that add incremental prognostic value to myocardial perfusion SPECT (MPS) imaging procedures for enhanced detection of cases as risk of cardiac death.

Implementation: Evaluation of outcome in cases subjected to adenosine (no additional exercise) stress MPS. Multivariable Cox proportional hazards analysis can be used to assess the prognostic value of hemodynamic variables in predicting cardiac death (CD).

Human Model: Postevaluation cases of adenosine stress myocardial perfusion studies (n = 3,444 cases; n = 53.5% women with a mean age 74.0 ± 8.4 years) during a 2.0 ± 0.8 year follow-up (monitoring) period.

Interpretation and Analysis: During an extended monitoring period of 2.0 ± 0.8 year, a relatively small percentage of cardiac deaths may be appreciated (e.g., n = 224/3,444 or 6.5%). Review of multivariable analysis of various parameters reveals a higher resting heart rate (HR) and to a lesser extent lower peak HR as viable markers of impending CD. In addition, peak/rest HR ratio is an independent predictor of CD when added to the multivariable model in place of peak and rest HR. Peak/rest HR ratios can also be used to risk stratify cases within each MPS category. A significant interaction can be appreciated between gender and peak systolic blood pressure (SBP), in which there is an increased risk associated with a low peak systolic blood pressure (SBP < 90 mm Hg at end of adenosine infusion) in men but not in women. Patients undergoing adenosine stress MPS with high rest HR and low peak/rest HR ratio have an increased risk of CD, as do male patients with a low peak SBP measurement. Detection of the hemodynamic response to adenosine adds incremental prognostic value to MPS results and enhances identification of patients at risk for CD.

Prognostic impact of hemodynamic response to adenosine in patients older than age 55 years undergoing vasodilator stress myocardial perfusion study.

Abidov A, Hachamovitch R, Hayes SW, Ng CK, Cohen I, Friedman JD, Germano G, Berman DS. Circulation 2003 Jun 17; 107 (23), pp. 2894–9.

Cardiomyopathy and Hypertension/Propanolol β-Adrenergic Receptor Occupancy/Positron Emission Tomography (PET) vs Single Photon Emission Computed Tomography (SPECT) Spatial Resolution/*In Vivo* and *Ex Vivo* Cardiac and Splenic Analyses

(1R,2S)-4-[^{18}F]-Fluorometaraminol/ [^{125}I]-Iodocyanopindolol/ [^{125}I]-Metaiodobenzylguanidine (MIBG)

Cellular/Molecular Mechanism of Action: [^{125}I]-iodocyanopindolol is a radioiodinated analogue of propanolol and is known to have binding avidity for and blocks the activity of β-adrenergic receptor complexes. (1R,2S)-4-[^{18}F]-Fluorometaraminol (4-FM) has similar binding avidity for β-adrenergic receptor complexes. Metaiodobenzylguanidine is an analogue of norepinephrine.

Application: [^{125}I]-Iodocyanopindolol can be used to detect alterations in β-adrenergic receptor expression and propanolol occupancy of β-adrenergic receptor complexes.

Dosage: [^{125}I]-Iodocyanopindolol (1.5 pmol/L *ex vivo* incubation); propranolol (10 μmol/L *ex vivo* incubation).

Implementation: Evaluate the relative uptake, metabolism, and β-receptor affinity of the new positron-emitting uptake-1 tracer (1R,2S)-4-[^{18}F]-fluorometaraminol (4-FM) with those of the SPECT pharmaceutical MIBG. One approach to achieving this objective can involve determining the biodistribution of no-carrier-added 4-[^{18}F]-FM *in vivo* and *in vitro* in retrograde-perfused hearts. Cardiac and extracardiac distribution can then be assessed, in concert with the detection of metabolite formation assessed by thin-layer chromatography techniques. Studies performed *in vivo* are then repeated with no-carrier-added [^{123}I]-MIBG. By means of autoradiography, the β-receptor affinity of 4-FM can be compared with that of MIBG and propranolol (10 μmol/L) through displacement of [^{125}I]-iodocyanopindolol (1.5 pmol/L) in *ex vivo* tissue slices.

Animal Model: Rats (Wistar Kyoto [WKY] rats and spontaneously hypertensive [SHR] rats).

***Ex Vivo* Model:** Rat (cardiac and spleen slices).

Interpretation and Analysis: Cardiomyopathic hearts show heterogeneous 4-[^{18}F]-FM uptake with gradients of up to 3.6 *in vivo* and *in vitro* between different regions of the heart. Control hearts display such gradients in 4-[^{18}F]-FM uptake only *in vitro*. [^{125}I]-MIBG exhibits a less heterogeneous *in vivo* distribution in SHR hearts. Extracardiac differences between WKY and SHR can be appreciated for uptake of 4-[^{18}F]-FM in the spleen (63.3% ± 4% vs 38.8% ± 5.7% of cardiac activity) and for renal uptake of [^{125}I]-MIBG (373% ± 27% vs 81.4% ± 17% of cardiac activity). Metabolites of 4-[^{18}F]-FM are found only in the liver, while those of [^{125}I]-MIBG are found in the liver and kidney with a nearly equal relative fraction in both types of animals of about 20%, 60%, and 30%, respectively. 4-FM suppresses cardiac-specific β-receptor binding of [^{125}I]-iodocyanopindolol in heart and spleen of both types of animals significantly, whereas MIBG has almost no effect. The more heterogeneous cardiac distribution of 4-[^{18}F]-FM suggests that it reflects alterations in uptake 1 better than [^{125}I]-MIBG in addition to the possibility of quantification and higher spatial resolution by PET compared with SPECT. Altered biotransformation in cardiomyopathic diseases may also impair the evaluation of [^{125}I]-MIBG SPECT data. The β-receptor binding of 4-[^{18}F]-FM must be further elucidated.

Relative uptake, metabolism, and β-receptor binding of (1R,2S)-4-[^{18}F]-fluorometaraminol and [^{123}I]-MIBG in normotensive and spontaneously hypertensive rats. Pissarek M, Ermert J, Oesterreich G, Bier D, Coenen HH. J Nucl Med 2002 Mar; 43 (3), pp. 366–73.

Cardiomyopathy (Dilated)/Left Ventricular Ejection Fraction (LVEF)/Predict Improved Cardiac Sympathetic Nerve Activity/Predict Improved Cardiac Function/Predict Improved Symptoms Posttreatment for Dilated Cardiomyopathy

Dobutamine/[^{123}I]-Metaiodobenzylguanidine (MIBG)

Cellular/Molecular Mechanism of Action: [^{123}I]-MIBG functions as an analogue of norepinephrine.

Physiological Mechanism of Action: Dobutamine exerts adrenergic/sympathomimetic properties.

Route of Administration: Dobutamine (intravascular).

Dosage: Dobutamine (5, 10, and 15 μg/kg/min).

Implementation: Measure LVEF at rest and in response to gradient increases in the dose of dobutamine infused before therapy in cases of dilated cardiomyopathy (DCM) according to protocols for dobutamine gated blood-pool scintigraphy (DOB-GBP). Examinations are performed before and after 1 year of therapy. The heart/mediastinum count (H/M) ratio and total defect score (TDS) are determined for [^{123}I]-MIBG images from anterior planar image and single photon emission computed tomography (SPECT) images. Left ventricular ejection fraction and left ventricular end-diastolic dimension (LVDd) are determined by echocardiography.

Human Model: Cases of DCM (n = 22).

Interpretation and Analysis: After 1 year of treatment, echocardiographic LVEF improves > 5% (e.g., n = 11/22 cases). Before treatment, TDS, H/M, LVEF, and LVDd are similar in both groups. However, there is a greater increase in the LVEF during dobutamine infusion in cases displaying improvement compared to those that do not improve (21 ± 8% vs 9 ± 3%, $p < 0.001$). If a critical value of 15% for the DeltaLVEF is used to predict the improvement in LVEF after treatment, sensitivity is 91% and specificity is 82%. The TDS, H/M ratio, LVDd, and New York Heart Association functional class improves in cases demonstrating a post-1 year response that is greater than comparable values for cases that do not demonstrate a response. Dobutamine gated blood-pool scintigraphy, therefore, can be used to predict improved cardiac sympathetic nerve activity, cardiac function, and symptoms after treatment in patients with DCM.

Dobutamine gated blood-pool scintigraphy predicts the improvement of cardiac sympathetic nerve activity, cardiac function, and symptoms after treatment in patients with dilated cardiomyopathy. Kasama S, Toyama T, Hoshizaki H, Oshima S, Taniguchi K, Suzuki T, Kurabayashi M. Chest 2002 Aug; 122 (2), pp. 542–8.

Coronary Artery Spasm/Adrenergic Sympathetic Innervation: Characterization of Abnormalities

[^{123}I]-Metaiodobenzylguanidine (MIBG)/Ergonovine

Considerations: It has been suggested that the sympathetic nervous system might play an important role in the development of coronary artery spasm. However, no cardiac imaging modality has been able to demonstrate abnormal sympathetic innervation in patients with coronary artery spasm.

The agent [^{123}I]-MIBG single photon emission computed tomography (SPECT) can non-invasively localize within regions of the coronary arteries affected by spasm. Invasive diagnostic coronary arteriography with ergonovine provocation test may be unnecessary for diagnosis of coronary artery spasm in cases with typical resting pain, negative exercise tests, or normal thallium perfusion scan results but that are showing abnormalities in [^{123}I]-MIBG SPECT.

Implementation: Assess the presence and location of abnormal sympathetic innervation using [^{123}I]-MIBG SPECT and evaluate the clinical efficacy of [^{123}I]-MIBG SPECT as a non-invasive screening test in cases suffering from coronary artery spasm. In this fashion, coronary arteriography and a provocative test with intravenous administration of ergonovine maleate can be utilized.

Human Model: Cases suspected of having a coronary artery spasm (n = 26 patients; 48.2 ± 12.0 years, range 20–67 years; n = 20/26 men). Cases are divided into 2 groups: Group 1 (n = 18 positive provocative test results) and Group 2 (n = 8 negative provocative test results); in addition to normal controls (n = 10).

Interpretation and Analysis: No abnormal MIBG uptake is observed in control subjects. Abnormal sympathetic nervous innervation using [^{123}I]-MIBG SPECT can be observed either as a reduced uptake or a defective pattern in the perfused areas (e.g., n = 13/18) supplied by vessels associated with ergonovine-induced vasospasm. Normal sympathetic innervation, as evidenced by normal [^{123}I]-MIBG uptake, can be noted in all of the 60 segments of normal vessel territories. Reduced uptake of [^{123}I]-MIBG cannot be detected in perfused areas of vasospasm-induced vessels such as perfused regions of left anterior descending coronary artery [LAD] and the right coronary artery [RCA] (e.g., n = 2 and 3 cases, respectively). Sensitivity and specificity of [^{123}I]-MIBG for detecting coronary artery spasm is 72.2% (95% confidence interval [CI] 55% to 89%) and 100%, respectively. The positive predictive and negative predictive values are 100% and 92.3% (95% CI 91% to 93%), respectively.

^{123}I-MIBG myocardial scintigraphy as a non-invasive screen for the diagnosis of coronary artery spasm. Ha JW, Lee JD, Jang Y, Chung N, Kwan J, Rim SJ, Lee YJ, Shim WH, Cho SY, Kim SS. J Nucl Cardiol 1998 Nov–Dec; 5 (6), pp. 591–7.

Cardiovascular/Coronary Artery Disease (CAD): Angina (Stress-Induced)/Myocardial Infarction

Iodophenyl-9-Methyl Pentadecanoic Acid (9MPA)/ [^{201}Tl]/[^{123}I]-β-Methyl Iodophenyl Pentadecanoic Acid ([^{123}I]-BMIPP)

Application: Detection and characterization of coronary/myocardial disease states.

Implementation: Evaluate the ability to detect CAD with a [^{123}I]-labeled branched fatty acid analog, 9MPA, compared to [^{123}I]-BMIPP and [^{201}Tl] utilizing single photon emission computed tomography (SPECT) imaging modalities. Images with 9MPA SPECT are obtained at 15 minutes after injection. Comparisons are performed with analysis from stress-redistribution [^{201}Tl] SPECT (e.g., n = 23 cases) and BMIPP myocardial fatty acid imaging (e.g., n = 9 cases). The regional uptakes of 9MPA, BMIPP, and [^{201}Tl] are scored semi-quantitatively and the segmental agreements are compared among them.

Human Model: Cases affected by effort angina (n = 24) or myocardial infarction (n = 13).

Interpretation and Analysis: In the segment-to-segment comparison, 9MPA shows reduced activity in comparison to stress-redistribution [^{201}Tl] imaging. The defect score of 9MPA is significantly greater than that of redistribution [^{201}Tl] images ($p < 0.001$). In addition, segmental 9MPA uptake is lower than BMIPP and its defect score is significantly greater than that of BMIPP ($p < 0.05$). When coronary angiography is used as the criterion, 9MPA showes higher sensitivity and lower specificity than stress-redistribution [^{201}Tl] ($p < 0.01$). In conclusion, fatty acid metabolic imaging with 9MPA is a sensitive but non-specific detector of CAD.

Detection of coronary artery disease by iodine-123-labeled iodophenyl-9-methyl pentadecanoic acid SPECT: Comparison with thallium-201 and iodine-123 BMIPP SPECT. Fukuchi K, Hasegawa S, Ito Y, Yamaguchi H, Yoshioka J, Uehara T, Nishimura T. Ann Nucl Med 2000 Feb; 14 (1), pp. 11–6.

Coronary Artery Lesions in Unstable Angina/ Myocardial Metabolic Abnormalities *[^{123}I]-β-Methyl Iodophenyl Pentadecanoic Acid ([^{123}I]-BMIPP)*

Application: Detection of atherosclerotic plaques (deposits) responsible for disease states, including stroke, aneurysm, and myocardial infarction. The imaging agent [^{123}I]-BMIPP is a β-methyl-branched fatty acid analogue that has demonstrated an ability to reveal abnormalities in fatty-acid-related metabolism.

Route of Administration: [^{123}I]-BMIPP (intravascular).

Implementation: Evaluation of [^{123}I]-BMIPP ^{201}thallium chloride ([^{201}Tl]Cl) imaging with single photon emission computed tomography (SPECT) for the capacity to detect anatomical and physiological abnormalities in cases with unstable angina.

Human Model: Cases of unstable angina without prior myocardial infarction (n = 100).

Interpretation and Analysis: Coronary arteries with stenosis due to plaque formation (deposits) demonstrate an increased uptake of [^{123}I]-BMIPP.

In cases of unstable angina without prior myocardial infarction (n = 100), evaluation with ^{123}I-BMIPP and [^{201}Tl]Cl imaging with SPECT and coronary and left ventricular cineangiography performed 1 week after the last episode of angina can reveal a variety of abnormalities, including reduced uptake of [^{123}I]-BMIPP imaging (n = 70/100 cases), reduced uptake of [^{201}Tl]Cl (n = 41/100), and/or abnormal left ventricular cineangiography (n = 49/100).

Significant increases in severity scores for [^{123}I]-BMIPP imaging along with increases in the number of stenosed coronary arteries and the severity of stenosis in individual coronary arteries can be appreciated. One month after percutaneous trans-lumination coronary angioplasty, a significant reduction can be appreciated in [^{123}I]-BMIPP severity scores ($p < 0.01$) along with a significant correlation between the severity scores of [^{123}I]-BMIPP and left ventricular cineangiography ($r = 0.579$, $p < 0.001$).

Overall rates of sensitivity and specificity in detecting significant coronary stenosis by [^{123}I]-BMIPP imaging have been found to be 74% and 86%, respectively, whereas rates of sensitivity and specificity in detecting significant coronary stenosis by [^{201}Tl]Cl are approximately 31% and 91%, respectively. [^{123}I]-BMIPP sensitivity increases to 86% if only advanced coronary stenosis of > 90% is included. Therefore, [^{123}I]-BMIPP myocardial imaging is an effective method of predicting coronary artery lesions of unstable angina patients without provocative testing.

Diagnostic usefulness of myocardial SPECT with [^{123}I]-β-methyl-iodophenyl pentadecanoic acid and [^{201}Tl] in unstable angina. Nakazawa Y, Tahara H, Suyama H, Kakio T, Ohue Y, Goto Y, Inoue K, Yamamoto Y, Nakamura N, Masui K, et al. Kaku Igaku 1995 Sep; 32 (9), pp. 953–8.

Myocardial Function and Perfusion/Incremental Cardiac Mortality Predictive Parameters *^{201}Thallium/Adenosine/[^{99m}Technetium] ([^{99m}Tc])-SestaMIBI*

Background Information: Availability of data is limited regarding the incremental value of adenosine stress myocardial perfusion single photon emission computed tomography (SPECT) (MPS) for the prediction of cardiac death in women vs men and the impact of diabetes mellitus on postadenosine MPS outcomes.

Application: Prediction of cardiac-related mortality. Adenosine MPS has comparable incremental value in predicting cardiac death in women and men.

Implementation: Characterization of case history following evaluation by rest thallium-201/adenosine technetium-99m sesta MIBI MPS (e.g., n = 2,656 women; n = 2,677 men).

Interpretation and Analysis: Women have significantly smaller adenosine stress, rest, and reversible defects than men. During 27.0 ± 8.8 month follow-up, cardiac death rates are lower in women than men (2.0%/year vs 2.7%/year, respectively, $p < 0.05$). Before and after risk adjustment, cardiac death risk increases significantly in both men and women as a function of MPS results. Multivariable models reveal that MPS results provide incremental prognostic value over prescan data for the prediction of cardiac death in both genders. Also, while comparative unadjusted rates of early (≤ 60 days posttest) coronary angiography (17% vs 23%) and revascularization (8% vs 12%) are significantly lower in women ($p < 0.05$), after adjusting for MPS, these rates are similar in men and women. Importantly, diabetic women have a significantly greater risk of cardiac death compared with other patients. Also, after risk adjustment, cases with insulin-dependent diabetes mellitus (IDDM) have a higher risk of cardiac death than patients with non-insulin-dependent diabetes mellitus. Attributes of MPS include its ability to influence decisions regarding the appropriateness of subsequent invasive management procedures (males and females). Diabetic women and patients with IDDM appear to have a greater risk of cardiac death than other patients for any MPS result.

Adenosine myocardial perfusion single photon emission computed tomography in women compared with men. Impact of diabetes mellitus on incremental prognostic value and effect on patient management. Berman DS, Kang X, Hayes SW, Friedman JD, Cohen I, Abidov A, Shaw LJ, Amanullah AM, Germano G, Hachamovitch R. J Am Coll Cardiol 2003 Apr 2; 41 (7), pp. 1125–33.

Myocardial Ischemia
[^{18}F]-Deoxyglucose/[^{99m}Technetium] ([^{99m}Tc])-Methoxy-Isobutylisonitrile (MIBI) Alternative

Cellular/Molecular Mechanism of Action: [^{18}F]-Deoxyglucose is a radiolabeled analogue of glucose that enters cells through glucose transport mechanisms.

Application: Detection and characterization of myocardial ischemia conditions.

Dosage: Glucose (25–50 g); [^{18}F]-fluoro-deoxy-glucose (370 MBq (10 mCi)); [^{99m}Tc]-MIBI (925 MBq (25 mCi)).

Implementation: Evaluation of conditions of myocardial ischemia utilizing both positron emission tomography (PET) and single photon emission computed tomography (SPECT) facilitated by the application of [^{18}F]-deoxyglucose and [^{99m}Tc]-MIBI. One investigative protocol that can be applied to achieve such a diagnostic objective entails delineation of rest metabolism/stress perfusion profiles facilitated by dual-isotope simultaneous-acquisition SPECT. In this context, glucose can be administered (25–50 g) followed approximately 60 minutes later by an injection of [^{18}F]-fluoro-deoxy-glucose (370 MBq (10 mCi)). After a 35-minute distribution phase, cases are then subjected to exercise or pharmacologic stress followed by administration of [^{99m}Tc]-MIBI (925 MBq [25 mCi]).

Human Model: Cases of myocardial ischemia (n = 5) evaluated by both PET and SPECT. Additional cases subjected to coronary angiography within 3 months of dual-isotope SPECT (n = 23; mean age = 54 + 6 years, range 30–83; n = 14 men, n = 9 women).

Interpretation and Analysis: Applying a window of 20% for both photopeaks and [^{99m}Tc]/[^{18}F] concentrations of 3.2:1, the "spillover" from [^{18}F] into the [^{99m}Tc] window is < 6% of the total counts in the window in patients with a normal distribution of both radiopharmaceuticals. Phantom images clearly demonstrate cardiac defects measuring 2 × 1 and 2 × 0.5 cm. There is no significant difference in images of cases undergoing both PET and SPECT (e.g., n = 5 cases). A considerable number of imaging studies will have normal results (e.g., n = 21), while some will display mismatched defects (e.g., n = 15); matched defects (e.g., n = 14); or both matched and mismatched defects (e.g., n = 7). In coronary angiography examinations, approximately one-third can yield normal findings (e.g., n = 7/23), in addition to the detection of matched defects (e.g., n = 1/23) and both matched and mismatched defects (e.g., n = 7). When stenosis of > 70% is used as the criterion for a diagnosis of coronary artery disease, dual-isotope SPECT has a sensitivity of 100%, specificity of 88%, positive predictive value of 93%, negative predictive value of 100%, and an accuracy of 96%. Therefore, dual-isotope SPECT may provide an alternative, accurate, cost-effective method to [^{13}N]-nitrogen ammonia/[^{18}F]-fluoro-deoxy-glucose PET or [^{201}Tl] reinjection for identifying injured or dysfunctional but viable myocardium.

Instrumentation: Dual-isotope single-acquisition SPECT protocol using a multihead SPECT camera equipped with an ultra-high energy collimator.

Evaluation of myocardial ischemia using a rest metabolism/stress perfusion protocol with fluorine-18 deoxyglucose/technetium-99m MIBI and dual-isotope simultaneous-acquisition single photon emission computed tomography. Sandler MP, Videlefsky S, Delbeke D, Patton JA, Meyerowitz C, Martin WH, Ohana I. J Am Coll Cardiol 1995 Oct; 26 (4), pp. 870–8.

Myocardial Ischemia/Perfusion-Metabolism Mismatch
[^{123}I]-(ρ-Iodophenyl)-3-R,S-Methylpentadecanoic Acid/Non-Metabolized [^{123}I]-β-Methyl Iodophenyl Pentadecanoic Acid ([^{123}I]-BMIPP) Myocardial Backdiffusion/Long-Chain Fatty Acid BMIPP: Decreased Tissue Uptake

Molecular/Cellular Mechanism of Action: BMIPP is a fatty acid analog.

Background Information: [^{123}I]-BMIPP is a fatty acid analogue for single photon emission computed tomography (SPECT) imaging. This radiopharmaceutical possesses a unique property, in that it produces imaging patterns of perfusion-metabolism mismatch during SPECT analyses in conditions of ischemic heart disease. However, the mechanism responsible for such properties remains unclear.

Application: Detection and characterization of perfusion-metabolism mismatch in cases with ischemic heart disease applying SPECT imaging methodologies.

Route of Administration: [^{123}I]-BMIPP (intravascular).

Implementation: The agent BMIPP is injected into the left anterior descending artery (LAD), and either blood samples are collected from the cardiac vein or abdominal aorta; or serial biopsy specimens are harvested from the LAD region for comparison to reference controls. The catabolites of BMIPP, including backdiffusion of non-metabolized BMIPP, are measured utilizing high-performance liquid chromatography (HPLC in efflux study). Thin-layer chromatography (TLC) techniques can be applied for the analytical evaluation of tissue specimens.

Animal Model: Canine (n = 11 dogs subjected to open-chest thoracotomy under anesthesia to facilitate a system developed for the release of all blood within the great cardiac vein outside without recirculation. In addition, the LAD is occluded for 30 minutes after

reperfusion (n = 6/11 dogs cardiac vein and abdominal aorta blood is collected post-BMIPP injection; n = 5/11 dogs used for collection of serial biopsy specimens from the LAD region).

Interpretation and Analysis: The agent BMIPP is rapidly extracted from the plasma by myocardiocytes (myocardium) and the subsequent retention is unchanged. The early washout (8 minutes) of radioactivity significantly increases (51% ± 12% to 65% ± 7%; $p < 0.05$) with ischemia. The metabolites from the myocardium consist of a backdiffusion of non-metabolized BMIPP, alpha, intermediate, and full oxidation metabolites. Among these metabolites, backdiffusion of non-metabolized BMIPP in blood significantly increases (27.9% ± 7.7% to 42.3% ± 8.1%; $p < 0.05$), especially in the early phase with ischemia. In tissues, radioactivity is concentrated in the triglyceride pool even in the early phase. In addition, BMIPP and alpha-oxidized metabolites significantly decreases in the early phase with ischemia (t = 1 minute after BMIPP injection, 25.9% ± 8.6% to 14.5% ± 2.1%, $p < 0.01$; t = 2 minutes, 8.9% ± 5.0% to 4.5% ± 1.7%, $p < 0.05$). Such findings demonstrate that backdiffusion of non-metabolized BMIPP from the myocardium increases and BMIPP (long-chain fatty acids) in tissue decreases with ischemia, suggesting backdiffusion of non-metabolized BMIPP might play an important role in myocardial perfusion-metabolism mismatch on SPECT images in cases of ischemic cardiac disease.

Myocardial metabolism of [^{123}I]-BMIPP in a canine model with ischemia: Implications of perfusion-metabolism mismatch on SPECT images in patients with ischemic heart disease. Hosokawa R, Nohara R, Fujibayashi Y, Okuda K, Ogino M, Hirai T, Fujita M, Tamaki N, Konishi J, Sasayama S. J Nucl Med 1999 Mar; 40 (3), pp. 471–8.

Myocardium/Ischemic Cardiomyopathy/Diabetes Mellitus

Acipomox/[^{18}F]-Fluoro-Deoxy-Glucose (FDG) Single Photon Emission Computed Tomography (SPECT)

Cellular/Molecular Mechanism of Action: The agent [^{18}F]-FDG functions as an analogue of glucose. Acipimox is a nicotinic acid derivative.

Application: Detection and characterization of alterations in glucose metabolism using [^{18}F]-FDG. Acipimox utilized in combination with [^{18}F]-FDG SPECT metabolic imaging can be used to assess conditions of ischemic cardiomyopathy even in cases suffering from diabetes mellitus.

Implementation: Evaluation of ischemic cardiomyopathy cases applying [^{18}F]-FDG SPECT imaging analysis in combination with acipimox to assess myocardial viability. Complementary image analysis involves performing resting 2-dimensional echocardiography in an effort to identify dysfunctional myocardial tissue. Image quality is then scored visually and quantitatively, while the myocardium-to-background ratio is determined by region-of-interest (ROI) analysis. The plasma concentrations of glucose and free fatty acids determined to evaluate metabolic status before and during [^{18}F]-FDG imaging.

Human Model: Ischemic cardiomyopathy (n = 70; n = 34/70 diabetes mellitus; n = 12/34 insulin-dependent diabetes mellitus, n = 22/34 non-insulin-dependent diabetes mellitus; n = 36/70 non-diabetic).

Interpretation and Analysis: Acipimox significantly lowers plasma levels of free fatty acids in both case category types. Approximately 50% of diabetic cases (e.g., n = 15/34) have plasma glucose levels of > 9 mmol/L, which is lowered successfully in essentially all cases when administered additional insulin. Visual evaluation of [^{18}F]-FDG images reveals they are of variable quality (diabetic/non-diabetic: n = 27/32 good; n = 5/4 moderate; n = 2/0 poor; p = not statistically significant). The myocardium-to-background ratio of [^{18}F]-FDG SPECT images is comparable in cases with and without diabetes mellitus (3.1 ± 1.0 vs 3.5 ± 0.9; p = not statistically significant). The type of diabetes has no influence on [^{18}F]-FDG image quality. Note: Severe side effects usually are not appreciated during [^{18}F]-FDG SPECT procedures. [^{18}F]-FDG SPECT metabolic imaging after acipimox appears to be safe and practical for routine assessment of viability in patients with ischemic cardiomyopathy. Image quality is good, even in patients with diabetes, although additional insulin is sometimes needed.

Effect of diabetes mellitus on myocardial ^{18}F-FDG SPECT using acipimox for the assessment of myocardial viability. Schinkel AF, Bax JJ, Valkema R, Elhendy A, van Domburg RT, Vourvouri EC, Bountioukos MA, Krenning EP, Roelandt JR, Poldermans D. J Nucl Med 2003 Jun; 44 (6), pp. 877–83.

Myocardial Metabolism: Substrate Imaging

[^{11}C]-Palmitate

Application: Characterization of myocardial substrate metabolism in health and disease.

Considerations: Glucose administration in fasted humans can serve as a provocative test of substrate regulation, which can be abnormal in myocardial disease and can be demonstrated in a non-invasive manner.

Implemenation: Determine non-invasively the changes that develop in myocardial substrate metabolism in normal and diseased human myocardium in response to altered substrate availability in blood and disease-related abnormalities. Such forms of evaluation can be achieved with injections of [^{11}C]-palmitate and serial positron emission tomography (PET) imaging performed after an overnight fast (control period) and again 2 hours later after oral glucose (50 g).

Interpretation and Analysis: The combined use of PET and [^{11}C]-palmitate allows non-invasive demonstration of the known response of substrate metabolism of the human heart to alterations in substrate availability. Myocardial [^{11}C] time-activity curves from serial PET images reveal biexponential clearance patterns. An early rapid phase, defined by relative size and clearance half-time, reflects [^{11}C]-palmitate oxidation and the late slow phase tracer deposition in the endogenous lipid pool. During the control period, the tracer fraction entering the early rapid phase averages 47 ± 13% (standard deviation) in normal subjects and 45 ± 12% in affected patients. Corresponding clearance half-times are 19 ± 7 and 20 ± 5 minutes, respectively. Heart rate and blood pressure remain unchanged after glucose administration, but plasma glucose levels increase by 72.5% in normal subjects and by 98.9% in affected patients, while free fatty acid levels decrease by 72% and 42% ($p < 0.001$), respectively. In normal subjects, the tracer fraction in the early rapid phase falls by 43% ($p < 0.005$) and the clearance half-time increases by 46% ($p < 0.01$). In affected patients, the response of [^{11}C]-palmitate tissue kinetics to glucose are variable. In some cases, the pattern is similar to that of normal subjects, while in other patients a "paradoxic" response may be observed. The tracer fraction entering the rapid clearance phase increases after glucose by 30% ($p < 0.05$) associated with a 36% ($p < 0.05$) decline in clearance half-times. The paradoxic response is unrelated to disease etiology or plasma substrate levels but occurs mostly in left ventricles displaying more severely depressed function.

Effects of substrate availability on myocardial C-11 palmitate kinetics by positron emission tomography in normal subjects and patients with ventricular dysfunction. Schelbert HR, Henze E, Sochor H, Grossman RG, Huang SC, Barrio JR, Schwaiger M, Phelps ME. Am Heart J 1986 Jun; 111 (6), pp. 1055–64.

Myocardial Perfusion Assessment
Dipyridamole/^{201}Thallium ([^{201}Tl]) Single Photon Emission Computed Tomography (SPECT)

Application: Detection and characterization of myocardial ischemia conditions.
Route of Administration: Dipyridamole (slow IV).
Considerations: Dipyridamole stress might be considered appropriate as a provocative test when physical exercise cannot be carried out.
Implementation: Evaluate the diagnostic capability of SPECT to detect diseased coronary vessels utilizing dipyridamole in concert with [^{201}Tl] and SPECT.

Assessment of myocardial infusion (± maximal ergometric exercise) is facilitated by utilizing dipyridamol infusion in concert with myocardial imaging techniques employing [^{201}Tl] and SPECT. To evaluate the diagnostic capability of SPECT in the detection of diseased coronary vessels, the left ventricular myocardium is subdivided into 6 segments related to the 3 major coronary arteries. Single photon emission computed tomography images are acquired after dipyridamole infusion (Methodology Type 1 with n = 41 cases) or after tracer injections at maximal ergometric exercise (Methodology Type 2 with n = 162 cases). Based on findings from [^{201}Tl] and dipyridamole evaluations, cases are then subdivided into 2 groups for diagnostic coronary angiography.

Human Model: Cases suffering from cardiovascular disease (n = 203).
Interpretation and Analysis: Sensitivity for the left anterior descending artery is 77% with Methodology Type I and 79% in Methodology Type II; specificity is 80% and 96%, respectively. Sensitivity for the right coronary artery is 91% with Method I and 85% with Method 2; specificity is 81% and 73%. For the left circumflex artery sensitivity is 65% with Method 1 and 67% for Method 2, while specificity is 89% and 88%, respectively. Myocardial SPECT results after ergometric exercise and dipyridamole infusion appear to be almost superimposable.

Diagnostic accuracy of single photon emission computed tomography with thallium-201 for the identification of diseased coronary arteries. Comparison between dipyridamole infusion and exercise stress test. Dondi M, Monetti N, Levorato M, Corbelli C, Zagni P, Tartagni F, Maiello L, Fallani F, Ortolani P. J Nucl Med Allied Sci 1990 Jan–Mar; 34 (1), pp. 19–23.

Cardiovascular: Myocardial Perfusion (Kawasaki Disease [KD])/Myocardial Perfusion/ Regional Hypoperfusion
[^{99m}Technetium] ([^{99m}Tc])-Tetrofosmin (TF)/ Dipyridamole

Physiological Mechanism of Action: Dipyridamole promotes vasodilator activity.
Background Information: The coronary artery abnormalities in KD often cause myocardial ischemia. Previous publications have described the use of ^{201}thallium myocardial perfusion imaging to determine the extent of ischemia in KD conditions. The technetium perfusion agents offer better resolution and may offer additional information about ventricular function in such conditions.
Application: Tetrofosmin myocardial perfusion imaging can detect regional areas of myocardial hypoperfusion (e.g., KD of children).
Implementation: Evaluation of myocardial perfusion in cases of KD applying [^{99m}Tc]-TF in conjunction with performing a dipyridamole vasodilator stress test. Significant coronary artery stenosis is classified as being ≥ a 75% reduction in luminal diameter. After administration of high-dose dipyridamole infusion (0.70 mg/kg), [^{99m}Tc]-TF is injected, followed by a 2nd [^{99m}Tc]-TF injection at rest 4 hours later. Single photon emission computed tomography (SPECT) images are obtained more than 30 minutes after TF injection.

Human Model: Kawasaki disease (n = 86 cases, 11.5 ± 6.4 years; n = 20 age-matched controls without heart disease). Dipyridamole (high-dose = 0.70 mg/kg); [^{99m}Tc]-TF (1st dose = 74–370 MBq; 2nd dose = 148–740 MBq).
Interpretation and Analysis: Significant coronary artery stenosis, coronary aneurysm without stenosis, and an absence of coronary lesions can be appreciated in a considerable number of cases (e.g., n = 20/86, n = 37/86, and n = 29/86, respectively). Regional myocardial hypoperfusion can be observed in a number of cases that have coronary artery stenosis of 75% or greater (n = 18/86, sensitivity 90%, and specificity 100%). A small percentage of cases do not demonstrate ischemic changes in coronary artery stenosis (n = 2) and some of these cases have good collateral blood flow (n = 1 of 2).

Myocardial ischemia in Kawasaki disease: Evaluation with dipyridamole stress technetium 99m tetrofosmin scintigraphy. Fukuda T, Ishibashi M, Yokoyama T, Otaki M, Shinohara T, Nakamura Y, Miyake T, Kudoh T, Oku H. J Nucl Cardiol 2002 Nov–Dec; 9 (6), pp. 632–7.

Myocardium/Pharmaceutical Efficacy Evaluation
[^{18}F]-Fluoro-Deoxy-Glucose (FDG)/Acipimox

Cellular/Molecular Mechanism of Action: Acipimox is a nicotinic acid derivative.
Background Information: Image quality of cardiac FDG studies is highly dependent on the metabolic conditions during the study; hyperinsulinemic euglycemic clamping ensures adequate image quality. However, the approach is time-consuming. Data in a small number of patients suggest that oral administration of a nicotinic acid derivative (Acipimox) results in good image quality.
Application: Acipimox can be applied to enhance myocardial FDG image quality.
Route of Administration: Acipimox (oral).
Dosage: Acipimox (250 mg; Byk, The Netherlands).
Implementation: Evaluation of the safety and image quality of cardiac FDG single photon emission computed tomography (SPECT) studies after acipimox administration. Image quality is assessed visually and quantitatively facilitated by the calculation of heart-to-lung, heart-to-liver, and myocardium-to-background ratios. Blood samples are drawn at baseline and at the time of FDG injection to determine levels of glucose, free fatty acids, and insulin.

Human Model: Cases receiving Acipimox (n = 21 patients, Type 2); compared to hyperinsulinemic euglycemic clamping (n = 69 cases Type 1).
Interpretation and Analysis: Baseline characteristics of Type 1 and Type 2 patients are comparable. Undesirable sequelae are usually only appreciated in Type 2 cases (n = 4/69 or 19% = paroxysmal flushing). Image quality, assessed visually, is good in 100% of Type 1 and 86% of Type 2 cases. All quantitative parameters of image quality (heart-to-lung, heart-to-liver, and myocardium-to-background ratios) are comparable between Type 1 and Type 2 cases. Baseline plasma levels of all substrates are comparable between groups. At the time of FDG injection, plasma levels of glucose and free fatty acids are comparable between Type 1 and 2 cases, and insulin is higher in Type 1 cases. Cardiac FDG SPECT after acipimox is a simple and safe approach that renders image quality comparable to that obtained during hyperinsulinemic euglycemic clamping.

Safety and feasibility of cardiac FDG SPECT following oral administration of acipimox, a nicotinic acid derivative: Comparison of image quality with

hyperinsulinemic euglycemic clamping in non-diabetic patients. Bax JJ, Visser FC, Poldermans D, Van Lingen A, Elhendy A, Boersma E, Sloof GW, Visser CA. J Nucl Cardiol 2002 Nov–Dec; 9 (6), pp. 587–93.

Sympathetic (Adrenergic) Receptor Expression/ Cardiac Arrythmia: Brugada Syndrome/ Sympathetic Innervation Dysfunction (Presynaptic) *[^{123}I]-Metaiodobenzylguanidine ([^{123}I]-MIBG)*

Cellular/Molecular Mechanism of Action: [^{123}I]-Metaiodobenzylguanidine is an analogue of the adrenergic neurotransmitter norepinephrine.

Background Information: Patients with Brugada syndrome present with characteristic electrocardiogram (ECG) abnormalities (atypical right bundle-branch block and ST-segment elevation) and life-threatening ventricular tachyarrhythmias despite structurally normal hearts. Involvement of the autonomic nervous system is suspected by the occurrence of ventricular tachyarrhythmias and sudden death at rest or during sleep and by changes of typical ECG signs under pharmacological modulation of the myocardial autonomic tone.

Application: Characterization of presynaptic sympathetic innervation to the heart in conditions of Brugada syndrome.

Route of Administration: [^{123}I]-MIBG (intravenous).

Implementation: Evaluation of the presynaptic cardiac neuronal reuptake of norepinephrine (uptake 1) in conditions of Brugada syndrome and age-matched control subjects using the norepinephrine analogue [^{123}I]-MIBG in concert with single photon emission computed tomography (SPECT) and quantitative 33-segment bull's-eye analysis.

Human Model: Brugada syndrome (n = 17; n = 10 age-matched controls).

Interpretation and Analysis: Regionally reduced [^{123}I]-MIBG uptake is present in almost half of all cases with Brugada syndrome (e.g., n = 8/17 or 47%) but not in reference controls. Quantitative analysis shows segmental reduction of [^{123}I]-MIBG uptake in the inferior and septal left ventricular wall in patients with Brugada syndrome compared with control subjects ($p < 0.05$). No correlation can be appreciated between the findings from [^{123}I]-MIBG SPECT and clinical characteristics of study patients. Abnormal [^{123}I]-MIBG uptake in Brugada syndrome cases indicates presynaptic sympathetic dysfunction exists within the heart. These findings may have potential impact on the pathophysiology and arrhythmogenesis in cases with Brugada syndrome. Future quantitative investigations of the presynaptic and postsynaptic sympathetic and parasympathetic branches of the cardiac autonomic nervous system may clarify whether these observations represent a primary adrenergic dysfunction or an imbalance between sympathetic and parasympathetic innervation of the heart.

Cardiac autonomic dysfunction in Brugada syndrome. Wichter T, Matheja P, Eckardt L, Kies P, Schäfers K, Schulze-Bahr E, Haverkamp W, Borggrefe M, Schober O, Breithardt G, Schäfers M. Circulation 2002 Feb 12; 105 (6), pp. 702–6.

Thrombosis: Arterial and Venous/Deep Vein Thrombosis/Pulmonary Embolism/Arterial Thromboembolic Disorders/Cerebral Vascular Stroke/Coronary Artery Thrombotic Disorders/Peripheral Artery Thromboses *Platelet GPIIb/IIIa Receptor Antagonist/ [^{99m}Technetium] ([^{99m}Tc])-DMP728/[^{3}H]-DMP728*

Cellular/Molecular Mechanism of Action: The agent DMP728 functions as a GPIIb/IIIa receptor antagonist on the exterior surface membrane of platelets.

Physiological Mechanism of Action: The composition of venous thrombi is predominantly polymerized fibrin monomer with variable degrees of cross-linking (e.g., XIIIa* activity). Conversely, arterial thrombi are composed of a much higher platelet content.

Background Information: Either venous or arterial thrombosis is a potentially life-threatening event and some diagnostic modalities can be inadequate for diagnostic purposes or for determining the actual morphology of the evolving thrombus. Thus, development of a non-invasive imaging agent that can detect clot location remains a critical and unresolved need in nuclear diagnostic medicine.

Application: Detection and characterization of intravascular venous and arterial thromboses.

Implementation: Evaluation of artificially (*in vitro*) created venous and arterial type thrombi using the potent radiolabeled GPIIb/IIIa receptor antagonist [^{3}H]-DMP728. Complementary investigation can involve the *in vivo* application of [^{99m}Tc]-DMP728 to determine the clot/blood distribution ratio (e.g., target:background ratio). In addition, non-invasive single photon emission computed tomography (SPECT) of venous clots in deep vein thrombosis can be performed as well. As a point of comparison, thrombin inhibitors can also be evaluated using these agents as efficacy probes.

Animal Model: Canine (dogs with mixed arterial/venous or venous clots in arteriovenous shunts, in addition to venous clot foci and deep vein thrombi).

Interpretation and Analysis: Radiolabeled preparations of the GPIIb/IIIa receptor antagonist DMP728 in the form of [^{3}H]-DMP728 and [^{99m}Tc]-DMP728 retain marked binding avidity for platelet GPIIb/IIIa receptor complexes. DMP728 demonstrates a relatively greater affinity for activated than for unactivated human platelets, which may be essential for attaining an optimal thrombus/blood (target/background) distribution ratio and optimal detection of small clots (i.e., greater sensitivity). Therefore, [^{99m}Tc]-GPIIb/IIIa receptor antagonists have potential utility in the diagnosis of venous clots in deep vein thrombosis, pulmonary embolism, and arterial thromboembolic disorders, including stroke and coronary and peripheral artery thrombotic disorders. Thrombin inhibitors do not appear to be as effective in this same context.

Novel technetium-99m-labeled platelet GPIIb/IIIa receptor antagonists as potential imaging agents for venous and arterial thrombosis. Mousa SA, Bozarth JM, Edwards S, Carroll T, Barrett J. Coron Artery Dis 1998; 9 (2–3), pp. 131–41.

CENTRAL NERVOUS SYSTEM (CNS)

Acetylcholine Muscarinic Receptors/Cardiac Muscarinic Acetylcholinergic Receptors/Central Nervous System (CNS) Muscarinic Acetylcholinergic Receptors/Carcinoma of the Colon *[^{123}I]-PIP/[^{125}I]-PIP*

Cellular/Molecular Mechanism of Action: The agent IPIP functions as a ligand for muscarinic acetylcholinergic complexes (mAChR).

Background Information: Prior to approval for *in vivo* use in humans, organ doses for radioiodinated IPIP ligands must 1st be evaluated.

Application: Radioiodinated IPIP ligands can be applied *in vivo* for imaging mAChR using various imaging modalities, including single photon emission computed tomography (SPECT).

Implementation: Identify the most optimum mAChR ligand-binding properties of 4 different IPIP sterioisomers through evaluation of their biodistribution pattern. A biokinetic model can be developed for the Z-(S)-IPIP stereoisomer for estimating the internal

absorbed dose in humans based on extrapolation from an appropriate rat model.

Animal Model: Rat (IPIP biokinetic model).

Interpretation and Analysis: The thyroid gland is the critical organ for this radiopharmaceutical, with an absorbed dose estimate of 2.4 mGy/MBq for both males and females, when labeled with [^{123}I]. Even when blocked, the thyroid is still the critical organ, yet with a 90% reduction in absorbed dose. The heart and brain receive the next highest doses in both males and females. Effective dose estimates for the use of pure [^{123}I]-PIP in humans are 0.16 mSv/MBq for males and 0.14 mSv/MBq for females. The biodistribution studies of the Z-(S)-IPIP stereoisomer show it has the most promise as a successful agent for imaging muscarinic receptor sites in the heart and brain. IPIP can potentially be applied as a therapeutic radiopharmaceutical for certain colon carcinomas where muscarinic receptor sites are expressed by tumor cells. These results provide preliminary data for use of IPIP in clinical studies in humans.

In vivo biodistribution of [^{125}I]-PIP and internal dosimetry of 123IPIP radioiodinated agents selective to the muscarinic acetylcholinergic receptor complex. Breeden WK 3rd, Hamby DM, Carey JE Jr, Eckerman KF, McPherson DW, Knapp FF Jr. Med Phys 2000 Apr; 27 (4), 778–86.

Acetylcholine (Muscarinic) Receptor Screening/ Quantitation of Endogenous Acetylcholine Levels *[^{18}F]-Piperidyl Benzilate/[^{18}F]-Pyrrolidyl Benzilate*

Cellular/Molecular Mechanism of Action: Piperidyl benzilate and pyrrolidyl benzilate both can function as ligands that bind to muscarinic acetylcholine receptor complexes.

Background Information: Compound names include N-(2-[^{18}F]fluoroethyl)-piperidyl benzilate and N-(2-[^{18}F]fluoroethyl)-pyrrolidyl benzilate (FEPB).

Application: Function as an *in vivo* probe for measuring endogenous acetylcholine levels.

Route of Administration: Intravenous.

Examples of Clinical Implementation: Retention is moderate in mouse brain utilizing 3-[^{18}F]-FEPB; however, blocking with scopolamine reveals that uptake is not muscarinic cholinergic receptor-mediated. Conversely, mice administered 4-[^{18}F]-FEPB exhibit high, receptor-mediated retention in mouse brain, with significant clearance after 1 hour. These results suggest that 4-[^{18}F]-FEPB could have application as an *in vivo* probe for measuring endogenous acetylcholine levels.

Interpretation and Analysis: The retention of [^{18}F]-piperidyl benzilate and [^{18}F]-pyrrolidyl benzilate occurs at moderate levels in mouse brain (3-[^{18}F]-FEPB). However, blocking with scopolamine indicates that uptake is not muscarinic cholinergic receptor-mediated. Conversely, some animal subjects (4-[^{18}F]-FEPB) exhibit high, receptor-mediated retention in mouse brain, with significant clearance after a 1-hour period. These results suggest that 4-[^{18}F]-FEPB could have application as an *in vivo* probe for measuring endogenous acetylcholine levels.

Chemical Synthesis: Based on the piperidyl or pyrrolidyl benzilate reference molecule, a variety of compounds can be produced from methyl benzilate and 4-piperidinol, (R)- ± 3-piperidinol, or (R)- ± 3-pyrrolidinol. Amine substituents can include alkyl and aralkyl groups. In the evaluation of such compounds, the *in vitro* K_i values usually range from 0.05 nM to > 100 nM. In preliminary investigations, (R)-*N*-(2-fluoroethyl)-3-piperidyl benzilate (3-FEPB, 22, K_i = 12.1 nM) and *N*-(2-fluoroethyl)-4-piperidyl benzilate (4-FEPB, 8, K_i = 1. 83 nM) have been radiolabeled with [^{18}F] and related radiohalogens. Using alkylation with 2-[^{18}F]-fluoroethyl triflate, 3-[^{18}F]-FEPB (42) and 4-[^{18}F]-FEPB (43) can be produced with radiochemical yields of 7 to 9% with levels of radiochemical purity of 97% or greater.

Synthesis, [18F]-labeling, and biological evaluation of piperidyl and pyrrolidyl benzilates as *in vivo* ligands for muscarinic acetylcholine receptors. Skaddan MB, Kilbourn MR, Snyder SE, Sherman PS, Desmond TJ, Frey KA. J Med Chem 2000 Nov 16; 43 (23), pp. 4552–62.

Acetylcholine Receptor Complexes *(R)-N-(2-Fluoroethyl)-3-Piperidyl Benzilate (3-FEPB)/ N-(2-Fluoroethyl)-4-Piperidyl Benzilate (4-FEPB)/ Scopolamine*

Cellular/Molecular Mechanism of Action: Scopolamine recognizes and physically binds to muscarinic cholinergic receptor complexes (e.g., functions as a competitive antagonist of acetylcholine at muscarinic receptor sites).

Application: Measurement of endogenous acetylcholine levels.

Semi-Synthetic Methods: Production of a series of 31 compounds based on the piperidyl or pyrrolidyl benzilate scaffold using methyl benzilate and 4-piperidinol, (R)- ± 3-piperidinol, or (R)- ± 3-pyrrolidinol. Amine substituents include alkyl and aralkyl groups. The agents 3-[^{18}F]-FEPB and 4-[^{18}F]-FEPB can be produced through alkylation reactions facilitated by the application of 2-[^{18}F]-fluoroethyl triflate.

Implementation: Evaluation of the retention of 3-[^{18}F]-FEPB and 4-[^{18}F]-FEPB within the central nervous system (CNS).

Animal Model: Murine (mouse CNS).

Interpretation and Analysis: *In vitro* K_i values range from 0.05 nM to > 100 nM. Optimal properties are associated with the agents (R)-N-(2-fluoroethyl)-3-piperidyl benzilate (3-FEPB, 22, K_i = 12.1 nM) and N-(2-fluoroethyl)-4-piperidyl benzilate (4-FEPB, 8, K_i = 1.83 nM). Radiolabling with [^{18}F] applying alkylation reactions to produce 3-[^{18}F]-FEPB and 4-[^{18}F]-FEPB results in a 7–9% radiochemical yield and a > 97% radiochemical purity. Under *in vivo* conditions, brain retention is moderate for 3-[^{18}F]-FEPB; however, blocking with scopolamine reveals that uptake is not muscarinic cholinergic receptor-mediated. Conversely, 4-FEPB exhibits high, receptor-mediated retention in mouse brain, with significant clearance after 1 hour. These results suggest that compound #43 could have applications as an *in vivo* probe for measuring endogenous acetylcholine levels.

Synthesis, [18F]-labeling, and biological evaluation of piperidyl and pyrrolidyl benzilates as *in vivo* ligands for muscarinic acetylcholine receptors. Skaddan MB, Kilbourn MR, Snyder SE, Sherman PS, Desmond TJ, Frey KA. J Med Chem 2000 Nov 16; 43 (23), pp. 4552–62.

Alzheimer's Disease (AD)/Muscarinic/ Cholinergic Investigative Probe *RS 86 (2-Ethyl-8-Methyl-2,8-Diazaspiro-[4,5]-Decan-1,3-Dion Hydrobromide)*

Cellular/Molecular Mechanism of Action: The agent 2-ethyl-8-methyl-2,8-diazaspiro-[4,5]-decan-1,3-dion hydrobromide (RS 86) recognizes and physically binds to cholinergic muscarinic receptor complexes as a component of the parasympathetic autonomic nervous system.

Application: The agent 2-ethyl-8-methyl-2,8-diazaspiro-[4,5]-decan-1,3-dion hydrobromide (RS 86) appears to be an adequate probe for the clinical examination of the cholinergic hypothesis of AD.

Implementation: The effects of the compound 2-ethyl-8-methyl-2,8-diazaspiro-[4,5]-decan-1,3-dion hydrobromide (RS 86) in a number of *in vitro* and *in vivo* test systems for muscarinic cholin-

ergic activity can be analyzed and compared to those of classical muscarinic receptor agonists.

Animal Model: Guinea pig (*in vitro* ileum preparations).

Animal Model: Rat (superior cervical ganglion).

Interpretation and Analysis: In radioligand binding assays, RS 86 displays high nanomolar apparent affinity only for sites labeled by [^{3}H]-muscarinic receptor agonists, while its apparent affinity for sites labeled by [^{3}H]-muscarinic receptor antagonists, including [^{3}H]-QNB, [^{3}H]-NMS, and [^{3}H]-pirenzepine, is in the micromolar range. RS 86 has no or only low affinity (IC_{50} greater than 10 μM) for other neurotransmitter or drug receptor sites. The compound induces scopolamine-sensitive contractions of isolated guinea pig ileum showing a pD2 of 6 in this model. In the isolated rat superior cervical ganglion RS 86 also functions as an agonist with a pD2 of 6.7. When given to mice or rats by different routes RS 86 induces central and peripheral effects typical of a muscarinic receptor agonist, such as hypothermia, tremor, mydriasis, salivation, lacrimation, diarrhea, and modification of behavior as observed in an open field. In several of these tests RS 86 is about 10 times less potent than oxotremorine but more potent than arecoline, pilocarpine, aceclidine, or the compound (cis) AF-30. The ED_{50} values for some central effects, including the induction of hypothermia and alert non-mobile behavior, are lower than those for tremor and peripheral effects. Some of the effects last for up to 6 hours depending on dose. Finally, RS 86 administration results in modifications of brain acetylcholine turnover and high affinity choline uptake typical of a central muscarinic receptor agonist. Taken together these results demonstrate clearly that RS 86 is a potent, centrally acting, selective muscarinic receptor agonist. RS 86 appears to be an adequate tool for the clinical examination of the cholinergic hypothesis of AD.

The pharmacological assessment of RS 86 (2-ethyl-8-methyl-2,8-diazaspiro-[4,5]-decan-1,3-dion hydrobromide). A potent, specific muscarinic acetylcholine receptor agonist. Palacios JM, Bolliger G, Closse A, Enz A, Gmelin G, Malanowski J. Eur J Pharmacol 1986 Jun 5; 125 (1), pp. 45–62.

Alzheimer's Disease (AD)/Cognitive Decline: Early Evaluation/Improved Diagnostic Accuracy/ Diminished Disease/Treatment-Related Morbidity of Dementia
2-Deoxy-2-[^{18}F]-Fluoro-D-Glucose

Cellular/Molecular Mechanism of Action: 2-Deoxy-2-[^{18}F]-fluoro-D-glucose is an analogue of endogenous glucose.

Background Information: Growing evidence indicates that appropriate incorporation of positron emission tomography (PET) into the evaluation of patients with early symptoms of cognitive decline can improve diagnostic and prognostic accuracy**.**

Application: 2-Deoxy-2-[^{18}F]-fluoro-D-glucose is an analogue of endogenous glucose that can be used as a probe to detect regional alterations in cellular metabolism. In this regard, 2-deoxy-2-[^{18}F]-fluoro-D-glucose can be applied to detect and characterize the early stages of AD in a manner that can improve therapeutic intervention strategies and patient management.

Route of Administration: 2-Deoxy-2-[^{18}F]-fluoro-D-glucose (intravenous).

Implementation: Evaluate the relative value of 2 strategies for assessing whether AD is responsible for cognitive declines in geriatric patients, and in subsequently managing those patients according to the recommended standards of the American Academy of Neurology (AAN). The 1st strategy is based on an approach already endorsed by the AAN, following evidence-based reviews carried out by its quality standards subcommittee. The 2nd approach is based on many of the same AAN recommendations with respect to initial general medical and neurologic examinations, structural imaging, and laboratory tests, as well as ultimate management, but additionally incorporated PET analyses in appropriate cases for the purpose of determining the presence or absence of a pattern of regional cerebral metabolism characteristic of AD conditions. Clinical outcomes accruing to each strategy are calculated using formalized tools of decision analysis.

Interpretation and Analysis: The utilization of the increased diagnostic accuracy of PET yields lower rates of both false negative (from 8.3 to 3.1%) and false positive (from 23.0 to 11.9%) diagnoses for AD compared with conventional strategies. When combined with AAN treatment recommendations for patients having (or not having) non-severe AD, these differences in diagnostic accuracy correspond to approximately a 62% decrease in avoidable months of nursing home care, and a 48% decrease in months of unnecessary drug therapy resulting from inaccurate diagnoses. The benefit in clinical outcome of the proposed strategy is maintained over a wide range of values for sensitivity, specificity, and projected impact on need for nursing home care. Therefore, the use of PET for evaluating early cognitive declines in geriatric cases can add valuable information to the clinical assessment, resulting in a greater number of conditions being accurately diagnosed and properly treated. The use of PET can diminish disease-related and treatment-related morbidity of dementia, through earlier institution of appropriate management.

Added clinical benefit of incorporating 2-deoxy-2-[18F]-fluoro-D-glucose with positron emission tomography into the clinical evaluation of patients with cognitive impairment. Silverman DH, Cummings JL, Small GW, Gambhir SS, Chen W, Czernin J, Phelps ME. Mol Imaging Biol 2002 Jul; 4 (4), pp. 283–93.

Alzheimer's Disease (AD)/Ayloid Beta (Abeta) Amyloid Peptides/Senile Plaques (Sps)/Abeta40-Positive Amyloid Angiopathy (AA) vs Abeta42-Positive AA
[^{125}I]-TZDM / [^{125}I]-IMSB (Styrylbenzene)

Background Information: Alzheimer's disease is linked to increased brain deposition of abeta peptides in SPs, and recent therapeutic efforts have focused on inhibiting the production or enhancing the clearance of abeta in brain. However, it has not been possible to measure the burden of SPs or assess the effect of potential therapies on brain abeta levels in patients.

Application: Detection and characterization of amyloid abeta peptides in senile plaques associated with conditions of AD.

Implementation: Development and evaluation of a radioligand, [^{125}I]-TZDM, that binds to abeta fibrils with high affinity (crosses the blood-brain barrier (BBB), and labels amyloid plaques *in vivo*).

Interpretation and Analysis: Compared to a styrylbenzene probe, [^{125}I]-IMSB, [^{125}I]-TZDM has a 10-fold greater brain penetration and labels plaques with higher sensitivity for *in vivo* imaging. However, this ligand also labels white matter, which contributes to undesirable high background regions of the brain. Interestingly, parallel to their differential binding characteristics onto fibrils composed of 40 (abeta40)- or 42 (abeta42)-amino acid long forms of abeta peptides, these radioligands display differential labeling of SPs in AD brain sections under experimental conditions. It has been observed that [^{125}I]-IMSB labels SPs containing abeta40, AA, and neurofibrillary tangles, whereas [^{125}I]-TZDM detects only SPs and abeta42-positive AA. Because increased production and deposition of abeta42 relative to abeta40 may be crucial for the generation of SPs, [^{125}I]-TZDM and related derivatives may be more attractive probes for *in vivo* plaque labeling. Further structural modifications of TZDM to lower the background labeling will be needed to optimize the plaque-labeling property.

Detection of amyloid plaques by radioligands for abeta40 and abeta42: Potential imaging agents in Alzheimer's patients. Kung MP, Skovronsky DM, Hou C, Zhuang ZP, Gur TL, Zhang B, Trojanowski JQ, Lee VM, Kung HF. J Mol Neurosci. 2003 Feb;20(1):15–24.

Alzheimer's Disease (AD): Amyloid Plaques (Abeta) *[^{11}C] Stilbene Derivatives*

Cellular/Molecular Mechanism of Action: Stilbene derivatives recognize and physically bind to amyloid plaques analogous to those associated with AD.
Application: [^{11}C]4, N-[^{11}C]-methylamino-4′-hydroxystilbene, may be useful as a positron emission tomography (PET) imaging agent for mapping brain abeta plaques in AD conditions.
Route of Administration: Intravenous.
Semi-Synthetic Methods: Synthesis of a series of stilbene derivatives can be successfully achieved by performing a simple Wadsworth-Emmons reaction between diethyl (4-nitrobenzyl)phosphonate and 4-methoxybenzaldehyde. The [^{11}C]-labeled 4-N-methylamino-4′-hydroxystilbene, [^{11}C]4, is prepared by [^{11}C] methylation of 4-amino-4′-hydroxystilbene.
Interpretation and Analysis: 4-N,N-dimethylamino-4′-methyoxy and the corresponding 4-N-monomethylamino-, 4′-hydroxy stilbenes show good binding affinities for abeta aggregates *in vitro* ($K_i < 10$ nM). The [^{11}C]4 analog displays a moderate lipophilicity (log P = 2.36), and shows very good brain penetration and washout from normal rat brain following intravenous injection. *In vitro* autoradiography of transgenic AD mouse brain sections shows a high specific labeling of beta-amyloid plaques, whereas control sections show no binding.

^{11}C-labeled stilbene derivatives as abeta-aggregate-specific PET imaging agents for Alzheimer's disease. Ono M, Wilson A, Nobrega J, Westaway D, Verhoeff P, Zhuang ZP, Kung MP, Kung HF. Nucl Med Biol 2003 Aug; 30 (6), pp. 565–71.

Amyloid: Beta-Sheet Proteins/Amyloid Plaques: Abeta Peptide/Neurofibrillary Tangles: Tau Protein *Thioflavine Derivatives/[N-Methyl-^{11}C]6-Me-BTA-1*

Cellular/Molecular Mechanism of Action: Thioflavine T (ThT) derivatives possess binding avidity for beta-sheet proteins deposited in amyloid plaques (abeta peptide) and neurofibrillary tangles (tau protein).
Background Information: Assessment of the beta-sheet proteins deposited *in vivo* in amyloid plaques (abeta peptide) or neurofibrillary tangles (tau protein) represents a target for the development of Alzheimer's disease (AD) biological marker systems.
Application: Detection and characterization of beta-sheet proteins deposited in amyloid plaques (abeta peptide) and neurofibrillary tangles (tau protein) similar to those associated with the pathogenesis of AD.
Route of Administration: [Intravenous] if eventually applied in a clinical environment.
Semi-Synthetic Methods: Production of ThT derivatives and the carbon-11 labeled compound [N-methyl-^{11}C]6-Me-BTA-1.
Implementation: Evaluation of [N-methyl-^{11}C]6-Me-BTA-1 to determine its capacity to enter into and be cleared from the central nervous system (e.g., brain).
Animal Model: Mouse (Swiss-Webster).
Interpretation and Analysis: These compounds lack the positively charged quaternary heterocyclic nitrogen of ThT and are therefore uncharged at physiological pH levels. They are 600-fold more lipophilic than ThT. Derivatives of ThT bind to abeta(1-40) fibrils with higher affinity (K_i = 20.2 nM) than ThT (K_i = 890 nM). The uncharged ThT derivatives stain both plaques and neurofibrillary tangles in postmortem AD brain, showing some preference for plaque staining.

The compound [N-methyl-^{11}C]6-Me-BTA-1 enters the brain at levels comparable to commonly used neuroreceptor imaging agents (0.223 % injected dose [%ID]-kg/g or 7.61 %ID/g at 2 minutes postinjection) and shows good clearance of free and non-specifically bound radioactivity in normal rodent brain tissue (brain clearance $T_{1/2}$ = 20 minutes). The combination of relatively high affinity for amyloid, specificity for staining plaques and neurofibrillary tangles in postmortem AD brain, and good brain entry and clearance makes [N-methyl-^{11}C]6-Me-BTA-1 a promising candidate as an *in vivo* positron emission tomography (PET) beta-sheet imaging agent.

Uncharged thioflavine T derivatives bind to amyloid beta protein with high affinity and readily enter the brain. Klunk WE, Wang Y, Huang GF, Debnath ML, Holt DP, Mathis CA. Life Sci 2001 Aug 17; 69 (13), pp. 1471–84.

Amyloid (Abeta) Fibrils/Alzheimer's Disease (AD): Senile Plaques and Neurofibrillary Tangles *[^{11}C]-Methoxy-X04 [Congo Red Derivative]/ Chrysamine G*

Cellular/Molecular Mechanism of Action: Methoxy-X04 is a derivative of both Congo red and chrysamine G that has retained binding avidity for amyloid (abeta) fibrils. Exposure of methoxy-X04 to certain wavelengths of light results in the emission of visibly detectable fluorescence.
Background Information: The identification of amyloid deposits in living AD patients is important for both early diagnosis and for monitoring the efficacy of newly developed antiamyloid therapies.
Application: Detection of senile plaques, neurofibrillary tangles, and cerebrovascular amyloid using either multiphoton microscopy to obtain fluorescent images (methoxy-X04) or positron emission tomography (carbon-11-labeled methoxy-X04).
Route of Administration: Methoxy-X04 (intravenous/intra peritoneal in mice).
Dosage: Methoxy-X04 (5–10 mg/kg intravenous or 10 mg/kg intraperitoneal).
Implementation: Administration of methoxy-X04 for the *in vivo* detection of senile plaques, neurofibrillary tangles, and cerebrovascular amyloid.
Animal Model: Mice (PSI/APP).
Interpretation and Analysis: Methoxy-X04 is a derivative of Congo red and chrysamine G that contains no acid groups and is therefore smaller and much more lipophilic than Congo red or chrysamine G. Methoxy-X04 retains *in vitro* binding affinity for amyloid beta (abeta) fibrils (K_i = 26.8 nM) very similar to that of chrysamine G (K_i = 25.3 nM). Methoxy-X04 is fluorescent and stains plaques, tangles, and cerebrovascular amyloid in postmortem sections of AD brain with good specificity. Using multiphoton microscopy to obtain high-resolution (1 μm) fluorescent images from the brains of living PSI/APP mice, individual plaques can be distinguished within 30 to 60 minutes after methoxy-X04 administration. A single intraperitoneal injection of methoxy-X04 also produces high-contrast images of plaques and cerebrovascular amyloid in PSI/APP mouse brain. Complementary quantitative studies using tracer doses of carbon-11-labeled methoxy-X04 show that it enters rat brain in amounts that suggest it is a viable candidate as an *in vivo* positron emission tomography (PET) amyloid-imaging agent.
Instrumentation: Multiphoton microscopy.

Imaging abeta plaques in living transgenic mice with multiphoton microscopy and methoxy-X04, a systemically administered Congo red deriv-

ative. Klunk WE, Bacskai BJ, Mathis CA, Kajdasz ST, McLellan ME, Frosch MP, Debnath ML, Holt DP, Wang Y, Hyman BT. J Neuropathol Exp Neurol 2002 Sep; 61 (9), pp. 797–805.

Amyloid: Abeta Fibrils (Alzheimer's Disease [AD])/ *Ex Vivo* Abeta Senile Plaques *(S)-Naproxen/(R)-Ibuprofen and (S)-Ibuprofen/ Congo Red/Thioflavine T/2-(1-[6-[(2-[^{18}F]-Fluoroethyl) (Methyl)Amino]-2-Naphthyl]Ethylidene)Malononitrile ([^{18}F]-FDDNP)*

Background Information: Epidemiological studies have suggested that the chronic use of non-steroidal anti-inflammatory drugs (NSAIDs) reduces the relative risk of AD. The possible neuroprotection by NSAIDs in AD is generally attributed to anti-inflammatory activity. An additional mode of drug action may involve an antiaggregatory effect on beta-amyloid (abeta) peptides by commonly used NSAIDs.

Implementation: Utilization of *in vitro* competition assays, autoradiography, and fluorescence microscopy to evaluate the binding of the *in vivo* molecular imaging probe [^{18}F]-FDDNP against (S)-naproxen and (R)-ibuprofen and (S)-ibuprofen (but not diclofenac) to abeta fibrils and *ex vivo* abeta senile plaques from AD brain specimens.

Interpretation and Analysis: The *in vivo* molecular imaging probe [^{18}F]-FDDNP demonstrates a concentration-dependent decrease in binding to abeta fibrils and *ex vivo* abeta senile plaques when applied against (S)-naproxen and (R)-ibuprofen and (S)-ibuprofen (but not diclofenac) preparations. Conversely, *in vitro* amyloid dyes Congo red and thioflavine T do not bind to the FDDNP binding site. Both FDDNP and the NSAIDs that share the same binding site also exhibit antiaggregation effects on abeta peptides, suggesting that the shared binding site on abeta fibrils and abeta plaques may be a site of antiaggregatory drug action. Obviously, the binding of select NSAIDs to plaques, specifically to the binding site of the molecular imaging probe [^{18}F]-FDDNP, is of distinct therapeutic significance in the management of AD. Expanding the current understanding about the molecular requirements of FDDNP binding may aid in optimizing the abeta antiaggregation potency of experimental drugs. [^{18}F]-FDDNP has been used to image plaques *in vivo* with positron emission tomography (PET), and investigations into the influence of abeta antiaggregation on the risk-reduction effects of NSAIDs on AD could utilize [^{18}F]-FDDNP and PET in determining the occupancy rate of NSAIDs and experimental drugs in plaques in the living brain of AD patients.

In vitro detection of (S)-naproxen and ibuprofen binding to plaques in the Alzheimer's brain using the positron emission tomography molecular imaging probe 2-(1-[6-[(2-[^{18}F]-fluoroethyl)(methyl)amino]-2-naphthyl]ethylidene)malononitrile. Agdeppa ED, Kepe V, Petri A, Satyamurthy N, Liu J, Huang SC, Small GW, Cole GM, Barrio JR. Neuroscience 2003; 117 (3), pp. 723–30.

Behavior/Depression and Emesis/Substance P (SP)-Neurokinin-1 (NK1) Receptor/ Aprepitant (MK-0869) Efficacy/Dose and Receptor Occupancy Correlations *[^{18}F]-SPA-RQ*

Substance P-NK1 receptor pathways have been implicated in the pathophysiology of emesis and depression. Autoradiographic studies in monkey and human brains have shown a high expression of NK1 receptors in regions important for the regulation of affective behaviors and the neurochemical response to stress. Furthermore, clinical studies have demonstrated that treatment with the SP (NK1 receptor) antagonist (SPA) aprepitant (also known as MK-0869) significantly improves depression symptoms and reduces the incidence of chemotherapy-induced nausea and vomiting. An important objective of all neuroscience drug discovery and development programs is to establish the correlation among dose, receptor occupancy, and the observed clinical effect (the dose-response relationship). These goals can be achieved using radioactive receptor-specific tracers and dynamic non-invasive brain imaging modalities, such as positron emission tomography (PET). In the SPA program, a tracer [^{18}F]-SPA-RQ has been utilized for PET studies on the basis of several criteria, including high affinity for the NK1 receptor, low non-specific binding, and good blood-brain barrier penetration. Positron emission tomography imaging studies in rhesus monkeys and humans have confirmed these tracer features and established the usefulness of this probe for *in vivo* NK1-receptor occupancy studies. Subsequent PET occupancy studies in humans predict that very high levels of central NK1-receptor occupancy ($> 90\%$) are associated with therapeutically significant antidepressant and antiemetic effects. Imaging studies that focus on quantification of NK1-receptor expression in depressed patients, both before and after successful treatment with antidepressants, will create greater knowledge about how to integrate diagnostic imaging capabilities with the design of effective therapeutic protocols.

Imaging substance P receptors (NK1) in the living human brain using positron emission tomography. Hargreaves R. J Clin Psychiatry 2002; 63 Suppl 11, pp. 18–24.

Behavior/Schizophrenia/Presynaptic Dopamine Metabolism *6-[^{18}F]-Fluoro-L-Dopa*

Cellular/Molecular Mechanism of Action: 6-[^{18}F]-Fluoro-L-dopa is an analogue of L-dopa and binds to membrane-associated dopa receptor complexes.

Application: Detection and characterization of alterations in presynaptic dopamine metabolism in conditions of schizophrenia.

Implementation: Evaluation of presynaptic dopamine metabolism in conditions of schizophrenia using 6-[^{18}F]-fluoro-L-dopa ([^{18}F]-dopa) and positron emission tomography (PET). The ratio of specific/non-specific activity can be calculated for 8 specific cortical and subcortical regions-of-interest (ROIs).

Human Model: Cases of schizophrenia ($n = 19$ drug-free cases; $n = 10$ cases on neuroleptics; $n =$ age- and gender-matched normal controls). The neuroleptic-treated patients receive typical neuroleptics ($n = 4$) or the atypical neuroleptic clozapine ($n = 6$).

Interpretation and Analysis: Cases that are medication-free have a significant reduction in [^{18}F]-dopa uptake in the ventral striatum ($p = 0.04$) and a significantly increased amount of uptake in the posterior cingulate ($p = 0.02$) compared with normal control subjects. The [^{18}F]-dopa PET technique is useful and sensitive in detecting *in vivo* changes in dopamine metabolism in schizophrenia and diagnostic results from using [^{18}F]-dopa as an investigative probe can provide evidence of aberrant dopamine systems in conditions of schizophrenia.

6-[18F]-dopa PET study in patients with schizophrenia. Positron emission tomography. Elkashef AM, Doudet D, Bryant T, Cohen RM, Li SH, Wyatt RJ. Psychiatry Res 2000 Nov 20; 100 (1), pp. 1–11.

Behavior: Schizophrenia: Dopamine Receptors/ Striatal D_2 Dopamine Receptor Occupancy *[^{123}I]-IBZM/Haloperidol/Olanzapine*

Dosage: Haloperidol (10 mg/day); olanzapine (10 mg/day).

Implementation: Delineation of (i) the *in vivo* striatal D_2 dopamine receptor occupancy induced by olanzapine and haloperidol in

schizophrenic conditions using a baseline-end point [^{123}I]-IBZM single photon computed emission tomography (SPECT) design; and (ii) assessement of the relationships of striatal D_2 receptor occupancy with clinical efficacy and extrapyramidal symptoms (EPS). The percentage of D_2 receptors occupied can be estimated using basal ganglia (striatum)/frontal cortex IBZM uptake ratios obtained before and after 4 weeks of maintained antipsychotic treatment.

Human Model: Schizophrenia and schizophreniform disorder cases (e.g., n = 27). Haloperidol (n = 13); olanzapine (n = 14). Ratings of clinical status and EPS can be obtained weekly.

Interpretation and Analysis: Olanzapine produces a mean striatal D_2 receptor occupancy of 49% (range 28–69%) and is significantly lower than that induced by haloperidol (mean 64%, range 46–90%). The baseline end point SPECT design reveals antipsychotic D_2 occupancy percentage values that are lower than those reported using other approaches. The degree of striatal D_2 receptor occupancy correlates with EPS, which predominantly appears in patients on haloperidol. No relationship can be appreciated between the striatal D_2 receptor occupancy and clinical improvement. Olanzapine induces a lower striatal D_2 occupancy than haloperidol. This low striatal D_2 occupancy, together with the lower incidence of EPS with olanzapine treatment contributes additional confirmation to observations regarding the atypical behavior of this antipsychotic pharmaceutical. Nevertheless, conclusions based on SPECT-estimated percentages of antipsychotic D_2 occupancy should be done with caution because SPECT design can influence the results. In this regard, SPECT studies, including baseline and end point examinations, should be encouraged.

Double blind olanzapine vs haloperidol D_2 dopamine receptor blockade in schizophrenic patients: A baseline end point. Bernardo M, Parellada E, Lomena F, Catafau AM, Font M, Gomez JC, Lopez-Carrero C, Gutierrez F, Pavia J, Salamero M. Psychiatry Res 2001 Aug 25; 107 (2), pp. 87–97.

Benzodiazepine Receptor/Prediction of Therapeutic Response/Mental Depression Pathogenesis *[^{123}I]-Ro 16-0154*

Cellular/Molecular Mechanism of Action: [^{123}I]-labeled Ro 16-0154 selectively recognizes and binds to benzodiazepine receptor complexes.

Application: Screening agent potentially applicable to predicting responsiveness to therapeutic intervention and possible characterization of the pathogenesis of mental depression.

Route of Administration: [^{123}I]-Ro 16-0154 (intravenous).

Implementation: Non-invasive *in vivo* evaluation of alterations in benzodiazepine receptor expression.

Animal Model: Primate (brain).

Interpretation and Analysis: Maximal brain uptake of [^{123}I]-Ro 16-0154 is reached at approximately 70 minutes after intravenous administration of the radioligand and represents approximately 10% of the total injected dose. The regional distribution of radioactive densities is consistent with the known distribution of benzodiazepine receptors within the brain, with highest uptake localized over the occipital area. Washout of radioactivity is relatively slow with a rate of 3% per hour after the time of peak radioactivity. Rapid decreases of more than 90% of total brain radioactivity associated with [^{123}I]-Ro 16-0154 uptake can be appreciated with benzodiazepine antagonists (e.g., Ro 15-1788: 0.2–0.3 mg/kg IV).

Instrumentation: Single photon emission computed tomography (SPECT).

SPECT imaging of the benzodiazepine receptor in non-human primate brain with [123I]-Ro 16-0154. Innis R, Zoghbi S, Johnson E, Woods S, al-Tikriti M, Baldwin R, Seibyl J, Malison R, Zubal G, Charney D, et al. Eur J Pharmacol 1991 Feb 7; 193 (2), pp. 249–52.

Metabolism of Glucose and Alterations in Disease/ (Alzheimer's, Epilepsy, Schizophrenia, Cranial Trauma, Brain Tumors) *[^{18}F]-Fluoro-Deoxy-Glucose (FDG)*

Cellular/Molecular Mechanism of Action: [^{18}F]-fluoro-deoxy-glucose is absorbed, diffuses across the blood-brain barrier, and is then intracellularly transported by cell populations within the central nervous system (CNS) in a manner highly analogus to endogenous glucose. Due to the fluoride moiety, [^{18}F]-labeled glucose is not rapidly metabolized intracellularly by glycolytic pathways. The exact trapping mechanisms and their relationships with potential clinical applications still remains to be elucidated.

Background Information: In recent years, significant progress has been made in the design and characterization of new CNS neuronal and postsynaptic receptor imaging agents for positron emission tomography (PET) and single photon emission computed tomography (SPECT). The new diagnostic agents are aimed at detecting and measuring localized changes of neuronal function.

Application: Characterization of alterations in glucose metabolism in various neurologic disorders, including Alzheimer's, epilepsy, schizophrenia, and cranial trauma in addition, to the diagnosis and monitoring of space-occupying and ischemic lesions affecting the brain and spinal cord.

Interpretation and Analysis: Agents like [^{18}F]-FDG likely have potential clinical application for the diagnosis of psychiatric disorders that do not involve morphological changes. Imaging studies using [^{18}F]-FDG with PET are currently the most promising diagnostic tool for the evaluation of various disease states, such as Alzheimer's disease, brain tumor, and epilepsy, as a function of alterations in local glucose metabolism.

Instrumentation: There are 2 types of imaging instruments, SPECT and PET, that use radiopharmaceuticals for the diagnosis of brain disorders. Positron emission tomography instrumention can be applied when the imaging agent [^{18}F]-FDG is administered for the diagnosis of various disease states affecting the CNS.

Overview of radiopharmaceuticals for diagnosis of central nervous disorders. Kung HF. Crit Rev Clin Lab Sci 1991; 28 (4), pp. 269–86.

The use of 2-deoxy-2-[18F]-fluoro-D-glucose positron emission tomography (FDG PET) in the routine diagnosis of epilepsy. Swartz BE, Brown C, Mandelkern MA, Khonsari A, Patell A, Thomas K, Torgersen D, Delgado-Escueta AV, Walsh GO. Mol Imaging Biol 2002 May; 4 (3), pp. 245–52.

Metabolism of Glucose/Schizophrenia Treatment Resistance (Clozapine)/Dopamine D1R Genotype/ Individualization of Antipsychotic Agent Dosage: Schizophrenia/Hepatic Cytochrome P450 2D6 (CYP2D6) Metabolizing Capacity *[^{18}F]-Fluoro-Deoxy-Glucose (FDG)/Clozapine*

Cellular/Molecular Mechanism of Action: The agent [^{18}F]-FDG functions as a false glucose analogue that can detect localized alterations in brain glucose metabolism.

Physiological Mechanism of Action: Clozapine potentiates the effects of GABA-mediated presynaptic and postsynaptic inhibitory pathways.

Background Information: A goal of pharmacogenetics is to clarify associations between allelic variation and risk factors in psychiatric illness.

Application: Characterization of different patterns in dopamine alleles that correlated with resistance to therapeutic management in

conditions of treatment-resistant schizophrenia. A close relationship exists between regional brain metabolic activity and clinical response to clozapine that is related to the D_1-receptor genotype.

Implementation: Evaluation of the capacity for positron emission tomography (PET) scans with [^{18}F]-FDG to detect and characterize cases of treatment-resistant schizophrenic subjects after 5 weeks of clozapine treatment (vs placebo).

Interpretation and Analysis: Significant regional brain metabolic effects can be found for D_1-receptor genotypes ($p < 0.05$: adjusted for multiple comparisons). Metabolic decreases for the 2,2 genotype but not the 1,2 genotype can be observed in all major sectors of the brain, with the exception of the ventral parts of the caudate and putamen. Frontal, temporal, parietal, and occipital neocortices show decreases in metabolism, as do the cingulate juxtaallocortex and the parahippocampal allocortex. Decreases can also be observed in the thalamus, amygdala, and cerebellum bilaterally. No significant metabolic differences by genotype have been observed for D_3, 5-HT_{2A}, and 5-HT_{2C} polymorphisms. In terms of clinical response, the DRD1 2,2 genotype significantly improves with clozapine treatment, demonstrating a 30% decrease in the Brief Psychiatric Rating Scale positive symptoms in contrast to a 7% worsening for the 1,2 genotype ($p < 0.05$). Therefore, brain metabolic activity and clinical response to clozapine appears to be related to the D_1-receptor genotype.

D1-receptor alleles predict PET metabolic correlates of clinical response to clozapine. Potkin SG, Basile VS, Jin Y, Masellis M, Badri F, Keator D, Wu JC, Alva G, Carreon DT, Bunney WE Jr, Fallon JH, Kennedy JL. Mol Psychiatry 2003 Jan; 8 (1), pp. 109–13.

Metabolism of Lipids: Fatty Acid Lipids/Central Nervous System [CNS]): Beta-Oxidation/ Incorporation into Membrane Structures
[U-^{14}C]-Palmitate/[1-^{14}C]-Arachidonate/ Methyl 2-Tetradecylglycidate

Cellular/Molecular Mechanism of Action: Both palmitate and arachidonic acid are saturated fatty acids that are a component of the external cell membrane lipid bilayer. In the CNS, [U-^{14}C]-palmitate undergoes beta-oxidation. Methyl 2-tetradecylglycidate (MEP) is an irreversible inhibitor of carnitine palmitoyltransferase I.

Application: In radiolabeled form, palmitate can be utilized as an *in vivo* probe for detecting alterations in brain lipid metabolism.

Route of Administration: [U-^{14}C]-palmitate (intravascular), [1-^{14}C]-arachidonate (intravascular), methyl 2-tetradecylglycidate (oral).

Dosage: Methyl 2-tetradecylglycidate (10–25 mg/kg).

Implementation: Determination of the effect of inhibiting mitochondrial beta-oxidation of free fatty acids on the incorporation of radiolabeled free fatty acids into brain lipids. Saturated fatty acid [U-^{14}C]-palmitic acid or the polyunsaturated fatty acid [1-^{14}C]-arachidonate (AA) are administered 2, 4, and 6 hours after methyl 2-tetradecylglycidate (MEP).

Animal Model: Rat (irreversible inhibition of carnitine palmitoyltransferase I in males induced through the use of methyl 2-tetradecylglycidate).

Interpretation and Analysis: Methyl 2-tetradecylglycidate increases brain [U-^{14}C]-palmitate-associated radioactivity 2-fold and decreases brain aqueous radioactivity 3- to 5-fold relative to control values at all pretreatment times. The effect is due to a prolongation of the plasma integral of [U-^{14}C]-palmitate due to peripheral inhibition of beta-oxidation, and to direct inhibition of beta-oxidation of the tracer within the brain. Conversely, methyl 2-tetradecylglycidate has no effect on brain organic radioactivity after infusion of [1-^{14}C]-arachidonic acid. Increasing the interval between methyl 2-tetradecylglycidate administration and [U-^{14}C]-palmitate infusion from 2 to 6 hours results in a dramatic redistribution of [U-^{14}C]-palmitate within brain lipids. The percentage of radioactivity in phospholipids decreases from 65 to 33%, whereas that in the free fatty acid fraction increases from 10 to 47% and that in triglycerides becomes elevated 2- to 3-fold over reference controls. Methyl 2-tetradecylglycidate may facilitate the use of radiolabeled palmitate as an *in vivo* probe for detecting alterations in brain lipid metabolism using quantitative autoradiography or positron emission tomography.

Instrumentation: Positron emission tomography.

Effect of inhibition of beta-oxidation on incorporation of [U-14C]-palmitate and [1-14C]-arachidonate into brain lipids. Freed LM, Wakabayashi S, Bell JM, Rapoport SI. Brain Res 1994 May 9; 645 (1–2), pp. 41–8.

Metabolism of Lipids: Phosphatidylinositol/Central Nervous System (CNS)
[^{11}C]-Inositol/[^{11}C]-Inositol-1-Phosphate (IP)

Application: Brain diagnostic imaging agent used in positron emission tomography (PET) imaging techniques for characterizing phosphatidylinositol metabolism.

Route of Administration: Intravenous.

Semi-Synthetic Methods: Radiolabeled inositol (Ins) and inositol-1-phosphate (IP) can be derived from radiolabeled glucose by utilizing brief sequential enzyme reactions. Rapid separation and fractionation of enzymes and labeled products from the reaction mixture can be achieved by high-performance liquid chromatography (HPLC) utilizing a gel-permeation chromatography column.

Interpretation and Analysis: Examination of the biodistribution of Ins, IP, and their acetylated analogs suggests that intact Ins labeled with [^{11}C] would be more effective than [^{11}C]-labeled acetylated Ins as a brain diagnostic agent for PET studies focused on determining the metabolism of phosphatidylinositol and its role as a 2nd messenger within the brain.

Instrumentation: Computer-integrated PET instrumentation.

Sequential enzymatic synthesis and biodistribution of radiolabeled inositol and inositol analogs. Sasaki T, Ogihara-Umeda I, Kojima S, Nishigori H. Int J Rad Appl Instrum [A] 1991; 42 (1), pp. 97–101.

Metabolism/Mitosis and Proliferation Rate
3′-Deoxy-3′-[^{18}F]-Fluorothymidine ([^{18}F]-FLT)

Cellular/Molecular Mechanism of Action: Thymidine is rapidly assimilated by proliferating cell populations (e.g., incorporated into nucleic acids).

Application: [^{18}F]-FLT has been designed as a new positron emission tomography (PET) imaging agent for *in vivo* visualizing of cellular proliferation based on the incorporation of thymidine into nucleic acid.

Route of Administration: Variable but most often intravascular.

Semi-Synthetic Methods: A reliable radiosynthesis of [^{18}F]-FLT has been developed based on [^{18}F] 10 mCi (370 MBq) of radiochemically pure [^{18}F] 1 Ci/μmol (37 GBq/μmol) at the end of synthesis (EOS) within 100 minutes and in 13% radiochemical yield (end of bombardment [EOB]; 7% EOS).

Implementation: Evaluation of neoplastic lesions that display relatively rapid rates of proliferation/growth.

Interpretation and Analysis: Detection of increased radioactivity at a specific anatomical location that corresponds with an anatomical region that has a relatively high rate of cellular proliferation.

Radiosynthesis of 3′-deoxy-3′-[^{18}F]-fluorothymidine: [^{18}F]-FLT for imaging of cellular proliferation *in vivo*. Grierson JR, Shields AF. Nucl Med Biol 2000 Feb; 27 (2), pp. 143–56.

Neurotoxicity: Cytarabine-Associated/Acute Leukemia (AL): Childhood Onset/Cerebral Perfusion/Relative Efficacy of Single Photon Emission Computed Tomography (SPECT) vs Magnetic Resonance Imaging (MRI) *[^{99m}Technetium] ([^{99m}Tc])-Hexamethyl-Propylene-Amine Oxime (HMPAO)*

Background Information: Cytarabine (ara-C) is one of the most effective chemotherapeutic agents in conditions of AL. In addition, it exerts a clear dose effect. Use of high-dose ara-C is hampered, however, by a noticeable toxicity, particularly to the central nervous system (CNS).

Application: Assess the usefulness of CNS perfusion imaging with [^{99m}Tc]-HMPAO SPECT concurrent with MRI to specifically assess the effects of standard- and high-dose ara-C in children with AL.

Implementation: Evaluation of cerebral perfusion by [^{99m}Tc]-HMPAO SPECT in cases of childhood acute leukemia after induction therapy consisting of a (i) standard-dose ara-C; (ii) immediately after consolidation with high-dose ara-C; and (iii) later during follow-up periods (range, 6–44 months). The chemotherapy-related adverse events are monitored and correlated to SPECT and MRI.

Human Model: Cases of childhood acute leukemia (n = 12; age range = 4–15 years; n = 26 perfusion studies).

Interpretation and Analysis: After the induction phase, all children are neurologically normal on MRI. On SPECT imaging, a number of children (e.g., n = 4/12) display a slightly heterogeneous perfusion. After high-dose ara-C (4–36 g/m^2), slightly more than a third of affected children have regressive neurologic signs of potential toxic origin (n = 5/12) and of these cases, a small percentage will have an abnormal MRI scan (n = 1/5), whereas all cases display evidence of diffuse cerebral and/or cerebellar heterogeneous perfusion on SPECT. In some cases that are without any neurologic symptoms (e.g., n = 7) and that have normal MRI scans, normal SPECT profiles will also be appreciated (n = 3/7 normal; n = 4/7 abnormal). On follow-up analysis of cases initially presented with clinical neurological toxicity, (i) a relatively large number display SPECT images that improve (n = 3/4); (ii) a small percentage remain unchanged (e.g., n = 1 of 4, or 25%); and (iii) some display delayed abnormalities that can be recognized on MRI scans (e.g., n = 2/4; T_2 white matter hypersignal and cerebellar atrophy). Diffuse heterogeneous brain hypoperfusion is often the sole early objective imaging feature identified by SPECT of high-dose ara-C neurotoxicity, when MRI still demonstrates normal imaging profiles.

Contribution of single photon emission computed tomography in the diagnosis and follow-up of CNS toxicity of a cytarabine-containing regimen in pediatric leukemia. Véra P, Rohrlich P, Stiévenart JL, Elmaleh M, Duval M, Bonnin F, Bok B, Vilmer E. J Clin Oncol 1999 Sep; 17 (9), pp. 2804–10.

Opioid Receptor Expression *[^{18}F]-Fluorophen*

Cellular/Molecular Mechanism of Action: (±)-5,9 α-Dimethyl-2-[2-(4-fluorophenyl)ethyl]-2′-hydroxy-6, 7-benzomorphan (fluorophen) is a fluorinated derivative of the benzomorphan opiate agonist phenazocine, which physically recognizes and binds to opiate receptor complexes. The agent is relatively selective for μ receptors, congruent for δreceptors at a level that is far greater than its binding avidity for κ receptor complexes.

Application: Detection of opiate receptor complexes.

Semi-Synthetic Methods: (±)-5,9 α-Dimethyl-2′-hydroxybenzomorphan is subjected to *N*-acylation utilizing (*p*-fluorophenyl)-acetyl chloride, followed by diborane reduction of the resulting amide.

Interpretation and Analysis: Fluorination produces only a 2-fold opiate receptor affinity loss when measured either by bioassay or receptor binding (selectivity for μ, congruent to δ and greater than kappa). Labeling of the pharmaceutical fluorophen with [^{18}F] creates an imaging agent sufficiently potent to be useful as a non-invasive *in vivo* probe for visualizing opiate receptor complexes.

Instrumentation: Positron emission trans-axial tomography.

Synthesis and pharmacological characterization of (±)-5,9 alpha-dimethyl-2-[2-(4-fluorophenyl)ethyl]-2′-hydroxy-6,7-benzomorphan (fluorophen), a ligand suitable for visualization of opiate receptors *in vivo.* Rice KC, Konicki PE, Quirion R, Burke TR Jr, Pert CB. J Med Chem 1983 Nov; 26 (11), pp. 1643–5.

Opioid Sigma$_1$-Receptor Complexes: Central Nervous System (CNS) Kinetics *[^{3}H]-Pentazocine/[^{11}C]-SA4503/±Pentazocine/Haloperidol*

Cellular/Molecular Mechanism of Action: The agents ±pentazocine and SA4503 have a high and selective affinity for opioid sigma$_1$-receptor complexes. Haloperidol is a sigma-receptor ligand. Pentazocine is a benzomorphan derivative.

Application: Comparison of brain kinetics for sigma$_1$ receptors. The sigma receptor has been speculated to be involved in several diseases affecting the CNS. It is expressed within the endocrine, immune, and other peripheral organ systems, in addition to a variety of human tumor cell types.

Implementation: Characterization of the biodistribution of sigma$_1$ receptors within the brain.

Animal Model: Murine (mouse brain).

Interpretation and Analysis: Murine brain uptake of [^{11}C]-SA4503 is high after intravenous injection followed by a gradual decrease, whereas that of [^{3}H] ±pentazocine rapidly decreases. The brain uptake of the 2 radioligands is dose-dependent reduced, but the reduction of [^{3}H] ±pentazocine is observed at higher doses. Percentage of saturable [^{3}H] ±pentazocine binding is much lower than that of [^{11}C]-SA4503. The brain uptake of [^{3}H] ±pentazocine is substantially reduced by SA4503 at a dose of 2 μmol/kg, while that of [^{11}C]-SA4503 is blocked by ±pentazocine at a dose of equal to or greater than 20 μmol/kg. Exposure of mice to cyclosporin-A (P-glycoprotein modulator) enhances [^{3}H] ±pentazocine uptake but not [^{11}C]-SA4503. Under control and P-glycoprotein-modulated conditions, brain uptake of [^{3}H] ±pentazocine and [^{11}C]-SA4503 is reduced by haloperidol (representative sigma-receptor ligand). Modulation of P-glycoprotein therefore results in different brain kinetic patterns for [^{3}H] ±pentazocine and [^{11}C]-SA4503, and the latter agent is capable of functioning as a suitable *in vivo* probe.

Instrumentation: Single photon emission computed tomography (SPECT) imaging modalities.

Different brain kinetics of 2 sigma$_1$-receptor ligands, [3H] ±pentazocine and [11C]-SA4503, by P-glycoprotein modulation. Kawamura K, Kobayashi T, Matsuno K, Ishiwata K. Synapse 2003 May; 48 (2), pp. 80–6.

The sigma receptor might be involved in several diseases in the central nervous system. It occurs in the endocrine, immune, and other peripheral organ systems and is expressed in a variety of human tumors. Elsinga PH, Kawamura K, Kobayashi T, Tsukada H, Senda M, Vaalburg W, Ishiwata K. Synapse 2002 Mar 15; 43 (4), pp. 259–67.

Opioid Sigma$_1$-Receptor Complexes (Central Nervous System [CNS])
[^{11}C]-SA4503/[^{11}C]1-([4-Methoxy-^{11}C]-3,4-Dimethoxyphenethyl)-4-(3-Phenylpropyl)Piperazine/[^{11}C]-SA5845/1-([4-Methoxy-^{11}C]3,4-Dimethoxyphenethyl)-4-[3-(4-Fluorophenyl) Propyl]piperazine/[^{11}C]-Ethoxy and [^{18}F]-Fluoroethoxy Analogs

Cellular/Molecular Mechanism of Action: Selectively recognize and physically bind to opioid sigma$_1$-receptor complexes.
Application: Detection and characterization of sigma$_1$-receptor complexes utilizing positron emission tomography (PET) imaging modalities.
Semi-Synthetic Methods: Preparation of 1-([4-methoxy-^{11}C]-3,4-dimethoxyphenethyl)-4-(3-phenylpropyl)piperazine ([^{11}C]-SA4 503) and its fluorinated analogue 1-([4-methoxy-[^{11}C]3,4-dimethoxyphenethyl)-4-[3-(4-fluorophenyl)propyl]piperazine, ([^{11}C]-SA 5845) and their [^{11}C]-ethoxy and [^{18}F]-fluoroethoxy analogs.
Implementation: Evaluation of [^{11}C]-SA4503 and its fluorinated analogue [^{11}C]-SA5845 and their [^{11}C]-ethoxy and [^{18}F]-fluoroethoxy analogs as potential agents for PET imaging.
Interpretation and Analysis: [^{11}C]-SA4503 is most selective for sigma$_1$ receptors, while the other 5 radioligands show affinities for sigma$_1$ and sigma$_2$ receptors to a variable extent. All radioligands show receptor-specific binding in the brain and visualize similar regional brain distribution patterns when evaluated by *ex vivo* autoradiography. The [^{11}C]-ethoxy analogs are relatively labile due to their vulnerability to metabolic degradation.

Synthesis and evaluation of ^{11}C- and ^{18}F-labeled 1-[2-(4-alkoxy-3-methoxyphenyl)ethyl]-4-(3-phenylpropyl)piperazines as sigma-receptor ligands for positron emission tomography studies. Kawamura K, Elsinga PH, Kobayashi T, Ishii S, Wang WF, Matsuno K, Vaalburg W, Ishiwata K. Nucl Med Biol 2003 Apr; 30 (3), pp. 273–84.

Opioid Sigma$_1$-Receptor Complexes (Central Nervous System [CNS])
Pentazocine/SA4503/Haloperidol/Cyclosporin A

Molecular/Cellular Mechanism of Action: Pentazocine and SA4503 have a high and selective affinity for opioid sigma$_1$-receptor complexes. Haloperidol also functions as a sigma receptor ligand. Cyclosporin A can function as a P-glycoprotein modulator.
Implementation: Comparison of the brain kinetics of radiolabeled ±pentazocine and SA4503.
Animal Model: Murine.
Interpretation and Analysis: Brain uptake of [^{11}C]-SA4503 is high after intravenous injection followed by a gradual decrease, whereas that of [^{3}H] ±pentazocine rapidly decreases. The brain uptake of the 2 radioligands is dose-dependently reduced, but the reduction of [^{3}H] ±pentazocine is recognized at higher doses. Percentages of the saturable binding of [^{3}H] ±pentazocine is much lower than that of [^{11}C]-SA4503. The brain uptake of [^{3}H] ±pentazocine is blocked to a great extent by SA4503 at a dose of 2 μmol/kg, while that of [^{11}C]-SA4503 is blocked by ±pentazocine at a dose of 20 μmol/kg or greater. In the presence of cyclosporin A, the uptake of [^{3}H] ±pentazocine is enhanced, but [^{11}C]-SA4503 uptake is not. Under control and P-glycoprotein-modulated conditions, the brain uptake of both radioligands is reduced by haloperidol to a different extent. Therefore, P-glycoprotein modulation results in the different brain kinetics of the 2 radioligands. The radiolabeled SA4503 is suitable as an *in vivo* probe, but radiolabeled ±pentazocine is not.

Different brain kinetics of 2 sigma$_1$-receptor ligands, [3H]±pentazocine and [11C]-SA4503, by P-glycoprotein modulation. Kawamura K, Kobayashi T, Matsuno K, Ishiwata K. Synapse 2003 May; 48 (2), pp. 80–6.

Parkinson's Disease (PD)
[^{18}F]-Fluoro-Deoxy-Glucose (FDG)

Cellular/Molecular Mechanism of Action: [^{18}F]-FDG is an analogue of glucose that can be used as a metabolic probe agent.
Background Information: In previous studies, [^{18}F]-FDG and PET have been utilized to quantify regional metabolic abnormalities in PD. The disease state is characterized reproducibly by a specific abnormal PD-related pattern (PDRP).
Application: Assessment of the effects of different stimuli and pharmaceutical agents (e.g., levodopa) on resting-state brain metabolism in PD conditions.
Implementation: Quantify the effects of dopamine replacement induced by IV levodopa infusion on regional metabolism and PDRP network activity. The hypothesis guiding such investigations proposes that clinical response to dopaminergic therapy correlates with such changes in metabolism.

In this context, FDG PET can be used to measure resting-state regional brain metabolism in conditions of PD whereby subjects are scanned both off levodopa and during an individually titrated constant-rate IV levodopa infusion. Statistical parametric mapping can then be used to identify significant changes in regional brain metabolism that occur with this form of intervention. Quantification of levodopa-induced changes in PDRP expression are also established.

Human Model: Cases with PD (n = 7; age, 59.4 ± 4.2 years; Hoehn and Yahr stage, 1.9 ± 0.7, mean ± standard deviation).
Interpretation and Analysis: Metabolic changes with levodopa correlate with clinical improvement as measured by changes in Unified PD Rating Scale (UPDRS) motor scores. Levodopa infusion improves UPDRS motor ratings (30.6% ± 12.0%, $p < 0.002$) and significantly decreases regional glucose metabolism in the left putamen, right thalamus, bilateral cerebellum, and left primary motor cortex ($p < 0.001$). Changes in pallidal metabolism correlate significantly with clinical improvement in UPDRS motor ratings ($p < 0.01$). Levodopa infusion also results in a significant ($p = 0.01$) decline in PDRP expression. The changes in PDRP activity mediated by levodopa correlate significantly with clinical improvement in UPDRS motor ratings ($r = -0.78$, $p < 0.04$).

Levodopa reduces brain metabolism in the putamen, thalamus, and cerebellum in PD patients. Additionally, levodopa reduces PD-related pattern activity, and the degree of network suppression correlates with clinical improvement. The response to dopaminergic therapy in patients with PD may be determined by modulation of cortico-striato-pallido-thalamocortical pathways.

Metabolic correlates of levodopa response in Parkinson's disease. Feigin A, Fukuda M, Dhawan V, Przedborski S, Jackson-Lewis V, Mentis MJ, Moeller JR, Eidelberg D. Neurology 2001 Dec 11; 57 (11), pp. 2083–8.

Parkinson's Disease/Adenosine A(2A) Receptor Selective Antagonist
[^{14}C]-KW-6002

Cellular/Molecular Mechanism of Action: The compound KW-6002 or [(E)-1,3-diethyl-8-(3,4-dimethoxystyryl)-7-methyl-3,7-dihydro-[^{1}H]-purine-2,6-dione] recognizes and selectively binds to adenosine A(2A) receptor complexes.
Physiological Mechanism of Action: The agent KW-6002 [(E)-1,3-diethyl-8-(3,4-dimethoxystyryl)-7-methyl-3,7-dihydro-[^{1}H]-purine-2,6-dione] functions as a selective adenosine A(2A) receptor

antagonist. KW-6002 also modulates the activity of striatopallidal enkephalin-containing neurons but not striatonigral substance P-containing neurons.

Application: Potential template for diagnostic imaging or platform for diagnostic pharmacology based on the capacity of KW-6002 to exert antiparkinsonian activity in rodent and primate models. In this context, orally administered KW-6002 is distributed selectively to the striatum.

Route of Administration: KW-6002 or [(E)-1,3-diethyl-8-(3,4-dimethoxystyryl)-7-methyl-3,7-dihydro-[^{1}H]-purine-2,6-dione] can be given per os (orally).

Dosage: KW-6002 or [(E)-1,3-diethyl-8-(3,4-dimethoxystyryl)-7-methyl-3,7-dihydro-[^{1}H]-purine-2,6-dione] administered at 0.1 to 0.3 mg/kg BW.

Implementation: Evaluation of the distribution of [^{14}C]-KW-6002 within the forebrain after administration of pharmacologically effective doses. In addition, the influence of [^{14}C]-KW-6002 can be monitored to determine its effects on preproenkephalin (PPE) and preprotachykinin (PPT) gene expression in rat striatum.

Animal Model: Rat.

Interpretation and Analysis: Highest levels of radioactivity are observed in the striatum after oral administration of [^{14}C]-KW-6002, and at 30 minutes after 0.1 and 0.3 mg/kg, the density values in the striatum are 2.45 and 2.43 times higher than those in reference regions (e.g., frontal cortex), respectively. At doses of 3 mg/kg (per os), the ratio is only 1.58 and the compound is distributed more extensively within the brain. The distribution pattern and intensity of radioactivity are maintained even 90 minutes after the administration of [^{14}C]-KW-6002. Oral administration of KW-6002 (0.3 and 3 mg/kg/day) to rats for 14 days reverses increased gene expression of PPE in striatum depleted of dopamine by prior treatment with 6-hydroxydopamine (6-OHDA). Alternatively, KW-6002 does not alter decreased PPT gene expression in 6-OHDA-treated rats.

Distribution of adenosine A(2A) receptor antagonist KW-6002 and its effect on gene expression in the rat brain. Aoyama S, Koga K, Mori A, Miyaji H, Sekine S, Kase H, Uchimura T, Kobayashi H, Kuwana Y. Brain Res 2002 Oct 25; 953 (1–2), pp. 119–25.

Parkinson's Disease (PD)/Dopaminergic Degeneration (Progressive Nigrostriatal)/ Biomarker System for Therapeutic Trials
[^{123}I]β-CIT

Background Information: [^{123}I]β-CIT and single photon emission computed tomography (SPECT) imaging of the dopamine transporter is a sensitive biomarker of PD onset and severity.

Application: In this study, the authors examine the change in [^{123}I]β-CIT uptake in sequential SPECT scans to assess the rate of progression of the dopaminergic terminal loss in patients with PD.

Human Model: Cases of PD (n = 32) and healthy controls (n = 24) recruited from the Yale Movement Disorders Center and subjected to repeat [^{123}I]β-CIT SPECT imaging during a 1- to 4-year period. The primary imaging outcome is categorized as the ratio of specific to non-displaceable striatal activity. Disease severity can be assessed by Hoehn and Yahr staging, and Unified PD Rating Scale after being 12 hours off drug.

Interpretation and Analysis: Sequential SPECT scans in PD subjects demonstrate a decline in [^{123}I]β-CIT striatal uptake of approximately 11.2%/year from the baseline scan, compared with 0.8%/year in healthy controls ($p < 0.001$). Although [^{123}I]β-CIT striatal uptake in PD subjects correlates with clinical severity, the annual percentage loss of [^{123}I]β-CIT striatal uptake does not correlate with the annual loss in measures of clinical function.

The rate of dopaminergic loss in PD is significantly greater than that of healthy controls, and [^{123}I]β-CIT SPECT imaging provides a quantitative biomarker for progressive nigrostriatal dopaminergic degeneration in PD. As new protective and restorative therapies for PD are developed, dopamine transporter imaging offers the potential to provide an objective end point for these therapeutic trials.

[123I]β-CIT SPECT imaging assessment of the rate of Parkinson's disease progression. Marek K, Innis R, van Dyck C, Fussell B, Early M, Eberly S, Oakes D, Seibyl J. Neurology 2001 Dec 11; 57 (11), pp. 2089–94.

Parkinson's Disease (PD)/Dopaminergic Neurotransporter Systems/Dopamine D_2 Receptors
[^{123}I]-Iodobenzamide (IBZM)/[^{123}I]-2-β-Carbomethoxy-3-β-(4-Iodophenyl)Tropane (β-CIT)

Cellular/Molecular Mechanism of Action: [^{123}I]-2-β-carbomethoxy-3-β-(4-iodophenyl)tropane (β-CIT) functions as a dopamine transporter (DAT) ligand, while [^{123}I]-iodobenzamide (IBZM) is a dopamine D_2 receptor (D_2R) ligand.

Application: Characterization of dopaminergic neurotransmission systems and dopamine receptor with the central nervous system (CNS) as potential diagnostic modalities related to PD and other CNS disorders.

Route of Administration: [^{123}I]-2-β-carbomethoxy-3-β-(4-iodophenyl)tropane (β-CIT) is administered intravenously prior to single photon emission computed tomography (SPECT) image analysis.

Implementation: Evaluation of the biodistribution of [^{123}I]2-β-carbomethoxy-3-β-(4-iodophenyl)tropane and [^{123}I]-iodobenzamide utilizing high-resolution SPECT provides a unique capability for imaging the biodistribution of radiolabeled molecules in small laboratory animals.

Animal Model: Marmoset (brain).

Interpretation and Analysis: Following injection of [^{123}I]β-CIT and [^{123}I]-IBZM, images can be obtained at 240 minutes and 60 minutes, respectively, within the striatum, which is a region of the CNS with a high density of dopaminergic synapses. Furthermore, a significantly low accumulation of [^{123}I]β-CIT in the striatum is observed in 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-treated animals compared to reference controls. Similar accumulations in controls can be observed with deprenyl pretreatment in MPTP-treated animals. However, the striatal accumulation of [^{123}I]-IBZM shows no changes among controls, MPTP-treated, and deprenyl-MPTP-treated groups. Results from SPECT images agree well with those of dopamine concentration and motor behavior. Because MPTP destroys nigrostriatal dopamine nerves and produces irreversible neurodegeneration associated with Parkinsonian syndrome, SPECT imaging data demonstrates that deprenyl shows its neuroprotective effect on Parkinsonism by protecting against the destruction of presynaptic dopamine neurons.

In vivo imaging of brain dopaminergic neurotransmission system in small animals with high-resolution single photon emission computed tomography. Saji H, Iida Y, Kawashima H, Ogawa M, Kitamura Y, Mukai T, Shimazu S, Yoneda F. Anal Sci 2003 Jan; 19 (1), pp. 67–71.

Parkinson's and Attention Deficit Hyperactivity Disorder (ADHD)/Typical Early Parkinson's Disease (PD) Detection
[^{123}I]-Altropane Single Photon Emission Computed Tomography (SPECT)/[^{18}F]-6-Flourodopa Positron Emission Tomography (PET)

Cellular/Molecular Mechanism of Action: Altropane is an iodinated form of the *N*-allyl analogue of WIN 35,428, which acts as a dopamine transport inhibitor.

Background Information: Altropane is currently in phase III clinical trials for PD and phase II clinical trials for ADHD.

Application: Altropane can be utilized as a potential radio-imaging agent in SPECT based modalities, for the early diagnosis of PD and ADHD.

Considerations: Positron emission tomography cameras are expensive and scarce, and the tests are non-reimbursable. A less costly and more available test such as SPECT may be helpful in the diagnosis of early or atypical PD if its sensitivity is comparable to PET scans.

Implementation: Evaluation of the biodistribution of [^{123}I]-altropane (SPECT) and [^{18}F]-6-flourodopa (PET) in cases of early PD with the aid of SPECT imaging.

Human Model: Cases of typical early PD (n = 2, ages 54 and 38 years) with imaging modalities performed within a 3-month period of time. Each case has a 1-year history of intermittent right hand tremor with right arm rigidity and hypokinesia and bradykinesia on fine finger movements. A significant and sustained improvement in Parkinsonian symptoms is noted using a dopamine agonist.

Interpretation and Analysis: Single photon emission computed tomography and PET scans show non-diagnostic fluorodopa PET scans with clear unilateral striatal reduction of tracer uptake contralateral to their Parkinsonian side on altropane SPECT scans. Therefore, when radiolabeled with the gamma emitting isotope [^{123}I], altropane serves as a SPECT ligand with high affinity and selectivity for dopamine transporter complexes. In this manner, it is a good marker for dopamine neurons and is useful for detecting the early stages of PD conditions. Further controlled studies are needed to define its potential role in detecting presymptomatic, early and atypical PD cases.

Instrumentation: Positron emission tomography studies can be performed using a PC-4096 scanner (Scanditronix AB, Sweden) with 15 axial slices and resolution of 6 mm FWHM. The SPECT acquisitions are performed on a MultiSPECT gamma camera (Siemens, Hoffman Estates, IL) equipped with fan-beam collimators with an intrinsic resolution of 4.6 FWHM (for Case 1) and a DSI Ceraspect camera with an annular crystal, with resolution of approximately 6.4 mm FWHM (for Case 2).

Altropane (Boston Life Science). Cattabeni F. Curr Opin Investig Drugs 2002 Nov; 3 (11), pp. 1647–51.

Is altropane SPECT more sensitive to fluorodopa PET for detecting early Parkinson's disease? Fernandez HH, Friedman JH, Fischman AJ, Noto RB, Lannon MC. Med Sci Monit 2001 Nov–Dec; 7 (6), pp. 1339–43.

Parkinson's Disease (PD)/Differentiation from Orthostatic Tremors (OTs) *[^{123}I]-2 β-Carbomethoxy-3β-(-4-Iodophenyl)-N-(3-Fluoropropyl)-Nortropane) ([^{123}I]-FP-CIT)/L-Dopa*

Cellular/Molecular Mechanism of Action: [^{123}I]-FP-CIT functions as a dopamine transporter tracer.

Background Information: There is increasing evidence of a potential role of the dopaminergic system in OT; correlations with Parkinsonism and treatment effects of L-dopa and dopamine agonists have been reported.

Application: Characterization of dopamine transporter function and expression in conditions including OT.

Implementation: Evaluation of cases affected by OT using the dopamine transporter tracer [^{123}I]-FP-CIT as dopamine transporter tracer in conjunction with single photon emission computed tomography (SPECT).

Interpretation and Analysis: A marked reduction in striatal tracer binding can be appreciated in cases of OT compared to normal controls ($p < 0.001$; n = 12 vs 12). Tracer uptake, however, is significantly higher and more symmetrical than in PD, and the caudate and putamen structures are equally affected. Challenges with L-dopa in OT cases (e.g., n = 7) reveal a small but non-significant improvement on electromyography (EMG) and a small but significant improvement in clinical parameters (blinded video rating). Two-month open-label L-dopa treatment (600 mg/day) produces a small improvement in approximately 40% (e.g., n = 2/5) of cases but no significant overall change can be appreciated. Olfactory function using the University of Pennsylvania Smell Identification Test is usually normal in most cases. The detection of marked reductions in tracer uptake on dopamine transporter SPECT therefore supports the concept of the probable role the dopaminergic system has in molecular pathogenesis of OT. Lack of evidence of a clinically relevant therapeutic response to L-dopa suggests that other mechanisms must also be involved in this disease process.

[^{123}I]-FP-CIT-SPECT demonstrates dopaminergic deficit in orthostatic tremor. Katzenschlager R, Costa D, Gerschlager W, O'Sullivan J, Zijlmans J, Gacinovic S, Pirker W, Wills A, Bhatia K, Lees AJ, Brown P. Ann Neurol 2003 Apr; 53 (4), pp. 489–96.

Parkinson's Disease (PD): Dopamine (D_2) Receptors *[^{11}C]/[^{123}I]-Epidepride/[^{11}C]/[^{18}F]-Fallypride/[^{11}C]/[^{125}I]-Nalipride [^{76}Br]-Isoremoxipride (FLB-457)/[^{125}I]-Ioxipride/Sulpiride and Remoxipride/Raclopride/Eticlopride*

Cellular/Molecular Mechanism of Action: Epidepride, fallypride, and isoremoxipride are members of a class of high-affinity dopamine D_2 receptor ligands.

Background Information: Starting in the late 1970s, halogenated analogs of (S)-sulpiride were evaluated in binding assays and behavioral studies, leading to the discovery of remoxipride. Remoxipride is 10 times weaker than sulpiride *in vitro* but 50 times more potent *in vivo*. The search for a putative active metabolite of remoxipride led to the discovery of raclopride and eticlopride, the former becoming a useful radioligand as tritium or carbon-11 labeled form for receptor binding and positron emission tomography (PET) studies, respectively. In the United States, the mono-iodine analogue of raclopride, [^{123}I]-iodobenzamide (IBZM), was found to have moderate putamen-to-cerebellum ratio in rat and human brain. Continued search for metabolites of remoxipride led to the discovery of its 3,6-dihydroxy derivative, NCQ-344, with an extremely potent *in vivo* activity in the rat. Structure-activity-relationship (SAR) studies of the metabolites of remoxipride led to the discovery of the 3-methoxy isomer, isoremoxipride (FLB-457), and its corresponding 6-hydroxy analog, FLB-463, both having affinities for the dopamine D_2 receptor in the 20–30 pM range. Later, the 5-[^{123}I]-iodo analogue of FLB-463, [^{123}I]-ioxipride ([^{123}I]-NCQ-298), became a potential single photon emission computed tomography (SPECT) imaging agent. In the meantime, the deshydroxy analogue of IBZM, [^{125}I]-iodopride, showed binding potential in the rat similar to [^{125}I]-IBZM. Epidepride was designed by combining the structure of isoremoxipride with that of iodopride. In 1988, epidepride was independently prepared and radiolabeled in 3 separate laboratories in Stockholm, Berkeley, and Nashville. Evaluation of 7 [^{125}I]-iodine substituted analogs of raclopride, including IBZM, revealed the unusual high striatum-to-cerebellum ratio of 234 of [^{125}I]-epidepride in the rat. Subsequent SPECT images with [^{123}I]-epidepride demonstrated its ability to identify extrastriatal dopamine D_2 receptors in the human brain. Exploration of the structure of epidepride confirmed its exceptional properties, to be exceeded only by its *N*-allyl homolog, [^{125}I]-nalepride. The design by other investigators of a series of potent 5-(3-[^{18}F]-fluoropropyl) substituted analogs of epidepride for PET imaging lead to the discovery of [^{18}F]-fallypride. By elucidating the role of lipophilicity in the substituted benzamides, the excellent

imaging characteristics of [^{11}C]/[^{123}I]-epidepride, [^{11}C]/[^{76}Br]-isoremoxipride, and [^{18}F]-fallypride could not only be explained but predicted with remarkable accuracy. By using the inverse product of receptor affinity (K_D), and the apparent partition constant of the radioligand ($P_{7.4}$), estimates of maximal binding potential of any radioligand for imaging of any neurotransmitter receptor or transporter site seems possible.

Application: [^{11}C]/[^{123}I]-epidepride, [^{11}C]/[^{18}F]-fallypride, and [^{11}C]/[^{76}Br]-isoremoxipride (FLB-457) can be utilized as high-affinity radioligands for SPECT or PET imaging of dopamine D_2 receptors in the human brain. In contrast to previously used imaging agents, [^{11}C]/[^{123}I]-epidepride, [^{11}C]/[^{18}F]-fallypride, and [^{11}C]/[^{76}Br]-isoremoxipride (FLB-457) are capable of identifying extrastriatal dopamine D_2 receptors.

Considerations: The design of substituted benzamides derive their origin from the atypical antipsychotic agent remoxipride.

The discovery of epidepride and its analogs as high-affinity radioligands for imaging extrastriatal dopamine D_2 receptors in human brain. de Paulis T. Curr Pharm Des 2003; 9 (8), pp. 673–96.

Parkinson's Disease (PD)/Dopamine Receptors
[^{18}F]-Dopa

Background Information: Advances in our understanding of the cause and pathogenesis of PD have permitted the rational selection of putative neuroprotective agents for study in PD. However, the list of agents that might provide neuroprotective effects derived from laboratory studies is daunting, and determining which agents to bring to the clinic and how to find the resources (patients and funds) to properly study so many promising therapeutic opportunities is a challenge. Appropriate outcome variables that are not confounded by any symptomatic effect of the drug and are acceptable to clinicians and regulatory authorities also remain to be defined. The 1st clinical trials designed to test the capacity of putative neuroprotective agents to alter the natural history of PD have now been performed and illustrate some of these problems. The DATATOP (Deprenyl and Tocopherol Antioxidant Therapy of PD) study used the time to reach a disease milestone in untreated PD patients (i.e., need for levodopa) as the primary end point. However, interpretation of results was confounded by the drug's symptomatic effect. The SINDEPAR (Sinemet-Deprenyl-Parlodel) study used the change in motor score between initial visit and final visit after washout of all study medications as the primary end point. However, here too there were concerns about confounding symptomatic effects, because antiparkinsonian medications have now been shown to have a long duration response that can persist for weeks and perhaps even months after withdrawal.

To date, no drug has been established to have a neuroprotective effect in PD, and none has been approved for a neuroprotective indication. Furthermore, regulatory agencies have not yet agreed that any of the outcome measures currently used will be acceptable for approval of a new drug. Resolution of these issues is of critical importance to convince pharmaceutical companies to expend the hundreds of millions of dollars necessary to bring a new drug to market. Drugs that already have been approved in PD for their symptomatic effects, such as dopamine agonists or propargylamines (e.g., selegiline), offer the best opportunity for establishing that a drug is neuroprotective in PD in the immediate future, but herein also lies the difficulty of establishing that any benefits observed are not solely because of the drug's symptomatic properties. Currently, this will most likely entail demonstrating that the drug provides benefit for PD patients for both imaging and clinical markers of disease progression.

Implementation: Integrity of nigrostriatal function can be ascertained with the application of surrogate marker systems, including the evaluation of striatal fluorodopa uptake on positron emission tomography (PET) or β-CIT on single photon emission computerized tomography (SPECT).

Interpretation and Analysis: Characterization of nigrostriatal function with surrogate marker systems involving the evaluation of striatal fluorodopa uptake on PET or β-CIT on SPECT can provide information that can be applied as primary outcome measures. Despite their effectiveness, the interpretation of PET and SPECT image analyses is complicated by the (i) lack of confirmation that striatal uptake of isotope agents does in fact correlate with the remaining number of dopamine neurons or terminals; and the (ii) possible confounding pharmacological effect exerted by diagnostic agents, which has not yet been completely excluded.

Neuroprotection in Parkinson's disease: Clinical trials. Stocchi F, Olanow CW. Ann Neurol 2003; 53 Suppl 3, pp. S87–97; discussion S97–9.

Parkinson's Disease (PD): Dopamine D_2 Receptors/Progression of Neurodegeneration/D_2 Receptor Agonist Response
[^{123}I]β-CIT

Application: [^{123}I]β-CIT single photon emission computed tomography (SPECT) is a useful tool for characterizing the progression of dopaminergic degeneration in PD and may provide an objective method of measuring the effectiveness of neuroprotective treatments.

Implementation: Delineation of the validity of [^{123}I]β-CIT SPECT for monitoring the progression of dopaminergic degeneration in PD and to investigate the influence of short-term treatment with D_2 receptor agonists on striatal [^{123}I]β-CIT binding. To this end, early-stage PD cases (e.g., $n = 50$) are examined involving the acquisition of 2 SPECT imaging series that are obtained 12 months apart. The mean annual change in the ratio of specific to non-specific [^{123}I]β-CIT binding to the striatum, putamen, and caudate nucleus is used as an outcome measure.

Interpretation and Analysis: A decrease in [^{123}I]β-CIT binding ratios between the 2 images is found in all regions of interest. The average decrease in [^{123}I]β-CIT binding ratios is about 8% in the whole striatum, 8% in the putaminal region, and 4% in the caudate region. Comparison of scans (e.g., $n = 9$) under 2 different conditions—in the off state and while on drug treatment—shows no significant alterations in the expression of striatal dopamine transporters as measured using [^{123}I]β-CIT SPECT. Power analysis indicates that to detect a significant ($p < 0.05$) effect of a neuroprotective agent with 0.80 power and 30% of predicted protection within 2 years, 216 cases are required in each group when the effects are measured in the whole putamen. Short-term treatment with a D_2 agonist does not have a significant influence on [^{123}I]β-CIT binding to dopamine transporters. If the latter finding is replicated in larger groups of patients, it supports the suitability of [^{123}I]β-CIT SPECT for examining the progression of neurodegeneration in patients being treated with D_2 receptor agonists.

[^{123}I]β-CIT SPECT is a useful method for monitoring dopaminergic degeneration in early stage Parkinson's disease. Winogrodzka A, Bergmans P, Booij J, van Royen EA, Stoof JC, Wolters EC. J Neurol Neurosurg Psychiatry 2003 Mar; 74 (3), pp. 294–8.

Parkinson's Disease (PD): Dopamine Transporter (DAT)/Attention Deficit Hyperactivity Disorder (ADHD)
[^{99m}Technetium] ([^{99m}Tc]) Tropane Ligands: 2nd Generation

Cellular/Molecular Mechanism of Action: Recognize and physically binds to DAT complexes located presynaptically on dopamine neurons.

Physiological Mechanism of Action: In ADHD, DAT density levels are elevated, while in PD the levels become depleted. The depletion of DAT levels also corresponds with the loss of dopamine.
Background Information: An additional feature of PD is a depletion of dopaminergic neurons within the substantia nigra accompanied by development of fibrillar Lewy bodies comprised primarily of α-synuclein.
Application: The DAT complex can function as a marker for PD and ADHD.
Interpretation and Analysis: The agent (*N*-[(2-((3′-*N*′-propyl-(1′′R)-3′′α-(4-fluorophenyl)tropane-2′′beta-1-propanoyl) (2-mercaptoethyl)amino)acetyl)-2-aminoethanethiolato]technetium (V)oxide) possesses improved selectivity and biological stability, allowing sufficient amounts of the agent to enter the brain and *in vivo* label DAT complexes sufficient to provide quantitative measurement of DAT density (non-human primates).

A 2nd-generation 99m technetium single photon emission computed tomography agent that provides *in vivo* images of the dopamine transporter in primate brain. Meltzer PC, Blundell P, Zona T, Yang L, Huang H, Bonab AA, Livni E, Fischman A, Madras BK. J Med Chem 2003 Jul 31; 46 (16), pp. 3483–96.

Parkinson's Disease (PD): Dopamine Transporter (DAT)
[^{99m}Technetium] ([^{99m}Tc])-TRODAT-1/6-[^{18}F]-Fluoro-L-Dopa ([^{18}F]-Fdopa)

Cellular/Molecular Mechanism of Action: ([2-[[2-[[[3-(4-chlorophenyl)-8-methyl-8-azabicyclo[3,2,1]oct-2-yl]methyl](2-mercaptoethyl)amino]ethyl]amino]ethanethiolato(3-)-N2,N2′,S2,S2′] oxo-[1R-(exo-exo)]), also referred to as TRODAT-1, is a potential agent that recognizes DAT complexes.
Application: [^{99m}Tc]-TRODAT-1 is used to detect and characterize DAT complexes when utilized in combination with single photon emission computed tomography (SPECT) imaging modalities. In contrast, [^{18}F]-Fdopa positron emission tomography (PET) is used for the quantitative assessment of presynaptic nigrostriatal dopaminergic function.
Route of Administration: [^{18}F]-Fdopa (intravascular).
Dosage: [^{18}F]-Fdopa (300 MBq).
Implementation: Evaluation of PD utilizing comparative image scans obtained with [^{18}F]-Fdopa and [^{99m}Tc]-TRODAT-1 functioning as *in vivo* molecular probes. Scans are performed on 2 separate occasions. In addition to visual inspection, specific uptake ratios (SURs) of [^{99m}Tc]-TRODAT-1 in the striatum and putamen are measured bilaterally. For PET, test cases receive carbidoma (100 mg), 90 minutes before [^{18}F]-Fdopa (300 MBq) injection. Images are acquired between 120 and 150 minutes after injection, using a whole-body PET scanner with settings identical to those for the SPECT studies. The SURs for PET are calculated similar to those for SPECT. Individual SURs of the striatum or putamen from SPECT are then correlated with the corresponding PET values using linear regression.
Human Model: Confirmed cases of PD (e.g., n = 20).
Interpretation and Analysis: A consistent image pattern between SPECT and PET is achieved by visual inspection except in approximately 15% of cases (e.g., n = 3/20). In a small percentage of cases (e.g., n = 1/20 with Hoehn and Yahr Scale I PD), the SPECT images are more compatible with the patient's clinical findings, whereas PET shows nearly normal uptake. A small percetage of other cases (e.g., n = 2/20, both cases with Hoehn and Yahr Scale II PD), have PET findings that correlate better with the clinical findings. The caudate and putamen nuclei are more discernable with PET imaging. An acceptable correlation of SUR, however, can be appreciated between SPECT and PET in both the striatum and the putamen ($p < 0.01$ for both). The comparability of [^{99m}Tc]-TRODAT-1 SPECT and [^{18}F]-Fdopa PET suggests that [^{99m}Tc]-TRODAT-1 SPECT may provide a reliable alternative to [^{18}F]-Fdopa PET in the evaluation of clinical PD cases.

Crossover study of [^{99m}Tc]-TRODAT-1 SPECT and [^{18}F]-Fdopa PET in Parkinson's disease patients. Huang WS, Chiang YH, Lin JC, Chou YH, Cheng CY, Liu RS. J Nucl Med 2003 Jul; 44 (7), pp. 999–1005.

Prion Plaques/Creutzfeldt-Jacob Disease (Sporadic and Variant CJD)/Gerstmann-Straussler-Scheinker Disease/Alzheimer's Disease (AD)
2-(1-[6-[(2-Fluoroethyl)(Methyl)Amino]-2-Naphthyl] Ethylidene) Malononitrile (FDDNP)/[^{18}F]-FDDNP

Cellular/Molecular Mechanism of Action: The agent FDDNP is a molecule that both emits fluorescent light energy and recognizes/physically binds to (i) plaques created in the central nervous system (CNS) by prion agents; and (ii) senile plaques and neurofibrillary tangles associated with AD.
Background Information: The fluorescent molecular-imaging probe FDDNP is a highly hydrophobic, viscosity-sensitive, solvent-sensitive, fluorescent substance whose radiofluorinated analogue [^{18}F]-FDDNP has recently been successfully used to label senile plaques and neurofibrillary tangles in the living brain of AD patients with positron emission tomography (PET).
Implementation: Evaluate the fluorescent molecular-imaging probe FDDNP for its ability to selectively and reproducibly label prion plaques in fixed, paraffin-embedded cerebellar sections from patients of confirmed Gerstmann-Straussler-Scheinker disease, sporadic CJD with kuru plaques, and variant CJD (vCJD).
Interpretation and Analysis: The agent FDDNP reliably identifies all prion plaques, including small cluster plaques in vCJD. This finding may open alternative *in vivo* diagnostic possibilities for vCJD.

Molecular-imaging probe 2-(1-[6-[(2-fluoroethyl)(methyl) amino]-2-naphthyl]ethylidene) malononitrile labels prion plaques *in vitro*. Bresjanac M, Smid LM, Vovko TD, Petric A, Barrio JR, Popovic M. J Neurosci. 2003 Sep 3; 23(22), pp. 8029–33.

Seizures and Behavior/Paroxysmal Kinesigenic Choreoathetosis/Dyskinetic Movement Attacks/ Choreoathetosis Attack (Impending): Associated Indicators/Contralateral Basal Ganglia Hyperactivity and Perfusion/Ictal Phase Imaging
[^{99m}Technetium] ([^{99m}Tc])-Ethyl Cysteinate Dimer

Background Information: Paroxysmal kinesigenic choreoathetosis is a rare neurologic disorder characterized by sudden attacks of brief involuntary dyskinetic movement that are precipitated by voluntary movement.
Application: Detection and characterization of contralateral basal ganglia perfusion (ictal phase imaging) in conditions of paroxysmal kinesigenic choreoathetosis.
Implementation: Evaluation of hemidystonia using [^{99m}Tc]-ethyl cysteinate dimer and ictal single photon emission computed tomography (SPECT).
Human Model: A case of hemidystonia (n = 1; 14-year-old male with frequent brief attacks triggered by sudden movement). Note: Normal findings from video electroencephalogram and magnetic resonance imaging.
Interpretation and Analysis: Ictal SPECT using [^{99m}Tc] ethyl cysteinate dimer can detect increases in the perfusion of the contralateral basal ganglia associated with the onset of choreoathetosis

attacks. Hyperactivity of the basal ganglia is associated with the dyskinetic attacks in paroxysmal kinesigenic choreoathetosis.

Ictal [99mTc] ECD SPECT in paroxysmal kinesigenic choreoathetosis. Ko CH, Kong CK, Ngai WT, Ma KM. Pediatr Neurol 2001 Mar; 24 (3), pp. 225–7.

Seizures/Epilepsy: Drug-Resistant Focal Type/ Accuracy of Amobarbital Target Delivery/ Temporary Neurologic Deficits/Risk Assessment of Postsurgical Motor Deficits Before Functional Hemispherectomy/Language Area Identification

Amobarbital (Sodium) Wada Test/[^{99m}Technetium] ([^{99m}Tc])-Hexamethyl-Propylene-Amine Oxime (HMPAO)/Electrical Stimulation Mapping

Cellular/Molecular Mechanism of Action: Amobarbital is a barbiturate.

Physiological Mechanism of Action: Amobarbital suppresses neurologic function.

Application: Analyze the role of selective middle cerebral artery (MCA) Wada tests in the presurgical workup of patients with drug-resistant focal epilepsies.

Route of Administration: Amobarbital is administered selectively into arterial branches supplying specific regions of the cerebral cortex using a catheter introduced into the carotid artery.

Implementation: Evaluation of cerebral cortex function in conditions of (i) motor cortex cerebral hemisphere lesions (connatal MCA infarct; unilateral cortical dysplasia; Rasmussen encephalitis); (ii) circumscribed neoplastic or non-neoplastic lesions adjacent to the motor cortex or classical regions; and (iii) sleep electrical status elepticus (ESES). Sodium amobarbital and [^{99m}Tc]-HMPAO are simultaneously injected through a microcatheter into the distal M1 segment, or the inferior MCA trunk, or into MCA branches in order to identify eloquent cortex.

Human Model: Cases of cerebral cortex dysfunction, including (i) hemispheric lesions involving the motor cortex (n = 9 cases, of which n = 5/9 have connatal MCA infarcts, n = 3/9 have unilateral cortical dysplasia, n = 1/9 Rasmussen encephalitis); (ii) circumscribed neoplastic or non-neoplastic lesions adjacent to the motor cortex or classic language areas (n = 5 cases); and (iii) purely electrophysiologic analyses of ESES conditions (n = 2 cases). Total Wada tests performed (n = 20).

Interpretation and Analysis: Co-registered single photon emission computed tomography (SPECT) and magnetic resonance imaging (MRI; n = 18) reveals that sodium amobarbital does not reach the target area in some procedures (e.g., n = 3/20). Temporary neurologic deficits can occur in slightly more than half of all Wada procedures performed (e.g., n = 12/20). Cases subjected to surgical intervention require the use of several different surgical approaches, including functional hemispherectomy (n = 3); partial or extended lesionectomy (n = 4); anterior temporal lobectomy (n = 1); and multiple subpial trans-sections (n = 3). Seizure freedom (Engel class I) can be achieved in a modest percentage of cases (e.g., n = 5/16 cases). The MCA Wada tests can therefore contribute to risk assessment concerning postsurgical motor deficits before functional hemispherectomy. Other indications are less clear. The identification of language areas is targeted primarily by electrical-stimulation mapping after subdural grid implantations, and selective MCA Wada tests in ESES patients have yet to be validated in large patient groups.

Selective middle cerebral artery Wada tests as a part of presurgical evaluation in patients with drug-resistant epilepsies. Urbach H, Von Oertzen J, Klemm E, Koenig R, Linke DB, Kurthen M, Schramm J, Elger CE. Epilepsia 2002 Oct; 43 (10), pp. 1217–23.

Seizures/Epileptic Foci/Psychiatric Disorder Receptor Changes/Parkinson's Disease (PD) Differential Diagnosis/Dopamine D_2/D_3 Receptors/ PD Differential/Neurodegenerative Disease/ Dopamine Transporter/PD/Dopamine Transporter

[^{123}I]-Iomazenil/Benzodiazepine (γ-Aminobutyric Acid) Receptors/[^{123}I]-Iodobenzamide/[^{123}I]-Epidepride/[^{123}I]-CIT (2-β-Carboxymethoxy-3-β(4-Iodophenyl)Tropane)/[^{123}I]-FP-β-CIT (N-Propyl-2-β-Carboxymethoxy-3-β(4-Iodophenyl)-Nortropane/[^{99m}Technetium] ([^{99m}Tc])-TRODAT/[^{99m}Tc]-2-[[2-[[[3-(4-Chlorophenyl)-8-Methyl-8-Azabicyclo [3,2,1]Oct-2-yl]-Methyl](2-Mercaptoethyl)-Amino]-Ethyl]-Amino]-Ethanethiolato(3-)]Oxo-[1R-(Exo-Exo)]-)

Background Information: In the past 10 years, significant progress has been made in the development of new brain-imaging agents for single photon emission computed tomography (SPECT). Most of the new radiopharmaceuticals have been designed to bind specific neurotransmitter receptor or transporter sites in the central nervous system. Most of the site-specific brain radiopharmaceuticals are labeled with [^{123}I]. Results from imaging of benzodiazepine (gamma-aminobutyric acid) receptors by [^{123}I]-iomazenil are useful in identifying epileptic seizure foci and changes of this receptor type in psychiatric disorders. Imaging of dopamine D_2/D_3 receptors (e.g., [^{123}I]-iodobenzamide and [^{123}I]-epidepride) and transporters (e.g., [^{123}I]-CIT (2-β-carboxymethoxy-3-β(4-iodophenyl)tropane) and [^{123}I]-FP-β-CIT (*N*-propyl-2-β-carboxymethoxy-3-β(4 iodophenyl)-nortropane) has proven to be a simple but powerful tool for differential diagnosis of Parkinson's and other neurodegenerative diseases. A [^{99m}Tc]-labeled agent, [^{99m}Tc]-TRODAT (technetium, 2-[[2-[[[3-(4-chlorophenyl)-8-methyl-8-azabicyclo [3,2,1]oct-2-yl]methyl]-(2-mercaptoethyl) amino]ethyl]amino] ethanethiolato(3-)]oxo-[1R-(exo-exo)]-), for imaging dopamine transporters in the brain, has been successfully applied in the diagnosis of PD. Despite the fact that [^{123}I] radiopharmaceuticals have been widely used in Japan and in Europe, clinical application of [^{123}I]-labeled brain radiopharmaceuticals in the United States is limited because of difficulties associated with supplying such agents. Development of [^{99m}Tc] agents will likely extend the application of site-specific brain radiopharmaceuticals for routine applications in aiding the diagnosis and monitoring treatments of various neurologic and psychiatric disorders.

Radiopharmaceuticals for single photon emission computed tomography brain imaging. Kung HF, Kung MP, Choi SR. Semin Nucl Med 2003 Jan; 33 (1), pp. 2–13.

Seizures/Epilepsy (Intractable): Wada Test Preoperative Foci Localization/Prediction of Residual Postoperative Deficits/Relationship between Hypoperfusion on Single Photon Emission Computed Tomography (SPECT) and Duration of Hemiplegia/Drug-Induced Delta Electroencephalogram (EEG) Activity/Hexamethyl-Propylene-Amine Oxime (HMPAO)-SPECT Assessment of Methohexital Distribution

Methohexital/[^{99m}Technetium] ([^{99m}Tc])-HMPAO

Physiological Mechanism of Action: Methohexital is a barbiturate that functions as a central nervous system (CNS) depressant.

Application: Methohexital can be applied to accurately localize foci or regions within the CNS responsible for intractable epilepsy conditions. Methohexital can also simultaneously function as a means for predicting the potential (anticipated) severity of postoper-

ative deficits. [^{99m}Tc]-HMPAO can be administered intravenously during the procedure to determine the intracerebral distribution of methohexital while performing the Wada test.

Route of Administration: Methohexital (superselective intracarotic delivery into specific predetermined anatomical regions of the CNS).

Implementation: Evaluation of epileptic conditions being considered for surgery for intractable epilepsy utilizing preoperative evaluation with the selective delivery of methohexital administered through a intracarotid catheter system. The lipophilic brain SPECT agent [^{99m}Tc]-HMPAO is administered intravenously during the procedure to determine the intracerebral distribution of methohexital.

The validity of intracarotid sodium methohexital (ISM) tests depends on consistent delivery of the anesthetizing agent to 1 hemisphere, including mesial structures of the temporal lobe. To prevent postoperative language and memory deficits, correct interpretation of the test results supposes a reliable knowledge of which regions of the brain have been anesthetized. Results of HMPAO-SPECT are compared with clinical and EEG video-monitoring data and with results of digital subtraction angiography (DSA) performed during the test in an effort to establish criteria for determining the level and topographical extent of anesthesia.

Human Model: Cases being considered for surgery for intractable epilepsy (n = 25).

Interpretation and Analysis: In the vast majority of cases, the effect of sodium methohexital (SM) is ipsilateral cerebral hypoperfusion on SPECT and crossed cerebellar diaschisis (e.g., n = 25/25). The distribution of HMPAO varies from patient to patient. The delivery of SM to mesial temporal lobe structures is not constant. Using non-parametric tests, it has been demonstrated that a statistically significant relationship exists between hypoperfusion on SPECT and duration of hemiplegia but not with the duration of aphasia. Hypoperfusion on SPECT is also related to the onset and duration of drug-induced delta activity on EEG. Single photon emission computed tomography reveals a statistically different distribution of SM in the brain from that predicted with DSA, while HMPAO-SPECT can be used for mapping the distribution of methohexital's effects during the ISM Wada test. Several investigations have confirmed that SPECT assessment may be an excellent way of determining the distribution of barbiturate during the examination. It increases confidence in interpreting results of speech and memory testing by detecting either contralateral diffusion of the drug due to crossflow between hemispheres or insufficient quantitative delivery to the homolateral hemisphere.

Monitoring sodium methohexital distribution with [99mTc]-HMPAO with single photon emission computed tomography during Wada test. Coubes P, Baldy-Moulinier M, Zanca M, Boire JY, Child R, Bourbotte G, Frerebeau P. Epilepsia 1995 Oct; 36 (10), pp. 1041–9.

Seizures/Epileptogenic Foci
[^{99m}Technetium] ([^{99m}Tc])-Bicisate Ictal Single Photon Emission Computed Tomography (SPECT)

Background Information: Magnetic resonance imaging (MRI) studies frequently fail to reveal an anatomic origin for the seizures, and scalp electroencephalography is often limited to identification of the involved hemisphere. Functional imaging modalities such as positron emission tomography (PET) and SPECT are more promising tools for this application because they reflect the functional pathology associated with the seizure. These changes are more pronounced ictally, but until recently, no radiopharmaceutical was available that could be used routinely for ictal SPECT.

Application: Nuclear medicine scintigraphic imaging of pediatric cases of refractory epilepsy with [^{99m}Tc]-bicisate. Examples of potential applications include (i) characterization of ictal SPECT in pediatric patients with refractory epilepsy; (ii) comparison of ictal and interictal blood flow patterns in cases of refractory epilepsy; and (iii) function as an effective adjunct diagnostic procedure that complements information obtained from other techniques and methodologies.

Route of Administration: Intravenous.

Implementation: Evaluation of anatomical localization information provided by [^{99m}Tc]-bicisate ictal SPECT compared to parameters acquired by other diagnostic modalities.

Human Model: Cases of pediatric epilepsy (n = 10 at 3 to 19 years of age; mean age 10.9 ± 4.3 years; n = 7 females) all of whom have no lesions detected on MRI scans that could responsible for the seizures.

Interpretation and Analysis: Ictal SPECT reveals the presence of focal perfusion abnormalities in a high percentage of affected cases. By comparison, interictal SPECT imaging (e.g., n = 4) detects regional hypoperfusion that corresponds to regions of hyperperfusion in the ictal studies, and some images (e.g., n = 3) show regional hyperperfusion corresponding to hyperperfused regions in the ictal studies. Some interictal studies (e.g., n = 3) reveal no abnormal perfusion patterns. Scalp electroencephalogram (EEG) can provide localization information in some cases (e.g., n = 5). Such observations suggest that ictal SPECT with [^{99m}Tc]-bicisate is a more promising tool for identifying epileptogenic foci than interictal SPECT or scalp EEG in cases without focal abnormalities on MRI.

Comparative study of 99mTc-ECD and 99mTc-HMPAO for peri-ictal SPECT: Qualitative and quantitative analysis. O'Brien TJ, Brinkmann BH, Mullan BP, So EL, Hauser MF, O'Connor MK, Hung J, Jack CR. J Neurol Neurosurg Psychiatry 1999 Mar; 66 (3), pp. 331–9.

Ictal and interictal technetium-99m-bicisate brain SPECT in children with refractory epilepsy. Packard AB, Roach PJ, Davis RT, Carmant L, Davis R, Riviello J, Holmes G, Barnes PD, O'Tuama LA, Bjornson B, Treves ST. J Nucl Med 1996 Jul; 37 (7), pp. 1101–6.

Serotonin (5-HT$_{1A}$) Autoreceptors: Dorsal Raphe Nuclei (DRN)/Pandolol Receptor Occupancy
[^{11}C]-WAY 100635

Cellular/Molecular Mechanism of Action: Pandolol and [^{11}C]-WAY 100635 possess binding avidity for membrane-associated serotonin (5-HT$_{1A}$) receptor complexes expressed by certain cell types within the central nervous system.

Background Information: Augmentation of selective serotonin reuptake inhibitor (SSRI) therapy by the 5-HT$_{1A}$ receptor agent pindolol may reduce the delay between initiation of antidepressant treatment and clinical response. The hypothesis is based on the ability of pindolol to block 5-HT$_{1A}$ autoreceptors in the DRN and to potentiate the increase in 5-HT transmission induced by SSRIs. However, placebo-controlled clinical studies of pindolol augmentation of antidepressant therapy have reported inconsistent results.

Application: The agent [^{11}C]-WAY 100635 can be applied to evaluate the differential occupancy levels of membrane-associated somatodendritic and postsynaptic 5-HT$_{1A}$ receptor complexes by established or prototype pharmaceutical agents (e.g., pidolol).

Implementation: Evaluate the occupancy of 5-HT$_{1A}$ receptors during treatment with controlled release (CR) pindolol detected with [^{11}C]-WAY 100635 using positron emission tomography imaging techniques. Cases are then studied 4 times: at baseline; following 1

week of pindolol CR 7.5 mg/day (4 and 10 hours postdose); and following 1 dose of pindolol CR 30 mg (4 hours postdose).

Human Model: Healthy subjects (n = 9).

Interpretation and Analysis: Occupancy of DRN is approximately 40 ± 29% on scan 2, 38 ± 26%; and 64 ± 15% (scan 2, scan 3, and scan 4, respectively). The average occupancy in all other regions is significantly lower at each dose (18 ± 5%, 12 ± 3%, and 42 ± 4%; scans 2, 3, and 4, respectively). Blockade within the DRN achieved under clinical conditions (7.5 mg/day) may be too low and variable to consistently augment the therapeutic effect of SSRIs. However, these data indicate that pindolol exhibits *in vivo* selectivity for DRN 5-HT_{1A} autoreceptors. As DRN selectivity is desirable for potentiation of 5-HT function, this observation represents an important proof of concept for the development of 5-HT_{1A} agents in this application.

Differential occupancy of somatodendritic and postsynaptic 5-HT_{1A} receptors by pindolol: A dose-occupancy study with [^{11}C]-WAY 100635 and positron emission tomography in humans. Martinez D, Hwang D, Mawlawi O, Slifstein M, Kent J, Simpson N, Parsey RV, Hashimoto T, Huang Y, Shinn A, Van Heertum R, Abi-Dargham A, Caltabiano S, Malizia A, Cowley H, Mann JJ, Laruelle M. Neuropsychopharmacology 2001 Mar; 24 (3), pp. 209–29.

Serotonin: 5-HT_{1A} Autoreceptor/Occupancy of Serotonin 5-HT_{1A} Autoreceptor: Dorsal Raphe Nuclei (DRN)/Dose Optimization for Serotonin 5-HT_{1A} Autoreceptor Agents *[Carbonyl-^{11}C]-WAY-100635*

Cellular/Molecular Mechanism of Action: The agent [carbonyl-^{11}C]-WAY-100635 or [carbonyl-^{11}C] *N*-(2-(4-(2-methoxyphenyl)-1-piperazinyl)ethyl)-*N*-(2-pyridyl)cyclohexa necarboxamide abbreviated as [^{11}C]-WAY-100635 possesses binding avidity for 5-hydroxytryptamine(1A) (5-HT_{1A}) receptor complexes.

Background Information: Preclinical studies in rodents suggest that augmentation of serotonin reuptake inhibitor (SSRI) therapy by the 5-HT_{1A} receptor agent pindolol might reduce the delay between initiation of treatment and antidepressant response. This hypothesis is based on the ability of pindolol to potentiate the increase in serotonin (5-HT) transmission induced by SSRIs, an effect achieved by blockade of the 5-HT_{1A} autoreceptors in the DRN. However, placebo-controlled clinical studies of pindolol augmentation of antidepressant therapy have reported inconsistent results.

Application: The binding avidity of [^{11}C]-WAY-100635 for 5-HT_{1A} receptor complexes can be utilized to evaluate occupancy of these membrane-associated sites. In this context, [^{11}C]-WAY-100635 can effectively assess new prototype pharmaceuticals through positron emission tomography (PET) imaging modalities to determine their selectivity for DRN. Such a strategy can be used as an investigative probe to establish appropriate doses for clinical trials.

Implementation: Evaluation of the occupancy of 5-HT_{1A} receptors following treatment with controlled release (CR) pindolol in 9 healthy volunteers with PET. Each subject is then studied 4 times, at (i) baseline (scan 1) following 1 week of oral administration of pindolol CR (7.5 mg/day) at peak levels; (ii) 4 hours after the dose (scan 2); (iii) 10 hours following the dose (scan 3); and (iv) following 1 dose of pindolol CR (30 mg) at peak levels, 4 hours (scan 4). Pindolol occupancy of 5-HT_{1A} receptors is then evaluated in the DRN and cortical regions as a decrease in binding potential (BP) of the radiolabeled selective 5-HT_{1A} antagonist [carbonyl-^{11}C]-WAY-100635.

Human Model: Healthy cases (n = 9).

Interpretation and Analysis: Pindolol dose-dependently decreases [^{11}C]-WAY-100635 BP. Combining all regions of interest, occupancy is 20 ± 8%; 14 ± 8%; and 44 ± 8% (scans 2, 3, and 4, respectively). Pindolol dose-dependently decreases the binding potential for [^{11}C]-WAY-100635 within the brain. Combining all regions of interest, 5-HT_{1A} receptor occupancy is 20 ± 8%; 14 ± 8%; and 44 ± 8% (scans 2, 3, and 4, respectively). Such findings suggest that with pindolol when used in clinical studies at doses capable of exerting an SSRI effect (e.g., 2.5 mg t.i.d.), the occupancy of 5-HT_{1A} receptors is moderate and highly variable between subjects. This factor may explain the variable results obtained in clinical studies. On the other hand, at each dose tested, pindolol occupancy of 5-HT_{1A} receptors is higher in the DRN compared to cortical regions, demonstrating a significant degree of *in vivo* selectivity for DRN 5-HT_{1A} autoreceptors relative to cortico-limbic postsynaptic receptors. Selectivity of this magnitude is necessary for the potentiation of 5-HT transmission, and this finding represents an important proof of concept in the development of 5-HT_{1A} agents for this application.

Positron emission tomography study of pindolol occupancy of 5-HT_{1A} receptors in humans: Preliminary analyses. Martinez D, Mawlawi O, Hwang DR, Kent J, Simpson N, Parsey RV, Hashimoto T, Slifstein M, Huang Y, Van Heertum R, Abi-Dargham A, Caltabiano S, Malizia A, Cowley H, Mann JJ, Laruelle M. Nucl Med Biol 2000 Jul; 27 (5), pp. 523–7.

5-Serotonin 5-HT_{1A} Receptor Complex Expression *[^{11}C]-CPC-222/(N-[2-[4-(2-Methoxyphenyl)-1-Piperazinyl]Ethyl]-N-(2-Pyridinyl)-2-Bicyclo [2,2,2] Octane Carboxamide)*

Cellular/Molecular Mechanism of Action: The radioligand N-[2-[4-(2-methoxyphenyl)-1-piperazinyl]ethyl]-N-(2-pyridinyl)-2-bicyclo [2,2,2]octane carboxamide ([^{11}C]-CPC-222) selectively binds as a ligand to 5-HT_{1A} receptor complexes.

Application: Detection and characterization of 5-HT_{1A} receptors complexes within the central nervous system (CNS), where it can be used as an *in vivo* probe for positron emission tomography (PET).

Route of Administration: [^{11}C]-CPC-222 (intravenous).

Implementation: Evaluation of the distribution for [^{11}C]-CPC-222 within the CNS applying PET over a 90-minute period following intravenous injection of the radioligand.

Human Model: Healthy volunteers (n = 3).

Interpretation and Analysis: The radioligand [^{11}C]-CPC-222 accumulates at high levels in brain regions with a high density of 5-HT_{1A} receptors. The peak cortical concentration is 1.0–2.5% of the injected dose per liter. The ratio of radioactivity in receptor-rich regions to that of the cerebellum reaches a plateau of 2.5 to 4.0 by 45 minutes after injection. Analysis of the plasma reveals no detectable amount of the potential metabolite, radiolabeled WAY-100634. The radioligand [^{11}C]-CPC-222 therefore appears to possess suitable properties for the study of human 5-HT_{1A} receptors applying PET imaging modalities.

Instrumentation: Positron emission tomography.

Imaging 5-HT_{1A} receptors with positron emission tomography: Initial human studies with [11C]-CPC-222. Houle S, Wilson AA, Inaba T, Fisher N, DaSilva JN. Nucl Med Commun 1997 Dec; 18 (12), pp. 1130–4.

Serotonin 5-HT_2 Receptor *[^{18}F]-Altanserin/Clomipramine*

Cellular/Molecular Mechanism of Action: Altanserin recognizes and binds to serotonin 5-HT_2 receptor complexes. Clomipramine functions as a serotonin reuptake inhibitor.

Application: The radioligand [^{18}F]-altanserin can be utilized *in vivo* to characterize the density and distribution of brain serotonin 5-HT_2 receptor complexes (e.g., positron emission tomography [PET] imaging modalities).

Route of Administration: Clomipramine (intravascular).
Dosage: Clomipramine (25 mg).
Implementation: The postsynaptic receptor binding potential of [^{18}F]-altanserin can be employed as a possible ligand indicator for synaptic serotonin content following pharmacological challenge (e.g., serotonergic antidepressive agents). To delineate such properties, serotonergic antidepressive treatment is administered to cases with recurrent major depression. Cases are then evaluated for PET measurements performed twice within 2 or 3 days and the serotonin reuptake inhibitor, clomipramine administered before acquisition of 1 of the PTE images. Data are analyzed using non-linear least-square regression and Logan's graphical method.
Interpretation and Analysis: Binding potential and distribution volume of altanserin decreases between 14% ($p = 0.03$) and 23% ($p = 0.004$) following clomipramine challenge. This effect is mainly seen in the absence of antidepressive medication. Clomipramine challenge probably increases the synaptic serotonin level, which competes with altanserin leading to a lowered binding potential. The paradigm might, thus, be useful to estimate serotonin release *in vivo*. Pretreatment with serotonergic antidepressants reduces the effect of clomipramine

Influence of synaptic serotonin level on [^{18}F]-altanserin binding to 5-HT$_2$ receptors in man. Larisch R, Klimke A, Hamacher K, Henning U, Estalji S, Hohlfeld T, Vosberg H, Tosch M, Gaebel W, Coenen HH, Muller-Gartner HW. Behav Brain Res 2003 Feb 17; 139 (1–2), pp. 21–9.

Serotonin (5-HT$_{1A}$) Receptor Complexes/Clozapine Response (Atypical)/Clozapine Receptor Occupancy *Carbonyl-[^{11}C]-WAY-100635 Ligand/Clozapine*

Application: Characterization of clozapine occupancy of serotonin 5-hydroxytryptamine$_{1A}$ [5-HT$_{1A}$] receptor subtypes through the application of positron emission tomography (PET) imaging.
Route of Administration: Clozapine (oral or intravenous).
Dosage: Clozapine (oral 200–800 mg vs 1.5 mg/kg–6.0 mg/kg IV).
Implementation: Characterization of clozapine occupancy of brain 5-HT$_{1A}$ receptor complexes utilizing intravenous doses capable of generating plasma concentrations that directly correlate with ranges achieved with oral admistration at the 200–800 mg dose range as recommended for clinical management scenarios (humans). Subjects are each examined (t.i.d.) with PET and the radioligand carbonyl-[^{11}C]-WAY-100635. The 1st measurement is performed at baseline conditions, the 2nd after clozapine 1.5 mg/kg, and the 3rd after 6 mg/kg. Two additional monkeys can be examined at baseline and after 15 mg/kg IV. Central 5-HT$_{1A}$ receptor occupancy is calculated using equilibrium-ratio analysis.
Animal Model: Primate (cynomolgus monkey).
Interpretation and Analysis: Occupancy of 5-HT$_{1A}$ receptor complexes ranges between 23 and 34% after clozapine (1.5 mg/kg) and from 36 to 49% after 6 mg/kg in different brain regions (e.g., n = 4 monkeys). Regional receptor occupancy values after 15 mg/kg are between 39 and 51% in some animal subjects (e.g., n = 2 monkeys). There is no evidence of a difference in image profiles for the frontal cortex, the temporal cortex, and the raphe nucleus. Clozapine readily appears to occupy 5-HT$_{1A}$ receptors in the primate brain at clinically relevant plasma concentrations. The 5-HT$_{1A}$ receptor therefore appears to be a candidate target that may explain the atypical drug actions of clozapine.

Occupancy of 5-HT$_{1A}$ receptors by clozapine in the primate brain: A PET study. Chou YH, Halldin C, Farde L. Psychopharmacology (Berl) 2003 Mar; 166 (3), pp. 234–40.

Serotonin 5-HT$_{2A}$ Receptor Complexes/ Paroxetine Response/Depression Disorders (Major) *[^{18}F] Fluoroethylspiperone ([^{18}F] FESP)/ Cortical Binding Index*

Cellular/Molecular Mechanism of Action: Fluoroethylspiperone functions as a 5-HT$_{2A}$ and D$_2$ receptor antagonist. Radiofluorinated [^{18}F] fluoroethylspiperone ([^{18}F] FESP) therefore can function as a positron emission tomography (PET) imaging agent for characterizing brain 5-HT$_{2A}$ receptor complex expression densities and distribution.
Application: Characterization of the regional distribution and expression density of 5-HT$_{2A}$ receptor complexes within the central nervous system.
Implementation: Investigate differences in 5-HT$_{2A}$ receptor binding between healthy volunteers and patients with major depressive disorder (MDD), either never treated before with antidepressants (drug-naive: DN) or responding to paroxetine treatment (drug-treated: DT). In this context, DN MDD cases (e.g., n = 19) and euthymic DT cases (paroxetine 4 weeks; e.g., n = 15) are compared with a group of normal healthy controls (e.g., n = 20) applying PET facilitated by the use of [^{18}F] FESP, a 5-HT$_{2A}$ and D$_2$ receptor antagonist. A "binding-index" (BI) of [^{18}F] FESP to cortical and basal ganglia region can be calculated as the ratio of the activity in these regions to that of the cerebellum. Differences in BI between groups (e.g., control vs DN or DT) can be assessed by ANOVA, with or without age as a covariate (ANCOVA).
Interpretation and Analysis: A significant reduction in BI (e.g., $p = 0.003$ ANOVA, $p = 0.001$ ANCOVA) can be appreciated in DN patients in the frontal, occipital, temporal, and cingulate cortices, but not in the striatum. No significant differences can be appreciated between control and DT patients. The reduction of [^{18}F] FESP BI in cortical areas of DN (depressed) but not euthymic DT cases suggests an association between the occurrence of depressive symptoms and impairment of cortical 5-HT$_{2A}$ receptors. The cortical BI for [^{18}F] FESP may ultimately function as an effective marker for depression.

5-HT$_{2A}$ receptor binding is reduced in drug-naive and unchanged in SSRI-responder depressed patients compared to healthy controls: A PET study. Messa C, Colombo C, Moresco RM, Gobbo C, Galli L, Lucignani G, Gilardi MC, Rizzo G, Smeraldi E, Zanardi R, Artigas F, Fazio F. Psychopharmacology (Berl) 2003 Apr; 167 (1), pp. 72–8. Epub 2003 Mar 11.

Serotonin 5-HT$_{1A}$ Receptor/Robozoltan (NAD-299) 5-HT$_{1A}$ Receptor Occupancy/Depression *Carbonyl-[^{11}C]-WAY-100635/Robalzotan (NAD-229)*

Background Information: The serotonin 5-HT$_{1A}$ receptor has been ascribed a putative role in the pathophysiology and therapeutic management of depression. NAD-299 (Robalzotan) is a new potential antidepressant with high affinity and selectivity for the 5-HT$_{1A}$ receptor.
Application: Characterization of the occupancy of brain serotonin 5-HT$_{1A}$ receptor complexes by Robalzotan (NAD-299) utilizing positron emission tomography (PET) imaging facilitated by the radioligand carbonyl-[^{11}C]-WAY-100635.
Route of Administration: NAD-299 (robalzotan) single oral doses.
Dosage: Single oral doses of NAD-299 (robalzotan) 0.5, 2.5, and 10 mg).
Implementation: Positron emission tomography examination of the extent and time course of brain 5-HT$_{1A}$ receptor occupancy by NAD-299 as a function of plasma concentration generated with

escalating single oral doses. Cases receive 1 or more single oral doses of NAD-299 (0.5, 2.5, and 10 mg) in aqueous solution under fasting conditions. Total and unbound (after ultrafiltration) plasma concentrations of NAD-299 are determined by liquid chromatography-mass spectrometry (LC-MC), over a tentative dosage interval of 8 hours. Regional 5-HT_{1A} receptor occupancy in the brain is calculated by the simplified reference tissue model using the radioligand carbonyl-[^{11}C]-WAY-100635.

Interpretation and Analysis: Robalzotan (NAD-299) doses of 10 mg produce high levels of occupancy in the raphe (62–85%) and neocortical regions (68–75%) at time point C_{max}, but decline considerably (17–44%) by 7 hours postadministration. The new selective 5-HT_{1A} antagonist NAD-299 therefore occupies 5-HT_{1A} receptors in the living human brain in a dose-dependent manner following oral dosage. The curvilinear relationship between NAD-299 drug concentration and 5-HT_{1A} receptor occupancy is established and can be used for dose selection in subsequent clinical patient studies.

Positron emission tomographic analysis of dose-dependent NAD-299 binding to 5-hydroxytryptamine-1A receptors in the human brain. Andree B, Hedman A, Thorberg SO, Nilsson D, Halldin C, Farde L. Psychopharmacology (Berl) 2003 Apr; 167 (1), pp. 37–45.

Serotonin Transporter
N,N-Dimethyl-2-(2-Amino-4-[^{18}F]-Fluorophenylthio) Benzylamine

Application: Serotonin transporter positron emission tomography (PET) imaging agent.

Semi-Synthetic Methods: The 403U76 analogs *N*,*N*-dimethyl-2-(2-nitro-4-bromophenylthio)benzylamine (4) and *N*,*N*-dimethyl-2-(2,4-dinitrophenylthio)benzylamine (8) can be prepared in multisteps synthesis as precursors for the synthesis of a new serotonin transporter imaging agent, *N*,*N*-dimethyl-2-(2-amino-4-[^{18}F]-fluorophenylthio)benzylamine (12a).

Implementation: Central nervous system (CNS) biodistribution image analysis for the identification and profiling of CNS serotonin transporter expression and function.

Interpretation and Analysis: Biodistribution studies in rats show that the uptake of compound 12a in rat brain is high (approximately 1%/g) and the ratio of the uptake of compound 12a in hypothalamus (a serotonin transporter-rich area) and cerebellum (a serotonin-transporter-devoid area) is 6/1 at 1 hour postinjection. Compound 12a may therefore be a potential new serotonin transporter PET imaging agent.

Synthesis of *N,N*-dimethyl-2-(2-amino-4-[^{18}F]-fluorophenylthio)benzylamine as a serotonin transporter imaging agent. Shiue GG, Fang P, Shiue CY. Appl Radiat Isot 2003 Feb; 58 (2), pp. 183–91.

Serotonin Transporters (SERT)/Cerebral Cortex/ Hypothalamus/Striatum/[Parkinson's Disease]/ Hippocampus
[^{125}I]-ADAM/[^{123}I]-ADAM/2-((2-((Dimethylamino) Methyl)- Phenyl)Thio)-5-Iodophenylamine)

Cellular/Molecular Mechanism of Action: The substances 2-((2-((dimethylamino)methyl)-phenyl)thio)-5-iodophenylamine paroxetine and (+)McN5652 function as ligands that selectively recognize and physically bind to serotonin transporter complexes.

Application: The iodinated tracer ADAM (2-((2-((dimethylamino)methyl)-phenyl)thio)-5-iodophenylamine) can be applied to detect and characterize SERT within the central nervous system (CNS).

Route of Administration: [^{125}I]-ADAM (intravenous).

Implementation: Detection of serotonic tranporters within the CNS using single photon emission computerized tomography (SPECT) imaging modalities.

Animal Model: Rat.

Interpretation and Analysis: Scatchard analysis of saturation binding profiles for [^{125}I]-ADAM to frontal cortical membrane homogenates (rat) produces K_d values of 0.15 ± 0.03 nM and B(max) values of 194 ± 65 fmol/mg protein. Biodistribution of [^{125}I]-ADAM within the brain postadministration reveals high specific binding within regions of the hypothalamus, cortex, striatum, and hippocampus, where SERT are concentrated and the specific binding peaks at 120 to 240 minutes postinjection ([hypothalamus-cerebellum]/cerebellum = 4.3 at 120 minutes post-IV injection). Moreover, specific hypothalamic uptake is blocked by pretreatment with SERT selective competing drugs, such as paroxetine and (+)McN5652, while other non-competing drugs, such as ketanserin, raclopride, and methylphenidate, exert no effect. Radioactive material recovered from rat brain homogenates at 120 minutes after [^{125}I]-ADAM injection is primarily the original compound (> 90%) and is a good indication of the *in vivo* stability of the agent within brain tissues. Both male and female rats show similar and comparable patterns of organ distribution and regional brain uptake. Autoradiograms (*ex vivo*) of rat brain sections (120 minutes after IV injection of [^{125}I]-ADAM) detect intense labeling in several regions (olfactory tubercle, lateral septal nucleus, hypothalamic and thalamic nuclei, globus pallidus, central gray, superior colliculus, substantia nigra, interpeduncular nucleus, dorsal and median raphes, and locus coerulus), which parallels known SERT expression densities. These results strongly suggest that the novel tracer ADAM is superior to the congers reported previously (i.e., IDAM). Labeling of ADAM with [^{123}I] to produce [^{123}I]-ADAM should produce an improved and useful SPECT imaging agent for SERT within the brain.

Selective *in vitro* and *in vivo* binding of [^{125}I]-ADAM to serotonin transporters in rat brain. Choi SR, Hou C, Oya S, Mu M, Kung MP, Siciliano M, Acton PD, Kung HF. Synapse 2000 Dec 15; 38 (4), pp. 403–12.

Serotonin Transporter (SERT)/Hypothalamus Region
[^{125}I]-ODAM/[^{125}I]-[5-Iodo-2-(2-Dimethylaminomethylphenoxy)-Benzyl Alcohol]

Background Information: The SERT is the primary binding sites for selective serotonin reuptake inhibitors, commonly used antidepressants such as fluoxetine, sertraline, and paroxetine. Imaging of SERT with positron emission tomography (PET) and single photon emission computed tomography (SPECT) in humans would provide a useful tool for understanding how alterations of this system are related to depressive illnesses and other psychiatric disorders.

Application: [^{125}I]-ODAM [(5-iodo-2-(2-dimethylaminomethylphenoxy)-benzyl alcohol, 9)] can be applied as an imaging agent for detecting and characterizing central nervous system (CNS) SERT.

Route of Administration: [^{125}I]-ODAM (intravenous injection).

Semi-Synthetic Methods: Radioiodination and semi-synthesis of [^{125}I]-ODAM. Reaction schemes have been developed for the preparation of [^{125}I]-ODAM and the corresponding tri-*n*-butyltin derivative (compound 10). A relatively high radiolabling efficiency (e.g., 95%) can be achieved upon reacting 10 with hydrogen peroxide and sodium [^{125}I]-iodide reagent.

Implementation: Characterization of the binding characteristics of ODAM for cortical membrane homogenates reveals good levels

of affinity ($K_i = 2.8 \pm 0.88$ nM). Using LLC-PK(1) cells specifically expressing the individual transporter (i.e., dopamine [DAT], norepinephrine [NET], and SERT, respectively), ODAM shows a strong inhibition of SERT ($K_i = 0.12 \pm 0.02$ nM). Inhibition constants for the other 2 transporters are lower ($K_i = 3.9 \pm 0.7$ μM and 20.0 ± 1.9 nM for DAT and NET, respectively). Biodistribution following intravenous injection of [^{125}I]-ODAM (rat) shows a rapid brain uptake and washout (2.03, 1.49, 0.79, 0.27, and 0.07% dose/organ at 2, 30, 60, 120, and 240 minutes, respectively). Hypothalamus regions that are rich with serotonin neurons exhibit high specific uptake profiles. Ratios of hypothalamus-cerebellum/cerebellum based on percent dose per gram of these 2 regions show values of 0.35, 0. 86, 0.86, 0.63, and 0.34 at 2, 30, 60, 120, and 240 minutes, post-IV injection, respectively. The specific uptake in hypothalamus can be effectively blocked by pretreatment of known SERT ligands and serves to validate that this ligand displays desirable *in vitro* and *in vivo* properties as a potential SERT imaging agent.

Animal Model: Rat (cortical brain homogenates and biodistribution).

A novel serotonin transporter ligand: (5-iodo-2-(2-dimethylaminomethylphenoxy)-benzyl alcohol. Zhuang Z, Choi S, Hou C, Mu M, Kung M, Acton PD, Kung HF. Nucl Med Biol 2000 Feb; 27 (2), pp. 169–75.

Serotonin Transporter (SERT)/Ecstacy-Induced SERT Alterations
[^{11}C]-±McN5652

Background Information: Alterations of the serotonergic system due to ecstasy consumption have been extensively documented in recent literature. However, reversibility of these neurotoxic effects still remains unclear.

Application: Characterization of various physiological and pharmacological stimuli on SERT complexes (e.g., influence of ecstacy on protracted alterations of the serotonin transporter).

Route of Administration: [^{11}C]-±McN5652 (intravascular).

Dosage: [^{11}C]-±McN5652 (500 MBq).

Implementation: Characterization of the potential influence of ecstacy on SERT can be delineated by positron emission tomography (PET) using the SERT ligand [^{11}C]-±McN5652. The technique that can be employed in such studies involves the intravenous administration of [^{11}C]-±McN5652 ligand (500 MBq IV). Scan images are acquired according to a dynamic scan protocol of 90 minutes using a full-ring whole-body PET system. Trans-axial slices are reconstructed using an iterative method. Individual brains are transformed to a template defined earlier. Distribution volume ratios (DVRs) are derived by the application of a reference tissue approach for reversible binding. Gray matter of the cerebellum can serve as a reference control. Serotonin transporter-rich brain regions (e.g., mesencephalon, putamen, caudate, and thalamus) are selected for the evaluation of SERT availability using volumes of interest predefined according to the standard template.

Human Model: Cases classified as ecstasy users (e.g., n = 117 subjects subdivided into 4 groups: actual ecstasy users [n = 30], former ecstasy users [n = 29], drug-naive control subjects [n = 29], and subjects with abuse of psychoactive agents other than ecstasy [n = 29]).

Interpretation and Analysis: Compared with drug-naive control subjects, the distribution volume ratios in actual ecstasy users is significantly reduced in the mesencephalon ($p = 0.004$) and the thalamus ($p = 0.044$). The DVR in former ecstasy users is very close to the DVR in drug-naive control subjects in all brain regions. The DVR in polydrug users is slightly higher than that in the drug-naive control subjects in all SERT-rich regions (not statistically significant). Ecstasy appears to induce protracted alterations of the SERT. However, availability of SERT may be reversible when evaluated by PET imaging but does not imply full reversibility of actual neurotoxic effects.

Long-term effects of "ecstasy" use on serotonin transporters of the brain investigated by PET. Buchert R, Thomasius R, Nebeling B, Petersen K, Obrocki J, Jenicke L, Wilke F, Wartberg L, Zapletalova P, Clausen M. J Nucl Med 2003 Mar; 44 (3), pp. 375–84.

Trauma (Brain/Cranial)/Long-Term Neuropsychological Outcome
[^{99m}Technetium] Ethyl Cystein Dimer Single Photon Emission Computed Tomography ([^{99}mTc] ECD SPECT)

Implementation: Assess the prognostic value of early brain scintigraphy in head injury and correlation to long-term neuropsychological behavior.

Human Model: Cases of cranial head trauma within 1 month of initial injury (e.g., n = 24 patients).

Interpretation and Analysis: Most affected cases (e.g., n = 24) have abnormalities that can be detected on single photon emission computed tomography (SPECT) scans. One year after trauma, slightly greater than half may have residual neuropsychological sequelae (e.g., n = 14/24 or 58%). The brain-to-cerebellum ratios in the left basal ganglia and brain stem are significantly decreased in patients with memory disorders ($p = 0.03$ and $p = 0.02$, respectively). Moreover, SPECT visual analysis indicates that low uptake in the basal ganglia, thalamus, and brain stem is associated with subsequent motor deficit, frontal behavior, and language and memory disorders. Therefore, brain SPECT can be valuable in predicting the neuropsychological behavior of survivors of severe head injury.

Technetium-99m ECD single photon emission computed tomography in brain trauma: Comparison of early scintigraphic findings with long-term neuropsychological outcome. Baulieu F, Fournier P, Baulieu JL, Dalonneau M, Chiaroni P, Eder V, Pottier JM, Legros B. J Neuroimaging 2001 Apr; 11 (2), pp. 112–20.

Vascular Perfusion: Cerebral Blood Flow
H_2[^{15}O]

Background Information: Blood vessels are usually conspicuous on dynamic computed tomography (CT) perfusion images. The presence of large vessels may lead to overestimation of the quantitative value of cerebral blood flow (CBF).

Application: Estimation of cerebral blood flow dynamics.

Route of Administration: H_2[^{15}O] (intravascular).

Dosage: H_2[^{15}O].

Implementation: Evaluation of the efficacy of the vascular-pixel elimination (VPE) method in quantitative CT perfusion imaging, compared to positron emission tomography (PET) pertaining to CBF dynamics. A 4-channel multidetector row CT scanner is used to perform dynamic cine scanning after a bolus injection of intravenous contrast agent. The CT-CBF is calculated by the central volume principle and deconvolution method. Alternatively, PET can be performed after infusion of [^{15}O]-labeled water and PET-CBF parameters calculated using a non-linear least squares method. Average CBF values of the whole section, gray matter, and white matter with both CT and PET are compared after image acquisition. The comparison is performed with and without VPE. In the VPE method, the vascular pixels are defined by the cerebral blood volume value of the pixel. The threshold of VPE is changed from 5 to 20 mL/100 g. Pixel-by-pixel correlation between CT-CBF and PET-CBF and linear regression analysis is then also performed.

Interpretation and Analysis: In the absence of vascular-pixel elimination, CT-CBF is almost invariably overestimated. As the vascular-pixel elimination threshold decreases, CT-CBF decreases and the correlation coefficient increases. The best correlation is observed at a VPE threshold of 8 mL/100 g (e.g., n = 4/5 cases). Average CT-CBF values, without VPE, of the whole section, gray matter, and white matter are 59.01, 66.73, and 42.53 mL/100 g/min, respectively. With VPE (threshold, 8 mL/100 g), average CT-CBF values of the whole section, gray matter, and white matter are 45.56, 52.75, and 30.38, respectively. The corresponding PET-CBF values are 46.86, 50.89, and 38.20 mL/100 g/min, respectively. Vascular pixels should be excluded from the calculation of CT-CBF to avoid overestimation of CBF values. If vascular pixels are excluded, CBF calculation with CT perfusion imaging is considerably accurate.

Quantitative cerebral blood flow measurement with dynamic perfusion CT using the vascular-pixel elimination method: Comparison with $H_2[^{15}]O$ positron emission tomography. Kudo K, Terae S, Katoh C, Oka M, Shiga T, Tamaki N, Miyasaka K. AJNR Am J Neuroradiol 2003 Mar; 24 (3), pp. 419–26.

Vasculature Perfusion: Cerebral/Cerebral Vascular Perfusion Alterations in Psychiatric Disorders/ Transient Ischemia/Stroke
[^{123}I] and [^{99m}Technetium] ([^{99m}Tc])-Brain Perfusion Agents

Background Information: In the past few years significant progress has been made in the design and characterization of new central nervous system (CNS) neuronal and postsynaptic receptor imaging agents for positron emission tomography (PET) and single photon emission computed tomography (SPECT). The new diagnostic agents are aimed at measuring localized changes in neuronal function. It is likely that these types of agents have potential for clinical application, especially in the diagnosis of psychiatric disorders that do not involve morphological changes.
Application: Detection of cerebral vascular abnormalities including stroke and transient ischemia.
Instrumentation: There are 2 types of imaging instruments, SPECT and PET, that use radiopharmaceuticals for the diagnosis of brain disorders. The use of SPECT in concert with brain perfusion imaging agents, labeled either with [^{123}I] or [^{99m}Tc], is useful in the detection of various cerebral vascular abnormalities, such as stroke and transient ischemia.

Overview of radiopharmaceuticals for diagnosis of central nervous disorders. Kung HF. Crit Rev Clin Lab Sci 1991; 28 (4), pp. 269–86.

Vascular Perfusion: Cerebral
[^{15}O]-Labeled H_2O: Positron Emission Tomography (PET) Imaging/Intravenous Contrast Agent: Computed Tomography (CT) Imaging

Background Information: Blood vessels are usually conspicuous on dynamic CT perfusion images. The presence of large vessels may lead to overestimation of the quantitative value of cerebral blood flow (CBF). Investigations have evaluated the efficacy of the vascular-pixel elimination (VPE) method in quantitative CT perfusion imaging, in comparison with PET.
Implementation: Comparison of CT perfusion and PET image analyses. Dynamic cine scanning is performed after bolus injection of an intravenous contrast agent. Computed tomography-CBF is calculated by the central volume principle and deconvolution method. Positron emission tomography is performed after infusion of [^{15}O]-labeled water. The PET-CBF is calculated by using a non-linear least squares method. Average CBF values of the whole section, gray matter, and white matter with both CT and PET are compared after image registration. The comparison is performed with and without VPE. In the VPE method, the vascular pixels are defined by the cerebral blood volume value of the pixel. The threshold of VPE is changed from 5 to 20 mL/100 g. Pixel-by-pixel correlation between CT-CBF and PET-CBF and linear regression analysis is also performed.
Human Model: Normal healthy cases.
Interpretation and Analysis: Computed tomography-CBF is overestimated in most instances without VPE. As the VPE threshold decreases, CT-CBF decreases and the correlation coefficient increases. The best correlation is observed at a VPE threshold of 8 mL/100 g (e.g., n = 4/5 cases). Average CT-CBF values, without VPE, of the whole section, gray matter, and white matter are 59.01, 66.73, and 42.53 mL/100 g/min, respectively. Average CT-CBF values of the whole section, gray matter, and white matter are 45.56, 52.75, and 30.38, respectively, with the application of VPE (threshold, 8 mL/100 g). The corresponding PET-CBF values are 46.86, 50.89, and 38.20 mL/100 g/min, respectively. Vascular pixels should be excluded from the calculation of CT-CBF to avoid overestimation of the CBF values. If vascular pixels are excluded, CBF calculation with CT perfusion imaging is considerably accurate.
Instrumentation: Computed tomography is performed with a 4-channel multidetector row CT scanner.

Quantitative cerebral blood flow measurement with dynamic perfusion CT using the vascular-pixel elimination method: Comparison with $H_2[^{15}O]$ positron emission tomography. Kudo K, Terae S, Katoh C, Oka M, Shiga T, Tamaki N, Miyasaka K. AJNR Am J Neuroradiol 2003 Mar; 24 (3), pp. 419–26.

Vascular Perfusion: Cerebral Blood Flow (CBF)/ Disease Probe/Pharmaceutical Evaluation
$H_2[^{15}O]$

Cellular/Molecular Mechanism of Action: The agent $H_2[^{15}O]$ mimics the diffusion and transport of natural H_2O molecules.
Application: Measurement of CBF.
Implementation: Evaluation of regional CBF (rCBF) during a passive visual stimulus in which pattern-flash frequency is parametrically manipulated. Goggles are used with a grid of red lights embedded into each lens. A total of 5 positron emission tomography (PET) $H_2[^{15}O]$ water scan images are then acquired for each test subject at alternating (left to right eye) flash frequencies of 0, 1, 4, 7, and 14 Hz.
Human Model: Healthy elderly subjects (n = 19; 64 ± 11 years).
Interpretation and Analysis: Biphasic rising and falling rCBF response can be appreciated within the striate cortex (7 Hz peak) and left anterior cingulate (4 Hz peak), 1 Hz activation in left middle temporal gyrus (V5), monotonically increasing rCBF in posterior areas (lateral and inferior visual association areas, Brodmann 18 and 19), and monotonically decreasing rCBF in anterior areas (frontal, cingulate, and superior temporal) predominantly in the right hemisphere. Striate rCBF changes at all frequencies primarily reflect lateral geniculate input, the middle temporal activation at 1 Hz reflects perception of apparent motion, and the posterior extrastriate rCBF monotonic increase represents a neural response to increasing luminance intensity and form and color complexity that occur as pattern-flash frequency increases. Anterior monotonic rCBF decreases may represent active cross-modal functional suppression of brain areas irrelevant for processing the passive visual stimulus. Pattern-flash rCBF responses are highly reproducible (no series effect), more so in

posterior than anterior brain regions. Reproducibility and systematically changing rCBF responses to this passive stimulus suggest that it could be successfully used as a disease probe to evaluate neural function and drug effects in cognitively impaired patients.

Frequency variation of a pattern-flash visual stimulus during PET differentially activates brain from striate through frontal cortex. Mentis MJ, Alexander GE, Grady CL, Horwitz B, Krasuski J, Pietrini P, Strassburger T, Hampel H, Schapiro MB, Rapoport SI. Neuroimage 1997 Feb; 5 (2), pp. 116–28.

Vascular Perfusion: Cerebral Hemisphere (Dural Arteriovenous Fistulas)/Altered Vascular Integrity/ Dural Arteriovenous Fistulas/Single Photon Emission Computed Tomography (SPECT)/ Preserved Vasoreactivity/SPECT/Hypoperfusion/ Venous Infarction/Presistent Symptoms/Prognostic Indicators
Acetazolamide

Cellular/Molecular Mechanism of Action: Acetazolamide functions as a carbonic anhydrase inhibitor.
Physiological Mechanism of Action: Acetazolamide can promote antiseizure activity and prevent absence seizures.
Background Information: Dural arteriovenous fistulas (DAVFs) with disturbed regional cerebral blood flow (rCBF) include retrograde leptomeningeal venous drainage (RLVD).
Application: Acetazolamide can be used as an adjunct diagnostic probe applied in conjuction with SPECT to characterize conditions of dural arteriovenous fistulas in a manner that can detect preservation or alterations in vasoreactivity that can correspond with either a good prognosis or evidience of venous infarction and persistence of symptoms.
Implementation: Characterization of pretreatment magnetic resonance imaging (MRI)/SPECT and posttreatment MRI/SPECT symptoms and response to therapeutic intervention in conditions of DAVFs with disturbed rCBF.
Human Model: Cases with DAVFs with disturbed rCBF and associated with various clinical symptoms (n = 22). Case Group 1 = retrograde leptomeningeal venous drainage (RLVD) into more than 1 venous sinus (n = 11/22 cases); and Case Group 2 = RLVD into a single venous sinus (n = 11/22 cases).
Interpretation and Analysis: In Case Group 1, preoperative T_2-weighted MR images show no hyperintense areas, and angiographic evidence displays flow into more than 1 venous sinus. Case Group 2 cases display preoperative SPECT with hypoperfused areas that coincide with hyperintense areas on T_2-weighted MR images. Following treatment, hyperintense areas disappear, and symptoms improve in a large number of these cases (e.g., n = 7/11 = Case Group 2a), and their preoperative SPECT studies demonstrate preservation of vasoreactivity after an acetazolamide challenge. In Case Group 2b, the hyperintense areas and symptoms persist in response to acetazolamide challenge (n = 4/11 cases) and reoperative SPECT studies reveal marked disturbances of vasoreactivity. Hyperintense MR images are consistently observed in cases with drainage into a single venous sinus. Hypoperfusion on SPECT scans apparently reflects venous congestion, whereas unpreserved vasoreactivity after an acetazolamide challenge on SPECT scans reflects venous infarction. The preservation of vasoreactivity after the challenge appears to be a good prognostic indicator.

Pre- and posttreatment MR imaging and single photon emission CT in patients with dural arteriovenous fistulas and retrograde leptomeningeal venous drainage. Kai Y, Hamada J, Morioka M, Todaka T, Mizuno T, Ushio Y. AJNR. Am J Neuroradiol 2003; 24 (4), pp. 619–25

CENTRAL NERVOUS SYSTEM (CNS): SPECIAL SENSES

Inner Ear: Autoimmune Disease
Heat Shock Protein/Potential Disease Indicator

Background Information: Autoimmune inner ear disease is a form of cochleovestibular disease associated with variable hearing loss and vertigo for which no reliable diagnostic tests are available.
Application: Assessment of autoimmune inner ear disease when applied in combination with heat shock protein 70 (HSP-70).
Implementation: Limited positron emission tomography (PET) of the inner ear for the characterization of conditions of autoimmune inner ear disease before and 4–6 weeks following high-dose tapering course prednisone. Complementary evaluation parameters can include cranial magnetic resonance imaging, audiometric and vestibular studies, and HSP-70 measurements.
Interpretation and Analysis: Of patients with established and stable autoimmune inner ear disease, approximately 80% (e.g., n = 4/5) will display no PET image abnormalities and negative HSP-70 concentrations. Cases with abnormal PET images can over a brief period of time subsequently manifest clinically active disease. Of cases with active autoimmune inner ear disease, serial monitoring reveals that approximately 80% (e.g., n = 4/5) initially have abnormal PET images in at least 1 ear that eventually become normal in the majority of instances following therarpy. As a complementary feature of PET imaging, HSP-70 correlates with disease activity. A small percentage of cases with clinically active autoimmune inner ear disease (e.g., 20% or n = 1/5) have a normal PET image before and after therapy (positive HSP-70 before therapy and negative after the therapy). Approximately 80–100% of normal subjects (e.g., n = 4/5) will have normal PET images. Positive findings in normal subjects may be accompanied by normal audiometric/vestibular studies and positive HSP-70.

The utility of positron emission tomography in the evaluation of autoimmune hearing loss. Mazlumzadeh M, Lowe VJ, Mullan BP, Fabry DA, McDonald TJ, Matteson EL. Otol Neurotol 2003 Mar; 24 (2), pp. 201–4.

GENE EXPRESSION

Gene Expression: Neoplasia/Herpes Simplex Virus Type I Thymidine Kinase (HSV1-tk)
2′-Deoxy-2′-Flouro-5-Methyl-1-β-D-Arabinofuranosyluracil (FMAU)/9-[(3-[^{18}F]-Fluoro-1-Hydroxy-2-Propoxy)Methyl]-Guanine ([^{18}F]-FHPG)/ 9-(4-[^{18}F]-Fluoro-3-Hydroxy-Methylbutyl)Guanine ([^{18}F]-FHBG)

Application: FMAU has demonstrated potential utilization as a positron emission tomography (PET) radiotracer for imaging HSV-TK gene expression.
Interpretation and Analysis: *In vitro* experiments demonstrate that the accumulation of [^{14}C]-FMAU in HSV-tk-expressing cells is 2.4-fold ($p < 0.02$), 4.0-fold ($p < 0.001$), and 5.3-fold ($p < 0.001$) higher than observed with wild-type cells at 1, 3, and 5 hours, respectively. *In vivo* studies reveal that the tumor uptake in HSV-tk-expressing cells is 2.3-fold ($p < 0.001$), 3.0-fold ($p < 0.001$), and 5.5-fold ($p < 0.001$) higher than the control cells at 1, 2, and 5 hours, respectively. FMAU is more sensitive compared to earlier studies using [^{18}F]-FHPG and [^{18}F]-FHBG in the same cell lines, although the specificity is less than FHBG. While FMAU labeled with PET isotopes may be useful for imaging HSV-tk-expressing tumors *in vivo*, multitracer studies across additional tumor models are necessary in order to identify an optimal PET radiotracer.

Evaluation of 2′-deoxy-2′-flouro-5-methyl-1-beta-D-arabinofuranosyluracil as a potential gene imaging agent for HSV-TK expression *in vivo*. Alauddin MM, Shahinian A, Gordon EM, Conti PS. Mol Imaging 2002 Apr–Jun; 1 (2), pp. 74–81.

Gene Expression: Thymidine Kinase Expression/ Neoplastic Disease: DNA Synthesis/Cellular Proliferation Rate

5-[^{125}I]-Iodo-4′-Thio-2′-Deoxyuridine (ITdU)/ 5-[^{125}I]-Iodo-2′-Deoxyuridine (IUdR)

Cellular/Molecular Mechanism of Action: 5-iodo-4′-thio-2′-deoxyuridine is a metabolically stable nucleoside that can function as a substrate for cellular thymidine kinase biochemical activity.
Application: Radioiodinated forms of ITdU and IUdR can be applied to detect elevations in DNA synthesis in cell populations that positively express thymidine kinase activity. In this capacity, both ITdU and IUdR can serve as indicator molecules for measuring alterations in cellular proliferation especially relevant to the characterization of neoplastic disease states.
Route of Administration: Usually ITdU or IUdR would most frequently be administered intravascularly. Theoretically, it may be possible to effectively image lesions if the agents are administered intrathecally for CNS tumors, by direct injection into tumors, or into the arterial network supplying a suspected neoplastic lesion.
Semi-Synthetic Methods: Radiolabeling of ITdU and 5-iodo-1-(4-thio-beta-D-arabinofuranosyl)uracil (ITAU) with [^{125}I] can be performed utilizing a destannylation reaction of the trimethylstannyl precursor of each nucleoside. The products can be isolated in high yields and with a $>$ 99% level of radiochemical purity.
Implementation: Evaluation of ITdU and ITAU for their ability to detect and characterize cellular proliferation rates as a function of thymidine kinase expression.

***Ex Vivo* Model:** Thymidine kinase-expressing L-M cells and thymidine kinase-deficient mutant L-M (TK$^-$) cells.
Interpretation and Analysis: [^{125}I]-ITdU is effectively phosphorylated by cytosolic nucleoside kinases and specifically incorporated into thymidine kinase-expressing L-M cells to a far greater extent than into thymidine kinase-deficient mutant L-M (TK$^-$) cells. In addition, *in vitro* cell metabolism studies employing [^{125}I]-ITdU reveal that [^{125}I]-ITdU is effectively and specifically incorporated into a DNA fraction ($>$ 90% at 60 minutes). Therefore, IUdR or [^{125}I]-ITdU appears to be an effective marker for the detection of DNA synthesis. Conversely, [^{125}I]-ITAU is neither remarkably phosphorylated by cytosolic nucleoside kinases nor notably incorporated into L-M cells relative to L-M (TK$^-$) cells. [^{125}I]-ITdU and [^{125}I]-ITAU show a higher resistance to phosphorolytic cleavage by recombinant thymidine phosphorylase than does [^{125}I]-IUdR. Furthermore, biodistribution of [^{125}I]-ITdU and [^{125}I]-ITAU display better *in vivo* radioiodination stability than do [^{125}I]-IudR preparations. [^{125}I]-ITdU also displays a significantly higher uptake in proliferating organs (thymus, spleen, small intestine, and bone) than in non-proliferating organs (brain, muscle, liver, and lung), as does [^{125}I]-IUdR, at 18 hours postinjection. As indicated by *in vitro* studies, [^{125}I]-ITAU does not show any significant uptake in proliferating organs. Therefore, radioiodinated ITdU is potentially useful as a proliferation-imaging agent, and further studies should clarify the usefulness of this compound as a SPECT tumor-imaging agent.

Rationale of 5-(125)I-iodo-4′-thio-2′-deoxyuridine as a potential iodinated proliferation marker. Toyohara J, Hayashi A, Sato M, Tanaka H, Haraguchi K, Yoshimura Y, Yonekura Y, Fujibayashi Y. J Nucl Med 2002 Sep; 43 (9), pp. 1218–26.

HEPATIC SYSTEM

Hepatic Function

1-[^{11}C]-Octanoate Positron Emission Tomography (PET)

Cellular/Molecular Mechanism of Action: 1-[^{11}C]-Octanoate.
Application: Evaluation of regional hepatic function using PET.
Considerations: The metabolism of 1-[^{11}C]-Octanoate in the liver is influenced by beta-oxidation.
Implementation: Evaluation of 1-[^{11}C]-Octanoate as a radiopharmaceutical for characterizing liver function when combined with PET.

Animal Model: Murine and rat.
Interpretation and Analysis: In biodistribution studies (mice), 1-[^{11}C]-octanoate is rapidly taken up by the liver. In the liver, 1-[^{11}C]-octanoate is present within parenchymal cells and is predominantly metabolized via beta-oxidation followed by a rapid clearance phase. In CCl_4-challenge tests (mice), significantly slower hepatic clearance is observed with 1-[^{11}C]-octanoate compared to negative reference controls. In PET studies (rats), the time-radioactivity curves in the liver show a 2-phase decrease, and compared with negative reference controls, the CCl_4-challenge test produces slower hepatic half-clearance time for the 1st phase that is related to beta-oxidation metabolism. A preliminary PET study of 1-[^{11}C]-octanoate metabolism in normal humans is consistent with findings observed in preliminary (animal) studies.

Evaluation of 1-[^{11}C]-octanoate as a new radiopharmaceutical for assessing liver function using positron emission tomography. Yamamura N, Magata Y, Kitano H, Konishi J, Saji H. Nucl Med Biol 1998 Jul; 25 (5), pp. 467–72.

Hepatic Function

[^{99m}Technetium] ([^{99m}Tc])-Diethylenetriamine Pentaacetic Acid (DTPA)-Galactosyl Human Serum Albumin

Cellular/Molecular Mechanism of Action: Diethylenetriamine pentaacetic acid generally functions as a chelating agent for heavy metal ion isotopes like [^{111}In].
Physiological Mechanism of Action: [^{99m}Tc]-DTPA-galactosyl human serum abumin is removed from the intravascular compartment by viable hepatocytes.
Application: Characterization of hepatic function without collection of blood samples for *in vitro* sample analysis.
Route of Administration: Intravenous.
Implementation: Delineate the clinical utility of a graphical method for estimating liver uptake and blood retention of [^{99m}Tc]-DTPA-galactosyl human serum albumin [^{99m}Tc]-GSA, using dynamic single photon emission computed tomography (SPECT) analysis. When considering the kinetics of [^{99m}Tc]-GSA, if it is assumed that (i) [^{99m}Tc]-GSA distributes only between blood and liver, and (ii) no metabolism of [^{99m}Tc]-GSA occurs during the observation period, a plot of liver counts vs cardiac blood-pool counts should, theoretically, be a straight line. From the slope and y-intercept of a regression line, coefficients for converting count-based liver and blood-pool data to the % injected dose (%ID) can be calculated. Applicability of the method can be delineated for dynamic SPECT data from cases of hepatic dysfunction. To validate this method, plasma concentrations (%ID/ml plasma) at 6, 15, and 30 minutes after the injection are estimated and compared with measured values. To investigate the clinical significance of the % liver uptake, the value obtained by this method is compared with results from conventional liver function tests, including serum albumin, the

hepaplastin test, prothrombin time, and indocyanine green clearance.

Human Model: (n = 30 cases with hepatic disease).

Interpretation and Analysis: In every data set, a plot of liver counts to cardiac blood-pool counts can be represented (fitted) well by a straight line ($p < 0.00001$). Plasma concentrations estimated by this method show good correlation with measured values at 6, 15 and 30 minutes after injection ($r = 0.748, 0.838, 0.875$, respectively; $p < 0.0001$). The liver uptake determined by the method shows good correlation with results from conventional hepatic function tests ($p < 0.002$). The described graphical method could provide an accurate estimate of %ID of [^{99m}Tc]-GSA in blood without the need for blood sampling. The liver uptake determined by this method could be a simple but useful quantitative indicator of hepatic function.

Estimation of fractional liver uptake and blood retention of [^{99m}Tc]-DTPA-galactosyl human serum albumin: An application of a simple graphical method to dynamic SPECT. Shuke N, Aburano T, Okizaki A, Zhao C, Nakajima K, Yokoyama K, Kinuya S, Watanabe N, Michigishi T, Tonami N. Nucl Med Commun 2003 May; 24 (5), pp. 503–11.

Hepatic Metabolism/Beta-Oxidation (Biochemical Capacity)
[^{123}I]-Para-Iodophenylvaleric ([^{123}I]-IPVA)/ [^{123}I]-Para-Iodophenylenanthic ([^{123}I]-IPEA)/ 1-[^{11}C]-Octanoate Positron Emission Tomography (PET) Alternative

Cellular/Molecular Mechanism of Action: Both [^{123}I]-IPVA and [^{123}I]-IPEA are metabolized primarily through biochemically mediated mechanisms of beta-oxidation (e.g., main pathway responsible for adenosine triphosphate [ATP] production in hepatocytes).

Application: Detection of alterations in beta-oxidation as a parameter for assessing hepatic function.

Implementation: The 2 radioiodinated omega-(4-iodophenyl)-medium chain fatty acids, IPVA and IPEA, can be utilized as radiopharmaceuticals for determining hepatocyte viability. Both *in vitro*/*in vivo* metabolite assays and biodistribution studies (normal mice) indicate that these compounds are actively assimilated by the liver and metabolized by beta-oxidation. However, the agent IPEA is more suitable as an imaging agent than is IPVA. Applying these imaging agents provides a methodology for evaluating postoperative prognosis or therapeutic efficacy.

Interpretation and Analyses: Imaging studies performed in cases of hepatitis applying [^{123}I]-IPEA as an imaging agent for single photon emission computed tomography (SPECT) reveal a 2-phase hepatic time-activity curve for the clearance of the radiopharmaceutical combination. However, the clearance is delayed depending on the severity of hepatitis. Such findings reflect a direct correlation that exists between 1st-phase clearance rate and hepatocyte ATP levels. Therefore, hepatocyte clearance rates can function as an index or parameter that reflects hepatocyte energy production capacity. Based on these considerations, [^{123}I]-IPEA can potentially be useful as a radiopharmaceutical for the diagnosis of hepatic viability based on energy metabolism.

Instrumentation: The application of [^{123}I]-IPVA and [^{123}I]-IPEA require the use of computer-integrated SPECT instrumentation, while 1-[^{11}C]-octanoate employs PET. The advantage of SPECT is that it is more widely used/available than is PET instrumentation.

Evaluation of radioiodinated medium chain fatty acids as new diagnostic agents for the determination of hepatic viability. Yamamura N, Magata Y, Konishi J, Saji H. Eur J Nucl Med 1999 Dec; 26 (12), pp. 1597–605.

Hepatic and Renal Cysts/Polycystic Kidney Disease: Autosomal Dominant
[^{18}F]-Fluoro-Deoxy-Glucose (FDG)

Background Information: Infection of a renal or hepatic cyst is a serious complication of autosomal dominant polycystic kidney disease (ADPKD). Although crucial for successful management, early diagnosis is difficult, largely because of non-specific symptoms and limitations of conventional imaging techniques. Because of an increased metabolic rate, inflammatory cells take up large amounts of glucose. [^{18}F]-FDG, therefore, represents a promising agent for detection of cyst infections using positron emission tomography (PET).

Implementation: Performance of [^{18}F]-FDG PET scan imaging in cases of ADPKD suspected of being affected by renal or hepatic cyst infection.

Human Model: Cases of suspected renal or hepatic cyst infection (e.g., n = 7 FDG PET scans in 3 ADPKD cases suspected of renal or hepatic cyst infection; n = 2 PET scans of case A [PET 1 and 2]; n = 1 PET scan of case B [PET 3]; and n = 4 PET scans of case C [PET 4, 5, 6, and 7].

Interpretation and Analysis: [^{18}F]-FDG PET can identify infected cysts in conditions of (i) renal cyst infection; (ii) hepatic cyst infection; and (iii) simultaneous renal and hepatic cyst infection. Evaluation of FDG PET imaging modalities has proven to be very helpful in establishing diagnoses and in excluding renal and hepatic cyst infections. Based on experience with FDG PET, this diagnostic strategy has promise as an imaging technique enabling early identification of renal and hepatic cyst infections in ADPKD patients.

Diagnosis of renal and hepatic cyst infections by 18-F-fluoro-deoxy-glucose positron emission tomography in autosomal dominant polycystic kidney disease. Bleeker-Rovers CP, de Sévaux RG, van Hamersvelt HW, Corstens FH, Oyen WJ. Am J Kidney Dis 2003 Jun; 41 (6), pp. E18–21.

Hepatic Function and Viability/Beta-Oxidation Capacity
p-[^{123}I]-Iodophenylenanthic Acid (IPEA)

Background Information: Radiopharmaceuticals that reflect beta-oxidation in hepatocytes will provide useful information on the prognosis after surgery or on the efficacy of treatment, because beta-oxidation is the main pathway responsible for the generation of adenosine triphosphate in hepatocytes. Previous reports have described 1-[^{11}C]-octanoate as a diagnostic agent for determination of hepatic viability by means of positron emission tomography (PET).

Application: The agent [^{123}I]-IPEA is a potentially useful radiopharmaceutical for the diagnosis of hepatic viability based on energy metabolism. Single photon emission computed tomography (SPECT) has the advantage of being more widely used than PET.

Route of Administration: [^{123}I]-IPEA (intravenous).

Semi-Synthetic Methods: Production of 2 radioiodinated omega-(4-iodophenyl)-medium chain fatty acids, *p*-iodophenylvaleric acid (IPVA) and *p*-iodophenylenanthic acid (IPEA), can be synthesized to determine their applicability as radiopharmaceuticals for determination of hepatic viability.

Implementation: Evaluation of IPVA and IPEA as candidate radiopharmaceuticals for characterizing hepatic viability. Subsequent evaluations can involve utilization of SPECT methodologies to determine the ability of [^{123}I]-IPEA to differentiate between conditions of hepatitis and normal liver function.

Animal Model: Rat (normal and hepatitis model).

Interpretation and Analysis: Metabolite analyses (*in vitro* and *in vivo*) and biodistribution studies in normal mice indicate that both compounds are actively taken up by the liver and metabolized by beta-oxidation. Investigations performed *in vivo,* however, indicate that [^{123}I]-IPEA is more suitable as an imaging agent than [^{123}I]-IPVA. Hepatic [^{123}I]-IPEA time-activity curves reveal a 2-phase clearance of radioactivity in both normal and hepatitis model rats, but the clearance is delayed depending on the severity of hepatitis. Furthermore, the clearance rate of the 1st phase correlates with ATP levels in hepatocytes, which can be used as an index for energy production capacity in hepatocytes. In conclusion, IPEA is metabolized predominantly by beta-oxidation, and the clearance of IPEA from the liver is closely associated with the ATP concentration in the liver. Thus, [^{123}I]-IPEA is a potentially useful radiopharmaceutical for diagnosis of hepatic viability based on energy metabolism.

Evaluation of radioiodinated medium chain fatty acids as new diagnostic agents for the determination of hepatic viability. Yamamura N, Magata Y, Konishi J, Saji H. Eur J Nucl Med 1999 Dec; 26 (12), pp. 1597–605.

Hepatic Function: Cirrhosis and Chronic Liver Disease/Single Photon Emission Computed Tomography (SPECT) Correlation with Hepatic Function Tests
[^{99m}Tc]-Phytate Colloid/Indocyanine Green

Cellular/Molecular Mechanism of Action: Indocyanine is removed from the intravascular compartment by the liver without being metabolized and is subsequently excreted into the bile.
Background Information: Accurate quantitative determination of liver function is critical in cirrhotic patients in order to predict outcome, particularly in cases that undergo hepatic resection or non-hepatic surgery. As colloid uptake by perfused Kupffer cells is proportional to perfused hepatocyte mass, quantitative liver/spleen scans may be used as an index of perfused hepatocyte mass.
Application: Indocyanine green hepatic-associated parameters can be correlated with findings observed with SPECT for the purpose of assessing liver function in various disease states, including hepatic cirrhosis.
Route of Administration: Indocyanine green (intravenous).
Implementation: Evaluate quantitative SPECT of [^{99m}Tc]-phytate colloid uptake by the liver as a test for hepatic function in cirrhotic patients. SPECT can be used to measure liver volume, quantitative colloid uptake by the liver, and percentage of injected dose/ml of liver tissue. Indocyanine green can be applied in concert with quantitative SPECT to assess liver function in conditions of hepatic cirrhosis.

Human Model: Cases of hepatic cirrhosis (n = 75); non-cirrhotic patients with chronic liver disease (n = 52); and patients without liver disease (n = 36).
Interpretation and Analysis: Although liver volume is similar among cirrhotic, non-cirrhotic, and chronic liver disease states, conditions of cirrhosis have significantly lower total quantitative uptake and quantitative uptake/ml compared to hepatic disease group types ($p < 0.001$). Quantitative liver uptake in cirrhotic patients highly correlates with Child-Pugh scores ($r = -0.64$, $p < 0.0001$) and with indocyanine green retention at 15 minutes ($r = -0.84$, $p < 0.0001$). Quantitative SPECT of the liver may be an additional, useful, non-invasive quantitative test for assessment of hepatic function and severity of liver disease in cirrhotic disease states.

Quantitative liver-spleen scan using single photon emission computerized tomography (SPECT) for assessment of hepatic function in cirrhotic patients. Zuckerman E, Slobodin G, Sabo E, Yeshurun D, Naschitz JE, Groshar D. J Hepatol 2003 Sep; 39 (3), pp. 326–32.

IMMUNE SYSTEM

Lymphocytes/Non-Invasive *In Vivo* Visualization/ Immunomodulating Agent Assessment/ Cell-Mediated Immune Responses
Adaptively Transferred Immune T-Lymphocytes/ Positron Emission Tomography (PET) Reporter Gene/ Micro-Positron Emission Tomography (Micro-PET)

Application: Non-invasive, quantitative, tomographic *in vivo* visualization of lymphocyte populations. Such methodologies can be used to assess the effects of immunomodulatory agents intended to potentiate the immune response to cancer, and can also be useful for the study of other cell-mediated immune responses, including autoimmune conditions.
Biological Cell Preparations: Splenic T lymphocytes are harvested and partially purified from animals that have rejected a tumor induced by Moloney murine sarcoma virus/Moloney murine leukemia virus (M-MSV/M-MuLV). A PET reporter gene is then introduced into the T lymphocyte populations and the preparations are then injected into tumor-bearing mice. Imaging analysis is performed by micro-PET using a substrate specific for the reporter gene. Specific localization of immune T cells to the antigen-positive tumor is detected over time, by sequential imaging.
Implementation: Characterization of neoplastic lesions in tumor-bearing mice facilitated by the injection of adoptively transferred immune T-lymphocytes applied in combination with micro-PET facilitated by the use of a reporter-specific substrate. Specific localization (migration) of immune T cells to the antigen-positive tumor is detected over time by sequential *in vivo* imaging.
Interpretation and Analysis: Naive T-lymphocytes do not localize to the tumor site and serves as an indication that preimmunization is a requirement. Autoradiography and immunohistochemistry analysis can be applied to corroborated micro-PET imaging analyses.

Quantitative imaging of the T cell antitumor response by positron-emission tomography. Dubey P, Su H, Adonai N, Du S, Rosato A, Braun J, Gambhir SS, Witte ON. Proc Natl Acad Sci U S A 2003 Feb 4; 100 (3), pp. 1232–7. Epub 2003 Jan 23.

INFLAMMATION AND SEPSIS

Bacterial Infections: Focal
[^{18}F]-2-Deoxy-2-Fluoro-D-Glucose (FDG)/[^{3}H]-FDG/ [^{125}I]-Human Serum Albumin ([^{125}I]-HSA)/L-[^{11}C]-Methionine/L-[^{3}H]-Methionine/[^{3}H]-Thymidine

Application: Detection of focal sites of septic inflammation within extravascular tissues applying positron emission tomography (PET) imaging modalities.
Implementation: Determination of the relative biodistribution of [^{18}F]- or [^{3}H]-FDG, [^{3}H]-thymidine, L-[^{11}C]- or [^{3}H]-methionine, gallium-67 citrate ([^{67}Ga]-citrate), and [^{125}I]-HSA in cases of focal sepsis (e.g., rat left calf muscles infected with *Escherichia coli* suspension). Uptake of [^{3}H]-FDG within infectious foci is evaluated by autoradiography of tissue histological sections.
Interpretation and Analysis: Although [^{18}F]-FDG, [^{67}Ga]-citrate, and [^{125}I]-HSA show comparatively high uptake in infected muscle (percentage activity of injected dose per gram of tissue normalized for weight in kilogram [%ID/g] $\times$ kg at 2 hours postinjection is approximately [^{18}F]-FDG, 0.184 ± 0.026 to 0.218 ± 0.046; [^{67}Ga]-citrate, 0.221 ± 0.016; [^{125}I]-HSA, 0.198 ± 0.019), the in-

fected muscle to blood ratio is much higher for [^{18}F]-FDG than for [^{67}Ga]-citrate or [^{125}I]-HSA ([^{18}F]-FDG, 10.31 ± 0.76 to 14.89 ± 2.26; [^{67}Ga]-citrate, 1.24 ± 0.67; [^{125}I]-HSA, 0.20 ± 0.02). Draining reactive lymph nodes also show higher accumulations of [^{18}F]-FDG than of [^{67}Ga]-citrate or [^{125}I]-HSA. The uptake of [^{3}H]-thymidine and L-[^{11}C]-methionine or [^{3}H]-methionine in the infected muscle is lower than that of [^{18}F]-FDG or [^{3}H]-FDG (at 2 hours postinjection, [^{3}H]-thymidine = 0.039 ± 0.005 and L-[^{3}H]-methionine = 0.063 ± 0.007 (%ID/g) × kg. Autoradiographs show that the highest [^{3}H]-FDG uptake is seen in the area of inflammatory cell infiltration surrounding the necrotic region. In conclusion, [^{18}F]-FDG, which rapidly accumulates in sites of bacterial infection and in reactive lymph nodes with a high target-to-background ratio, appears to be a promising agent for the detection of infection.

Uptake of positron emission tomography tracers in experimental bacterial infections: a comparative biodistribution study of radiolabeled FDG, thymidine, L-methionine, [^{67}Ga]-citrate, and [^{125}I]-HSA. METABOLISM: HYPOXIA, ISCHEMICA, MITOSIS AND PROLIFERAITON

Metabolism/Hypoxia of Tissues
2-Nitroimidazoles/[^{18}F]-Labeled EF5

Cellular/Molecular Mechanism of Action: The class of pharmaceuticals typified by the 2-nitroimidazoles is bioreductively activated and bind to cell populations in tissues that have developed a hypoxic environment.

Background Information: The measurement of pathologically low levels of tissue pO_2 is an important diagnostic goal for determining the prognosis of many clinically important diseases, including cardiovascular insufficiency, stroke, and cancer.

Application: Potential application as a carrier imaging agent in the detection of ischemic lesions, including those recognized in cardiovascular insufficiency, CNS stroke, and neoplastic disease.

Route of Administration: Intravenous.

Dosage: Dependent upon molecular detector system applied according to conditions of the pathological state.

Interpretation and Analysis: Bioreductively activated pharmaceuticals like the 2-nitroimidazole class compounds bind to cells at a rate that is maximal under conditions of severe hypoxia (e.g., less than 0.05% oxygen) and are inhibited as a function of increasing oxygen concentration (according to Michaelis-Menten kinetics). A number of detection possibilities exist for the drug adducts, including invasive assays that can measure drug adducts in tissue sections at cell-to-cell levels of resolution. Use of such agents in non-invasive assays is important and, to this end, a number of drugs have been conjugated with radioactive isotopes suitable for detection by nuclear medicine techniques. In contrast to invasive assays, resolution and contrast are much more limited with non-invasive assays. Thus, there are many factors contributing to the balance of pros and cons for the non-invasive vs invasive use of 2-nitroimidazole drugs as tissue/organ/lesion hypoxia detectors. Such compounds are suitable for clinical use as molecular platforms for positron emission tomography (PET) imaging (e.g., [^{18}F]-labeled EF5: current clinical trials using invasive assays).

Non-invasive PET and SPECT imaging of tissue hypoxia using isotopically labeled 2-nitroimidazoles. Koch CJ, Evans SM. Adv Exp Med Biol 2003; 510, pp. 285–92.

Metabolism: Hypoxia of Tissues/Cardiovascular Insufficiency/Stroke/Neoplastic Disease
2-Nitroimidazole/[^{18}F]-Labeled EF5

Background Information: A class of bioreductively activated drugs, typified by the 2-nitroimidazoles, has excellent potential for measuring pathologically low tissue pO_2 levels. Such drugs bind to cells at a rate that is maximal under conditions of severe hypoxia (e.g., less than 0.05% oxygen) and are inhibited, with Michaelis-Menten kinetics, as a function of increasing oxygen concentration. A number of detection possibilities exist for the drug adducts, including invasive assays that can measure drug adducts in tissue sections at cell-to-cell levels of resolution. Use of such agents in non-invasive assays is important and, to this end, a number of drugs have been conjugated with radioactive isotopes suitable for detection by nuclear medicine techniques. In contrast with the invasive assays, resolution and contrast are much more limited with the non-invasive assays. Thus, there are many factors contributing to the balance of pros and cons for the non-invasive vs invasive use of 2-nitroimidazole drugs as hypoxia detectors.

Application: Potential utilization for the detection and characterization of pathologically hypoxic regions within tissues and organ systems relevant to the diagnosis and prognosis of disease states related to cardiovascular insufficiency, stroke, and cancer.

Non-invasive PET and SPECT imaging of tissue hypoxia using isotopically labeled 2-nitroimidazoles. Koch CJ, Evans SM. Adv Exp Med Biol 2003; 510, pp. 285–92.

Metabolism: Hypoxia of Tissues/Neoplastic Disease/ Cardiovascular: Myocardial Ischemia Secondary to Infarction/Central Nervous System (CNS): Vascular Stroke
[^{18}F]-Fluoroazomycinarabinofuranoside ([^{18}F]-FAZA)/ [^{18}F]-Fluoromisonidazole ([^{18}F]-FMISO)

Cellular/Molecular Mechanism of Action: [^{18}F]-FAZA, a recently developed hypoxia tracer for positron emission tomography (PET) imaging of tissue hypoxia, with an established tracer [^{18}F]-FMISO, both function as tracers or indicator molecules for tissue hypoxia.

Application: Potential detection of conditions associated with tissue hypoxia such as those recognized with neoplastic disease, CNS vascular stroke, and myocardial ischemia secondary to vascular infarction.

Implementation: Comparison of the uptake of [^{18}F]-FAZA with [^{18}F]-FMISO. Analysis can be performed *in vitro* with carcinoma cell lines or *in vivo* in natural or experimentally transplanted neoplastic lesions.

Animal and Cellular Models: Rat (Walker 256 rat carcinosarcoma cells propagated *in vitro* in tissue culture and *in vivo* in experimental rat tumors 11–12 days after tumor cell implantation).

Interpretation and Analysis: Hypoxia-selective uptake *in vitro* of both [^{18}F]-FAZA and [^{18}F]-FMISO in tumor cells, 20 and 100 minutes postincubation, is of the same magnitude (20 minutes: 1.24 ± 0.4% ([^{18}F]-FAZA); 1.19 ± 0.7% ([^{18}F]-FMISO); 100 minutes: 3.6 ± 1.6% ([^{18}F]-FAZA); 3.3 ± 1.7% ([^{18}F]-FMISO)). Positron emission tomography imaging reflects a similar radiotracer distribution in rat tumors for [^{18}F]-FAZA and [^{18}F]-FMISO 1 hour after radiotracer injection. The concentration of [^{18}F]-FAZA in tumors as measured by PET, however, is lower in comparison to [^{18}F]-FMISO [SUV (FAZA) = 0.61 ± 0.2 vs SUV(FMISO) = 0.92 ± 0.3, $p < 0.05$] although the tumor-to-muscle ratios for [^{18}F]-FAZA and [^{18}F]-

FMISO do not differ in the PET images obtained after 1 hour [SUV(FAZA) = 2.5 ± 0.5 vs SUV(FMISO) = 2.9 ± 0.7]. A comparison of PET data 3 hours postinjection [SUV(FAZA) = 3.0 ± 0.5 vs SUV(FMISO) = 4.6 ± 1.8, $p < 0.05$] demonstrates a lower [^{18}F]-FAZA uptake that indicates a lower sensitivity of [^{18}F]-FAZA compared to [^{18}F]-FMISO for detecting hypoxic regions at a longer time period. However, there is a faster elimination of [^{18}F]-FAZA from blood, viscera, and muscle tissue, via the renal system. The advantage of a faster reduction of nonspecific binding, in light of similar or marginally lower tumor uptake, warrants further investigation of [^{18}F]-FAZA as a marker of regional hypoxia in tumors.

[^{18}F]-fluoroazomycinarabinofuranoside (^{18}FAZA) and [^{18}F]-fluoromisonidazole (^{18}FMISO): A comparative study of their selective uptake in hypoxic cells and PET imaging in experimental rat tumors. Sorger D, Patt M, Kumar P, Wiebe LI, Barthel H, Seese A, Dannenberg C, Tannapfel A, Kluge R, Sabri O. Nucl Med Biol 2003 Apr; 30 (3), pp. 317–26.

Metabolism: Hypoxia of Tissues/Neoplastic Disease/ Design of Cancer Treatment Schedules
Hypoxia-Activated Diagnostic Pharmaceuticals

Conclusive research has shown that regions of acute/chronic hypoxia, which exist within the majority of solid tumors, have a profound influence on the therapeutic outcome of cancer chemotherapy and radiotherapy and are a strong prognostic factor of disease progression and survival. A strong argument therefore exists for assessing the hypoxic fraction of tumors prior to patient treatment, and for tailoring this treatment accordingly. Tumor hypoxia also provides a powerful physiological stimulus that can be exploited as a tumor-specific condition, allowing for the rational design of hypoxia-activated anticancer drugs or novel hypoxia-regulated gene therapy strategies.

Hypoxia and oxidative stress. Tumor hypoxia-therapeutic considerations. Williams KJ, Cowen RL, Stratford IJ. Breast Cancer Res. 2001; 3 (5), pp. 328–31. Epub 2001 Aug 07.

Metabolism: Hypoxia of Tissues/Neoplastic Disease: Prognostic Indicator for Therapeutic Intervention
[2-(2-Nitro-1[H]-Imidazol-1-yl)-N-(2,2,3,3,3-Pentafluoropropyl)-Acetamide]/[^{18}F]-EF5

Background Information: Tumor hypoxia is an important prognostic indicator for cancer therapy outcome. EF5 [2-(2-nitro-1[H]-imidazol-1-yl)-N-(2,2,3,3,3-pentafluoropropyl)-acetamide] has been employed to measure tumor hypoxia in animals and humans using immunohistochemical methods. EF5 is a lipophilic molecule designed to produce a very uniform biodistribution, a feature of obvious benefit for use in positron emission tomography (PET) imaging. Previous studies have demonstrated that early tissue culture passage 9L tumors are not severely hypoxic and that Q7 tumors are characterized by heterogeneous regions of tumor hypoxia (e.g., Q7 tumors are usually more hypoxic than early passage 9L tumors).
Application: Non-invasive PET imaging of tumors using [^{18}F]-labeled EF5 (rats).
Route of Administration: [^{18}F]-EF5 (intravascular). [^{18}F]-EF5 is excreted primarily via the urinary system.
Dosage: [^{18}F]-EF5 (50–100 μCi in 30 mg/kg carrier non-radioactive EF5). The carrier is used to ensure drug biodistribution comparable to prior studies using immunohistochemical methods.
Implementation: In tumors of a small size, partial volume effects may result in underestimation of concentration of the compound. Validation of PET data can be performed by gamma counting of imaged tissue. Acceptable tumor models include Morris 7777 (Q7) hepatoma (e.g., n = 5) and 9L glioma (e.g., n = 2) grown subcutaneously in rats. Demonstration of non-invasive PET imaging of rat (e.g., n = 7) with tumors using [^{18}F]-labeled EF5 is performed at various time points following [^{18}F]-EF5 administration.
Interpretation and Analysis: Images obtained 10 minutes following drug administration demonstrate that EF5 distributes evenly to all organ systems, including brain. Later images show increased uptake in most Q7 tumors compared with muscle. Liver uptake remains relatively constant over the same time period. Tumor-to-muscle ratios range from 0.82 to 1.73 (based on PET images at 120 minutes postinjection) and 1.47 to 2.95 (based on gamma counts at approximately 180 minutes postinjection). Tumors are easily visible by 60 minutes postinjection when the final tumor-to-muscle ratios (based on gamma counts) are 2 or greater. Neither the 9L tumors nor the smallest Q7 tumor meet this criterion, and therefore these tumors are not seen on the PET images. These preliminary results suggest that [^{18}F]-EF5 is a promising agent for non-invasive assessment of tumor hypoxia. Research investigations are under way to delineate the diagnostic efficacy of such preparations in brain tumor cases.
Instrumentation: HEAD Penn-PET scanner.

Non-invasive imaging of tumor hypoxia in rats using the 2-nitroimidazole [^{18}F]-EF5. Ziemer LS, Evans SM, Kachur AV, Shuman AL, Cardi CA, Jenkins WT, Karp JS, Alavi A, Dolbier WR Jr, Koch CJ. Eur J Nucl Med Mol Imaging 2003 Feb; 30 (2), pp. 259–66. Epub 2002 Nov 23.

Metabolism: Ischemic Lesions/Central Nervous System (Brain)/N-Methyl-D-Aspartate (NMDA) Receptor Activation
N-(1-Naphthyl)-N′-(3-[^{125}I]-Iodophenyl)-N′-Methylguanidine

Cellular/Molecular Mechanism of Action: N-(1-naphthyl)-N′-(3-iodophenyl)-N′-methylguanidine or CNS 1261 is a ligand that interacts with NMDA receptors following their activation.
Application: [^{125}I]-CNS 1261 can potentially function as a radioligand for imaging NMDA receptor activation.
Route of Administration: [^{125}I]-CNS 1261 (intravascular).
Semi-Synthetic Methods: Preparation of [^{125}I]-CNS 1261 can be prepared by radioiodination of *N*-(1-naphthyl)-*N′*-(3-tributylstannylphenyl)-*N′*-methylguanidine using Na[^{125}I] and peracetic acid.
Implementation: Detection of regional areas of cerebral ischemia.
Animal Model: Rat.
Interpretation and Analysis: Uptake of [^{125}I]-CNS 1261 *in vivo* reflects NMDA receptor distribution in normal rat brain, whereas in ischemic rat brain, uptake is markedly increased in areas of NMDA receptor activation. Radiolabeled CNS 1261 appears to be a good candidate for further development as a single photon emission computed tomography tracer in the investigation of NMDA receptor activation in conditions of cerebral ischemia.

Synthesis and binding characteristics of N-(1-naphthyl)-N′-(3-[^{125}I]-iodophenyl)-N′-methylguanidine ([^{125}I]-CNS 1261): A potential SPECT agent for imaging NMDA receptor activation. Owens J, Tebbutt AA, McGregor AL, Kodama K, Magar SS, Perlman ME, Robins DJ, Durant GJ, McCulloch J. Nucl Med Biol 2000 Aug; 27 (6), pp. 557–64.

Metabolism of Lipids: Fatty Acid Lipids/Central Nervous System [CNS]): Beta-Oxidation/ Incorporation into Membrane Structures
[U-^{14}C]-Palmitate/[1-^{14}C]-Arachidonate/Methyl 2-Tetradecylglycidate

Cellular/Molecular Mechanism of Action: Both palmitate and arachidonic acid are saturated fatty acids that are a component of

the external cell membrane lipid bilayer. In the CNS, [U-^{14}C]-palmitate undergoes beta-oxidation. Methyl 2-tetradecylglycidate (MEP) is an irreversible inhibitor of carnitine palmitoyltransferase I.

Application: In radiolabeled form, palmitate can be utilized as an *in vivo* probe for detecting alterations in brain lipid metabolism.

Route of Administration: [U-^{14}C]-palmitate (intravascular), [1-^{14}C]-arachidonate (intravascular), methyl 2-tetradecylglycidate (oral).

Dosage: Methyl 2-tetradecylglycidate (10–25 mg/kg).

Implementation: Determination of the effect of inhibiting mitochondrial beta-oxidation of free fatty acids on the incorporation of radiolabeled free fatty acids into brain lipids. Saturated fatty acid [U-^{14}C]-palmitic acid or the polyunsaturated fatty acid [1-^{14}C]-arachidonate (AA) are administered 2, 4, and 6 hours after methyl 2-tetradecylglycidate (MEP).

Animal Model: Rat (irreversible inhibition of carnitine palmitoyltransferase I in males induced through the use of methyl 2-tetradecylglycidate).

Interpretation and Analysis: Methyl 2-tetradecylglycidate increases brain [U-^{14}C]-palmitate-associated radioactivity 2-fold and decreases brain aqueous radioactivity 3- to 5-fold relative to control values at all pretreatment times. The effect is due to a prolongation of the plasma integral of [U-^{14}C]-palmitate due to peripheral inhibition of beta-oxidation, and to direct inhibition of beta-oxidation of the tracer within the brain. Conversely, methyl 2-tetradecylglycidate has no effect on brain organic radioactivity after infusion of [1-^{14}C]-arachidonic acid. Increasing the interval between methyl 2-tetradecylglycidate administration and [U-^{14}C]-palmitate infusion from 2 to 6 hours results in a dramatic redistribution of [U-^{14}C]-palmitate within brain lipids. The percentage of radioactivity in phospholipids decreases from 65 to 33%, whereas that in the free fatty acid fraction increases from 10 to 47% and that in triglycerides becomes elevated 2- to 3-fold over reference controls. Methyl 2-tetradecylglycidate may facilitate the use of radiolabeled palmitate as an *in vivo* probe for detecting alterations in brain lipid metabolism using quantitative autoradiography or positron emission tomography.

Instrumentation: Positron emission tomography.

Effect of inhibition of beta-oxidation on incorporation of [U-14C]-palmitate and [1-14C]-arachidonate into brain lipids. Freed LM, Wakabayashi S, Bell JM, Rapoport SI. Brain Res 1994 May 9; 645 (1–2), pp. 41–8.

Metabolism of Lipids: Phosphatidylinositol/ Central Nervous System (CNS) *[^{11}C]-Inositol/[^{11}C]-Inositol-1-Phosphate (IP)*

Application: Brain diagnostic imaging agent used in positron emission tomography (PET) imaging techniques for characterizing phosphatidylinositol metabolism.

Route of Administration: Intravenous.

Semi-Synthetic Methods: Radiolabeled inositol (Ins) and inositol-1-phosphate (IP) can be derived from radiolabeled glucose by utilizing brief sequential enzyme reactions. Rapid separation and fractionation of enzymes and labeled products from the reaction mixture can be achieved by high-performance liquid chromatography (HPLC) utilizing a gel-permeation chromatography column.

Interpretation and Analysis: Examination of the biodistribution of Ins, IP, and their acetylated analogs suggests that intact Ins labeled with [^{11}C] would be more effective than [^{11}C]-labeled acetylated Ins as a brain diagnostic agent for PET studies for determining the metabolism of phosphatidylinositol and its role as a 2nd messenger within the brain.

Instrumentation: Computer-integrated PET instrumentation.

Sequential enzymatic synthesis and biodistribution of radiolabeled inositol and inositol analogs. Sasaki T, Ogihara-Umeda I, Kojima S, Nishigori H. Int J Rad Appl Instrum [A] 1991; 42 (1), pp. 97–101.

Metabolism/Mitosis and Proliferation Rate *3′-Deoxy-3′-[^{18}F]-Fluorothymidine ([^{18}F]-FLT)*

Cellular/Molecular Mechanism of Action: Thymidine is rapidly assimilated by proliferating cell populations (e.g., incorporated into nucleic acids).

Application: [^{18}F]-FLT has been designed as a new positron emission tomography (PET) imaging agent for *in vivo* visualizing of cellular proliferation based on the incorporation of thymidine into nucleic acid.

Route of Administration: Variable but most often intravascular.

Semi-Synthetic Methods: A reliable radiosynthesis of [^{18}F]-FLT has been developed based on [^{18}F]10 mCi (370 MBq) of radiochemically pure [^{18}F]1 Ci/μmol (37 GBq/μmol) at end of synthesis (EOS) within 100 minutes and in 13% radiochemical yield (end of bombardment [EOB]; 7% EOS).

Implementation: Evaluation of neoplastic lesions that display relatively rapid rates of proliferation/growth.

Interpretation and Analysis: Detection of increased radioactivity at a specific anatomical location corresponds to a region that has a relatively high rate of cellular proliferation.

Radiosynthesis of 3′-deoxy-3′-[^{18}F]-fluorothymidine: [^{18}F]-FLT for imaging of cellular proliferation *in vivo*. Grierson JR, Shields AF. Nucl Med Biol 2000 Feb; 27 (2), pp. 143–56.

Metabolism/Mitosis and Proliferation Rate *2′-Deoxy-2′-[^{18}F]-Fluoro-β-D-Arabinofuranosyl/ [^{18}F]-FAU, [^{18}F]-FMAU, [^{18}F]-FBAU, [^{18}F]-FIAU*

Semi-Synthetic Methods: Efficient and reliable synthesis of 2′-deoxy-2′-[^{18}F]-fluoro-β-D-arabinofuranosyl nucleosides.

Interpretation and Analysis: Overall decay-corrected radiochemical yields of 35 to 45% of 4 analogs, FAU, FMAU, FBAU, and FIAU, are routinely obtained in $>$ 98% radiochemical purity and with specific activities of greater than 3 Ci/μmol (110 MBq/μmol) in a synthesis time frame of approximately 3 hours. When approximately 220 mCi (8.15 GBq) of starting [^{18}F]-fluoride is used, 25–30 mCi (0.93–1.11 GBq) of product (enough to image 2 patients sequentially) is typically obtained.

Synthesis of 2′-deoxy-2′-[^{18}F]-fluoro-beta-D-arabinofuranosyl nucleosides, [^{18}F]-FAU, [^{18}F]-FMAU, [^{18}F]-FBAU, and [^{18}F]-FIAU, as potential PET agents for imaging cellular proliferation. Synthesis of [^{18}F]-labeled FAU, FMAU, FBAU, FIAU. Mangner TJ, Klecker RW, Anderson L, Shields AF. Nucl Med Biol 2003 Apr; 30 (3), pp. 215–24.

Metabolism/Mitosis and Proliferation Rate *3′-Deoxy-3′-[^{18}F]-Fluorothymidine ([^{18}F]-FLT)*

Cellular/Molecular Mechanism of Action: [^{18}F]-FLT is a nucleoside analogue that enters cells and is phosphorylated by human thymidine kinase 1, but the 3′ substitution prevents further incorporation into DNA.

Application: [^{18}F]-FLT is a positron emission tomography (PET) imaging agent that shows promise for studying cellular proliferation in human cancers.

Implementation: Estimations of radiation dosimetry for [^{18}F]-FLT can be calculated based on data for time-dependent tissue concentrations of radioactivity for blood samples and PET images (e.g., n = 18 cases) after intravenous injection. Radiation-absorbed doses are calculated using the Medical Internal Radiation Dose (MIRD)

Committee methods, taking into account variations that are based on the distribution of activities observed in individual cases. Effective dose equivalent (EDE) is calculated using International Commission on Radiological Protection Publication 60 tissue-weighting factors for the standard man and woman.

Interpretation and Analysis: For a single bladder voiding at 6 hours after [^{18}F]-FLT injection, the [^{18}F]-FLT EDE (mean ± standard deviation [SD]) is 0.028 ± 0.012 mSv/MBq (103 ± 43 mrem/mCi) for a standard male patient and 0.033 ± 0.012 mSv/MBq (121 ± 43 mrem/mCi) for a standard female patient. The organ that receives the highest dose is the bladder (male, 0.179 mGy/MBq [662 mrad/mCi]; female, 0.174 mGy/MBq [646 mrad/mCi]), followed by the liver (male, 0.045 mGy/MBq [167 mrad/mCi]; female, 0.064 mGy/MBq [238 mrad/mCi]), the kidneys (male, 0.035 mGy/MBq [131 mrad/mCi]; female, 0.042 mGy/MBq [155 mrad/mCi]), and the bone marrow (male, 0.024 mGy/MBq [89 mrad/mCi]; female, 0.033 mGy/MBq [122 mrad/mCi]).

Organ dose estimates for [^{18}F]-FLT are comparable to those associated with other commonly performed nuclear medicine tests, and the potential radiation risks associated with [^{18}F]-FLT PET imaging are within accepted limits.

[^{18}F]-fluorothymidine radiation dosimetry in human PET imaging studies. Vesselle H, Grierson J, Peterson LM, Muzi M, Mankoff DA, Krohn KA. J Nucl Med 2003 Sep; 44 (9), pp. 1482–8.

Metabolism/Mitosis and Proliferation Rate
[^{18}F]-FAU ([^{18}F] 1-(2′-Deoxy-2′-Fluoro-β-D-Arabinofuranosyl)Uracil)

Cellular/Molecular Mechanism of Action: The agent FAU or [1-(2′-deoxy-2′-fluoro-beta-D-arabinofuranosyl)uracil] is incorporated into strands of DNA as a "false" or "decoy" nucleotide and functions as an inhibitor of DNA synthesis.

Physiological Mechanism of Action: Functions as an inhibitor of DNA synthesis, thereby inhibiting the synthesis of viable messenger RNA (mRNA/transcription) or biologically functional protein fractions (translation).

Application: Radiofluorination of FAU to produce [^{18}F]-FAU or [^{18}F] 1-(2′-deoxy-2′-fluoro-beta-D-arabinofuranosyl)uracil is suitable as a diagnostic radiopharmaceutical for positron emission tomography (PET) imaging procedures.

Route of Administration: [^{18}F]-FAU.

Implementation: Determination of the pharmacokinetic and relative organ/tissue distribution of [^{18}F]-FAU following injection of the tracer through the combined application of PET imaging (duration = ≥ 4 hours) and high-performance liquid chromatography (HPLC) analysis of collected blood, urine, and tissues/organs.

Animal Model: Canine (e.g., n = 3 normal dogs).

Interpretation and Analysis: In an *in vivo* environment, [^{18}F]-FAU is evenly distributed throughout most of organ systems and tissues. In sharp contrast to thymidine and its analogs, the marrow has less retention of [^{18}F]-FAU than non-proliferating tissues.

Imaging [^{18}F]-FAU [1-(2′-deoxy-2′-fluoro-beta-D-arabinofuranosyl) uracil] in dogs. Sun H, Collins JM, Mangner TJ, Muzik O, Shields AF. Nucl Med Biol 2003 Jan; 30 (1), pp. 25–30.

Metabolism/Mitosis and Proliferative Activity/ Neoplastic Disease: DNA Synthesis/Cellular Proliferation Rate/Thymidine Kinase Expression
5-Iodo-4′-Thio-2′-Deoxyuridine (ITdU)

Cellular/Molecular Mechanism of Action: ITdU is a metabolically stable nucleoside that can function as a substrate for cellular thymidine kinase biochemical activity.

Application: Radioiodinated forms of ITdU and 5-iodo-2′-deoxyuridine (IUdR) can be applied to detect elevations in DNA synthesis in cell populations that positively express thymidine kinase activity. In this capacity, both ITdU and IUdR can serve as indicator molecules for measuring alterations in cellular proliferation especially relevant to the characterization of neoplastic disease states.

Route of Administration: Usually ITdU or IUdR would most frequently be administered intravascularly. Theoretically, it may be possible to effectively image lesions if the agents are administered intrathecally for central nervous system (CNS) tumors, by direct injection into tumors, or into the arterial network supplying a suspected neoplastic lesion.

Semi-Synthetic Methods: Radiolabeling of ITdU and 5-iodo-1-(4-thio-beta-D-arabinofuranosyl)uracil (ITAU) with [^{125}I] can be performed utilizing a destannylation reaction of the trimethylstannyl precursor of each nucleoside. The products can be isolated in high yields and with a > 99% level of radiochemical purity.

Implementation: Evaluation of ITdU and ITAU for their ability to detect and characterize cellular proliferation rates as a function of thymidine kinase expression.

***Ex Vivo* Model:** Thymidine kinase-expressing L-M cell rather than a thymidine kinase-deficient mutant L-M (TK$^-$) cell.

Interpretation and Analysis: [^{125}I]-ITdU is effectively phosphorylated by cytosolic nucleoside kinases and specifically incorporated into thymidine kinase-expressing L-M cells to a far greater extent than into thymidine kinase-deficient mutant L-M (TK$^-$) cells. In addition, *in vitro* cell metabolism studies employing [^{125}I]-ITdU reveal that [^{125}I]-ITdU is effectively and specifically incorporated into a DNA fraction (> 90% at 60 minutes). Therefore, IUdR or [^{125}I]-ITdU appears to be an effective marker for the detection of DNA synthesis. Conversely, [^{125}I]-ITAU is neither remarkably phosphorylated by cytosolic nucleoside kinases nor notably incorporated into L-M cells relative to L-M (TK$^-$) cells. [^{125}I]-ITdU and [^{125}I]-ITAU show a higher resistance to phosphorolytic cleavage by recombinant thymidine phosphorylase than does [^{125}I]-IUdR. Furthermore, biodistribution of [^{125}I]-ITdU and [^{125}I]-ITAU display better *in vivo* radioiodination stability than do [^{125}I]-IudR preparations. [^{125}I]-ITdU also displays a significantly higher uptake in proliferating organs (thymus, spleen, small intestine, and bone) than in non-proliferating organs (brain, muscle, liver, and lung), as does [^{125}I]-IUdR, at 18 hours postinjection. As indicated by *in vitro* studies, [^{125}I]-ITAU does not show any significant uptake in proliferating organs. Therefore, radioiodinated ITdU is potentially useful as a proliferation-imaging agent, and further studies should clarify the usefulness of this compound as a single photon emission computed tomography (SPECT) tumor-imaging agent.

Rationale of 5-[^{125}I]-iodo-4′-thio-2′-deoxyuridine as a potential iodinated proliferation marker. Toyohara J, Hayashi A, Sato M, Tanaka H, Haraguchi K, Yoshimura Y, Yonekura Y, Fujibayashi Y. J Nucl Med 2002 Sep; 43 (9), pp. 1218–26.

MUSCULOSKELETAL SYSTEM

Osteomyelitis (Chronic)/Inflammatory Spondylitis
[^{18}F]-Fluoro-Deoxy-Glucose (FDG)

Cellular/Molecular Mechanism of Action: Fluoro-deoxyglucose functions as a biochemical analogue of endogenous deoxyglucose within various cell populations.

Application: Detection and characterization of septic osteomyelitis and inflammatory spondylitis conditions and their response to therapeutic intervention. Unlike computed tomography and magnetic resonance imaging, FDG positron emission tomography (PET) is not affected by metal implants used for the management of fractures.

In the early postoperative phase, FDG PET seems to be of limited value owing to unspecific tracer uptake.

Implementation: Detection and characterization of acute or chronic osteomyelitis and inflammatory spondylitis (e.g., n = 15 cases). Results from FDG PET image analysis are subsequently correlated with histopathological findings applying tissue samples collected intraoperatively (e.g., n = 15/21).

Interpretation and Analysis: Histopathological analysis is able to detect evidence of osteomyelitis or inflammatory spondylitis in a high percentage of cases (e.g., n = 15/15; n = 7/15 acute osteomyelitis, n = 8/15 chronic osteomyelitis or inflammatory spondylitis). Similarly, image analysis using FDG PET is also highly sensitive in detecting cases of acute or chronic osteomyelitis and inflammatory spondylitis (e.g., n = 15/15). Tracer uptake almost invariably correlates with histopathological findings (e.g., n = 15/15). Bone scintigraphy yields a high percentage of true-positive images (e.g., n = 10/11) with a small probability of false-negative results (e.g., n = 1/11). Monitorization of cases in concert with a normalization of clinical parameters usually corresponds to normal or clearly reduced tracer uptake in situations of resolving osteomyelitis and inflammatory spondylitis (e.g., n = 2/2). In early postoperative monitoring, it is impossible to differentiate between postsurgical reactive changes and further infection using FDG PET. Therefore, acute and chronic osteomyelitis of the peripheral as well as the central skeleton can be detected using FDG PET. Osteomyelitis can be differentiated from soft tissue infection surrounding the bone.

Fluorine-18 fluoro-deoxy-glucose PET in infectious bone diseases: Results of histologically confirmed cases. Kalicke T, Schmitz A, Risse JH, Arens S, Keller E, Hansis M, Schmitt O, Biersack HJ, Grunwald F. Eur J Nucl Med 2000 May; 27 (5), pp. 524–8.

NEOPLASIA

Neoplastic Disease Imaging
[^{18}F]-2-Fluoro-2-Deoxy-D-Glucose (FDG)/ [^{18}F]-2-Fluoro-2-Deoxy-D-Mannose (FDM)

Cellular/Molecular Mechanism of Action: Radiofluorinated [^{18}F] glucose analogs are preferentially assimilated by neoplastic cell types at a higher level than normal cells in part due to differences in biochemical metabolism. [^{18}F]-FDM is a byproduct of [^{18}F]-FDG synthesis.

Application: Detection and characterization of neoplastic disease states applying nuclear imaging techniques (e.g., positron emission tomography [PET]).

Implementation: Evaluation of the relationship between pharmacokinetic profiles and capacity to detect neoplastic disease utilizing [^{18}F]-FDG and [^{18}F]-FDM glucose analogs.

Animal Model: Rat (tumor).

Interpretation and Analysis: Neoplastic lesions can be detected by increased uptake of radiofluorinated glucose analogs utilizing nuclear medicine scintigraphy imaging techniques.

Tissue distribution studies have shown high tumor uptake for both [^{18}F]-FDG and [^{18}F]-FDM reagents. Tumor uptake reaches 2.65 ± 0.61% dose [^{18}F]-FDG/g and 2.65 ± 0.81% dose [^{18}F]-FDM/g at 60 minutes and remains relatively constant until 120 minutes. Blood clearance for both [^{18}F]-FDG and [^{18}F]-FDM is very rapid and tumor-to-blood ratios reach 22.1 and 29.4 at 60 minutes, respectively. Tumor-to-tissue ratios for both radiopharmaceuticals is very high in most organs, especially in the liver, kidney, and pancreas. Positron emission tomography of rabbit tumor with [^{18}F]-FDM clearly can delineate the main tumor, central necrosis, and lymph node metastases.

Experimental data suggest that [^{18}F]-FDM, which is a byproduct of [^{18}F]-FDG synthesis, is also an excellent cancer diagnostic agent, as is [^{18}F]-FDG. This is not only a new feature of [^{18}F]-FDM but also an economical improvement on cancer diagnosis by PET.

Experimental study for cancer diagnosis with positron-labeled fluorinated glucose analogs: [^{18}F]-2-fluoro-2-deoxy-D-mannose: A new tracer for cancer detection. Fukuda H, Matsuzawa T, Abe Y, Endo S, Yamada K, Kubota K, Hatazawa J, Sato T, Ito M, Takahashi T, Iwata R, Ido T. Eur J Nucl Med 1982; 7 (7), pp. 294–7.

Neoplasia: Brain/Astrocytoma (Low Grade): Central Nervous System (CNS)/Intra-Axial Brain Tumors
([^{201}Tl]-Pentetreotide/[^{111}In]-Pentetreotide/ ([Gd]-Enhanced Magnetic Resonance Imaging [MRI])

Background Information: Highly undifferentiated glial tumors do not express somatostatin receptors (SSR), in contrast to low-grade astrocytomas, which contain SSR. To differentiate a malignant glioma from a low-grade astrocytoma and to distinguish an SSR-positive intra-axial brain tumor from an SSR negative 1, [^{111}In]-pentetreotide brain single photon emission computed tomography (SPECT) can be prospectively undertaken.

Application: Detection and characterization of intra-axial brain tumors.

Implementation: Evaluation of intra-axial brain tumors utilizing [^{201}Tl]- and [^{111}In]-pentetreotide brain SPECT performed using a 3-day to 4-day interval before surgery. Results from SPECT analyses are compared with those of [Gd]-enhanced MRI.

Human Model: Cases with intra-axial brain tumors (n = 8; n = 3/8 glioblastoma multiforme, n = 1/8 low-grade astrocytoma, n = 1/8 lymphoma, n = 1/8 medulloblastoma, n = 1/8 neurocytoma, n = 1/8 metastatic tumor).

Interpretation and Analysis: Increased uptake of [^{111}In]-pentetreotide can be appreciated in a high percentage of cases with glioblastoma multiforme (n = 2 grade (−); n = 1 grade (+); positive uptake n = 3/3 or 100% of cases) despite lack of SSR.

Low-grade astrocytomas exhibit minimal uptake of [^{111}In]-pentetreotide (grade +). Remaining tumors have an intense uptake of [^{111}In]-pentetreotide. [^{201}Tl] SPECT reveals similar findings to those observed with [^{111}In]-pentetreotide scintigraphy except in some conditions of glioblastoma multiforme (e.g., n = 2). Rare cases that have a negative [^{201}Tl] scan will usually show increases in [^{111}In]-pentetreotide uptake. Similarly, a small percentage of cases that have minimal uptake of [^{111}In]-pentetreotide will usually display increased thallium uptake. The uptake pattern of both [^{201}Tl] and [^{111}In]-pentetreotide appears to correlate with [Gd]-enhanced MRI. [^{111}In]-pentetreotide scintigraphy is sensitive for the detection of intra-axial brain tumors; however, it has no role in assessing the tumor grading or in the definition of receptor profiles.

Indium-111-pentetreotide imaging in intra-axial brain tumors: Comparison with thallium-201 SPECT and MRI. Lee JD, Kim DI, Lee JT, Chang JW, Park CY. J Nucl Med 1995 Apr; 36 (4), pp. 537–41.

Neoplasia: Brain/Cerebral Metastasis/ Detection of Primary Site of Metastasis
[^{18}F]-Fluoro-Deoxy-Glucose (FDG) Positron Emission Tomography (PET)

Cellular/Molecular Mechanism of Action: Radiofluorinated ([^{18}F]) analogues of glucose ([^{18}F]-FDG) are assimilated by neoplastic cell types at a higher level than normal parenchymal cells in part due to biochemical differences in glucose metabolism.

Background Information: Identification of unknown primary tumors in patients presenting with cerebral metastasis is a continued diagnostic challenge. Despite extensive and lengthy diagnostic

work-up, the primary tumors will often remain obscure in a significant proportion of affected patients.

Application: Detection of unknown primary tumors in patients with cerebral metastases.

Implementation: Evaluate the capacity for whole-body [^{18}F]-FDG PET scanning to identify the anatomical location of primary neoplastic lesions in conditions of metastatic disease affecting the brain. Confirmation of tumor lesions can be determined either by direct histological verification or indirectly by the observation of lesion appearance or lesion growth on structural imaging.

Human Model: Cases with histologically confirmed metastatic brain tumors (n = 16 from 34–74 years of age).

Interpretation and Analysis: Whole-body [^{18}F]-FDG PET may identify pulmonary foci of probable primary tumors in a high percentage of cases (e.g., n = 16/16). Successful confirmation may only be achieved in approximately 50% of affected cases (e.g., n = 8/16). In the remaining 50% of cases (e.g., n = 8/16) appropriate tissue samples may not be available (e.g., death or lost to follow-up; note n = 1/16 pulmonary malignant melanoma metastases). Therefore, whole-body [^{18}F]-FDG PET scanning is a sensitive tool in the search for unknown primary tumors of patients with confirmed cerebral metastases, allowing early and focused histological confirmation from suspicious lesions.

Instrumentation: Positron emission tomography instrumentation.

Detection of unknown primary tumors in patients with cerebral metastases using whole-body ^{18}F-flouoro-deoxy-glucose positron emission tomography. Klee B, Law I, Højgaard L, Kosteljanetz M. Eur J Neurol 2002 Nov; 9 (6), pp. 657–62.

Neoplasia: Brain/Gliomas: Heterogeneous/ Stereotactic Biopsy: Improve Accuracy of Lesion Localization and Sampling *[^{18}F]-Fluoro-Deoxy-Glucose (FDG)*

Background Information: A wide variety of metabolic features of brain tumors can be imaged using positron emission tomography (PET), including glucose metabolism, blood flow, oxygen consumption, amino acid metabolism, and lipid synthesis. Currently, FDG is the most widely available PET tracer for body imaging and brain imaging.

Application: [^{18}F]-FDG.

Route of Administration: [^{18}F]-FDG.

Dosage: [^{18}F]-FDG.

Interpretation and Analysis: Malignant brain tumors, like many other soft tissue tumors, show increased glucose metabolism, which is detectable in FDG PET images. FDG PET imaging of brain tumors provides information on tumor grade and prognosis. Compared with other organ systems, FDG PET imaging of the brain presents unique challenges because of the high background glucose metabolism of normal gray matter structures. Co-registration of the magnetic resonance imaging (MRI) or CT and FDG PET images is essential for accurate evaluation of brain tumors and is performed routinely at several institutions. The heterogeneous nature of gliomas can result in significant sampling errors when patients are biopsied for primary tumor diagnosis or recurrent disease. FDG PET can be used to define the most metabolically active targets for stereotactic biopsy. This in turn can improve diagnostic accuracy and reduce the number of biopsy samples required. FDG PET is also useful for evaluating residual or recurrent tumor following therapy, and can be used to survey patients with low-grade brain tumors for evidence of progression into high-grade malignancy. In the case of suspected tumor recurrence or progression, PET can aid in defining appropriate targets for biopsy. One limitation of FDG PET is the occasional inability to distinguish radiation necrosis from recurrent high-grade tumor. A 2nd limitation is that FDG PET is less sensitive than contrast-enhanced MRI for detecting intracranial metastases, and it is the opinion of some clinicians that brain studies should not be included as part of routine whole-body PET studies. Other tracers, such as [^{11}C]-methionine and [^{18}F]-fluorocholine (FCH), also avidly accumulate in brain tumors and have the advantage of low background cortical activity. The relationship between degree of uptake of these agents and tumor grade has not been established. These tracers may be useful in specific clinical situations, however, such as tumor localization for treatment planning or evaluation of low-grade tumors.

Positron emission tomography imaging of brain tumors. Wong TZ, van der Westhuizen GJ, Coleman RE. Neuroimaging Clin N Am. 2002 Nov; 12 (4), pp. 615–26.

Neoplasia: Brain/Glioma/Temozolomide Pharmacokinetics and Tumor Uptake *[^{11}C]-Temozolomide/Dual Radiolabeled at 3-N-Methyl and 4-Carbonyl*

Background Information: Previous reports have postulated that temozolomide undergoes decarboxylation and ring opening at the 3-4 position to produce the highly reactive methyldiazonium ion that alkylates DNA.

Application: Detection and characterization of neoplastic disease states.

Considerations: Dual radiolabeling of [^{11}C]-temozolomide in the 3-*N*-methyl and 4-carbonyl positions to delineate if temozolomide undergoes decarboxylation and ring opening in the 3-4 position to produce the highly reactive methyldiazonium ion that alkylates DNA. Characterization of such processes can facilitate determination if the [^{11}C] in the C-4 position of [4-[^{11}C]-carbonyl]-temozolomide is converted to [^{11}C]CO_2, which would result in lower accumulation of [^{11}C]-temozolomide within neoplastic lesions.

Semi-Synthetic Methods: Dual radiolabeling strategy involving separate radiolabeling of [^{11}C]-temozolomide in the 3-*N*-methyl and 4-carbonyl positions.

Implementation: Quantitate and confirm the mechanism of *in vivo* metabolic activation of temozolomide in addition to evaluation of tumor lesions, normal tissue, and plasma pharmacokinetics of temozolomide *in vivo*, and establish to what extent pharmacokinetics influence tumor targeting. Dual radiolabeled [^{11}C]-temozolomide at the 3-*N*-methyl or 4-carbonyl position is administered systemically to generate corresponding pharmacokinetic profiles (e.g., men) using positron emission tomography (PET). Paired studies are performed with both forms of [^{11}C]-temozolomide in glioma conditions. Another PET scan with [^{11}C]-radiolabeled bicarbonate can be performed and used to account for metabolites of temozolomide using a detailed analytical approach. Plasma is analyzed for [^{11}C]-temozolomide and [^{11}C] metabolites throughout the scan duration. Exhaled air can also be sampled throughout the scan for [^{11}C]CO_2 content. The percentage ring opening of temozolomide over 90 minutes can subsequently be calculated to evaluate whether there is a differential level of metabolic breakdown among plasma, normal tissue, and tumors.

Human Model: Cases of glioma (n = 6).

Interpretation and Analysis: Both radiolabeled forms of [^{11}C]-temozolomide display a rapid systemic clearance over a 90-minute period (0.2 liter/min/m^2), with [^{11}C]CO_2 being the primary elimination product. Plasma [^{11}C]CO_2 is present in all of the studies with [4-[^{11}C]-carbonyl]-temozolomide and in half the studies with [3-*N*-[^{11}C]-methyl]-temozolomide. The mean contributions to total plasma activity by [^{11}C]CO_2 at 10 and 90 minutes are 12% and 28% with [4-[^{11}C]-carbonyl]-temozolomide, and 1% and 4% with [3-N-[^{11}C]-methyl]-temozolomide, respectively. There is a 5-fold increase in

exhaled [^{11}C]CO_2 sampled with [4-[^{11}C]-carbonyl]-temozolomide compared with [3-*N*-[^{11}C]-methyl]-temozolomide ($p < 0.05$). A decrease in tissue exposure [area-under-the-curve between 0 and 90 minutes (AUC(0–90 minutes))] to [^{11}C]-temozolomide is also observed with [4-[^{11}C]-carbonyl]- temozolomide compared with [3-*N*-[^{11}C]-methyl]-temozolomide. A potential therapeutic advantage is the higher [^{11}C]-radiotracer and [^{11}C]-temozolomide exposure (AUC (0–90 minutes)) in tumors compared with normal tissue. [^{11}C]-temozolomide ring opening over 90 minutes is less in plasma (20.9%; $p < 0.05$) compared with tumor (26.8%), gray matter (29.7%), and white matter (30.1%), with no differences ($p > 0.05$) between tumor and normal tissues. The significantly higher amounts of [^{11}C]CO_2 sampled in plasma and exhaled air, in addition to the lower normal tissue and tumor [^{11}C]-temozolomide AUC(0–90 minutes) observed with [4-[^{11}C]-carbonyl]-temozolomide, suggest that [^{11}C] in the C-4 position of [4-[^{11}C]-carbonyl]-temozolomide is converted to [^{11}C]CO_2, resulting in lower [^{11}C]-temozolomide tumor exposure. The higher tumor [^{11}C]-temozolomide AUC(0–90 minutes) in tumors compared with normal tissue and the tissue-directed metabolic activation of temozolomide may confer potential therapeutic advantage in the activity of this agent.

Metabolic activation of temozolomide measured *in vivo* using positron emission tomography. Saleem A, Brown GD, Brady F, Aboagye EO, Osman S, Luthra SK, Ranicar AS, Brock CS, Stevens MF, Newlands E, Jones T, Price P. Cancer Res 2003 May 15; 63 (10), pp. 2409–15.

Neoplasia: Brain/Gliomas
p-[^{123}I]-Iodo-L-Phenylalanine (IPA)

Cellular/Molecular Mechanism of Action: The agent IPA functions as an analogue of phenylalanine and is preferentially assimilated by certain cell types due to its ability to biologically mimic this amino acid molecule.

Background Information: IPA is a recently described radiopharmaceutical that accumulates in gliomas at relatively high levels.

Application: Detection and characterization of gliomas within the central nervous system.

Dosage: IPA (average effective dose for adults is estimated to be 0.0152mSv*MBq^{-1}, leading to an effective dose of 3.8mSv in a typical brain single photon emission computed tomography [SPECT] investigation with 250 MBq IPA).

Implementation: Evaluate the feasibility of SPECT with IPA to image brain tumors under routine clinical conditions. One approach to achieving this objective can involve delineation of whole-body kinetic profiles and brain SPECT, in addition to plasma, urinary, and dosimetric analysis in glioma cases following intravenous IPA injection. Results obtained by IPA SPECT are then compared with histopathology, magnetic resonance images, and positron emission tomography employing [^{18}F]-fluoro-deoxy-glucose.

Human Model: Cases of glioma (n = 4).

Interpretation and Analysis: Tumor lesions can be clearly demonstrated by IPA SPECT at 30 minutes, 1 hour, and 4.5 hours postinjection, even in cases of low-grade gliomas. In conditions of glioblastoma, excellent visualization of the tumor is possible even at 7 hours postinjection, indicative of high retention of the radiopharmaceutical within cerebral gliomas. Analysis of radioactivity within plasma and urine samples serves to validate the high *in vivo* stability of IPA. Blood clearance of IPA is rapid (> 65% after 10 minutes) and elimination is predominantly facilitated by renal excretion with urinary radioactivity excretion ranging from 27% at 1 hour to 54% of injected doses at 5 hours postinjection. The IPA agent is a potentially valuable brain tumor imaging agent for widespread clinical studies with SPECT. Its high specific tumor uptake and retention even in low-grade gliomas represent a major advantage compared to presently available SPECT radiopharmaceuticals. Moreover, the radiation dose estimates indicate that clinical use of IPA will result in acceptable radiation dose levels in humans.

Instrumentation: Dual- and a triple-headed SPECT camera.

Initial evaluation of the feasibility of single photon emission tomography with *p*-[^{123}I]-iodo-L-phenylalanine for routine brain tumor imaging. Samnick S, Hellwig D, Bader JB, Romeike BF, Moringlane JR, Feiden W, Kirsch CM. Nucl Med Commun 2002 Feb; 23 (2), pp. 121–30.

Neoplasia: Brain/Gliomas/Differentiation of High-Grade Tumor vs Radiation Necrosis
[^{201}Tl]/[^{18}F]-2-Fluoro-2-Deoxy-D-Glucose (FDG)

Background Information: Over the last 2 decades the large volume of research involving the development and assessment of various brain tracers has shed invaluable light on the pathophysiology of cerebral neoplasms. Yet the question remains as to how best to incorporate this newly acquired insight into a clinical context.

Application: Methoxy-isobutylisonitrile (MIBI) has been used to detect and characterize postoperative tumor recurrence. [^{18}F]-FDG positron emission tomography (PET) is capable of predicting tumor grade, and the metabolic activity of brain tumors has prognostic significance but limited value in evaluating postoperative tumor recurrence.

Interpretation and Analysis: Many, but not all, studies have shown a relationship between [^{201}Tl] uptake and tumor grade. Due to the overlap between tumor uptake and histologic grades, [^{201}Tl] cannot be used as the sole non-invasive diagnostic or prognostic tool in brain tumor patients. However, it may help to differentiate a high-grade tumor recurrence rate from radiation necrosis. MIBI is theoretically a better imaging agent than [^{201}Tl] but it has not convincingly been shown to differentiate tumors according to grade. MDR-1 gene expression as demonstrated by MIBI does not correlate with chemoresistance in high-grade gliomas. Currently, the clinical role of MIBI in brain tumor imaging has yet to be defined. IMT, a radiolabeled amino acid analog, may be useful for identifying postoperative tumor recurrence and, in this application, appears to be a cheaper, more widely available tool than PET. However, its ability to accurately identify tumor grade is limited. [^{18}F]-FDG PET predicts tumor grade, and the metabolic activity of brain tumors has prognostic significance. Whether FDG uptake has any independent prognostic value that is superior to histology remains debatable. FDG PET is effective in differentiating recurrent tumors from radiation necrosis for high-grade tumors, but has limited value in defining the extent of tumor involvement and recurrence of low-grade lesions. Amino acid tracers, such as MET, perform better for this purpose and thus play a complementary role to FDG. Given the poor prognosis of patients with gliomas, particularly with high-grade lesions, the overall clinical utility of single photon emission computed tomography (SPECT) and PET in characterizing recurrent lesions remains dependent on the availability of effective treatments. These tools are thus mostly suited to the evaluation of treatment response in experimental protocols designed to improve the patients' outcome.

Imaging gliomas with positron emission tomography and single photon emission computed tomography. Benard F, Romsa J, Hustinx R. Semin Nucl Med 2003 Apr; 33 (2), pp. 148–62.

Neoplasia: Brain/Gliomas (Heterogeneous)/Biopsy/ Stereotactic Biopsy: Improve Accuracy of Lesion Localization and Sampling
[^{18}F]-Fluoro-Deoxy-Glucose (FDG)

Cellular/Molecular Mechanism of Action: [^{18}F]-FDG is an analogue of glucose that is perceived (intracellularly assimilated) by cell populations as endogenous glucose.

Background Information: A wide variety of metabolic features of brain tumors can be imaged using positron emission tomography (PET), including glucose metabolism, blood flow, oxygen consumption, amino acid metabolism, and lipid synthesis. Currently, FDG is the most widely available PET tracer for body imaging and brain imaging.
Application: [^{18}F]-FDG has been utilized to detect and characterize certain neoplastic disease states.
Route of Administration: [^{18}F]-FDG is usually non-selectively or selectively administered intravascularly.
Interpretation and Analysis: Malignant brain tumors, like many other soft tissue tumors, show increased glucose metabolism that can be detected by FDG PET imaging. FDG PET imaging of brain tumors provides information on tumor grade and prognosis. Compared with other organ systems, FDG PET imaging of the brain presents unique challenges because of the high background glucose metabolism of normal gray matter structures. Co-registration of the magnetic resonance imaging (MRI) (or or computed tomography [CT]) and FDG PET images is essential for accurate evaluation of brain tumors and is performed routinely at several institutions. The heterogeneous nature of gliomas can result in significant sampling errors when patients are biopsied for primary tumor diagnosis or recurrent disease. FDG PET can be used to define the most metabolically active targets for stereotactic biopsy. This in turn can improve diagnostic accuracy and reduce the number of biopsy samples required. FDG PET is also useful for evaluating residual or recurrent tumor following therapy, and can be used to survey patients with low-grade brain tumors for evidence of degeneration into high-grade malignancy. In the case of suspected tumor recurrence or progression, PET can aid in defining appropriate targets for biopsy. One limitation of FDG PET is the occasional inability to distinguish radiation necrosis from recurrent high-grade tumor. A 2nd limitation is that FDG PET is less sensitive than contrast-enhanced MRI for detecting intracranial metastases, and it has been the experience of some clinicians that brain studies should not be included as part of routine whole-body PET studies. Other tracers, such as [^{11}C]-methionine and [^{18}F]-fluorocholine (FCH), also avidly accumulate in brain tumors and have the advantage of low background cortical activity. The relationship between degree of uptake of these agents and tumor grade has not been thoroughly established. However, these tracers may be useful in specific clinical situations such as tumor localization for treatment planning or evaluation of low-grade tumors.

Positron emission tomography imaging of brain tumors. Wong TZ, van der Westhuizen GJ, Coleman RE. Neuroimaging Clin N Am 2002 Nov; 12 (4), pp. 615–26.

Neoplasia: Brain/Glioma/Mitotic Rate and Proliferation Activity
[^{99m}Technetium] ([^{99m}Tc])-Methoxy-Isobutylisonitrile (MIBI)/Thallium-201 ([^{201}Tl])/MI/MIB Index/Early and Delayed and Retention Ratios/[Antiglioma Ki-67 Antigen IgG Validation]

Background Information: [^{99m}Tc]-MIBI, like [^{201}Tl], is a highly efficient agent for the detection of glioma tumors and monitoring of their growth. Although [^{201}Tl] uptake is known to be partly associated with proliferative activity, little is known about the correlation between MIBI uptake and glioma proliferation activity.
Application: Detection and characterization of central nervous system gliomas, including estimation of proliferative activity.
Implementation: Evaluate the degree of correlation between MIBI uptake and proliferative activities in gliomas. Validation of results can be estimated utilizing staining methods that employ anti-Ki-67 antigen monoclonal antibody(MIB-1). By comparing results with those of [^{201}Tl], it is possible to determine which tracer is suitable for estimating proliferative activities. In this context, affected cases are given MIBI and [^{201}Tl] single photon emission computed tomography (SPECT). Early (10 minutes after injection) and delayed images (3 hours after injection) are then obtained for both MIBI and [^{201}Tl] scintigraphy. Single photon emission computed tomography parameters, early ratio (ER), delayed ratio (DR), and retention index (RI) values are obtained for both radiopharmaceuticals. Immunostaining of lesion samples obtained by surgical excision is then detected with a monoclonal antibody to Ki-67 antigen (MIB-1) staining method in order to facilitate calculation of the MI/MIB index. To evaluate the relationship between the proliferative activity and SPECT parameters, correlation analysis can then be performed.

Human Model: Cases of presurgical glioma (n = 24; n = 6 low-grade gliomas, n = 5 anaplastic astrocytomas, n = 13 glioblastomas). Surgical excision performed in all cases following initial evaluation with both MIBI and [^{201}Tl] scintigraphy.
Interpretation and Analysis: Values for MI correlate with calculated MIBI uptake ratios (r = 0.75 for ER, and r = 0.7 for DR). Both DR and RI for [^{201}Tl] also correlate with MI, but to a lesser degree (r = 0.6 for DR, and r = 0.59 for RI). There appears to be no significant correlation between the MIB-1 index and other parameters. MIBI-uptake parameters demonstrate a stronger positive correlation with the MIB-1 index than that of [^{201}Tl]. With the use of MIBI SPECT, it is possible to estimate the proliferative activity of gliomas non-invasively.

The correlation between ^{99m}Tc-MIBI uptake and MIB-1 as a nuclear proliferation marker in glioma—A comparative study with [^{201}Tl]. Nagamachi S, Jinnouchi S, Nabeshima K, Nishii R, Flores L 2nd, Kodama T, Kawai K, Tamura S, Yokogami K, Samejima T, Wakisaka S. Neuroradiology 2001 Dec; 43 (12), pp. 1023–30.

Neoplasia/Carcinoid and Endocrine Neoplasias/ Foregut Carcinoid/Endocrine Pancreatic Tumors (Functioning and Non-Functioning)/ Adenocorticotropic Hormone (ACTH)-Producing Bronchial Carcinoids (Small Pancreatic and Thorax Lesions)/Liver and Lymph Node Metastases: Increased Detection/Monitoring Treatment Effects/ Reduced Positron Emission Tomography (PET) Renal Artifact
[^{11}C]-5-Hydroxytryptophan (5-HTP)/Carbidopa/ [^{11}C]-Labeled L-dopa/Harmine

Cellular/Molecular Mechanism of Action: 5-hydroxytryptophan is a precursor in the synthesis of serotonin. Carbidopa is an inhibitor of decarboxylase biochemical activity. [^{11}C]-labeled L-dopa is an analogue of L-dopa that can function as a substrate precursor for the production of adrenergic neurotransmitters. Harmine is an inhibitor of monoamineoxidase (MAO-A) biochemical activity.
Background Information: Positron emission tomography performed with various radiolabeled compounds facilitates the study of tumor biochemistry. If the tumor uptake of an administered tracer is greater than that of surrounding normal tissue, it is also possible to localize the tumor. Previous studies utilizing [^{18}F]-labeled deoxyglucose (FDG) have attempted to visualize tumors because this tracer has been successfully used in oncology based on the increased level of glucose metabolism in neoplastic cell populations. However, this tracer has not been found to have any significant degree of uptake by the neuroendocrine tumors.

Pancreatic endocrine tumors (PETs) are rare neoplasms originating from the amine precursor uptake and decarboxylation (APUD) stem cells.

Application: The agent [^{11}C]-labeled 5-HTP can be utilized to detect and characterize primary and metastatic carcinoid neoplastic lesions. Carbidopa can be applied to diminish renal excretion-associated imaging artifacts and improve tumor visualization. Collective application of these agents can also provide valuable information about response to therapeutic intervention. [^{11}C]-labeled L-dopa has been used to characterize functional endocrine pancreatic tumors, while MAO-A inhibitors can be of value in profiling non-functional endocrine pancreatic neoplastic disease states.

Route of Administration: [^{11}C]-labeled 5-HTP (intravascular); carbidopa (peroral premedication).

Implementation: Evaluation of schemes for (i) detection and treatment monitoring of carcinoid tumors, endocrine pancreatic tumors (functional), foregut carcinoids (thoracic and abdominal) with [^{11}C]-labeled 5-HTP and [^{11}C]-labeled L-DOPA; (ii) endocrine pancreatic tumors (non-functional) with MAO-A inhibitors (e.g., harmine); and (iii) urinary artifact reduction (carbidopa).

Interpretation and Analysis: The serotonin precursor [^{11}C]-labeled 5-HTP displays increased uptake and irreversible trapping within carcinoid tumors. The uptake is selective and the resolution is so high that it is possible to detect a greater number of liver and lymph node metastases with PET than with computed tomography (CT) or octreotide scintigraphy. However, high renal excretion of the tracer is a problem because it produces streaky artifacts in the region/area of interest. Premedication with carbidopa decreases renal excretion approximately 6-fold, while at the same time tumor uptake increases 3-fold in a manner that enhances tumor visualization. Monitoring during treatment periods with PET using 5-HTP as a tracer reveals a $>$ 95% correlation between changes in urinary 5-hydroxyindoleacetic acid (U-5-HIAA) and changes in the 5-HTP transport rate. Therefore, PET can be used to monitor treatment effects.

Elevations in U-5-HIAA are considered to be uncommon in endocrine pancreatic tumors (EPTs). In this context, [^{11}C]-labeled L-dopa can be applied due to speculation that it is another amine important in the APUD system. Utilizing L-dopa for such purposes reveals that it is capable of detecting about half of EPTs that are primarily functional tumors. 5-Hydroxytryptophan can potentially be used as a universal tracer in PET whole-body imaging strategies designed to detect and characterize EPTs and foregut carcinoids that can invade both the thorax and abdomen. Utilizing this approach, small lesions can be visualized within the pancreas and thorax (e.g., ACTH-producing bronchial carcinoids) that cannot be detected by other methods (e.g., octreotide scintigraphy, magnetic resonance imaging [MRI], CT).

Several other tracers, like the agent harmine, have demonstrated promising results in characterizing non-functioning pancreatic endocrine tumors. Several laboratories have explored a wide range of biochemical systems, including enzymes and receptors, both for neurotransmitters and for peptides and proteins for *in vitro* assays, with the potential to use some of the developed tracers for *in vivo* visualization and tumor biological studies. Therefore, it appears that PET is a valuable tool in the diagnosis of neuroendocrine tumors. It can detect small lesions in the thorax and abdomen not detected by other methods, which has been of great value preoperatively in several cases. It detects more lesions in the liver and lymph nodes than is possible with other methods and, furthermore, it can be used to monitor treatment effectiveness.

Use of PET in neuroendocrine tumors. *In vivo* applications and *in vitro* studies. Eriksson B, Bergström M, Orlefors H, Sundin A, Oberg K, Längström B. Q J Nucl Med 2000 Mar; 44 (1), pp. 68–76.

Neoplasia/Colon Carcinoma: Carcinoembryonic Antigen Positive
[^{64}Cu]-DOTA-Anti-CEA Minibody/Anticarcinoembryonic Antigen (Anti-CEA)

Cellular/Molecular Mechanism of Action: Anticarcinoembryonic antigen monoclonal antibody possesses binding avidity for carcinoembryonic antigen.

Background Information: Rapid imaging by antitumor antibodies has been limited by the prolonged targeting kinetics and clearance of labeled whole antibodies. Genetically engineered fragments with rapid access and high retention in tumor tissue combined with rapid blood clearance are suitable for labeling with short-lived radionuclides, including positron-emitting isotopes for positron emission tomography (PET).

Route of Administration: Intravenous.

Semi-Synthetic Methods: Engineering of a "minibody" fragment of high-affinity anti-CEA monoclonal antibody (T84.66). The single-chain variable "minibody" fragment, (Fv)-C(H)3, is then converted to a bivalent 80-kDa dimer. The macrocyclic chelating agent 1,4,7,10-tetraazacyclododecane-N,N′,N′′, N′′′-tetraacetic acid (DOTA) can then be conjugated to anti-CEA minibody for labeling with copper-64, a positron-emitting radionuclide ($t_{1/2}$ = 12.7 hours).

Implementation: Determination of the *in vivo* distribution in animal models for neoplastic disease.

Animal Model: Mice (athymic strain bearing paired LS174T human colon carcinoma [CEA positive]) and rats (C6 rat glioma [CEA negative] xenografts).

Interpretation and Analysis: At 5 hours after injection with [^{64}Cu]-DOTA-minibody, micro-PET imaging shows high uptake in CEA-positive tumors (17.9% injected dose per gram [%ID/g] $\pm$ 3.79) compared with control tumors (6.0% %ID/g $\pm$ 1.0). In addition, significant uptake can be seen in the liver, with low uptake in other tissues. Average target/background ratios are 3–4:1 relative to neighboring tissues. Engineered antibody fragments labeled with positron-emitting isotopes such as [^{64}Cu] provide a new class of agents for PET imaging of tumors.

High-resolution micro-PET imaging of carcinoembryonic antigen-positive xenografts by using a copper-64-labeled engineered antibody fragment. Wu AM, Yazaki PJ, Tsai S, Nguyen K, Anderson AL, McCarthy DW, Welch MJ, Shively JE, Williams LE, Raubitschek AA, Wong JY, Toyokuni T, Phelps ME, Gambhir SS. Proc Natl Acad Sci U S A 2000 Jul 18; 97 (15), pp. 8495–500.

Neoplasia/Colorectal Carcinoma/Prediction of Therapeutic Sensitivity
[^{18}F]-5-Fluorouracil (5-FU)

Application: Radiopharmaceutical biodynamic evaluation of 5-FU chemotherapeutic efficacy (antineoplastic properties).

Considerations: The colon 38 carcinoma cell type is 5-FU sensitive in contrast to R1-rhabdomyosarcoma, which is 5-FU resistant.

Semi-Synthetic Methods: Optimized methods for the synthesis of [^{18}F]-labeled 5-FU have been described.

Implementation: Delineation of the relationship between [^{18}F]-5-fluorouracil cellular pharmacodynamics and chemotherapeutic sensitivity to 5-FU chemotherapy in colorectal carcinoma cell types.

Interpretation and Analysis: Instead of initial tumor uptake, chemotherapeutic sensitivity to 5-FU correlates best with carcinoma [^{18}F] efflux out of lesion sites.

An optimized synthesis of [^{18}F]-labeled 5-fluorouracil and a reevaluation of its use as a prognostic agent. Visser GW, Gorree GC, Braakhuis BJ, Herscheid JD. Eur J Nucl Med 1989; 15 (5), pp. 225–9.

Neoplasia/Colorectal Carcinoma/ Pretargeting: Monoclonal Antibody-Mediated/ Human Xenographs (SW1222) in Mice *[^{64}Cu]-DOTA-Biotin/[^{64}Cu]-DOTA-NR-LU-10*

Background Information: Pretargeting involves administration of a tumor-targeting monoclonal antibody (MAb) covalently linked to a molecule having a high-affinity binding site for a rapidly distributed radiolabeled effector/marker molecule.
Application: Pretargeted [^{64}Cu]-DOTA-biotin should afford markedly superior positron emission tomography (PET) imaging contrast and therapeutic efficacy due to its extremely rapid tumor uptake and blood clearance.
Semi-Synthetic Methods: DOTA-biotin (biotinylated 1,4,7,10-tetraazacyclododecane-N,N′,N′′,N′′′-tetraacetic acid) and the intact immunoconjugate DOTA-NR-LU-10 are labeled to high specific activities with [^{64}Cu], and the serum stabilities and target binding capabilities of each agent are then assessed (*in vitro*).
Implementation: Evaluate the relative effectiveness of pretargeting strategies and conventionally labeled antibody for tumor targeting of the intermediate-lived radionuclide [^{64}Cu]. In both PET imaging procedures and radioimmunotherapy protocols, [^{64}Cu] has demonstrated measurable attributes. One approach for characterizing "pretargeting" strategies can involve labeling of DOTA-biotin (DOTA = 1,4,7,10-tetraazacyclododecane-N,N′,N′′,N′′′-tetraacetic acid) and the intact immunoconjugate DOTA-NR-LU-10 with [^{64}Cu] at high specific activities. Efficacy can be evaluated *in vitro* by assessing serum stabilities and target binding capabilities. Evaluation of *in vivo* efficacy can be determined in nude mice bearing SW1222 human colorectal carcinoma xenografts by administering (i) [^{64}Cu]-DOTA-biotin, with and without pretreatment with the MAb-streptavidin conjugate NR-LU-10/SA and the synthetic clearing agent Biotin-GalNAc(16); or injection of (ii) [^{64}Cu]-DOTA-NR-LU-10. Biodistribution profiles for each of the two agents are then obtained from 5 minutes to 48 hours after injection.

Animal Model: Mice (e.g., nude mide bearing SW1222 human colorectal carcinoma xenographs).
Interpretation and Analysis: Both [^{64}Cu]-DOTA-biotin and [^{64}Cu]-DOTA-NR-LU-10 are 100% stable *in vitro* in serum. [^{64}Cu]-DOTA-biotin exhibits a > 98% specific binding for immobilized streptavidin, whereas the immunoreactivity averages nearly 80% for [^{64}Cu]-DOTA-NR-LU-10 preparations. Biodistributions in SW1222-bearing mice show that NR-LU-10/SA-pretargeted [^{64}Cu]-DOTA-biotin attains a peak tumor uptake of 18.9% of the injected dose per gram (%ID/g) at 1 hour, with concomitant rapid disappearance from blood and renal excretion. In the absence of pretargeting, [^{64}Cu]-DOTA-biotin has very similar biodistribution and clearance properties, except with extremely low non-specific tumor uptake. In contrast, [^{64}Cu]-DOTA-NR-LU-10 reaches 80.3 %ID/g in tumor tissue after 48 hours, whereas blood clearance is considerably slower than with pretargeted [^{64}Cu]-DOTA-biotin strategies. Comparison of the time-activity curves for tumor uptake and blood clearance of pretargeted [^{64}Cu] and the [^{64}Cu]-labeled antibody reveal that the maximum tumor accumulations of radioactivity are similar for each agent (e.g., 17.9 percentage injected activity per gram [%IA/g] and 20.7 %IA/g, respectively). However, the tumor-to-blood ratio of areas-under-the-curves is 14 times higher for pretargeted [^{64}Cu]-DOTA-biotin because of the substantial increase in blood clearance of the small effector molecule. The extremely rapid tumor uptake and blood clearance of pretargeted [^{64}Cu]-DOTA-biotin should afford markedly superior PET imaging contrast and therapeutic efficacy, compared with conventionally labeled [^{64}Cu]-DOTA-NR-LU-10. Further comparison of the therapeutic efficacy, toxicity, and dosimetry of these 2 agents is warranted.

In vivo evaluation of pretargeted [^{64}Cu] for tumor imaging and therapy. Lewis MR, Wang M, Axworthy DB, Theodore LJ, Mallet RW, Fritzberg AR, Welch MJ, Anderson CJ. J Nucl Med 2003 Aug; 44 (8), pp. 1284–92.

Neoplasia/Colorectal Cancer: Recurrent/ Carcinoembryonic Antigen/Indications for Laparotomy/Resectable Disease Prediction *2-[^{18}F]-Fluoro-2-Deoxy-D-Glucose (PET)/ [^{99m}Technetium] ([^{99m}Tc])-Labeled Arcitumo Monoclonal Antibody (MAb)/Carcinoembryonic Antigen (CEA) Alternative*

Cellular/Molecular Mechanism of Action: Preferentially binds physically to CEA expressed at relatively higher concentrations on the surface membranes of certain neoplastic cell types. Alternatively, [^{18}F]-FDG functions as a glucose analogue and is assimilated by neoplastic cell types at a higher level than normal cells in part due to biochemical differences in glucose metabolism.
Background Information: An increasing CEA level in the absence of disease on imaging studies can be a diagnostic challenge.
Application: Prediction of cases of colorectal cancer that would likely benefit from a laparotomy.
Route of Administration: Intravenous.
Implementation: Evaluation of 2-[^{18}F]-FDG and positron emission tomography (FDG PET) and CEA scans before 2nd-look laparotomy as a means of localizing recurrent colorectal cancer. Cases undergo computed tomography scan, bone scan, colonoscopy, and magnetic resonance imaging, and those without evidence of disease or resectable disease within the abdomen that are evaluated with FDG PET and CEA scans. At 2nd-look laparotomy, a surgeon blinded to the results of the FDG PET and CEA scans performs an exploration and maps their interpretations. A 2nd surgeon, with knowledge of the FDG PET and CEA scans, then explores the case and all lesions are biopsied or resected for pathology.
Interpretation and Analysis: In cases found to have resectable disease or disease that could be treated with regional therapy (e.g., n = 16), FDG PET scan is capable of accurately predicting the effectiveness of such strategies 81% of the time, in contrast to 13% for CEA scans. FDG PET scans can predict unresectable disease in 90% of patients. CEA scans usually fail to predict unresectable disease. In affected cases explored, disease may be found in 94% (n = 26/28), some of which have unresectable disease (n = 10/26). An FDG PET scan can predict unresectable disease in 90% of cases. A CEA scan fails to predict unresectable disease in the vast majority of cases.

Therefore, FDG PET scan can predict those patients who would likely benefit from a laparotomy. If the FDG PET scan indicates resectable disease, laparotomy can be considered. However, if the findings predict unresectable disease or the absence of disease, the patient should pursue systemic therapy or continued observation.

A prospective study of 2-[^{18}F]-fluoro-2-deoxy-D-glucose/positron emission tomography scan, [^{99m}Tc]-labeled arcitumomab (CEA-scan), and blind 2nd-look laparotomy for detecting colon cancer recurrence in patients with increasing carcinoembryonic antigen levels. Libutti SK, Alexander HR Jr, Choyke P, Bartlett DL, Bacharach SL, Whatley M, Jousse F, Eckelman WC, Kranda K, Neumann RD, Carrasquillo JA. Ann Surg Oncol 2001 Dec; 8 (10), pp. 779–86.

Neoplasia/Colorectal Carcinoma: Recurrent Postresection/Surgical Intervention Decision Making/Nuclear Scan vs Computed Tomography (CT) Scan *[^{111}In]-CYT-103 Monoclonal Antibody (MAb)*

Background Information: Recurrent colorectal cancer is seen in as many as 40% of cases after curative resection. In view of the

limitations of endoscopic and cross-sectional imaging, external immunoscintigraphy has been added to the follow-up regimen in conditions at high risk of recurrent disease.

Application: Detection and characterization of colorectal carcinoma as an aid to deciding the merits of surgical intervention.

Route of Administration: Intravascular.

Considerations: Provocative agents (histamine, glucagon, tyramine) are rarely needed. Preoperative localization of tumor lesions can be done with nephrotomography intravenous pyelogram (IVP), computerized axial tomography, ultrasound, [^{131}I]-19-iodocholesterol scan, arteriography, and venography.

Semi-Synthetic Methods: Labeling of CYT-103 MAb (1.0 mg) with [^{111}In] radioisotope (approximately 4.3 mCi).

Implementation: Evaluation of the utility of immunoscintigraphy in conditions of suspected colorectal carcinoma utilizing MAb (e.g., B72.3 or CYT-103) site-specifically labeled with [^{111}In] conjugate. Planar and single photon emission computed tomography (SPECT) imaging is then performed 2–5 days after infusion of, for example, [^{111}In]-CYT-103 preparations.

Human Model: Cases of suspected recurrences of previous "curative" colorectal carcinoma resections.

Interpretation and Analysis: Local or regional recurrences (4 cases) and liver metastasis (6 cases) may be indicated by physical examination and CT. Alternatively, some cases (e.g., n = 9) may have occult disease with increasing serum carcinoembryonic antigen (CEA) levels and negative conventional workups. Serum CEA levels are elevated (mean, 22 ng/ml) in the vast majority of cases (e.g., 100%). A final diagnosis of recurrence or metastasis can be established in a number of cases by 2nd-look surgery or biopsy (e.g., n = 18). Tumors may potentially be identified at the following locations: pelvis (e.g., n = 12 cases), abdominal wall (e.g., n = 2 cases), retroperitoneum (e.g., n = 1 case), liver (e.g., n = 5 cases), and omentum (e.g., n = 2 cases). Superiority of MAb scans is supported by the capacity to detect pelvic and intra-abdominal recurrences (100%) at a higher success rate than CT scan (43%). Liver metastases are identified equally well by both modalities. [^{111}In]-CYT-103 scan findings may influence the management of approximately 55% of affected cases (e.g., n = 10/18). Surgery may be avoided in conditions with scan-detected disseminated metastases. Correct identification of occult local recurrences can be made in some cases (e.g., n = 6). Isolated liver metastasis may be confirmed in instances of equivocal CT scan results. Finally, additional intra-abdominal lesions may also be detected. Such observations suggest an important and beneficial role for [^{111}In]-CYT-103 MAb imaging in conditions of suspected recurrent colorectal carcinomas, particularly in cases with negative cross-sectional imaging results; such imaging may prevent cases from undergoing unnecessary surgical explorations.

In-111 CYT-103 monoclonal antibody imaging in patients with suspected recurrent colorectal cancer. Doerr RJ, Herrera L, Abdel-Nabi H. Cancer 1993 Jun 15; 71 (12 Suppl), pp. 4241–7.

Neoplasia/Differentiation of High-Grade Tumor vs Radiation Necrosis/Prognostic Predictive Capabilities for Neoplastic Disease/Postoperative Tumor Recurrence

[^{102}Tl]/[^{18}F]-2-Fluoro-2-Deoxy-d-Glucose (FDG)/ Methoxy-Isobutylisonitrile (MIBI)/IMT/MET

Background Information: Over a period of 2 decades, a large volume of research has been devoted to the design and development of various brain tracers that has shed invaluable insight about the pathophysiology of cerebral neoplasms. Yet the question remains as to how best to incorporate this newly acquired knowledge into clinical environments.

Application: MIBI has been used to detect and characterize postoperative tumor recurrence. [^{18}F]-FDG positron emission tomography (PET) is capable of predicting tumor grade, and the metabolic activity of brain tumors has prognostic significance but has limited value in evaluating postoperative tumor recurrence.

Interpretation and Analysis: Many, but not all, studies show a relationship between [^{201}Tl] uptake and tumor grade. Due to the overlap between tumor uptake and histologic grades, [^{201}Tl] cannot be used as the sole non-invasive diagnostic or prognostic tool in brain tumor patients. However, it may help in differentiating high-grade tumor recurrence from radiation necrosis. MIBI is theoretically a better imaging agent than [^{201}Tl] but it has not convincingly been shown to differentiate tumors according to grade. MDR-1 gene expression as demonstrated by MIBI does not correlate with chemoresistance in high-grade gliomas. Currently, MIBI's clinical role in brain tumor imaging has yet to be defined. IMT, a radiolabeled amino acid analog, may be useful for identifying postoperative tumor recurrence and, in this application, appears to be a cheaper, more widely available tool than PET. However, its ability to accurately identify tumor grade is limited. FDG PET predicts tumor grade, and the metabolic activity of brain tumors has a prognostic significance. Whether FDG uptake has an independent prognostic value above that of histology remains debated. FDG PET is effective in differentiating recurrent tumor from radiation necrosis for high-grade tumors but has limited value in defining the extent of tumor involvement and recurrence of low-grade lesions. Amino acid tracers, such as MET, perform better for this purpose and thus play a complementary role to FDG. Given the poor prognosis of patients with gliomas, particularly with high-grade lesions, the overall clinical utility of single photon emission computed tomography (SPECT) and PET in characterizing recurrent lesions remains dependent on the availability of effective treatments. These tools are thus mostly suited to the evaluation of treatment response in experimental protocols designed to improve the patients' outcome.

Imaging gliomas with positron emission tomography and single photon emission computed tomography. Benard F, Romsa J, Hustinx R. Semin Nucl Med 2003 Apr; 33 (2), pp. 148–62.

Neoplasia/Epidermal Growth Factor Receptor Tyrosine Kinase

[^{11}C]-N-Acryl Amides/[^{11}C]-Acryloyl Chloride: Labeling Synthon/[^{11}C]-6-Acrylamido-4-(3,4-Dichloro-6-Fluoroanilino)-Quinazoline

Cellular/Molecular Mechanism of Action: [^{11}C]-acryloyl chloride functions as a labeling synthon for the production of [^{11}C]-N-acryl amides.

Application: Synthetic preparations of [^{11}C]-6-acrylamido-4-(3,4-dichloro-6-fluoroanilino)-quinazoline (ML03) can be used as a biomarker targeting platform in positron emission tomography (PET) imaging studies for the detection of epidermal growth factor receptor tyrosine kinase (EGFr-TK) in certain conditions of neoplastic disease.

Semi-Synthetic Methods: The reagent [^{11}C]-acryloyl chloride can be used in automated formats for the radiosynthesis of [^{11}C]-labeled N-acryl amides (e.g., [^{11}C]-6-acrylamido-4-(3,4-dichloro-6-fluoroanilino)-quinazoline [ML03]) and other anticancer chemotherapeutics.

Interpretation and Analysis: The potency of ML03 to inhibit autophosphorylation of EGFr-TK as evaluated by an ELISA assay indicates a low IC_{50} of 0.037nM.

Radiosynthesis of ML03, a novel positron emission tomography biomarker for targeting epidermal growth factor receptor via the labeling synthon: [^{11}C]-acryloyl chloride. Ben-David I, Rozen Y, Ortu G, Mishani E. Appl Radiat Isot 2003 Feb; 58 (2), pp. 209–17.

Neoplasia/Folate Receptors/Neoplastic Disease
[^{67}Ga]-Folate-DF-Folate-(α)/ [^{67}Ga]-Folate-DF-Folate-(γ)

Cellular/Molecular Mechanism of Action: Folate is used as a carrier targeting molecule for the radioisotopes due to its binding avidity for folate receptors expressed at relatively high concentrations by certain tumor cell types compared to normal cell populations. Deferoxamine (DF) functions as a chelating agent for certain radioisotopes (e.g., [$^{67}Ga^{3+}$]).
Application: Identification of folate receptor-positive neoplastic lesions applying nuclear medicine imaging techniques.
Route of Administration: Intravenous.
Semi-Synthetic Methods: The vitamin folic acid can be covalently linked to the chelating agent DF via an amide bond using a simple carbodiimide coupling reaction. A mixture of 2 isomers, DF-folate-(α) and DF-folate-(γ) can be generated by producing chemical interactions with a carboxyl group at either the α- or γ- position of folic acid, respectively. Isomer separation is feasible applying anion-exchange chromatography and NH_4HCO_3 buffer gradients.
Experimental Interpretation: Competitive binding studies reveal that only the DF-folate-(γ) is recognized by the folate receptor on KB cells and interacts with an affinity comparable to unconjugated folic acid. The DF-folate conjugates can be radiolabeled with the gamma-emitting radionuclide [$^{67}Ga^{3+}$] to test for uptake by cultured KB cells overexpressing the folate receptor.
Interpretation and Analysis: The cellular accumulation of [^{67}Ga]-DF-folate-(γ) tracer exhibits rapid uptake kinetics in cell culture with a $T_{1/2}$ of approximately 3 minutes. The KB cell associated [^{67}Ga]-DF-folate-(γ) radioactivity is competitively blocked by free folic acid, indicating that uptake of the [^{67}Ga]-DF-folate-(γ) is specifically mediated by folate receptors. Because folate receptors are overexpressed on the surfaces of many neoplastic cells, these results suggest that the [^{67}Ga]-DF-folate-(γ) complex might be useful as a diagnostic agent for the non-invasive imaging of folate receptor-positive tumors.
Instrumentation: Computer-integrated nuclear medicine scintigraphy imaging camera.

Preparation of [^{66}Ga]- and [^{68}Ga]-labeled Ga(III)-deferoxamine-folate as potential folate-receptor-targeted PET radiopharmaceuticals. Mathias CJ, Lewis MR, Reichert DE, Laforest R, Sharp TL, Lewis JS, Yang ZF, Waters DJ, Snyder PW, Low PS, Welch MJ, Green MA. Nucl Med Biol 2003 Oct; 30 (7), pp. 725–31.

Neoplasia/Gene Expression/Herpes Simplex Virus Tyrosine Kinase (HSV-tk)
2′-Deoxy-2′-Flouro-5-Methyl-1-β-D-Arabinofuranosyluracil/9-[(3-[^{18}F]-Fluoro-1-Hydroxy-2-Propoxy)Methyl]-Guanine/9-(4-[^{18}F]-Fluoro-3-Hydroxy-Methylbutyl)Guanine

Application: 2′-Deoxy-2′-flouro-5-methyl-1-β-D-arabinofuranosyluracil (FMAU) has demonstrated potential utilization as a positron emission tomography (PET) radiotracer for imaging HSV-TK gene expression.
Interpretation and Analysis: *In vitro* experiments demonstrate that the accumulation of [^{14}C]-FMAU in HSV-tk-expressing cells is 2.4-fold ($p < 0.02$), 4.0-fold ($p < 0.001$), and 5.3-fold ($p < 0.001$) higher than the wild-type cells at 1, 3, and 5 hours, respectively. *In vivo* studies reveal that the tumor uptake in HSV-tk-expressing cells is 2.3-fold ($p < 0.001$), 3.0-fold ($p < 0.001$), and 5.5-fold ($p < 0.001$) higher than control cells at 1, 2, and 5 hours, respectively. FMAU is more sensitive compared to earlier studies using 9-[(3-[^{18}F]-fluoro-1-hydroxy-2-propoxy)methyl]-guanine ([^{18}F]-FHPG) and 9-(4-[^{18}F]-fluoro-3-hydroxy-methylbutyl)guanine ([^{18}F]-FHBG) in the same cell lines, although the specificity is less than FHBG. While FMAU labeled with PET isotopes may be useful for imaging HSV-tk-expressing tumors *in vivo*, multitracer studies across additional tumor models are necessary in order to identify an optimal PET radiotracer.

Evaluation of 2′-deoxy-2′-flouro-5-methyl-1-beta-D-arabinofuranosyluracil as a potential gene imaging agent for HSV-TK expression *in vivo*. Alauddin MM, Shahinian A, Gordon EM, Conti PS. Mol Imaging 2002 Apr–Jun; 1 (2), pp. 74–81.

Neoplasia/Hypoxia with Neoplastic Lesions
N-(2-Hydroxy-3,3,3-Trifluoropropyl)-2-(2-Nitro-l-Imidazolyl) Acetamide/Positron Emission Tomography (PET) and Magnetic Resonance Spectroscopy (MRS) Imaging Modalities

Background Information: Hypoxia occurs to a variable extent in a vast majority of rodent and human solid tumors. It results from an inadequate and disorganized tumor vasculature and hence an impaired oxygen delivery. A probe for the non-invasive detection of tumor hypoxia could find important utility in the selection of patients for therapy with bioreductive agents, antiangiogenic/antivascular therapies, and hypoxia-targeted gene therapy. In addition, tumor hypoxia has been shown to predict treatment outcome following radio- or chemotherapy in human cancers, the underlying mechanism for which may involve hypoxia driving genetic instability and resulting tumor progression. Beyond oncology, utility may also include stroke, ischemic heart disease, peripheral vascular disease, arthritis, and other disorders.
Semi-Synthetic Methods: Relevant design goals include: (i) a nitro group with appropriate redox potential for selective reduction and binding in hypoxic tumor cells; (ii) hydrophilic/hydrogen bonding character in the side chain to limit nervous tissue penetration and prevent neurotoxicity; and (iii) 3 equivalent fluorine atoms to enhance MRS/magnetic resonance imaging (MRI) detection, located in a metabolically stable position.
Implementation: Design, validation, and preclinical development of a fluorinated 2-nitroimidazole, N-(2-hydroxy-3,3,3-trifluoropropyl)-2-(2-nitro-l-imidazolyl) acetamide (SR 4554, CRC 94/17) for the purpose of detecting and measuring tumor hypoxia by MRS. Quantitative MRS can additionally be used to assess the retention of [^{19}F] signal in neoplastic lesions.
Animal Model: Murine (tumor bearing with mouse tumors and human tumor xenographs).
Interpretation and Analysis: Reduction of SR 4554 by mouse liver microsomes is dependent on oxygen content, with a half-maximal inhibition at 0.48 ± 0.06%. Under *in vitro* conditions, SR 4554 undergoes nitroreduction by hypoxic but not oxic tumor cells, and electron energy loss spectroscopic analysis shows selective retention in the hypoxic regions of multicellular tumor spheroids.

Pharmacokinetic analyses reveal that low brain tissue concentrations develop in contrast to excellent tumor levels, as measured by high performance liquid chromatography. The extent of this restricted entry into brain tumor is surprising given the overall octanol/water partition coefficient and can be attributed to the hydrophilic/hydrogen bonding character of the side chain. The [^{19}F] retention index (FRI; ratio of [^{19}F] signal levels at 6 hours relative to that at 45 minutes) range from 0.5 to 1.0 and 0.2 to 0.9 for murine tumors and human xenografts, respectively. The correlation between SR 4554 retention and pO_2 is not linear, but when FRI is > 0.5, the % $pO_2 \leq$ 5 mm Hg is always $> 60\%$, indicating that high FRI is associated

with low levels of oxygenation. Finally, whole-body [^{19}F]-MRI in mice reveals that SR 4554 and related metabolites localize mainly in tumor, liver, and bladder regions. A selective MRS signal is readily detectable in tumors at doses at least 7-fold lower than those likely to cause toxicity in mice.

The agent fluorinated 2-nitroimidazole, N-(2-hydroxy-3,3,3-trifluoropropyl)-2-(2-nitro-l-imidazolyl) acetamide (SR 4554, CRC 94/17) therefore is capable of functioning as a non-invasive MRS/MRI probe for detecting and measuring tumor hypoxia. Potentially, this same molecular probe may have potential application in PET methodologies to facilitate improved detection of tumor hypoxia.

Preclinical development and current status of the fluorinated 2-nitroimidazole hypoxia probe N-(2-hydroxy-3,3,3-trifluoropropyl)-2-(2-nitro-1-imidazolyl) acetamide (SR 4554, CRC 94/17): A non-invasive diagnostic probe for the measurement of tumor hypoxia by magnetic resonance spectroscopy and imaging, and by positron emission tomography. Aboagye EO, Kelson AB, Tracy M, Workman P. Anticancer Drug Des 1998 Sep; 13 (6), pp. 703–30.

Neoplasia: Lymphoma/Hodgkin's Lymphoma and Non-Hodgkin's Lymphoma
Positron Emission Tomography (PET) Imaging

Positron emission tomography has now gained a place in the management of patients with cancer, including those with Hodgkin's disease and non-Hodgkin's lymphoma. Restaging studies and those addressing the monitoring of response to treatment are especially in focus. Most of the knowledge gained has been achieved with dedicated bismuth germinate (BGO)-based PET technology, but there are a number of developments that will impact on the use of this metabolic imaging technique in the investigation of patients with lymphoma. The challenges ahead are determined by the need for high-quality whole-body imaging associated with increased patient throughput and the need to investigate the role of new labeled ligands. The latter are likely to yield new insights into tumor cell characterization, tumor behavior, and tumor outcome assessment. The study of new radiolabeled ligands will impose further demands for rapid dynamic data acquisition and accurate tracer quantification. Current and future developments in PET technology range from the use of new detector materials to different detector geometries and data acquisition modes. The search for alternatives to BGO scintillation materials for PET has led to the development of PET instruments that utilize new crystals such as lutetium orthosilicate (LSO) and gadolinium oxyorthosilicate (GSO). The use of these new detectors and the increased sensitivity achieved with 3D data acquisitions represent the most significant current developments in the field. With the increasing demands imposed on the clinical utilization of PET, issues such as study cost and patient throughput will emerge as significant future factors. As a consequence, low-cost units are being offered by manufacturers through the utilization of gamma camera-based single photon emission computed tomography (SPECT) systems for PET coincidence imaging. Unfortunately, clinical studies in lymphoma and other cancers have already demonstrated the limitations of this technology, with 20% of lesions < 15 mm in size escaping detection. On the other hand, the recent development of combined PET/computed tomography (CT) devices attempts to address the lack of anatomical information inherent with PET images, taking advantage of further improvement in patient throughput and hence cost-effectiveness. Preliminary studies using this multimodality imaging approach have already demonstrated the potential of the technique. Although the potential exists, certain technical issues with PET/CT require refinement of the methodology. Such issues include organ movement (such as respiratory motion), which strongly influences the image fusion of a rapidly acquired CT scan with the slower acquisition of a PET dataset, and the derivation of CT-based attenuation coefficients in the presence of contrast agents or metallic implants. The application of the technology for radiotherapy planning also poses a number of associated challenges. Finally, the development of dedicated PET systems based on planar detector arrangements with new detector components has the potential to improve clinical throughput by over 100%, but clinical trials using such systems still have to be carried out in order to establish the associated whole-body image quality.

Impact of technology on the utilization of positron emission tomography in lymphoma: Current and future perspectives. Visvikis D, Ell PJ. Eur J Nucl Med Mol Imaging 2003 Jun; 30 Suppl 1, pp. S106–16. Epub 2003 May 13.

Neoplasia: Lymphoma/Hodgkin's Lymphoma/ Non-Hodgkin's Lymphoma (NHL)/Benign Fibrotic or Necrotic Tissue Differentiation/Prognosis (Morbidity/Mortality)
[^{18}F]-Fluoro-Deoxy-Glucose (FDG)/[^{67}Ga]Gallium

Background Information: Until recently, gallium-67 scintigraphy (GS) has been the best available functional imaging modality for evaluating patients with NHL and Hodgkin's disease (HD).
Application: Fluorine-18 FDG positron emission tomography (PET) and gallium-67 scintigraphy can be used to detect and characterize Hodgkin's lymphoma and NHL.
Implementation: As [^{67}Ga] is a tumor viability agent, the role of gallium-67 scintigraphy is primarily as a complementary follow-up diagnostic procedure.
Interpretation and Analysis: The diagnostic accuracy of gallium-67 scintigraphy in detecting lymphoma is based on optimization of the imaging protocol, knowledge of potential physiological and benign sites of [^{67}Ga] uptake, and the Ga avidity characteristics of individual lymphoma types. A residual mass persisting on CT after treatment poses a common clinical dilemma: It may indicate the presence of viable lymphoma, which requires further treatment, or it can be benign, consisting of only fibrotic and necrotic tissues. Gallium-67 scintigraphy can successfully differentiate between these conditions. Routine follow-up with gallium-67 scintigraphy may allow early diagnosis of recurrence and early institution of treatment. Reversion of a positive gallium-67 scintigraphy to a negative test, and the rapidity with which this occurs, has a high predictive value for prognosis (morbidity/mortality). Lymphoma lesions that appear normal on gallium-67 scintigraphy early during treatment have a better prognosis than lymphoma with persistence of pathological findings. Other tumor-seeking single photon emitting agents, such as thallium-201, technetium-99m methoxy-isobutylisonitrile (MIBI), and indium-111 octreotide, have been investigated in lymphoma, primarily as an alternative to gallium-67 scintigraphy in specific clinical settings, but are of limited value. The role of radioimmunoscintigraphy is gaining importance in conjunction with radioimmunotherapy. Fluorine-18 FDG imaging of lymphoma using either dedicated or camera-based PET systems is gradually replacing gallium-67 scintigraphy for assessment of lymphoma. Fluoro-deoxy-glucose overcomes some of the limitations of gallium-67 scintigraphy, while sharing its tumor viability characteristics. The extensive clinical knowledge and experience accumulated over 3 decades with gallium-67 scintigraphy in lymphoma provides a solid background as well as a model for the assessment of new functional imaging techniques.

Gallium-67 scintigraphy: A cornerstone in functional imaging of lymphoma. Even-Sapir E, Israel O. Eur J Nucl Med Mol Imaging 2003 Jun; 30 Suppl 1, pp. S65–81. Epub 2003 Mar 18.

Neoplasia/Mammary Carcinoma/Estrogen Receptor Expression
[^{123}I]-Labeled Estradiol Derivatives

Background Information: Radiolabeled estrogen receptor ligands are tracers that can be used for functional receptor characterization. Their specificity towards receptors, together with the fact that only 50–70% of mammary carcinomas are receptor-positive, renders them unsuitable for detection of primary tumors or metastases, and this means that estrogen receptor scintigraphy can be used neither for tumor screening nor for staging. However, both [^{18}F]-labeled and [^{123}I]-labeled estradiol derivatives are suitable for *in vivo* imaging of estrogen receptors.
Application: Detection and characterization of mammary carcinoma lesions that express estrogen receptor complexes.
Route of Administration: [^{123}I]-labeled estradiol derivatives (intravascular).
Interpretation and Analysis: The high specificity of both [^{18}F]-labeled and [^{123}I]-labeled estradiol derivatives *in vivo* in animal experiments and related *in vitro* studies has been reproduced *in vivo* in humans. Tracers with positron radiation emitters are, however, hardly suitable for broad application, owing to the short half-life of [^{18}F], which means that users need to be situated close to a cyclotron and a correspondingly equipped radiochemical laboratory. The number of available positron emission tomography (PET) scanners, on the other hand, has increased over the last few years, especially in Germany, so that this, at least, does not present a limiting factor. All the same, [^{123}I]-labeled estradiol derivatives will find more widespread application because the number of gamma cameras incorporating modern multihead systems is several times greater. The results of studies with [^{123}I]-E2-scintigraphy published to date are very promising, even given the initial technical problems just mentioned. As a method of examination, it could be enhanced by using improved tracers with a higher tumor contrast and less disturbance from overlapping in diagnostically relevant locations, for instance, by selecting tracers with higher activities whose excretion is more renal than hepatobiliary. The use of modern multihead camera systems can also be expected to improve the photon yield.

Estrogen receptor scintigraphy. Scheidhauer K, Scharl A, Schicha H. Q J Nucl Med 1998 Mar; 42 (1), pp. 26–32.

Neoplasia/Mammary Carcinoma
N-(N-Benzylpiperidin-4-yl)-2-[^{18}F]-Fluorobenzamide

Cellular/Molecular Mechanism of Action: The molecular agent *N*-(*N*-benzylpiperidin-4-yl)-2-[^{18}F]-fluorobenzamide is selectively assimilated by human mammary carcinoma cell types.
Background Information: *N*-(*N*-benzylpiperidin-4-yl)-2-[^{18}F]-fluorobenzamide, functioning as a ligand for positron emission tomography (PET) imaging of sigma-receptor complexes, has been found to potentially serve as an agent for breast cancer detection.
Application: Detection and characterization of human mammary carcinoma.
Route of Administration: *N*-(*N*-benzylpiperidin-4-yl)-2-[^{18}F]-fluorobenzamide.
Implementation: Detection of mammary carcinoma neoplastic lesions *in vivo* applying PET imaging modalities.

Animal Model: Mice (severe combined immunodeficient [SCID] mice bearing MDA-MB231 tumor and "wild-type" explants of human mammary carcinoma).
Interpretation and Analysis: *In vivo* studies in SCID mice bearing MDA-MB231 tumors reveal (i) a high uptake of compound 2 in neoplastic lesions (3.8%/g); and (ii) ratios of tumor/muscle and tumor/blood of approximately 6.2 and 7.0, respectively, at 1 hour postinjection. Pretreatment of SCID mice with haldol increases the uptake of compound 2 in blood, muscle, and other well-perfused organs, while decreasing its uptake by tumors. The ratios of tumor/muscle and tumor/blood decreases from 6.2 and 7.0 to 1.3 and 1.1, respectively, at 1 hour postinjection. At 2 hours postinjection, the ratios of tumor/muscle and tumor/blood decrease from 4.9 and 7.8 to 1.4 and 1.4, respectively. The tumor uptake of compound 2 in SCID mice bearing primary tumor explants from human cases of breast cancer can be lower than observed with MDA-MB231 tumors (1.66%/g vs 3.78%/g), and the ratios of tumor/muscle and tumor/blood are 3.5 and 3.7, respectively, at 1 hour postinjection. These results suggest that compound 2 may be a potential ligand for PET imaging of breast cancer.

N-(*N*-Benzylpiperidin-4-yl)-2-[^{18}F]-fluorobenzamide: A potential ligand for PET imaging of breast cancer. Shiue C, Shiue GG, Benard F, Visonneau S, Santoli D, Alavi AA. Nucl Med Biol 2000 Nov; 27 (8), pp. 763–7.

Neoplasia/Mammary Carcinoma/ O(6)-Alkylguanine-DNA Alkyltransferase (AGT)
[^{11}C]-p-O(6)[(Methoxymethyl)Benzyl]Guanines/ [^{11}C]-m-O(6)[(Methoxymethyl)Benzyl]Guanines/ [^{11}C]-o-O(6)[(Methoxymethyl)Benzyl]Guanines

Application: Evaluation of the DNA repair protein AGT expression in conditions of mammary carcinoma applying positron emission tomography (PET) imaging modalities.
Semi-Synthetic Methods: Preparation and radiolabeling of O(6)-benzylguanine derivatives 6-O-[^{11}C]-[(methoxymethyl)benzyl] guanines [^{11}C]-*p*-O(6)-MMBG; [^{11}C]-*m*-O(6)-MMBG, 1b; and [^{11}C]-*o*-O(6)-MMBG, 1c.

Synthesis and preliminary biological evaluation of 6-O-[^{11}C]-[(methoxymethyl)benzyl]guanines, new potential PET breast cancer imaging agents for the DNA repair protein AGT. Liu X, Zheng QH, Fei X, Wang JQ, Ohannesian DW, Erickson LC, Stone KL, Hutchins GD. Bioorg Med Chem Lett 2003 Feb 24; 13 (4), pp. 641–4.

Neoplasia/Mammary Gland Disease Differentiation
Gadolinium/Indocyanine Green (ICG)/Near-Infrared Diffuse Optical Tomography (DOT)

Cellular/Molecular Mechanism of Action: Indocyanine green can function as an albumin-bound absorbing dye within the intravascular compartment.
Application: Indocyanine green is an absorbing dye commonly used as a marker system within the plasma compartment. Under certain conditions, ICG possesses the potential to differentiate disease based on the quantified enhancement of suspicious lesions using magnetic resonance imaging (MRI) concurrently with near-infrared DOT (contrast enhancement properties).
Route of Administration: Intravascular.
Implementation: Near-infrared DOT analysis of the mammary gland applied in combination or concurrently with an MRI. Results are then correlated with histopathological evaluation of suspicious lesions.

Human Model: Cases scheduled for excisional biopsy or surgery.
Interpretation and Analysis: The ICG-enhanced optical images co-register accurately with gadolinium-enhanced magnetic resonance images, thereby validating the ability of DOT to image breast tissue. In contrast to simple transillumination, DOT appears to provide for localization and quantification of exogenous tissue chro-

mophore concentrations. Additionally, ICG has demonstrated a potential to differentiate disease based on the quantified enhancement of suspicious lesions.

Concurrent MRI and diffuse optical tomography of breast after indocyanine green enhancement. Ntziachristos V, Yodh AG, Schnall M, Chance B. Proc Natl Acad Sci U S A 2000 Mar 14; 97 (6), pp. 2767–72.

Neoplasia/Mediastinal Tumors: Primary/ Differentiation of Malignant and Benign/Thymic Carcinoma/Thymoma Invasiveness/Malignant Potential of 1° Mediastinal Masses
[^{18}F]-2-Fluoro-2-Deoxy-D-Glucose (FDG)

Cellular/Molecular Mechanism of Action: Preferential uptake of [^{18}F]-FDG by neoplastic tissues related to the elevated level of glucose metabolism observed in cancer cell types relative to normal cells.
Application: Preoperative detection of malignant primary mediastinal tumors applying positron emission tomography (PET). The mean FDG uptake for malignant tumors is significantly higher than that observed for benign tumors. Both thymic cancer and invasive thymoma show high FDG uptake.
Route of Administration: Intravenous.
Considerations: Malignant neoplastic cell types that preferentially assimilate FDG include thymic carcinoma, lymphomas, invasive thymomas, and certain cases of sarcoidosis. Moderate levels of FDG uptake can be appreciated in cases of myeloma, non-invasive thymomas, and schwannoma, whereas a low uptake of FDG is observed in teratoma and various types of benign cysts.
Interpretation and Analysis: Preferential sequestration of FDG within neoplastic lesions can be detected by positron emission tomography. False-positive and false-negative images can be observed utilizing PET, which can be lower than noted with computed tomography (CT) examinations when attempting to predict tumor invasion. Therefore, the use of FDG with PET is clinically helpful in evaluating the malignant nature of primary mediastinal tumors. Investigations have demonstrated that a high level of FDG uptake reflects the invasiveness of the malignant nature of thymic tumors.
Instrumentation: Computer-integrated PET instrumentation.

PET imaging of primary mediastinal tumours. Kubota K; Yamada S; Kondo T; Yamada K; Fukuda H; Fujiwara T; Ito M; Ido T. Br J Cancer] 1996 Apr; Vol. 73 (7), pp. 882–6.

Neoplasia/Mitosis and Proliferation Rate
3′-Deoxy-3′-[^{18}F]-Fluorothymidine ([^{18}F]-FLT)

Cellular/Molecular Mechanism of Action: Thymidine is rapidly assimilated by proliferating cell populations (e.g., incorporated into nucleic acids).
Application: 3′-Deoxy-3′-[^{18}F]-fluorothymidine has been designed as a new positron emission tomography (PET) imaging agent for *in vivo* visualizing of cellular proliferation based on the incorporation of thymidine into nucleic acid.
Route of Administration: Variable but most often intravascular.
Semi-Synthetic Methods: A reliable radiosynthesis of [^{18}F]-FLT has been developed based on [^{18}F]10 mCi (370 MBq) of radiochemically pure [^{18}F] 1 Ci/μmol (37 GBq/μmol) at end of synthesis (EOS) within 100 minutes and in 13% radiochemical yield (end of bombardment [EOB]; 7% EOS).
Implementation: Evaluation of neoplastic lesions that display relatively rapid rates of proliferation/growth.
Interpretation and Analysis: Detection of increased radioactivity at a specific anatomical location corresponds to an anatomical region that has a relatively high rate of cellular proliferation.

Radiosynthesis of 3′-deoxy-3′-[^{18}F]-fluorothymidine: [^{18}F]-FLT for imaging of cellular proliferation *in vivo*. Grierson JR, Shields AF. Nucl Med Biol 2000 Feb; 27 (2), pp. 143–56.

Neoplasia/Mitosis and Proliferation Rate
2′-Deoxy-2′-[^{18}F]-Fluoro-β-D-Arabinofuranosyl/ [^{18}F]-FAU, [^{18}F]-FMAU, [^{18}F]-FBAU, [^{18}F]-FIAU

Semi-Synthetic Methods: Efficient and reliable synthesis of 2′-deoxy-2′-[^{18}F]-fluoro-β-D-arabinofuranosyl nucleosides.
Interpretation and Analysis: Overall decay-corrected radiochemical yields of 35 to 45% of 4 analogs, FAU, FMAU, FBAU, and FIAU, are routinely obtained in $>$ 98% radiochemical purity and with specific activities of greater than 3 Ci/μmol (110 MBq/μmol) in a synthesis time frame of approximately 3 hours. When approximately 220 mCi (8.15 GBq) of starting [^{18}F]-fluoride is used, 25–30 mCi (0.93–1.11 GBq) of product (enough to image 2 patients sequentially) is typically obtained.

Synthesis of 2′-deoxy-2′-[^{18}F]-fluoro-β-D-arabinofuranosyl nucleosides, [^{18}F]-FAU, [^{18}F]-FMAU, [^{18}F]-FBAU, and [^{18}F]-FIAU, as potential PET agents for imaging cellular proliferation. Synthesis of [^{18}F]-labeled FAU, FMAU, FBAU, FIAU. Mangner TJ, Klecker RW, Anderson L, Shields AF. Nucl Med Biol 2003 Apr; 30 (3), pp. 215–24.

Neoplasia/Mitosis and Proliferation Rate
3′-Deoxy-3′-[^{18}F]-Fluorothymidine ([^{18}F]-FLT)

Cellular/Molecular Mechanism of Action: [^{18}F]-FLT is a nucleoside analogue that enters cells and is phosphorylated by human thymidine kinase 1, but the 3′ substitution prevents further incorporation into DNA.
Application: [^{18}F]-FLT is a positron emission tomography (PET) imaging agent that shows promise for studying cellular proliferation in human cancers.
Implementation: Estimations of radiation dosimetry for [^{18}F]-FLT can be calculated based on data for time-dependent tissue concentrations of radioactivity for blood samples and PET images (e.g., n = 18 cases) after intravenous injection. Radiation-absorbed doses are calculated using the Medical Internal Radiation Dose (MIRD) Committee methods, taking into account variations that are based on the distribution of activities observed in individual cases. Effective dose equivalent (EDE) is calculated using International Commission on Radiological Protection Publication 60 tissue-weighting factors for the standard man and woman.
Interpretation and Analysis: For a single bladder voiding at 6 hours after [^{18}F]-FLT injection, the [^{18}F]-FLT EDE (mean ± standard deviation) is 0.028 ± 0.012 mSv/MBq (103 ± 43 mrem/mCi) for a standard male patient and 0.033 ± 0.012 mSv/MBq (121 ± 43 mrem/mCi) for a standard female patient. The organ that receives the highest dose is the bladder (male, 0.179 mGy/MBq [662 mrad/mCi]; female, 0.174 mGy/MBq [646 mrad/mCi]), followed by the liver (male, 0.045 mGy/MBq [167 mrad/mCi]; female, 0.064 mGy/MBq [238 mrad/mCi]), the kidneys (male, 0.035 mGy/MBq [131 mrad/mCi]; female, 0.042 mGy/MBq [155 mrad/mCi]), and the bone marrow (male, 0.024 mGy/MBq [89 mrad/mCi]; female, 0.033 mGy/MBq [122 mrad/mCi]).

Organ dose estimates for [^{18}F]-FLT are comparable to those associated with other commonly performed nuclear medicine tests, and the potential radiation risks associated with [^{18}F]-FLT PET imaging are within accepted limits.

[^{18}F]-fluorothymidine radiation dosimetry in human PET imaging studies. Vesselle H, Grierson J, Peterson LM, Muzi M, Mankoff DA, Krohn KA. J Nucl Med 2003 Sep; 44 (9), pp. 1482–8.

Neoplasia/Mitosis and Proliferation Rate
[^{18}F]-FAU/[^{18}F] 1-(2′-Deoxy-2′-Fluoro-β-D-Arabinofuranosyl)Uracil

Cellular/Molecular Mechanism of Action: The agent FAU or [1-(2′-deoxy-2′-fluoro-beta-D-arabinofuranosyl)uracil] is incorporated into strands of DNA as a "false" or "decoy" nucleotide and functions as an inhibitor of DNA synthesis.
Physiological Mechanism of Action: Functions as an inhibitor of DNA synthesis, thereby inhibiting the synthesis of viable messenger RNA (mRNA) (transcription) or biologically functional protein fractions (translation).
Application: Radiofluorination of FAU to produce [^{18}F]-FAU or [^{18}F] 1-(2′-deoxy-2′-fluoro-beta-D-arabinofuranosyl)uracil is suitable as a diagnostic radiopharmaceutical for positron emission tomography (PET) imaging procedures.
Route of Administration: [^{18}F]-FAU.
Implementation: Determination of the pharmacokinetic and relative organ/tissue distribution of [^{18}F]-FAU following injection of the tracer through the combined application of PET imaging (duration = ≥ 4 hours) and high-performance liquid chromatography (HPLC) analysis of collected blood, urine, and tissues/organs.
Animal Model: Canine (e.g., n = 3 normal dogs).
Interpretation and Analysis: In an *in vivo* environment, [^{18}F]-FAU is evenly distributed throughout most of organ systems and tissues. In sharp contrast to thymidine and its analogs, the marrow has less retention of [^{18}F]-FAU than non-proliferating tissues.

Imaging [^{18}F]-FAU [1-(2′-deoxy-2′-fluoro-beta-D-arabinofuranosyl) uracil] in dogs. Sun H, Collins JM, Mangner TJ, Muzik O, Shields AF. Nucl Med Biol 2003 Jan; 30 (1), pp. 25–30.

Neoplasia/Neuroendocrine Neoplasias: Catecholamine-Secreting/Neuroblastoma/ Pheochromocytoma
[^{131}I]-Metaiodobenzylguanidine (MIBG)/[^{123}I]-MIBG

Cellular/Molecular Mechanism of Action: Metaiodobenzylguanidine is classified as a norepinephrine analog.
Application: Metaiodobenzylguanidine has been in clinical use for 15 years and has been shown to have high sensitivity (about 85%) and specificity (> 95%) for the location of all types of pheochromocytomas. Similar levels of success have been observed with the diagnostic detection of neuroblastoma. Other neuroendocrine lesions have been imaged at lower levels of sensitivity, including carcinoids, medullary thyroid cancer, and non-secretory paragangliomas.
Interpretation and Analysis: Alternative analogs of radiolabeled somatostatin may have greater utility for improved detection of neuroendocrine lesions, including carcinoids, medullary thyroid cancer, and non-secretory paragangliomas. Metaiodobenzylguanidine scintigraphy may also provide a different *in vivo* diagnostic approach for evaluating the sympathetic autonomic nervous system, particularly with respect to cardiac function.
Instrumentation: Various radiolabels for MIBG and its analogs permit planar scintigraphy, single photon emission computed tomography (SPECT), positron emission tomography (PET), intraoperative probe localization, and radiopharmaceutical therapy.

The current status of metaiodobenzylguanidine and related agents for the diagnosis of neuroendocrine tumors. Shapiro B, Sisson JC, Shulkin BL, Gross MD, Zempel S. Quart J Nucl Med 1995 Dec; 39 (4 Suppl 1), pp. 3–8.

Neoplasia/Otolaryngological Conditions/ Thyrotoxicosis and Solitary Thyroid Nodules/ Thyrotoxicosis/Solitary Thyroid Nodules/ Parathyroid Adenoma/Salivary and Lachrymal Gland/Bone
[^{99m}TcO^{-4}]/[^{123}I]/[^{99m}TcO^{-4}]/[^{201}T1]/[^{99m}TcO^{-4}]/ [^{99m}TcO^{-4}]-MDP

Background Information: Nuclear medicine has a distinct role to play in otolaryngological practice. Accurate diagnosis of endocrine conditions is now possible using precise *in vitro* hormone measurements. Specific clinical questions can be answered using *in vivo* investigations. [^{99m}TcO^{-4}]/[^{123}I] scintigraphy is used to evaluate thyrotoxicosis and solitary thyroid nodules. [^{99m}TcO^{-4}]/[^{201}T1] subtraction scanning is of value in the preoperative localization of parathyroid adenomas, and [^{99m}TcO^{-4}] is particularly useful in assessing salivary and lachrymal gland function and drainage. [^{99m}TcO^{-4}]-MDP bone scanning is useful in the evaluation of osteomyelitis, temporomandibular joint dysfunction, bone graft viability, and some facial fractures. The role of radioisotopes in the management of differentiated and medullary carcinoma of the thyroid is now well established.
Application: Detection of thyrotoxicosis and solitary thyroid nodules by scintigraphic imaging.
Interpretation and Analysis: Although there are many other agents available to image head and neck cancer, few can actually achieve the required diagnostic sensitivity and specificity. The introduction of monoclonal antibodies into routine imaging has been hampered by distinct practical problems and the search is now on for more sensitive non-specific diagnostic agents. It is now possible to evaluate new [^{99m}Tc]-labeled tumor-imaging agents using animal tumor model systems, and the use of radioactivity in all aspects of otolaryngological research adds an extra quantitative dimension. Together with single photon emission computed tomography (SPECT), and the introduction of positron emission tomography (PET) to image the physiology of normal tissues and tumors, the use of radionuclide investigations can lead only to an increase in ear, nose, and throat (ENT) diagnostic sensitivity and specificity and, subsequently, to an overall improvement in the diagnosis, staging, and treatment of cancer affecting the head and neck.

Nuclear medicine in otolaryngology. Watkinson JC. Clin Otolaryngol 1990 Oct; 15 (5), pp. 457–69.

Neoplasia/Parathyroid Adenoma
[^{99m}Technetium] ([^{99m}Tc])/ [^{201}T1] Subtraction Scanning

Application: Preoperative localization of parathyroid adenomas by scintographic imaging.
Considerations: Although there are many other agents available to image head and neck cancer, few can actually achieve the required diagnostic sensitivity and specificity. The introduction of monoclonal antibodies into routine imaging has been hampered by distinct practical problems and the search is now on for more sensitive non-specific diagnostic agents. It is now possible to evaluate new [^{99m}Tc]-labeled tumor-imaging agents using animal tumor models, and the use of radioactivity in all aspects of otolaryngological research adds an extra quantitative dimension.

Together with single photon emission computed tomography (SPECT) and the introduction of positron emission tomography (PET) to image the physiology of normal tissues and tumors, the use of radionuclide investigations can lead only to an increase in ear, nose, and throat (ENT) diagnostic sensitivity and specificity and,

subsequently, to an overall improvement in the diagnosis, staging, and treatment of cancer involving the head and neck.

Nuclear medicine in otolaryngology. Watkinson JC. Clin Otolaryngol 1990 Oct; 15 (5), pp. 457–69.

Neoplasia/Parathyroid Adenoma/Thyroid Nodules/ Improved Accuracy of Surgical Resection *[^{99m}Technetium] ([^{99m}Tc]) SestaMIBI/[^{123}I]/ Subtraction Scanning*

Cellular/Molecular Mechanism of Action: The isotope [^{123}I] is assimilated by the thyroid gland in a manner consistent with nonradioactive iodine.

Application: Parathyroid scanning, based on simultaneous recording of technetium [^{99m}Tc]-sestaMIBI and ^{123}iodine images, is able to identify patients with multiple parathyroid gland disease and is a safe imaging technique for unilateral parathyroid surgery. [^{99m}Tc]-SestaMIBI or [^{99m}Tc]-MIBI or [^{99m}Tc]-tetrofosmin are primarily only applied for detecting certain neuroendocrine tumors (NETs) such as medullary thyroid cancer.

Implementation: Evaluation of scintigraphic criteria to determine eligibility for unilateral surgery with findings compared to observations noted with conventional bilateral surgery. In this context, dual-isotope scanning is performed before performing conventional surgery.

Human Model: Seventy consecutive referral cases with primary hyperparathyroidism.

Interpretation and Analysis: A large number of cases (e.g., n = 41/70) may have scan findings compatible with unilateral surgery, with a single focus of high intensity seen on the anterior and lateral views. A smaller but substantial number of residual cases (e.g., n = 29/70) may have one or more criteria of ineligibility including (i) scan findings pointing to multiple gland disease; (ii) no well-identified focus; (iii) contralateral thyroid nodule requiring surgical management; or (iv) family history of hyperparathyroidism or multiple endocrine disease.

In the assessment of the number of enlarged parathyroid glands at surgical inspection and calcemia follow-up, a very low percentage of cases with a single well-defined focus on the scan image show evidence of multiple parathyroid involvement (e.g., n = 0/41 or 0%). Each parathyroid adenoma can usually be resected from the precise site predicted by subtraction scans. Approximately 13% of cases (e.g., n = 9/41) may have surgical findings of multiple parathyroid gland disease (ineligible for inclusion based on preoperative image findings). Unilateral surgery therefore can be safely offered to 60% of patients with primary hyperparathyroidism, on the basis of simultaneous [^{99m}Tc]-sestaMIBI and [^{123}I] scanning. Such diagnostic practices can reduce the duration of surgical procedures, anesthetic dose delivered, hospital stay, and the risks of hypoparathyroidism and injury to the recurrent laryngeal nerve.

Unilateral surgery for primary hyperparathyroidism on the basis of technetium-99m sestaMIBI and iodine-123 subtraction scanning. Hindié E, Mellière D, Jeanguillaume C, Ure$n$a P, deLabriolle-Vaylet C, Perlemuter L. Arch Surg 2000 Dec; 135 (12), pp. 1461–8.

Neoplasia/Pharmacokinetics and Tumor Uptake/ Temozolomide/Glioma *[^{11}C]-Temozolomide/Dual Radiolabeled at 3-N-Methyl and 4-Carbonyl*

Background Information: Previous reports have postulated that temozolomide undergoes decarboxylation and ring opening at the position 3-4 to produce the highly reactive methyldiazonium ion that alkylates DNA.

Application: Detection and characterization of neoplastic disease states.

Considerations: Dual radiolabeling of [^{11}C]-temozolomide in the 3-*N*-methyl and 4-carbonyl positions can be performed to delineate if temozolomide undergoes decarboxylation and ring opening in the 3-4 position to produce the highly reactive methyldiazonium ion that alkylates DNA. Characterization of such processes can facilitate determination if the [^{11}C] in the C-4 position of [4-[^{11}C]-carbonyl]-temozolomide is converted to [^{11}C]CO_2, which would result in lower accumulation of [^{11}C]-temozolomide within neoplastic lesions.

Semi-Synthetic Methods: Dual radiolabeling strategy involving separate radiolabeling of [^{11}C]-temozolomide in the 3-*N*-methyl and 4-carbonyl positions.

Implementation: Quantitate and confirm the mechanism of *in vivo* metabolic activation of temozolomide in addition to evaluation of tumor lesions, normal tissue, and plasma pharmacokinetics of temozolomide, and establish to what extent pharmacokinetics influence tumor targeting. Dual radiolabeled [^{11}C]-temozolomide at the 3-*N*-methyl or 4-carbonyl position is administered systemically to generate corresponding pharmacokinetic profiles (e.g., men) using positron emission tomography (PET). Paired studies are performed with both forms of [^{11}C]-temozolomide in glioma conditions. Another PET scan with [^{11}C]-radiolabeled bicarbonate can be performed and used to account for metabolites of temozolomide using a detailed analytical approach. Plasma is analyzed for [^{11}C]-temozolomide and [^{11}C] metabolites throughout the scan duration. Exhaled air can also be sampled throughout the scan for [^{11}C]CO_2 content. The percentage of temozolomide ring opening over 90 minutes can subsequently be calculated to evaluate whether there is a differential in metabolic breakdown among plasma, normal tissue, and tumor.

Human Model: Cases of glioma (n = 6).

Interpretation and Analysis: Both radiolabeled forms of [^{11}C]-temozolomide display a rapid systemic clearance over a 90-minute period (0.2 liter/min/m^2), with [^{11}C]CO_2 being the primary elimination product. Plasma [^{11}C]CO_2 is present in all of the studies with [4-[^{11}C]-carbonyl]-temozolomide and in half the studies with [3-*N*-[^{11}C]-methyl]-temozolomide. The mean contributions to total plasma activity by [^{11}C]CO_2 at 10 and 90 minutes are 12% and 28% with [4-[^{11}C]-carbonyl]-temozolomide, and 1% and 4% with [3-N-[^{11}C]-methyl]-temozolomide, respectively. There is a 5-fold increase in exhaled [^{11}C]CO_2 sampled with [4-[^{11}C]-carbonyl]-temozolomide compared with [3-*N*-[^{11}C]-methyl]-temozolomide ($p < 0.05$). A decrease in tissue exposure [area-under-the-curve between 0 and 90 minutes (AUC(0–90 minutes))] to [^{11}C]-temozolomide is also observed with [4-[^{11}C]-carbonyl]- temozolomide compared with [3-*N*-[^{11}C]-methyl]-temozolomide. A potential therapeutic advantage is the higher [^{11}C]-radiotracer and [^{11}C]-temozolomide exposure (AUC(0–90 minutes)) in tumors compared with normal tissue. [^{11}C]-temozolomide ring opening over 90 minutes is less in plasma (20.9%; $p < 0.05$) compared with tumor (26.8%), gray matter (29.7%), and white matter (30.1%), with no differences ($p > 0.05$) between tumor and normal tissues. The significantly higher amounts of [^{11}C]CO_2 sampled in plasma and exhaled air, in addition to the lower normal tissue and tumor [^{11}C]-temozolomide AUC(0–90 minutes) observed with [4-[^{11}C]-carbonyl]-temozolomide, suggest that [^{11}C] in the C-4 position of [4-[^{11}C]-carbonyl]-temozolomide is converted to [^{11}C]CO_2, resulting in lower [^{11}C]-temozolomide tumor exposure. The higher tumor [^{11}C]-temozolomide AUC(0–90 minutes) in tumors compared with normal tissue and the tissue-directed metabolic activation of temozolomide may confer potential therapeutic advantage in the activity of this agent.

Metabolic activation of temozolomide measured *in vivo* using positron emission tomography. Saleem A, Brown GD, Brady F, Aboagye EO, Osman S, Luthra SK, Ranicar AS, Brock CS, Stevens MF, Newlands E, Jones T, Price P. Cancer Res 2003 May 15; 63 (10), pp. 2409–15.

Neoplasia/Pharmacokinetics: Chemotherapeutics/ Receptor Expression/Metabolism of Neoplastic Cells/ Signal Transduction/Proliferation Cycle Characteristics/Cell Death/Resistance to Chemotherapy/Angiogenesis: Neoplastic Cell Blood Supply

Radiolabeled 5-Fluorouracil (5-FU)/Radiolabeled Temozolomide/Radiolabeled N-[2-(Dimethylamino)Ethyl]Acridine-4-Carboxamide (DACA)/16-α-[^{18}F]-Fluoro-17β-Oestradiol (FES)/ [^{18}F]-Fluoro-Deoxy-Glucose (FDG)/ [^{11}C]-Methyl-Choline/[^{11}C]-Thymidine/[^{124}I]-Annexin V/ [^{124}C]-Colchicine/[^{124}I]-Anti-VEGF

Background Information: Positron emission tomography (PET) provides the oncologist with information about tumor diagnosis, key malignant transformation pathways, delineation of chemotherapeutic pharmacokinetics/pharmacodynamics, and strategies for monitoring treatment response. Mathematical modeling of tissue data and online plasma radioactive metabolite profiling enable delineation of important tissue kinetic parameters related to uptake, distribution, and washout as well as arterial input function to be derived. The resultant kinetic data allow for not only diagnosis but also the assessment of therapeutic response end points. These end points can be used to measure specific therapeutic effects. This novel application of PET can provide information that is often difficult to measure in intact *in vivo* systems, including pharmcokinetic profiles, ligand-receptor interactions, pathways involved in metabolism, signal transduction, cell cycle and proliferation, cell death, drug resistance, and angiogenesis.

Application: Characterization of *in vivo* ligand-receptor interactions in neoplastic disease states for the purpose of diagnosis, discovery, and characterization of key malignant transformation pathways, delineation of chemotherapeutic pharmacokinetics/ pharmacodynamics, and strategies for monitoring treatment response. Examples include (i) pharmacokinetics of radiolabeled chemotherapeutics: DACA, temozolomide, and 5-FU; (ii) radiolabeled ligands that recognize receptor complexes such as FES; (iii) probes for profiling neoplastic cell metabolism pathways: [^{18}F]-FDG; (iv) signal transduction: [^{11}C]-methyl-choline; (v) cell-cycle and proliferation: 2-[^{11}C]-thymidine; (vi) cell death: [^{124}I]-annexin V; (vii) drug resistance patterns: [^{124}C]-colchicines; and (viii) angiogenesis: [^{124}I]-anti-VEGF.

Neoplasia: Pulmonary/Non-Small Cell Lung Carcinoma/Surgical Resection Response

[^{18}F]-2-Fluoro-2-Deoxy-d-Glucose (FDG)

Background Information: Surgical resection after preoperative chemotherapy in patients with non-small cell lung cancer might only be best for patients who are responders.

Implementation: Evaluate of positron emission tomography (PET) scanning with FDG compared to computed tomography (CT) scanning to determine the effectiveness of surgical resection of primary tumors (non-small cell lung cancer) and at N1 and N2 lymph nodes.

Human Model: Cases with non-small cell lung cancer that have initial FDG PET scan staging with tissue biopsy, neoadjuvant chemotherapy, repeat FDG PET scanning, and repeat biopsies. Reference population: (i) n = 34 cases (24 men; median age, 64 years); (ii) n = 11 cases with N2 disease; (iii) n = 7 cases with N1 disease; (iv) n = 27 cases receiving chemotherapy; (v) n = 7 cases receiving chemotherapy and radiation therapy; and (vi) all cases except n = 9 cases receiving surgical resection.

Interpretation and Analysis: Statistical analysis reveals that FDG PET scanning is more specific ($p < 0.0001$), has a higher positive predictive value ($p = 0.0018$), and has a higher negative predictive value ($p < 0.0001$) than CT scanning for predicting residual tumor at the primary site. FDG PET scanning is more sensitive ($p < 0.0001$) and more accurate ($p < 0.0001$), has a higher positive predictive value ($p < 0.0001$), and has a higher negative predictive value ($p = 0.0002$) than CT scanning for paratracheal nodes (number 2 and 4 lymph nodes). FDG PET scanning has a higher positive predictive value ($p < 0.0001$) than CT scanning for the other N2 (numbers 5, 6, 7, 8, and 9) lymph nodes. Repeat FDG PET scanning is more specific and has a higher positive predictive value and negative predictive value than CT scanning for detecting residual tumor in the lung of patients with non-small cell lung cancer who have received preoperative chemotherapy. It is more sensitive and accurate for paratracheal N2 nodes as well. However, there is no significant difference in its detection of N1 lymph nodes.

Positron emission tomography scanning with 2-fluoro-2-deoxy-d-glucose as a predictor of response of neoadjuvant treatment for non-small cell carcinoma. Cerfolio RJ, Ojha B, Mukherjee S, Pask AH, Bass CS, Katholi CR. J Thorac Cardiovasc Surg 2003 Apr; 125 (4), pp. 938–44.

Neoplasia/Pulmonary/Non-Small Cell Lung Cancer (NSCLC)/Detection of Elevated Cellular Proliferation Rate/Risk of Recurrence Postresection/Response to Cell Cycle Targeted Chemotherapy

3′Deoxy-3′-[^{18}F]-Fluorothymidine (FLT)

Cellular/Molecular Mechanism of Action: Thymidine is a nucleic acid precursor that is incorporated into nuclear DNA in mitotically dividing cell populations.

Background Information: Tumor proliferation has prognostic value in resected early stage NSCLC and can, therefore, predict which NSCLCs are at high risk for recurrence after resection and would benefit from additional therapy. It may also predict which tumor will respond to cell cycle targeted chemotherapy and help assess the tumor response, besides helping to differentiate benign from malignant lung lesions.

Application: Labeled thymidine (e.g., [^{3}H]-thymidine) can be used to assess the rate of mitotic activity within dividing cell populations. Characterizing the uptake of the positron emission tomography (PET) tracer FLT in a series of suspected NSCLCs correlates with tumor proliferation assessed by Ki-67 immunohistochemistry and flow cytometry.

Route of Administration: FLT (intravenous).

Dosage: FLT (0.07 mCi/kg).

Implementation: Evaluation of cases with biopsy-proven or clinically suspected NSCLC applying FLT as an imaging agent (PET 2-hour dynamic study). Tumor FLT uptake is quantitated with the

maximum pixel standardized uptake value (maxSUV), the partial volume corrected maxSUV (PV-corr-maxSUV), the average SUV over a small region-of-interest (aveSUV), and with Patlak analysis of FLT flux (aveFLTflux). Lesion diameter from computed tomography is used to correct the maxSUV for PV effects using recovery coefficients determined for the PET scanner. Immunohistochemistry can be performed to identify Ki-67 expression (proliferation index marker; e.g., n = 11 tissue specimens) and flow cytometry analysis to identify S-phase fraction (SPF; e.g., n = 10 cases). Tissue specimens are reviewed for histology and cellular differentiation (poor, moderate, well). Lesions can range from 1.6 to 7.7 cm.

Human Model: Cases of suspected or biopsy-proven NSCLC (n = 11; n = 10/11 imaged by PET).

Interpretation and Analysis: A small percentage of cases may be inflammatory in nature (e.g., n = 2/11), while a relatively large percentage of cases will be positively identified as NSCLC (e.g., n = 9/11). Excellent correlation exists between SUV measures of FLT uptake and Ki-67 scores [percentage of positive cells; maxSUV vs Ki-67: $\rho = 0.78$, $p = 0.0043$ (n = 11); PV-corr-maxSUV vs Ki-67: $\rho = 0.83$, $p = 0.0028$ (n = 10); aveSUV vs Ki-67: $\rho = 0.84$, $p = 0.0011$ (n = 11)]. Correlation between Ki-67 proliferation scores and Patlak measures of FLT uptake are also strong: aveFLTflux vs Ki-67: $\rho = 0.94$, $p < 0.0001$ (n = 11). The correlation between the SPF and all indices of FLT uptake is weaker and reaches statistical significance for only 2 uptake indices [maxSUV vs SPF: $\rho = 0.69$, $p = 0.03$ (n = 10); PV-corr-maxSUV vs SPF: $\rho = 0.36$, $p = 0.35$ (n = 9); aveSUV vs SPF: $\rho = 0.67$, $p = 0.03$ (n = 10); aveFLTflux vs SPF: $\rho = 0.46$, $p = 0.18$ (n = 10)]. FLT PET may be used noninvasively to assess *in vivo* proliferation rates of lung masses. Therefore, FLT PET may play a significant role in the evaluation of indeterminate pulmonary lesions, in the prognostic assessment of resectable NSCLC, and possibly in the evaluation of NSCLC response to chemotherapy.

Instrumentation: General Electric Advance PET scanner.

In vivo validation of 3′deoxy-3′-[^{18}F]-fluorothymidine ([^{18}F]-FLT) as a proliferation imaging tracer in humans: Correlation of [^{18}F]-FLT uptake by positron emission tomography with Ki-67 immunohistochemistry and flow cytometry in human lung tumors. Vesselle H, Grierson J, Muzi M, Pugsley JM, Schmidt RA, Rabinowitz P, Peterson LM, Vallieres E, Wood DE. Clin Cancer Res 2002 Nov; 8 (11), pp. 3315–23.

Neoplasia/Thyroid Cancer: Metastatic/Recurrent or Metastatic Disease

[^{99m}Technetium] ([^{99m}Tc])-Furifosmin/[^{99m}Tc]-Methoxy-Isobutylisonitrile (MIBI)/[^{99m}Tc]-SestaMIBI/[^{99m}Tc]-Tetrofosmin/[^{18}F]-Fluoro-Deoxy-Glucose (FDG) Positron Emission Tomography (PET)

Many isotopes are available for imaging patients with suspected thyroid cancer recurrence and metastases. Thyroid-stimulating hormone (TSH)-stimulated low-dose [^{131}I] whole-body scanning with serum thyroglobulin either by standard LT4 withdrawal or rhTSH stimulation is the preferred test for monitoring patients without palpable disease or elevated serum thyroglobulin on LT4 therapy. This approach has the advantage of finding disease that may be amenable to [^{131}I] therapy, although low-dose [^{131}I] scans are less sensitive than are scans utilizing other imaging agents. [^{123}I] has better imaging characteristics than [^{131}I] and has been shown to be equivalent or superior to low-dose [^{131}I] in recent studies. As the availability of [^{123}I] increases, and cost decreases, this agent may replace [^{131}I] in imaging for recurrent or metastatic thyroid cancer. Patients who have an elevated serum thyroglobulin on LT4 therapy or after TSH stimulation but have a negative low-dose [^{131}I] scan require other imaging procedures to find the suspected disease. Many diagnostic imaging services perform a sensitive neck ultrasound to look for surgically remediable disease and consider a non-contrast computed tomography (CT) scan of the chest to look for small pulmonary metastases that poorly concentrate low doses of [^{131}I]. Fluoro-18-deoxy-glucose PET, [^{99m}Tc]-MIBI, [^{201}Tl], and [^{99m}Tc]-tetrofosmin are primarily useful in the setting of a negative whole-body [^{131}I] scan and elevated serum thyroglobulin. [^{18}F]-FDG PET seems to have the highest sensitivity in this setting and would be the preferred imaging agent, but availability and cost are major issues. Although some researchers have advocated these radiopharmaceuticals as 1st-line agents replacing [^{131}I], there is little support for this position. This approach to imaging is not cost-effective because positive scans in these patients would most likely require [^{131}I] scintigraphy to determine whether the lesions are amenable to radioiodine therapy. [^{99m}Tc]-pertechnetate, [^{99m}Tc]-furifosmin, and somatostatin receptor scintigraphy have a limited role in imaging for recurrent or metastatic differentiated thyroid carcinoma. In choosing among [^{99m}Tc]-MIBI, [^{201}Tl], and [^{99m}Tc]-tetrofosmin, technetium-labeled sesta-MIBI and tetrofosmin result in better image quality and faster imaging than [^{201}Tl]. Although [^{99m}Tc]-sestaMIBI and [^{99m}Tc]-tetrofosmin have not been compared in a large trial series, the higher tumor-to-background ratio and consistently high sensitivities of [^{99m}Tc]-tetrofosmin suggest that it could potentially have additional value over [^{99m}Tc]-sestaMIBI, but to date, experience with [^{99m}Tc]-tetrofosmin is limited.

Isotope imaging for metastatic thyroid cancer. Haugen BR, Lin EC. Endocrinol Metab Clin North Am 2001 Jun; 30 (2), pp. 469–92.

Neoplasia/Topoisomerase I and II/Adenocarcinoma (HT29)/Gliobastoma (U87MG)/Melanoma (A375M Antigen Positive)

[^{11}C]-9-Methoxyphenazine-1-Carboxamide/[^{11}C]2-(4-Pyridyl)Quinoline-8-Carboxamide/[^{11}C]-DACA/[Topoisomerases I and II]

Cellular/Molecular Mechanism of Action: The tricyclic carboxamide *N*-[2-(dimethylamino)ethyl]acridine-4-carboxamide (DACA) is a DNA-intercalating agent capable of inhibiting both topoisomerase I and II enzyme fractions.

Background Information: The tricyclic carboxamide DACA is currently in phase II clinical trial. Many related analogs have been developed, but despite their potent *in vitro* cytotoxicities, they exhibit poor extravascular distribution.

Application: Delineation of rational drug selection.

Semi-Synthetic Methods: Each candidate compound shares a common structural feature, *N*-dimethyl side chain, which can be radiolabeled with the positron-emitting radioisotope carbon-11.

Implementation: Evaluate the biodistribution and metabolite profiles of the prototype compound, DACA, with 3 analogs to aid rational drug selection in order to identify agents that are "minimal intercalators" that have lower DNA association constants. In this fashion, promising candidates will be identified in emerging preclinical studies in animals that can ultimately be evaluated in humans using positron emission tomography (PET).

Animal Model: Murine (mice bearing human tumor xenografts).

Interpretation and Analysis: Acridine DACA, phenazine SN 23490, pyridoquinoline SN 23719, and dibenzodioxin SN 23935 are cytotoxic when evaluated with *in vitro* assays utilizing HT29, U87MG, and A375M cell lines (IC50 of 1.4 to 1.8 μM, 0.4 to 0.6

μM, 1.3 to 1.6 μM, and 24 to 36 μM, respectively). *Ex vivo* biodistribution studies with carbon-11 radiolabeled compounds in mice bearing human tumor xenografts show rapid clearance of [^{11}C]-radioactivity (parent drug and metabolites) from blood and major organs. Rapid hepatobiliary clearance and renal excretion can also be observed. There is low (< 5% of injected dose/gram [%ID/g]) and variable uptake of [^{11}C]-radioactivity in 3 tumor types for all of the compounds. Tumor (U87MG) to blood [^{11}C]-radioactivity for [^{11}C]-DACA, [^{11}C]-(9-methoxyphenazine-1-carboxamide (SN 23490), [^{11}C]2-(4-pyridyl)quinoline-8-carboxamide (SN 23719), and [^{11}C]-dibenzo[1,4]dioxin-1-carboxamide (SN 23935) at 30 minutes is approximately 2.9 ± 1.1, 2.3 ± 0.6, 2.6 ± 0.6, and 0.7 ± 0.2, respectively. For SN 23719, the distribution of [^{11}C]-radioactivity in normal tissues and tumors determined *ex vivo* is in broad agreement with that determined *in vivo* by whole-body PET scanning. [^{11}C]-DACA is rapidly and extensively metabolized to several plasma metabolites and a major tumor metabolite. In contrast, [^{11}C]-SN 23935, [^{11}C]-SN 23490, and [^{11}C]-SN 23719 shows less extensive metabolism. In tumor samples, parent [^{11}C]-DACA and [^{11}C]-SN 23935 is present at between 0.3 and 1.5 %ID/g, whereas [^{11}C]-SN 23490 and [^{11}C]-SN 23719 is present at between 1.5 and 2.8 %ID/g. Therefore, by using a strategy employing [^{11}C]-labeling, it is possible to determine the tissue distribution and metabolic stability of novel tricyclic carboxamides.

Given the objective of identifying analogs with potentially improved *in vivo* activity against solid tumors, the agents SN 23490 and SN 23719 have more favorable distribution and metabolic stability compared with DACA and SN 23935. Such observations suggest that further development and evaluation is warranted. The radiolabeling strategy used allows *ex vivo* and *in vivo* evaluation of promising anticancer agents in animals and offers the potential of rapid translation to studies in humans using PET.

Comparative biodistribution and metabolism of carbon-11-labeled N-[2-(dimethylamino)ethyl]acridine-4-carboxamide and DNA-intercalating analogues. Osman S, Rowlinson-Busza G, Luthra SK, Aboagye EO, Brown GD, Brady F, Myers R, Gamage SA, Denny WA, Baguley BC, Price PM. Cancer Res 2001 Apr 1; 61 (7), pp. 2935–44.

Neoplasia/Treatment Response Prediction/ 5-Fluorouracil
[^{18}F]-2-Fluoro-2-Deoxy-D-Glucose (FDG)/ [^{18}F]-2-Fluoro-2-Deoxy-D-Mannose (FDM)

Background Information: There is a clinical need for early detection of tumor response to therapy.
Route of Administration: FDG (intraperitoneal).
Dosage: FDG (1.4 mmol/kg [rat]).
Implementation: Evaluation of the ability for metabolites of FDG to detect responses of solid tumors to 5-fluorouracil chemotherapy applying [^{19}F] magnetic resonance spectroscopy (^{19}F MRS). Following FDG injection, uptake and metabolism are monitored for 2 hours in RIF-1 tumors. Mice treated with 5-fluorouracil (130 mg/kg) receive a repeat dose of FDG 48 hours later.
Animal Model: Murine (mouse *in situ* solid tumor).
Interpretation and Analysis: FDG is detectable immediately and 10 minutes after injection (2nd broad peak detected 5–6 ppm upfield). [^{19}F] MRS *in vitro* analysis of cell and tumor extracts shows that the upfield peak (≥ 15% of total detectable [^{19}F] signal) consists of the epimer α-fluorodeoxymannose (FDM) and various conjugates. The change in the rate of FDM formation, but not FDG or total [^{19}F] signal, correlates significantly with response to 5-fluorouracil ($p = 0.032$), suggesting that [^{19}F] MRS of FDM metabolism *in vivo* may be a novel means of predicting tumor response. Since FDG and FDM employ a fluoride atom, it is possible that they could also be labeled with [^{18}F] for position emission investigations.

Metabolites of 2′-fluoro-2′-deoxy-D-glucose detected by [^{19}F] magnetic resonance spectroscopy *in vivo* predict response of murine RIF-1 tumors to 5-fluorouracil. McSheehy PM, Leach MO, Judson IR, Griffiths JR. Cancer Res 2000 Apr 15; 60 (8), pp. 2122–7.

Neoplasia/Treatment Response (Radiation Therapy)/Glucose Metabolism/Amino Acid Metabolism/Nucleic Acid Metabolism
[^{18}F]-5-Fluorodeoxyuridine/L-Methyl-[^{14}C]-Methionine/ 6-[^{3}H]-Thymidine/2′-Deoxy-5-[^{18}F]-Fluorouridine

Cellular/Molecular Mechanism of Action: Reflects neoplastic cell nucleic acid metabolism.
Application: Diagnostic imaging of neoplastic lesions.
Route of Administration: [^{18}F]-5-fluorodeoxyuridine (usually intravascular).
Implementation: Evaluation of metabolic tracers for glucose, amino acid, and nucleic acid metabolisms (2-deoxy-2-[^{18}F]-fluoro-D-glucose (^{18}FDG), L-methyl-[^{14}C]-methionine ([^{14}C]-Met), 6-[^{3}H]thymidine (^{3}H-Thd), and 2′-deoxy-5-[^{18}F]-fluorouridine (^{18}FdUrd)), and the conventional radionuclide [^{67}Ga]-citrate can be used to assess the feasibility of monitoring the effectiveness of tumor radiotherapy using a quadruple tracer technique. In this context, 2 combinations of 4 tracers ([^{18}F]-FDG or ^{18}FdUrd, [^{14}C]-Met, [^{3}H]-Thd, and [^{67}Ga]) can be compared in a time-course study after single-dose irradiation (20 Gy) and also used in a dose-dependency study performed 6 days after 5, 10, 15, or 20 Gy of irradiation.
Animal Model: Rat AH109A tumor model.
Interpretation and Analysis: [^{18}F]-FDG shows a large change in uptake and a steady response to radiotherapy. Fluorodeoxyuridine shows a rapid decrease after radiotherapy, but the range of change in uptake is narrow. [^{67}Gallium] cannot detect tumor response early after treatment, but shows a marked change in uptake later. 6-[^{3}H]-Thd and [^{14}C]-Met show a rapid response to irradiation and a high sensitivity for monitoring radiotherapy, suggesting that they may be applicable for PET studies.

Tracer feasibility for monitoring tumor radiotherapy: A quadruple tracer study with fluorine-18-fluoro-deoxy-glucose or fluorine-18-fluorodeoxyuridine, L-[methyl-^{14}C]-methionine, [6-3H]thymidine, and gallium-67. Kubota K, Ishiwata K, Kubota R, Yamada S, Tada M, Sato T, Ido T. J Nucl Med 1991 Nov; 32 (11), pp. 2118–23.

Neutrophil Metabolism
Deoxyglucose/Formyl-Methionyl-Leucyl-Phenylalanine (fMLP)/Tumor Necrosis Factor-Alpha (TNF-α)

Cellular/Molecular Mechanism of Action: The chemotactic agent *f*MLP stimulates respiratory burst activity in neutrophil populations.
Background Information: Neutrophil granulocytes play a key role in the pathogenesis of a wide variety of pulmonary diseases. In many such conditions, the injury observed reflects the activation status rather than the total number of inflammatory cells present. The metabolic activity of neutrophils can now be assessed non-invasively using PET to measure the regional uptake of [^{18}F]-FDG after intravenous injection.
Application: Characterization of neutrophil dexoxyglucose metabolism as a model for understanding *in vivo* [^{18}F]-FDG uptake pertaining to viable neutrophil populations.

Implementation: Utilization of tritiated deoxyglucose (DG) in neutrophils isolated from human peripheral blood to discover and characterize the mechanisms responsible for increases in [^{18}F]-FDG signals detected by PET under *in vivo* conditions.

Interpretation and Analysis: The chemotactic agent *f*MLP stimulates (neutrophil) respiratory burst activity and [^{3}H]-DG uptake. Each of these processes is temporally dissociated from 1 another. The neutrophil-priming agent TNF-α causes an identical increase in [^{3}H]-DG uptake compared with *f*MLP but without affecting respiratory burst activity. The stimulation of TNF-α primed cells with *f*MLP causes a major upregulation of superoxide anion generation (O_2^-) in the absence of any incremental increase in [^{3}H]-DG uptake. Furthermore, direct activation of reduced nicotinamide adenine dinucleotide phosphate oxidase activity with the ester phorbol 12-myristate 13-acetate (PMA) results in a concentration-dependent loss of cell-associated [^{3}H]-DG, and preincubation of neutrophils with the phosphoinositide 3-kinase inhibitor wortmannin, which abolished both agonist-stimulated superoxide anion generation and degranulation, but has no effect on TNF-α-stimulated or *f*MLP-stimulated [^{3}H]-DG uptake. In contrast, *f*MLP-stimulated changes in neutrophil shape is not influenced by priming or wortmannin, and this appears to correlate with the functional response of [^{3}H]-DG uptake. In summary, deoxyglucose uptake occurs in both primed and activated neutrophils. It does not correlate with respiratory burst or secretory activity but may reflect the polarization and migrational status of these cells.

Dissociation between respiratory burst activity and deoxyglucose uptake in human neutrophil granulocytes: implications for interpretation of [^{18}F]-FDG PET images. Jones HA, Cadwallader KA, White JF, Uddin M, Peters AM, Chilvers ER. J Nucl Med 2002 May; 43 (5), pp. 652–7.

Renal and Hepatic Cysts/Polycystic Kidney Disease: Autosomal Dominant
[^{18}F]-Fluoro-Deoxy-Glucose (FDG)

Background Information: Infection of a renal or hepatic cyst is a serious complication of autosomal dominant polycystic kidney disease (ADPKD). Although crucial for successful management, early diagnosis is difficult, largely because of non-specific symptoms and limitations of conventional imaging techniques. Because of an increased metabolic rate, inflammatory cells take up large amounts of glucose. [^{18}F]-FDG, therefore, represents a promising agent for detection of cyst infections using positron emission tomography (PET).

Implementation: Performance of [^{18}F]-FDG PET scan imaging in cases of ADPKD suspected of being affected by renal or hepatic cyst infection.

Human Model: Cases of suspected renal or hepatic cyst infection (e.g., n = 7 FDG PET scans in 3 ADPKD cases suspected of renal or hepatic cyst infection; n = 2 PET scans of case A [PET 1 and 2]; n = 1 PET scan of case B [PET 3]; and n = 4 PET scans of case C [PET 4, 5, 6, and 7]).

Interpretation and Analysis: [^{18}F]-FDG PET can identify infected cysts in conditions of (i) renal cyst infection; (ii) hepatic cyst infection; and (iii) simultaneous renal and hepatic cyst infection. Evaluation of FDG PET imaging modalities has proven to be very helpful in establishing diagnoses and in excluding renal and hepatic cyst infections. Based on experience with FDG PET, this diagnostic strategy has promise as an imaging technique enabling early identification of renal and hepatic cyst infections in ADPKD patients.

Diagnosis of renal and hepatic cyst infections by 18-F-fluoro-deoxy-glucose positron emission tomography in autosomal dominant polycystic kidney disease. Bleeker-Rovers CP, de Sévaux RG, van Hamersvelt HW, Corstens FH, Oyen WJ. Am J Kidney Dis 2003 Jun; 41 (6), pp. E18–21.

20 Radiographic Image-Enhancing Agents

CONVENTIONAL RADIOGRAPHY

Adverse Reactions: Allergic Reactions to Iodinated Contrast Agents/Nephrostolithotomy/Antegrade Pyelography with Nephroureteral Stent/ Nephrostogram with Nephroureteral Stent
Gadodiamide [Gd]

Application: Contrast imaging agent that can be applied as an alternative to iodinated preparations in situations where allergy/ hypersensitivity reactions exist against iodinated contrast agents.
Implementation: Utilized as a contrast agent to facilitate diagnostic procedures, including percutaneous access for nephrostolithotomy, antegrade pyelography with nephroureteral stent placement, and diagnostic nephrostogram with nephroureteral stent exchange. In cases with histories of severe allergic reactions to iodinated contrast or marked renal insufficiency, interventional uroradiologic procedures can performed using full-strength [Gd] as a contrast agent in place of iodinated contrast material.
Interpretation and Analysis: Fluoroscopy can be applied to visualize [Gd] for the generation of "satisfactory" digital radiographs without allergic reaction or worsening renal function. In this context, [Gd] can be useful in guiding interventional uroradiologic procedures when iodinated contrast agents are contraindicated.

Interventional uroradiologic procedures performed using gadodiamide as an alternative to iodinated contrast material. Spinosa DJ, Angle JF, Hagspiel KD, Hartwell GD, Jenkins AD, Matsumoto AH. Cardiovasc Intervent Radiol 2000 Jan–Feb; 23 (1), pp. 72–5.

Adverse Effects: Cardiovascular Alterations
Iodinated Contrast Agents

The ideal intravascular contrast agent would be biologically inert and have no pharmacologic actions. Pharmacologic actions of currently used radiographic contrast agents are determined principally by 3 physicochemical properties of the iodine-bearing molecule and its formulation: osmolality, sodium concentration and calcium-binding properties. Within this framework, the calcium-binding 1.5 ratio agents have the most marked effects, and the 3.0 ratio non-ionic agents the least, while the non-calcium-binding formulations of 1.5 ratio agents and ioxaglate (the only 3.0 ratio ionic agent) are in between. Differences in hemodynamic effects are predominantly related to osmolality with the 3.0 agents causing less hemodynamic disturbance. The magnitude of difference is small enough that the 3.0 ratio agents have no important clinical advantage when used in patients with good or moderately impaired left ventricular function. However, the difference may be important in patients with severely impaired circulatory performance. The principal electrophysiologic differences are between the calcium-binding 1.5 ratio agents (which are associated with a clear-cut greater frequency of ventricular fibrillation during coronary injection than the non-calcium-binding 1.5 ratio agents) and the 3.0 ratio agents. There is no justification for the use of calcium-binding 1.5 ratio agents, because non-calcium-binding formulations of the same molecule are available at the same price. The circulatory reserve of most patients makes the differences between 3.0 ratio agents and non-calcium-binding 1.5 ratio agents clinically unimportant. In view of the substantial price disparity between 1.5 ratio and 3.0 ratio agents, non-calcium-binding 1.5 ratio agents are appropriate for patients with good circulatory performance and 3.0 ratio agents are best reserved for patients with impaired circulatory performance.

Cardiovascular effects of iodinated contrast agents. Hirshfeld JW Jr. Am J Cardiol 1990 Oct 26; 66 (14), pp. 9F–17F.

Adverse Reactions: Cardiovascular/Cardiac Angiography Imaging
Iodixanol/Iohexol

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.
Application: Iodixanol and iohexol are iodinated positive contrast image-enhancing agents that can be applied during diagnostic cardiac angiography procedures. Iodixanol is a ratio 6 non-ionic iodinated contrast agent with an osmolality equivalent to serum.
Implementation: Comparison of iodixanol with iohexol in elective diagnostic cardiac angiography procedures (e.g., n = 101 iodixanol studies; and n = 99 iohexol studies).
Interpretation and Analysis: There are no differences that can be detected between iodixanol and iohexol pertaining to mean changes in systolic or diastolic blood pressure or heart rate during or immediately after any angiography procedure. However, significantly more cases will develop decreases in diastolic blood pressure of > 20 mm Hg during left coronary angiography with iodixanol. The only significant differences in any electrophysiologic parameters is a slightly more prolongation of the PR interval during left coronary angiography with iodixanol and more ST-segment depression with iohexol during coronary angiography. Neither of these alterations can be considered to be clinically significant. Injection-associated discomfort occurs with both agents, but moderate to severe discomfort is more prevalent with iohexol (52%) than with iodixanol (17%) ($p < 0.001$). Potentially serious adverse events, such as ventricular fibrillation can rarely be observed with iohexol (e.g., n = 1/99). Overall, angiographic quality is equal with all angiograms being assessed as good or excellent in both groups ($p = 0.885$). In this low-risk population undergoing cardiac angiography, iodixanol is safe and effective without clinically important differences from iohexol. Additional studies in patients at high risk for complications should help further define the role of iodixanol in cardiac angiography.

Iodixanol, a new isosmotic non-ionic contrast agent compared with iohexol in cardiac angiography. Hill JA, Cohen MB, Kou WH, Mancini GB, Mansour M, Fountaine H, Brinker JA. Am J Cardiol 1994 Jul 1; 74 (1), pp. 57–63.

Adverse Effects: Coronary Microvasculature *Ex Vivo* Vasoactive Responses
Diatrizoate Meglumine

Background Information: Iodinated contrast media can cause a number of well-described acute hemodynamic and vascular effects, including vascular spasm, hypotension, and arrhythmias.
Route of Administration: Diatrizoate meglumine (intravascular).
Dosage: Diatrizoate meglumine (5 ml/injection with a cumulative dose of 60 mL).
Implementation: Examine the endothelium-dependent and endothelium-independent vasodilator responses of the microvessels after previous contrast media administration in a clinically relevant setting. Left coronary angiography (e.g., n = 6 pigs) using high-dose, diatrizoate meglumine (cumulative dose of 60 mL [5 mL/injection]) as a high-osmolar contrast agent. After 1 hour of reperfusion, epicardial coronary microvessels are studied *in vitro* in a pressurized, no-flow state with video microscopy. The vasodilators bradykinin, calcium ionophore A23187, and sodium nitroprusside are sequentially applied extraluminally after preconstriction. Serotonin and the thromboxane A2 analogue U46619 are studied without preconstriction.

Animal Model: Swine (n = 6).
Interpretation and Analysis: Microvessels exposed to diatrizoate meglumine have normal relaxation responses to the endothelium-dependent vasodilators bradykinin and calcium ionophore A23187 when compared to control vessels. The vasoconstrictor responses to U46619 and serotonin are not significantly altered compared to control vessels. Responses to the endothelium-independent vasodilator sodium nitroprusside are not reduced or are slightly enhanced after exposure to contrast media. In summary, coronary resistance vessel response to the endothelium-dependent vasodilators bradykinin and calcium ionophore A23187 are not diminished after previous exposure to diatrizoate meglumine. The vasoconstrictor responses to U46619 and serotonin are similarly unaffected by previous exposure to contrast media. Such observations suggest that, when used in clinically relevant amounts, diatrizoate meglumine does not cause functional endothelium or vascular smooth muscle impairment.

Coronary microvascular responses after exposure to iodinated contrast media. Piana RN, Banitt PF, Nunez BN, Dai HB, Sellke FW. Invest Radiol 1994 Oct; 29 (10), pp. 877–81.

Adverse Reactions: Cardiovascular and Hemodynamic Effects
Gadolinium Diethylenetriamine Pentaacetic Acid ([Gd]-DTPA)/Diatrizoate/Iopamidol

Cellular/Molecular Mechanism of Action: Gadolinium and iodinated compounds possess radiopaque properties. The agent DTPA functions as a chelating agent for either radioactive or non-radioactive heavy metal ions.
Application: Conventionally [Gd] in the form of [Gd]-DTPA, diatrizoate (ionic), and iopamidol (non-ionic) can be used as positive contrast image-enhancing agents for the detection of anatomical anomalies affecting the cardiovascular system (conventional radiography and magnetic resonance imaging).
Route of Administration: [Gd]-DTPA, diatrizoate, and iopamidol can all be given intravascularly as a bolus injection for the detection of anatomical anomalies affecting the cardiovascular system.
Dosage: Gadopentate dimeglumine ([Gd]-DTPA [Magnevist] at high dose = 0.6 mmol/kg or 1.2 ml/kg in swine). Diatrizoate (Urografin 76% at high dose = 0.6 mmol/kg or 1.2 ml/kg in swine). Iopamidol (Solutrast 370% at high dose = 0.6 mmol/kg or 1.2 ml/kg in swine).
Implementation: Evaluation of the hemodynamic reactions induced by high-dose [GD]-DTPA compared with the side effects of high-dose ionic (diatrizoate: Urografin 76%) and non-ionic (iopamidol, Solutrast 370) radiographic contrast media.

Study Design: Assessement of pressure and flow of the systemic and pulmonary circulation following intracardiac bolus injections delivered over a time period of 2 to 4 seconds.

Animal Model: Porcine (e.g., n = 18 swine).
Interpretation and Analysis: Gadolinium, diatrizoate, and iopamidol all decrease the aortic pressure transiently ([Gd]-DTPA and diatrizoate: −25%, iopamidol: −10%; $p < 0.01$). Pulmonary artery pressure, cardiac output, and stroke volume remain increased for several minutes, while vascular resistance declines. Diatrizoate induces stronger and longer-lasting side effects ($p < 0.01$) than [Gd]-DTPA and iopamidol. Despite similar osmolalities, [Gd]-DTPA induces weaker side effects than equivalent volumes of diatrizoate. Other than osmolality, additional factors such as viscosity and chemotoxicity also influence the occurance of contrast mediated–associated side effects.

Gadopentetate dimeglumine and iodinated contrast media. Hemodynamic side effects after bolus injections in pigs. Kuhtz-Buschbeck JP, Ehrhardt K, Kohnlein S, Radtke W, Heintzen P. Invest Radiol 1997 Feb; 32 (2), pp. 111–9.

Adverse Effects: Cardiovascular: Vasodilatory Properties/Nitric Oxide (NO) Release
Iopromide/Iohexol/Iodixanol

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties. Iopromide and iohexol are triiodinated monomers, while iodixanol is a hexaiodinated dimer.
Application: Iohexol and iodixanol can be used as positive contrast imaging agents (e.g., conventional radiography).
Route of Administration: Anticipated to be intravascular with potential applications for direct infusion into body fluid compartments.
Dosage: Iodixanol (320 mg/ml in *ex vivo* perfused arteries) and iopromide (300 mg/ml in *ex vivo* perfused arteries).
Implementation: Method I: Evaluation of the vasodilator effects of iohexol (300 mg/ml) and iodixanol (320 mg/ml) utilizing *ex vivo* endothelium-intact rings (rabbit and dog). Method II: Evaluation of the vasodilator effects of iohexol (300 mg/ml) and iodixanol (320 mg/ml) utilizing isolated perfused arteries (rabbit and dog).

Animal *Ex Vivo* Model: Canine and rabbit (*ex vivo* perfused artery preparations).
Interpretation and Analysis: Increasing concentrations of iohexol or iodixanol cause concentration-dependent relaxations of detector tissue that are insensitive to 100 μM NG-nitro L-arginine methyl ester (L-NAME) and 10 μM indomethacin, whereas viscosity-associated relaxations induced by the "inert" agent dextran (MW 80,000; 1–4%) are attenuated by inhibition of NO synthesis. Relaxations of endothelium-intact rings by exposure to acetylcholine (ACh) are attenuated by preincubation with iohexol or iodixanol, whereas relaxations to sodium nitroprusside (SNP) in endothelium-denuded rings are unaffected. Inhibitory activity does not correlate with either molarity or iodine concentration. Mannitol causes an inhibition of both ACh- and SNP-induced responses. In isolated perfused arteries the depressor response to iodixanol (320 mg/ml) and iopromide (300 mg/ml) administered as a closed arterial bolus attains a plateau with maximal dilatations of approximately 25% and approximately 60%, respectively. Addition of 100 μM NG-nitro L-arginine (L-NOARG) and/or 10 μM indomethacin to the perfusate

does not effect the responses to either contrast agent. Iodinated radiographic contrast media therefore exerts a direct effect on the endothelium in a manner that inhibits NO production rather than an action on vascular smooth muscle. Shear stress-induced stimulation of NO production by iodinated radiographic contrast media is unlikely to contribute to their vasodilator activity *in vivo* when administered during angiography despite high intrinsic levels of viscosity.

Iodinated radiographic contrast media inhibit shear stress- and agonist-evoked release of NO by the endothelium. Hutcheson IR, Griffith TM, Pitman MR, Towart R, Gregersen M, Refsum H, Karlsson JO. Br J Pharmacol 1999 Sep; 128 (2), pp. 451–7.

Adverse Effects: Cardiovascular: Vasodilation Postinjection/Comparison Study
Iodixanol/Iopromide

Cellular/Molecular Mechanism of Action: Iodixanol and iopromide are iodinated organic compounds that possess radiopaque properties.
Application: Iodixanol and iopromide can be applied as radiopaque image contrast-enhancing agents in conventional radiographic methodologies.
Route of Administration: Iodixanol and iopromide (intravenous).
Dosage: Formulation of iodixanol and iopromide at 320 mg I/ml and 300 mg I/ml, respectively.
Implementation: Assess the correlation between flow-dependent and contrast-related vasodilatation associated with the administration of iodixanol or iopromide and evaluate the impact of plaque formation on vasodilatation in coronary arteries. Such an objective can be achieved by evaluating controlled randomized paired cross-over comparisons between iodixanol and iopromide. Vessel area, endosonics and blood flow velocity measurements, and cardiometrics are recorded simultaneously at an identical position, at baseline, after intracardiac bolus injection of 10 ml physiologic saline (flow-dependent vasodilatation), and after randomized application of either iodixanol or iopromide contrast agents.

Human Model: Human cases evaluated by diagnostic intracoronary artery angiography procedures ($n = 10$).
Interpretation and Analysis: The action of iodixanol and iopromide on the vascular wall does not differ and is equal to local flow-dependent vasodilatation induced by a saline bolus (correlation 0.95–0.98). The increase in local luminal area after injection of saline, iodixanol and iopromide in morphologically normal vessels (approximately 2.5 mm^2) is absent in atherosclerotic segments. Both contrast agents and saline demonstrate nearly identical flow increases. If iodixanol or iopromide are used as contrast agents, contrast-related vessel area increases *in vivo* seem to be endothelium-dependent.
Instrumentation: (i) Visions Five-64 F/X intravascular ultrasound-catheter; (ii) 0.014 inches Doppler guide wire.

Is contrast-related vasodilatation after intra-coronary iodixanol and iopromide *in vivo* endothelium-dependent? Wellnhofer E, Dreysse S, Fleck E. Eur J Echocardiogr 2001 Dec; 2 (4), pp. 285–91.

Adverse Effects: Coronary Artery: Decreased Resistance
Ioxaglate (Low Osmolar)/Iohexol (Non-Ionic)/ Diatrizoate Meglumine (Ionic)

Cellular/Molecular Mechanism of Action: L-nitro-arginine is a competitive inhibitor of nitric oxide (NO) synthase (NOS). L-arginine is a substrate for NOS. Nitric oxide is considered to be one of the endogenous mediators of inflammatory responses.
Physiological Mechanism of Action: Meglumine sodium ioxaglate, iohexol, diatrizoate meglumine, and ditrizoate sodium promote vasodilatory responses.
Application: Meglumine sodium ioxaglate, iohexol, diatrizoate meglumine, and ditrizoate sodium promote vasodilatory responses and are traditionally used as positive contrast image-enhancing agents during the course of a variety of diagnostic procedures, including angiography procedures.
Route of Administration: Meglumine sodium ioxaglate, iohexol, diatrizoate meglumine, and ditrizoate sodium can all be delivered intravascularly.
Implementation: Evaluation of changes in coronary blood flow and coronary vascular resistance induced in response to the intracoronary artery injection of saline solution (0.5 mol/L, isosmolar with plasma) and 3 different contrast agents, including meglumine sodium ioxaglate (Hexabrix), a low-osmolar ionic contrast agent; iohexol (Omnipaque 300), a non-ionic contrast agent; and diatrizoate meglumine 66%, diatrizoate sodium 10% (MD-76), an ionic contrast agent. Measurements are made during 3 experimental conditions, including coronary artery infusion of (i) saline solution, control; (ii) L-nitro-arginine (LNNA; 10^{-3} mol/L and 10^{-2} mol/L), a competitive inhibitor of NO synthase; and (iii) L-arginine 10^{-1} mol/L, a substrate for nitric oxide (NO) synthesis.

Animal Model: Anesthetized, open-thorax swine on assisted ventilation.
Interpretation and Analysis: The infusion of L-nitro-arginine (LNNA) produces an increase in baseline coronary vascular resistance ($p < 0.001$), but it does not attenuate the vasodilatory response to the infusion of the contrast-enhancing imaging agents. Both the high and low-osmolar ionic and non-ionic contrast media cause decreases in baseline coronary vascular resistance. For all 3 conditions, diatrizoate sodium (MD-76: highest osmolality preparation) produces the greatest decrease in coronary vascular resistance. The vasodilatory response of the coronary vasculature to contrast agents is directly related to osmolality and is not mediated by NO generation.

Effect of contrast media on coronary vascular resistance: contrast-induced coronary vasodilation. Baile EM, Pare PD, D'yachkova Y, Carere RG. Chest 1999 Oct; 116 (4), pp. 1039–45.

Adverse Effects: Central Nervous System (CNS)/ Synaptic Transmission/Weak Transcient Excitation/ Epileptogenic Activity/Inhibitory Activity
Iomeprol/Ioversol/Iopentol/Ioxaglate/Diatrizoate

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.
Physiological Mechanism of Action: Certain iodinated contrast agents influence normal neurophysiological processes.
Background Information: All contrast agents should be neurologically safe because although some are not indicated for procedures, such as myelography, just the same they may come in contact with nervous tissue during contrast-enhanced imaging. In part, this is because even when they are injected intravascularly, the presence of undiagnosed injury to the blood-brain barrier may allow penetration across such protective anatomical structures.
Application: Positive contrast image enhancement agent for application within the intravascular system and other body fluid compartments.
Implementation: Delinate the neurologic safety of iomeprol and other widely used radiographic contrast agents by *in vitro* studying of

its potential effects on CNS synaptic transmission. One approach to addressing this objective includes the evaluation of CNS synaptic transmission in terms of evoked field potentials recorded from the pyramidal region of hippocampal slices to determine the influence of radiographic contrast media on CNS function. Field potentials can be evoked by electrical stimulation of the Schaffer collateral pathway. Effects and influences of individual contrast agents can be established in terms of the number and amplitude of population spikes (PS) and as the maximal slope of the excitatory postsynaptic potentials (EPSP). The contrast agents are tested at final concentrations of 3, 10, and 30 mg (iodine)/mL in iso-osmolar conditions with respect to artificial cerebrospinal fluid (CSF).

Animal Model: Rat (measurement of CNS synaptic transmission in the form of evoked field potentials recorded from the pyramidal region of hippocampal slices).

Interpretation and Analysis: Iomeprol, like ioversol, principally exerts a mild inhibitory effect on CNS synaptic transmission, an effect that is preceded by a weak, transient excitation phase. Iopentol exerts a rapid and complete inhibition of synaptic transmission without showing any excitatory effects. Iobitridol, though belonging to the non-ionic monomeric class, exerts, surprisingly, an epileptogenic action at the highest concentration, whereas its inhibitory action is slow and mild. Diatrizoate exerts an epileptogenic activity even at low concentrations, followed by a marked inhibitory action. Ioxaglate, because it is an ionic though dimeric contrast agent, exerts an epileptogenic action at an intermediate concentration, whereas it barely demonstrates an inhibitory effect at all. The effects associated with iopentol, iobitridol, diatrizoate, and ioxaglate tend to reverse with CNS parenchyma tissue washout.

Even taking into account the limitation because of the use of an *in vitro* approach and high contrast agent concentrations, it can be conclude that the positive neuro-tolerability of iomeprol has been further confirmed, and is apparently devoid of epileptogenic activity. Similarly, when compared among other contrast agents exhibiting inhibitory action, iomeprol is the contrast agent with the least amount of activity. In addition, contrary to reports generally described in the literature, non-ionic, low osmolal contrast agents are not all identical in their neuro-tolerability when assessed in the rat hippocampal slice model.

Effect of iomeprol on rat hippocampal slice synaptic transmission: Comparison with other x-ray contrast agents. Frigeni V, Samuelli G, Miragoli L, Grotti A, Lorusso V. Invest Radiol 2002 Apr; 37 (4), pp. 222–31.

Adverse Effects: Central Nervous System (CNS) Sensory Function (Taste, Heat, Pain/Cardiovascular) *Iomeprol/Iohexol/Iomeprol/Iopamidol/Iopromide*

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.

Background Information: Unlike older ionic agents, iomeprol has low chemotoxicity, osmolality, and viscosity and high water solubility. Compared with other non-ionic contrast media, the osmolality and viscosity are lower and the water solubility is reportedly higher with iomeprol.

Application: Iomeprol functions as a non-ionic, monomeric iodinated positive contrast image-enhancing agent for use in conventional radiology.

Route of Administration: Iomeprol (formulated at 150 to 400 mg/ml of iodine).

Interpretation and Analysis: Most radiographs (about 67 to 100%) obtained with iomeprol (containing 150–400 mg/ml of iodine) are of good or excellent quality in non-comparative and comparative trials undergoing various radiographic procedures (e.g., trail size n = 40–6,127 cases). The diagnostic efficacy of iomeprol does not differ significantly from that of other non-ionic agents (iopamidol, iopromide, iohexol, and iotrolan). Iomeprol (containing 150–400 mg/ml of iodine) is well tolerated in clinical trials. Most adverse events are transient and of mild to moderate intensity and similar to those observed with other contrast media. The overall incidence of adverse events range from 3.0% to 49.7% and mainly include focal pain (≤6%) and heat sensations (8–45%), taste disturbances (3–27%) and various pseudoallergic reactions (≤ 20% for each type of event). The incidence of heat or pain and taste disturbances with iomeprol are similar to that observed with iopromide and iopamidol. Pain (but not heat sensations) is reported to be significantly less frequently and taste disturbances are reported to be significantly more frequent with iomeprol than with iohexol in comparative trials. Pseudoallergic reactions (such as nausea, vomiting, skin reactions, dizziness, headache) are significantly less common with iomeprol than with ioxaglate and occur at a similar frequency relative to iopromide and iopamidol. Cardiovascular events are rarely observed with iomeprol. Currently available iomeprol solutions contain a range of iodine concentrations (150 to 400 mg/ml) and are approved for a wide variety of diagnostic procedures. Iomeprol solutions are chemically stable, which negates the need for chelating agents. Formulations of this agent were therefore the 1st not to contain edetic acid (EDTA). Iomeprol shows equivalent diagnostic efficacy, and a similar adverse event profile, to that of other non-ionic contrast media. The availability of a range of iodine concentrations enables iomeprol to be used in a variety of diagnostic procedures. Iomeprol, like others in its class, is suitable for use in diagnostic imaging.

Iomeprol: A review of its use as a contrast medium. Dooley M, Jarvis B. Drugs 2000 May; 59 (5), pp. 1169–86.

Adverse Effects: Coagulation Alterations: Anticoagulant Properties *Iopiperidol/Ioxaglate/Iodixanol*

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.

Background Information: Iopiperidol, a non-ionic, triiodinated contrast agent.

Implementation: Characterization of the *in vitro* and *in vivo* anticoagulant effects of iopiperidol following single or repeated intravenous injections (rats) can be established by the measurement of prothrombin time, activated partial thromboplastin time, thrombin time, thrombin activity, thrombin generation, and fibrinogen tests. Complementary evaluations include analysis of the effect of iopiperidol on adenosine diphosphate- and collagen-induced platelet aggregation both *in vitro* and *in vivo* after single or repeated intravenous administrations (rat).

Animal Model: Rat.

Interpretation and Analysis: Anticoagulant properties of iopiperidol *in vitro* are similar or superior to those of the ionic contrast agent ioxaglate. Iopiperidol also inhibits collagen-induced platelet aggregation significantly more than does iodixanol or ioxaglate ($p < 0.05$). No significant *in vivo* differences between iopiperidol and ioxaglate can be appreciated after either single or repeated administrations. The *in vitro* anticoagulant effect of iopiperidol is similar or even superior to that of ioxaglate; and its *in vivo* effect is similar to that of reference non-ionic contrast media.

Iopiperidol: Non-ionic iodinated contrast medium with promising anticoagulant and antiplatelet properties. Valenti R, Motta A, Merlini S, Morisetti A, Tirone P. Acad Radiol 1999 Jul; 6 (7), pp. 426–32.

Adverse Reactions: Coagulation Alterations/ Antithrombotic Properties: Iodinated Contrast Agents/Synergistic Antiplatelet Aggregatory Properties
Iohexol/Iodixanol/Ioxaglate

Route of Administration: Iohexol and iodixanol (intravenous)
Dosage: Iohexol and iodixanol (both administered at 1,600 mg iodine/kg).
Implementation: The antithrombotic potential of low-osmolar ionic (ioxaglate Na/meglumine) or non-ionic contrast media (iohexol and iodixanol) can be assessed by measuring the time to occlusion (TTO) of the carotid artery and the thrombus weight (TW). Isotonic saline and iso-osmolar (280 mOsm/kg) and hyperosmolar (560 mOsm/kg) solutions of meglumine hydrochloride, meglumine ioxaglate (560 mOsm/kg), sodium ioxaglate (600 mOsm/kg) and sodium and meglumine ioxaglate (commercial solution) can be tested under similar conditions. Interaction with clopidogrel is evaluated by injecting a lower dose of iodinated contrast media (960 mg iodine/kg) 2 hours after clopidogrel (2 mg/kg per os).

Animal Model: Rats with carotid thrombosis induced extravascularly with $FeCl_3$ (35% vol/wt soaked filter paper) applied topically utilizing a soaked section of filter paper. Ultrasound flow imaging is then performed distal to the site of topical $FeCl_3$ application,
Interpretation and Analysis: (i) Ioxaglate prolongs the TTO parameter when compared with saline (30.0 ± 1.1 minute vs 19.6 ± 2.4 minutes, $p < 0.001$), whereas iohexol has no effect (21.3 ± 1.3 minutes). Ioxaglate's effect is associated with a reduction in thrombus-weight with ioxaglate relative to saline (2.6 ± 0.4 mg and 4.7 ± 0.7 mg, respectively, $p < 0.05$) whereas thrombus-weight remains unchanged with iohexol group (4.2 ± 0.4 mg). The non-ionic dimer iodixanol induces a direct vasoconstrictor effect on the carotid artery. (ii) Neither iso-osmolar nor hyperosmolar solutions of meglumine have any effect on TTO, whereas both sodium and meglumine salts of ioxaglic acid prolong the TTO parameter, suggesting that the antithrombotic effect of ioxaglate is mediated by the ioxaglic acid moiety alone because neither meglumine, osmolality, or sodium play a significant role. (iii) A synergistic effect on TTO can be appreciated when ioxaglate is associated with clopidogrel whereas no such effect is appreciated with iohexol. A greater *in vivo* antithrombotic potential can be expected with the application of the ionic contrast medium ioxaglate compared to iohexol (non-ionic contrast media). In addition, a synergistic *in vivo* effect appears to exist between contrast medium and platelet antiaggregatory pharmaceutical agents.

In vivo comparative antithrombotic effects of ioxaglate and iohexol and interaction with the platelet antiaggregant clopidogrel. Labarthe B, Idee JM, Burnett R, Corot C. Invest Radiol. 2003 Jan; 38 (1), pp. 34–43.

Adverse Reactions: Coagulation Alterations/ Anticoagulant Properties/Antiplatelet Properties
Ioxaglate/Iohexol/Iodixanol

Background Information: Thromboembolic complications have been attributed to the use of radiographic contrast media (CM) during interventional procedures for arterial revascularization. However, due to the low frequency of adverse events, comparisons between different CM have been difficult to perform, although it has been suggested that ionic (vs non-ionic) CM may be associated with fewer thrombotic events.
Implementation: Comparison of different CM under physiologically relevant and controlled conditions of blood flow, exposure time, and agent concentration (e.g., ioxaglate, iohexol, and iodixanol). Individual CMs are locally infused into the proximal segment of femoral arteriovenous shunts. Palmaz-Schatz stents (4 mm i.d.) and expanded tubular segments (9 mm i.d.), that exhibit venous-type flow recirculation and stasis characteristics, are deployed into shunts distally. Saline can be infused in identical control studies. Contrast media concentrations within the flowfield can be predicted using computational fluid dynamic techniques.

Animal Model: Primate (baboon thrombosis). Blood flow is maintained at 100 ml/min. Thrombosis phenomenon are measured over a blood exposure period of 2 hours by gamma camera imaging with [^{111}In] platelets and by gamma counting of deposited [^{125}I] fibrin.
Interpretation and Analysis: At infusion rates of 0.1 and 0.3 ml/minute, the low-osmolar ionic CM ioxaglate reduces both platelet and fibrin deposition on the stents by 75% to 80% ($p < 0.005$), while both iohexol and iodixanol reduce platelet deposition by 30% to 50% ($p < 0.05$). In the regions of low shear flow, ioxaglate (0.3 ml/min) also reduces platelet deposition significantly (by 52% vs control results; $p < 0.05$). Thus the 3 contrast agents, ioxaglate, iohexol, and iodixanol, all produce anticoagulant and antiplatelet effects and *in vivo* inherently exert antithrombotic properties. The most striking effects can be appreciated with low osmolarity, ionic contrast agents like ioxaglate.

Antithrombotic effects of ionic and non-ionic contrast media in non-human primates. Markou CP, Chronos NA, Hanson SR. Thromb Haemost 2001 Mar; 85 (3), pp. 488–93.

Adverse Reactions: Coagulation Alterations/ Hemostatic Effects (Hemostatic and Platelet)
Ioxaglate/Iopromide

Cellular/Molecular Mechanism of Action: Ioxaglate (ionic) and iopromide (non-ionic) are iodinated compounds that possess radiopaque properties.
Application: Diagnostic angiography and other procedures requiring the use of a radiopaque tracer contrast image-enhancing agents.
Route of Administration: Intravascular when used in diagnostic angiography procedures.
Implementation: Evaluation of the influence of ioxaglate and iopromide on platelet function (platelet reactivity and serotonin concentration) and expression of coagulation markers [thrombin-antithrombin III complexes, prothrombin fragments (F1+2) and the D-dimers].

***Ex Vivo* Model:** Human blood collected from coronary angiography cases ($n = 40$).
Interpretation and Analysis: The use of an ionic x-ray contrast agent (XCA) (ioxaglate) in diagnostic cardiac catheterisation angiography is associated with lower thrombin generation and lower activation potential of platelets than is associated with the application of iopromide (non-ionic XCA). Such observations confirm the results of various *in vitro* studies and animal investigations.
Instrumentation: Platelet aggregometer and coagulation evaluation instrumentation.

Effect of an ionic compared to a non-ionic x-ray contrast agent on platelets and coagulation during diagnostic cardiac catheterisation. Jung F, Spitzer SG, Pindur G. Pathophysiol Haemost Thromb 2002 May–Jun; 32 (3), pp. 121–6.

Adverse Reactions: Coagulation Alterations/ Thrombogenic Properties
Iopromide

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.
Application: Iopromide is a non-ionic, iodinated, monomeric, radiographic contrast (imaging enhancing) agent that can be applied in arteriography procedures.
Background Information: Non-ionic contrast media have been postulated to have a higher risk of thrombosis compared with ionic contrast media.
Route of Administration: Iopromide (intravascular).
Dosage: Iopromide.
Implementation: Characterization of the interaction of iopromide with thrombin in order to determine the (i) rate, extent, specificity, and reversibility of the thrombin inhibition promoted by iopromide; (ii) integrity of the thrombin-iopromide complex; (iii) inhibitory potency of iopromide using a validated assay methodology; and (iv) determination of the specificity of iopromide mediated inhibition of thrombin protease activity. Methodologies that can be applied to achieve this objective involve the mixing of iopromide with purified thrombin or pooled serum. The final concentrations of iopromide in the presence of estimated physiologic concentrations of thrombin (1 nmol/L) are 0–184 mmol/L. After incubation for defined time intervals, the activity of thrombin is determined by adding substrate and measuring the absorbance of the generated chromophores at 405 nm. A positive reference controls should include a known thrombin inhibitor (e.g., Thromstop) in order to assess the relative potency of iopromide.
Interpretation and Analysis: The inhibition of thrombin by iopromide is immediate, rapidly reversible, and proportionate to iopromide concentration. The minimum inhibitory concentration of iopromide is 50 mmol/L. At an iopromide concentration of 184 mmol/L, the mean inhibition of thrombin activity is 44.5% approximately. The mean concentration of iopromide associated with a 50% inhibition was 206 mmol/L. The inhibitory potency of iopromide is 4×10^6 times smaller than Thromstop. The inhibition of thrombin by iopromide is specific, because trypsin is not inhibited by iopromide. The results indicate that *in vitro* iopromide at clinically relevant concentrations partially inhibits thrombin activity. However, some *in vitro* models do not consider other factors that may be relevant for the overall coagulation response *in vivo*.

Inhibition of thrombin by iopromide *in vitro*. Graf LL, Young DA, Kressin DC, Marlar RA, Jacob GB, Hinderling PH. Ther Drug Monit 2001 Apr; 23 (2), pp. 93–9.

Adverse Reactions/Lethal Effects/Comparative Median Lethal Dose/Physiological Tolerability
Iomeprol/Iopamidol/Iohexol

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.
Implementation: Evaluation of the toxicology of pharmaceutical formulations of iomeprol (non-ionic iodinated radiographic contrast agent).
Animal Model: Rodent (murine, rat, guinea pig) and non-rodent (rabbit, canine) animal species.
Interpretation and Analysis: When injected intravascularly, the acute toxicity of iomeprol, both in terms of median lethal dose and symptoms, is comparable to that of analogous triiodinated non-ionic contrast media. Intravenous daily dosing for 4 weeks reveals that iomeprol is well tolerated at doses as high as the maximum dose anticipated for clinical use. Moreover, the compound does not possess reproductive, developmental, or genetic toxicity. Tissue tolerability is completely superimposable on those of reference contrast media reagents, including iopamidol and iohexol. Finally, no antigenic potential can be detected either in mice or guinea pigs. These favourable toxicological characteristics bode well for iomeprol as an intravascular radiographic contrast agent.

Toxicological safety assessment of iomeprol, a new x-ray contrast agent. Morisetti A, Tirone P, Luzzani F, de Haen C. Eur J Radiol 1994 May; 18 Suppl 1, pp. S21–31.

Adverse Reactions: Nephrotoxicity
Gadolinium/Digital Subtraction Angiography (DSA)

Background Information: To prevent iodinated contrast medium-induced nephrotoxicity, gadolinium has been used increasingly for magnetic resonance angiography (MRA) or conventional DSA to visualize arterial anatomy in patients undergoing vascular surgery that are considered to be at high risk because of chronic renal insufficiency.
Application: Postive contrast imaging agent in DSA and magnetic resonance imaging procedures.
Dosage: Gadolinium-based contrast agents ($\geq$ 0.25 mmol/kg)
Implementation: Contrast enhancement of images acquired by magnetic resonance and DSA procedures.
Experimental Model: Single-center retrospective study evaluating the extent of nephrotoxicity induced during the course of MRA procedures (e.g., n = 218) and cases evaluated by DSA (e.g., n = 42) applying gadolinium as the sole contrast agent for diagnostic procedures performed between December 1999 and January 2001. Relevant variables recorded include patient comorbid conditions, indications for vascular imaging, contrast dose, urine output, baseline and postprocedure serum creatinine concentration (SCr), and outcome. Each of these features can provide insight into the relative toxicity of gadolinium contrast media and biological/physiological factors that may contribute to the development of sequelae.
Interpretation and Analysis: In cases with preimage baseline chronic renal insufficiency, approximately 3.5% will develop acute renal failure following administration of gadolinium-based contrast preparations (e.g., n = 7/195; n = 3/153 MRA; n = 4/42 DSA). In cases classified as having baseline chronic renal insufficiency, serum creatinine concentrations can average approximately 38.2 $\pm$ 1.6 mL/min/1.73 m^2, in contrast values of 32.5 $\pm$ 7.8 mL/min/1.73 m^2 for conditions of acute renal failure (p = 0.33). Doses for gadolinium in cases demonstrating renal failure postinjection can range from 0.31 to 0.41 mmol/kg for MRA and 0.27 to 0.42 mmol/kg for DSA procedures. Interestingly, acute renal failure rarely develops in cases with normal baseline serum creatinine levels (e.g., n = 0/65).

Despite reports of negligible nephrotoxicity, rarely gadolinium-based contrast agents can cause acute renal failure in instances where underlying chronic renal insufficiency exists. Estimation of creatinine clearance alone does not enable accurate prediction of which cases are likely to develop acute renal failure. Cases at high risk should be identified, and prophylactic measures exercised to reduce the risk of induced nephrotoxicity.

Safety of gadolinium contrast angiography in patients with chronic renal insufficiency. Sam AD 2nd, Morasch MD, Collins J, Song G, Chen R, Pereles FS. J Vasc Surg 2003 Aug; 38 (2), pp. 313–8.

Adverse Reactions: Nephrotoxicity: Contrast-Induced/Renal Transplant Conditions/Renal Artery Stenosis/Cyclosporin/Diabetes Meletus Contrast Agent

Background Information: Intravenous administration of radiographic contrast agents is an important cause of acute renal failure, accounting for one-third of the cases of hospital-acquired acute renal failure in patients with native kidneys. The safety of intravenous contrast has not been studied in renal allograft recipients because of the availability of cyclosporine as a maintenance immunosuppressive therapy.

Considerations: Cases with renal transplantation may be at a higher risk of contrast-induced nephrotoxicity (CIN) due to concomitant use of cyclosporine and due to a higher prevalence of coexisting diabetes and renal insufficiency.

Implementation: Evaluation of functioning renal allografts with intravenous or intra-arterial contrast agent studies (ICS: allograft angiography with angioplasty for renal artery stenosis).

Examples of relevant intra-arterial contrast studies performed include (i) coronary angiogram (e.g., n = 6); (ii) computed tomography (CT) scan with intravenous contrast (e.g., n = 11); (iii) angiogram for evaluation of peripheral vascular disease (e.g., n = 11); (iv) allograft angiogram with angioplasty (e.g., n = 5); (v) pulmonary angiogram (e.g., n = 1); and (vi) intravenous pyelogram (e.g., n = 1).

Human Model: Renal allograft cases (e.g., n = 44). Pre- and postintravascular contrast study renal function tests (e.g., n = 35/44). Case parameters include (i) mean age equals 42 ± 2.1 years; (ii) mean serum creatinine 2.3 ± 0.25 mg/dl (mean ± standard error of measurement [SEM]); (iii) diabetes (n = 14/35 or 40%); (iv) chronic rejection (n = 9/35 or 25.7%); and (v) cyclosporin administration at the time of ICS (n = 33/35 or 94%).

Interpretation and Analysis: Approximately 25% of renal allowgraft cases will experience a rise in serum creatinine from baseline following intravascular contrast studies (e.g., n = 9/35; diabetes = 5/7; chronic rejection 2/7). Prophylaxis with IV hydration does not guarantee intravenous contrast-induced nephrotoxicity will be avoided (e.g., n = 4/7). The baseline serum creatinine values are not different in patients who have no changes in renal function to those who develop intravenous contrast-induced nephrotoxicity (1.97 ± 0.20 vs 1.54 ± 0.17 mg/dl, p = 1.5, mean ± SEM). More than a 50% increase in baseline serum creatinine can be appreciated in many of these cases (e.g., n = 3/7; diabetes n = 2/3; chronic rejection/congestive heart failure n = 1/3; hydration prophylaxis n = 0/3). Dialysis may not be required in affected cases (e.g., n = 0). Conversely, some cases will display > 25% decreases in baseline serum creatinine after ICS (n = 3).

The incidence of intravascular contrast-induced nephrotoxicity in renal allograft recipients applying a broader classification of ≥ 25% increase in baseline serum creatinine is approximately 21.2% (n = 7/33 cases). The incidence of intravascular contrast-induced nephrotoxicity is 15.3% lower in cases that receive intravenous hydration (e.g., n = 4/26), compared to an incidence of 42.8% (e.g., n = 3/7) in cases receiving no prophylaxis prior to intravascular contrast-induced nephrotoxicity.

Contrast-induced nephrotoxicity in renal allograft recipients. Ahuja TS, Niaz N, Agraharkar M. Clin Nephrol 2000 Jul; 54 (1), pp. 11–4.

Adverse Reactions: Nephrotoxicity (Geriatric Vulnerability)
Ioversol 300

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.

Background Information: Ioversol 300 is a low-osmolality iodinated contrast agent.

Application: Iodinated contrast media in fluid form are applied to detect anatomical abnormalities within body fluid compartments.

Route of Administration: Ioversol 300 (intravascular).

Dosage: Ioversol 300 (300 mg I/ml: mean dose of 1.36 ± 0.06 ml/kg; range 1–2 ml/kg BW).

Implementation: Ioversol is injected as a bolus for computed tomography (CT) imaging procedures. Evaluation parameters include serum creatinine levels and creatinine clearance calculated at 24, 48, and 72 hours after examination with values and compared to a reference serum creatinine value taken before CT imaging. Findings are compared with a control group

Human Model: Cases subjected to CT imaging procedures using iversol contrast media (e.g., n = 44 cases that are age-matched to control subjects).

Interpretation and Analysis: No significant increase in serum creatinine (+0.6 mmol/l) or in creatinine clearance (+0.7 ml/min) can be detected during the 72 hour period following ioversol injection. Rarely, geriatric patients may develop elevations in serum creatine (e.g., n = 1/47). Some geriatric patients may therefore have subclinical renal impairment detected as decreases in initial creatinine clearance. The use of low-osmolality ioversol makes it possible to perform examinations with an iodinated contrast agent without increasing the incidence of nephrotoxicity in elderly subjects.

Effects of the low-osmolality contrast medium ioversol (Optiray) on renal function in a geriatric population. Louvel JP, Primard E, Henry J, Houlette C, Weinstein A, Janvresse A. Acta Radiol 1996 Nov; 37 (6), pp. 950–3.

Adverse Reactions: Neurotoxicity as a Function of Hydrophobicity
Ioversol/Iopromide/Iohexol/Iopamidol

Cellular/Molecular Mechanism of Action: Iodinated organic contrast agents are relatively radiodense and serve as liquid marker preparations to detect anatomical alterations within fluid compartments when applied with conventional radiographic imaging techniques.

Physiological Mechanism of Action: Ideally, iodinated organic agents are physiologically inert.

Background Information: The neurotoxicity of an x-ray contrast medium appears inversely related to hydrophilicity characteristics.

Application: In a clinical scenario, non-ionic x-ray contrast agents (ioversol, iopromide, iohexol, and iopamidol) can be applied to detect and evaluate anatomical abnormalities affecting the cerebral spinal fluid space surrounding the spinal cord.

Implementation: Delineation of the effect of 4 non-ionic x-ray contrast agents, differing in hydrophilicity (ioversol, iopromide, iohexol, and iopamidol), following injection at the cisternal magna.

Animal Model: Rats (ether-anesthetized).

Interpretation and Analysis: Iopromide has an acute median lethal dose of 122 mg I/kg. Other signs of toxicity include convulsions, apnea, dyspnea and hypoactivity. Conversely, ioversol, iohexol and iopamidol cause no deaths when administered intracisternally, up to a dose of 1000 mg I/kg. Animals administered these non-ionic agents display signs of convulsions, apnea, dyspnea, chewing and hypoactivity. Iopromide possesses a hydrophilicity (e.g., water to octanol partition coefficient) approximately 8.5 times smaller than ioversol, 4.6 times smaller than iohexol, and 2.3 times smaller than iopamidol. Based on these observations, triiodinated x-ray contrast

materials with smaller degrees of hydrophilicity appear to produce greater toxicity to the central nervous system.

Neurotoxicity of non-ionic x-ray contrast media after intracisternal administration in rats. Wible JH Jr, Barco SJ, Scherrer DE, Wojdyla JK, Adams MD. Eur J Radiol 1995 Mar; 19 (3), pp. 206–11.

Adverse Reactions: Nephrotoxicity: Renal Tubular Function Alterations (Relative)/Pharmacokinetics *Iodixanol/Iohexol/Ioxaglate*

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.
Application: Iodixanol, iohexol, and ioxaglate can be applied as positive contrast image-enhancing agents. Iodixanol is a dimeric, ratio 6 radiographic contrast medium formulated to be isotonic relative to plasma in all concentrations fasciliated by the balanced addition of electrolytes.
Implementation: Evaluation of the clinical-chemical parameters and tolerability of iodixanol.
Interpretation and Analysis: Increases in femoral blood flow following administration of iodixanol is significantly smaller than that seen with most other non-ionic contrast media. Iodixanol appears to have less impact than other non-ionic media on renal tubular function. Unlike iohexol and ioxaglate, the rate of adverse events after iodixanol administration is essentially the same for normal cases compared to scenarios of increased risk for negative reactions (cases with previous adverse reactions to contrast administration). The risk following administration of iodixanol also appears to be similar in normal controls and in cases with other risk factors, including those with a history of congestive heart failure, renal insufficiency or disease (e.g., asthma, diabetes, hypertension, vascular disorders). A significant reduction in the sensation of injection-associated heat and pain has been noted for iodixanol relative to ioxaglate. Cardiac electrophysiological and contractility measurements reveal minimal interference associated with iodixanol administration. Iodixanol is a safe and effective non-ionic, isotonic contrast medium that may offer several clinical advantages.

Safety, tolerance, and pharmacokinetics of iodixanol injection, a non-ionic, isosmolar, hexaiodinated contrast agent. Fountaine H, Harnish P, Andrew E, Grynne B. Acad Radiol 1996 Sep; 3 Suppl 3, pp. S475–84.

Adverse Reactions: Neophrotoxicity/Renal Morphological Changes *Iobitridol/Iohexol*

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.
Route of Administration: Iopamidol (intravascular), iobitridol (intravascular), iohexol (intravascular)
Dosage: Iopamidol (3 g iodine/kg: rat), iobitridol (3 g iodine/kg: rat), iohexol (3 g iodine/kg: rat).
Implementation: Detection of renal morphologic changes induced by intravenously injected contrast media (CM) following 24 hours of water deprivation. Renal specimens are collected and fixed by perfusion for light and electron microscopy 2 hours postinjection of iopamidol, iobitridol, or iohexol (controls receive physiologic saline). In the 2nd part of the study, fixation is performed 48 hours after the injection of the corresponding dose of iobitridol or iohexol.
Animal Model: Rat (n = 40 Wistar strain deprived of water 24 hours prior to contrast injection).
Interpretation and Analysis: Semi-quantitative evaluation of renal structural changes reveals moderate changes in lysosomes within proximal convoluted tubular cells 2 hours after iopamidol injection. Iobitridol and iohexol induce prominent lysosomal alterations with signs of cytoplasmic injury. After 48 hours, the changes induced by iobitridol have almost disappeared, whereas the iohexol group still shows statistically significant levels of vacuolization. Although the general physicochemical properties of iobitridol and iohexol appear similar (*in vitro*), the different lysosomal alteration may reflect differences in their *in vivo* characteristics.

Structural changes in the renal proximal tubular cells induced by iodinated contrast media. Tervahartiala P, Kivisaari L, Kivisaari R, Vehmas T, Virtanen I. Nephron 1997; 76 (1), pp. 96–102.

Adverse Reactions: Prevention of Ioxaglate-Mediated Effects/Protein Extravasation Prophylaxis/Pulmonary Edema Prophylaxis/Decreased Arterial Partial Oxygen Prevention *Gabexate Mesilate/Nafamostate Mesilate*

Cellular/Molecular Mechanism of Action: Gabexate mesilate and nafamostate mesilate function as synthetic protease-inhibitor anticoagulant agents. Iodinated compounds, including ioxaglate, possess radiopaque properties.
Application: Gabexate mesilate and nafamostate mesilate are both prophylactically effective in preventing ioxaglate-induced protein extravasation and pulmonary edema. Ioxaglate is an iodinated positive contrast image-enhancing agent that can be used in conventional diagnostic radiography procedures.
Route of Administration: Ioxaglate (intravenous); gabexate mesilate (intravenous); nafamostat mesilate (intravenous).
Dosage: Gabexate mesilate (10 and 50 mg/kg at 5 minutes prior to ioxaglate injection) or nafamostat mesilate (3 and 10 mg/kg); ioxaglate (4 g iodine /kg).
Implementation: Evaluation of the potential ability of ioxaglate to promote marked protein extravasation, pulmonary edema and decreases in the arterial partial oxygen pressure (e.g., rats).
Interpretation and Analysis: Pretreatment with gabexate mesilate (10 and 50 mg/kg, 5 minutes prior to injection) and nafamostat mesilate (3 and 10 mg/kg) can both prevent all of these reactions induced by ioxaglate associated with protein extravasation and pulmonary edema. In this context, injection of nafamostat mesilate at a dosage of 10 mg/kg results in complete inhibition.

One of the effects evoked by ioxaglate is an enhancement of nafamostat-sensitive protease activity in the extracellular fluid of rat peritoneal mast cell suspensions. An enzyme fraction that gabexate mesilate and nafamostat mesilate inhibit includes the biochemical activity associated with purified human lung tryptase, although nafamostate mesilate is far more potent in this regard. Physiologically, tryptase enhances the permeability of protein through the monolayer of cultured human pulmonary arterial endothelial cells. Ioxaglate, when applied in combination with rat peritoneal mast cells, also creates endothelial barrier dysfunction. These effects of tryptase and ioxaglate are reversed by nafamostat mesilate. Furthermore, immunofluorescence morphological analysis reveals that tryptase or ioxaglate in combination with mast cells increases actin stress fiber formation, while decreasing VE-cadherin immunoreactivity. Both of these actions of tryptase and ioxaglate are reversed by nafamostat mesilate. Therefore, the liberation of tryptase from mast cells plays a crucial role in ioxaglate-induced pulmonary dysfunction. In this respect, nafamostat mesilate may become a useful agent for the cure or prevention of severe adverse reactions to radiographic contrast media.

A potent tryptase inhibitor nafamostat mesilate dramatically suppressed pulmonary dysfunction induced in rats by a radiographic contrast medium.

Sendo T, Itoh Y, Goromaru T, Sumimura T, Saito M, Aki K, Yano T, Oishi R. Br J Pharmacol 2003 Mar; 138 (5), pp. 959–67.

Adverse Reactions/Prophylactic Inhibition of Contrast Media Nephropathy
Acetylcysteine

Cellular/Molecular Mechanism of Action: Acetylcysteine functions as a reducing (antioxidant) agent. Such properties are mediated by its free sulfhydryl group, which donates hydrogen ion to oxidized disulfide bond structures.
Background Information: Radiographic contrast media are used at an increasing rate for a variety of diagnostic and therapeutic applications. As a result, the incidence of contrast agent-induced nephropathy is likely to become a more important sequellae. Efforts to discovery and validate strategies for the prevention of radiographic contrast-induced nephropathy is mandatory. The pathogenesis of radiographic contrast agent-induced nephropathy is considered to be associated with vasoconstriction-mediated renal medullary ischemia and direct toxic damage to renal tubular epithelial cells. These effects may be partly mediated by the generation of reactive oxygen species. Data from experimental studies indicate that antioxidants like acetylcysteine, may prevent radiocontrast-induced nephropathy.
Application: Prophylactic agent to prevent the development of renal dysfunction and injury associated with contrast agent administration especially in cases already suffering from variable degree and nephropathy/dysfunction.
Route of Administration: Aetylcysteine (oral/per os).
Dosage: Acetylcysteine (600 mg b.i.d.).
Considerations: In theory, other antioxidant reagents, including DMSO and vitamin E and vitamin E/selenium, might complement the prophylactic properties associated with acetylcysteine related to renal nephropathy precipitated by the intravascular administration of positive contrast media.
Implementation: Administration of acetylecysteine in cases suffering from moderate renal insufficiency to determine its capacity to function as a prophylactic agent to prevent compromised renal function precipitated by radiocontrast administration.
Interpretation and Analysis: Prophylatic oral administration of acetylcysteine combined with hydration prevents the reductions in renal function following radiocontrast administration. The use of acetylcysteine together with hydration is one of the treatments of choice to protect against radiographic contrast media–induce nephropathy.

Acetylcysteine and contrast media nephropathy. Tepel M, Zidek W. Curr Opin Nephrol Hypertens 2002 Sep; 11 (5), pp. 503–6.

Adverse Reactions/Prophylaxis of Contrast Media (CM)-Induced Nephropathy
Acetylcysteine/Endothelin Blockers/Fenoldopam

Cellular/Molecular Mechanism of Action: Acetylcysteine functions as a reducing (antioxidant) agent. This property is mediated by its free sulfhydryl group, which donates hydrogen ion to oxidized disulfide bond structures. Endothelin blockers/inhibitors (bosentan) prevent endothelin-induced activation of protein kinase-C, thereby suppressing the overproduction of oxidative species that contribute to the mechanisms of endothelial dysfunction. Fenoldopam functions as an intrarenal vasodialator agent mediated through dopamine D1-receptor complexes.
Background Information: Contrast media–associated nephropathy has become a major cause of iatrogenic acute renal failure, especially with the increasing use of radiographic CM in both diagnostic and interventional procedures. Contrast media–associated nephropathy is the 3rd most common cause of iatrogenic acute renal failure, and is associated with increased morbidity and in-hospital mortality.
Application: Acetylcysteine, endothelin blockers, and fenoldopam can be applied as prophylactic agents to prevent contrast agent–induced nephropathy, especially in scenarios of pre-existing renal dysfunction/pathology. Acetylcysteine has also been used as an antioxidant mucolytic agents. Fenoldopam has been successfully applied to prevent renal dysfunction associated with hypotension and hypothermia evoked during cardio-bypass procedures.
Interpretation and Analysis: Contrast media–associated nephropathy typically presents as an acute rise in serum creatinine levels, usually within 48 hours after exposure to CM. Renal medullary ischemia secondary to contrast-induced vasoconstriction is now believed to be the most likely cause of CM-associated nephropathy, although direct renal tubular cytotoxicity does appear to also play a role. The occurrence of CM-associated nephropathy is directly related to the number of coexisting clinical risk factors. Among the many risk factors, pre-existing renal impairment, the presence of diabetes mellitus and the volume of the contrast agent administered are the most important. The most effective means of reducing the incidence of CM-associated nephropathy is through prevention, by 1st identifying the risk factors and then attempting to correct for them before the administration of contrast material. Although it was the earliest and most well tested preventive measure, intravenous hydration continues to be the most effective way to prevent CM-associated nephropathy, recent studies have provided many new preventive modalities. The growing use of these new agents, such as acetylcysteine, endothelin blockers, and most recently fenoldopam, has increased the options available for the prevention of CM-associated nephropathy.

Contrast-associated nephropathy. Soma VR, Cavusoglu E, Vidhun R, Frishman WH, Sharma SK. Heart Dis 2002 Nov–Dec; 4 (6), pp. 372–9.

Adverse Reactions/Pulmonary Artery Pressure Alterations/Cardiopulmonary Angiography Procedures
Iohexol/Ioxaglate

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.
Application: Iohexol and ioxaglate can both be applied as positive imaging enhancing contrast agents to facilitate the conduction of angiography procedures.
Route of Administration: Iohexol (intravascular); ioxaglate (intravascular).
Dosage: Iohexol (40 ml); ioxaglate (40 ml) within 2 seconds at 600 psi (0.17 kg/m^2).
Implementation: Evaluation of alterations in pulmonary artery pressure induced by iodine-based positive contrast imaging agents (e.g., iohexol, ioxaglate) in cases of suspected pulmonary emboli (e.g., n = 99). Mean pulmonary arterial pressure, pulse rate, and blood pressure are recorded before, immediately after, and 2, 5, and 10 minutes following injection.
Interpretation and Analysis: Pulmonary arterial pressure increases to a maximum at 2 minutes and is higher in patients with pulmonary emboli ($p = 0.06$). Usually, no significant differences can be appreciated between iohexol vs ioxaglate contrast media. The systolic blood pressure and pulse rate in patients with pulmonary emboli increase significantly more with ioxaglate ($p = 0.03$ and 0.04, respectively). In approximately 90% of the images acquired with both contrast image-enhancing agents, the quality of the resulting radiographs is of an excellent quality. Both contrast agents are

safe for pulmonary angiography and yield similar image quality. There appears to be a positive inotropic effect of ioxaglate.

Hemodynamic effects and image quality of low-osmolar ionic and non-ionic contrast media during pulmonary angiography. Smit EM, van Beek EJ, Bakker AJ, Reekers JA. Acad Radiol 1995 Jul; 2 (7), pp. 609–13.

Adverse Reactions/Safety and Diagnostic Effiacy of Contrast Agents/ Excretory Urography
Iodixanol/Iohexol

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.
Physiological Mechanism of Action: Iodixanol is a non-ionic, dimeric, iodinated contrast agent, whereas iohexol is a monomeric agent.
Application: Iodixanol and iohexol are contrast agents that can be applied to perform excretory urography diagnostic imaging procedures.
Route of Administration: Iodixanol (intravascular).
Dosage: Iodixanol (270 mg I/ml and 320 mg I/ml) compared to iohexol (300 mg I/ml). The dose for every case is 1 ml/kg of body weight (human).
Implementation: Utilization of iodixanol and iohexol to perform excretory urography procedures. Evaluation of the efficacy and safety of the agents can be assessed by recording image quality, alterations in vital signs, laboratory value variations, and adverse reactions. Radiographic images are also interpreted and evaluated for enhancement of image quality.

Human Model: Cases subjected to excretory urography procedures (e.g., n = 75 cases; randomized, double blind, parallel comparison design).
Interpretation and Analysis: Evaluation of each phase of the radiographic study reveals almost uniform good-to-excellent opacification, with no significant differences appreciated among the 3 agents. No significant differences can be detected in vital signs, hematology, blood and urine chemistry, and injection discomfort for iodixanol (270 mg I/ml), iodixanol (320 mg I/ml) or iohexol (300 mg I/ml). Deaths or serious reactions are extremely rare (e.g., n = 0/75) and there are no statistically significant differences in the number of adverse events. Iodixanol at both 270 and 320 mg I/ml is a safe and effective contrast material for intravenous urography. The profile for iodixanol is essentially indistinguishable from that of iohexol at 300 mg I/ml.

Comparison of iodixanol with iohexol in excretory urography. Siegle RL, Gavant ML. Acad Radiol 1996 Sep; 3 Suppl 3, pp. S524–7.

Adverse Reactions/Safety of Contrast Agents (Relative)
Iotrolan/Iohexol

Route of Administration: Iotrolan (selective intracoronary artery delivery); iohexol (selective intracoronary artery delivery).
Dosage: Iotrolan (concentration = 320 mg I/ml); iohexol (concentration = 350 mg I/ml).
Implementation: Evaluate selective coronary angiography and left ventriculography with iotrolan compared to iohexol (e.g., n = 120 cases). Relevant variables that can be measured include maximum increase of the left ventricular end-diastolic pressure up to 6 minutes after ventriculography; hemodynamic and electrocardiographic variables; arrhythmogenicity; clinical laboratory parameters; tolerance; adverse events and diagnostic efficacy.
Interpretation and Analysis: Iotrolan produces a smaller change in left ventricular end-diastolic pressure compared to iohexol, but the difference is not statistically significant. Transient changes in left ventricular systolic pressure, intra-arterial systolic pressure, intra-arterial diastolic pressure, and in electrocardiographic parameters, occur after injections, but they are not clinically significant. Changes in clinical laboratory markers from baseline values are comparable between the 2 groups and confirm good levels of renal and hepatic tolerance. During the acquisition of ventriculograms, iotrolan evokes fewer sequelae compared to iohexol ($p = 0.002$). Adverse events, that are mild or moderate in most cases, are not statistical different between the 2 agents. The contrast quality of both agents is good and not statistically different. No significant difference exists between iotrolan 320 and iohexol 350 with regard to cardiovascular safety or patient tolerance, except for a minor difference in the intensity of induced heat/warmth sensations.

Comparison of iotrolan 320 and iohexol 350 in cardiac angiography: A randomised double blind clinical study. Mezilis N, Salame MY, Dyet JF, Arafa SO, Oakley GD, Cumberland DC. Eur J Radiol 1998 Sep; 28 (2), pp. 171–5.

Adverse Reactions/Safety and Tolerance/ Radiographic Enhancement/Angiography Contrast Agents
Iodixanol/Ioxaglate

Cellular/Molecular Mechanism of Action: Iodixanol is an iodinated compound that has radiopaque properties. Iodixanol is a new isosmotic hexaiodinated non-ionic contrast agent being evaluated for intravascular use.
Background Information: Iodixanol is a hexaiodinated non-ionic compound formulated as an isosmotic liquid that has been designed to provide improved *in vivo* safety and tolerance.
Application: Iodixanol is an iodinated preparation that is utilized as a radiopaque contrast agent in angiography (aortography) diagnostic procedures.
Route of Administration: Iodixanol (intravascular).
Implementation: Delineation of the relative (i) safety and tolerance of iodixanol compared with ioxaglate; and (ii) radiographic enhancement provided by iodixanol compared to ioxaglate by evaluation of their efficacy in renal angiography, visceral angiography, and aortography procedures (e.g., n = 44 cases). Parameters assessed include adverse events, injection-associated discomfort, changes in laboratory parameters, and variations in vital signs. Efficacy is measured by the overall quality of angiographic image enhancement.
Interpretation and Analysis: During the vast majority of diagnostic procedures, no serious adverse events can be appreciated (e.g., n = 0/44). Mild-to-moderate adverse events are more common in cases receiving ioxaglate ($p = .041$). Injection-associated pain is reported in a small percentage of cases receiving ioxaglate (e.g., n = 3/44) but is much more infrequent with iodixanol (e.g., n = 0/44; $p = .093$). Clinical laboratory and vital-sign data show no difference between groups, and there is no difference in the overall quality of angiographic visualization ($p = 0.711$). Iodixanol is associated with improved safety and patient tolerability, while it provides images of equivalent diagnostic efficacy compared with ioxaglate.

Comparison of iodixanol and ioxaglate for adult aortography and renal/visceral angiography: A phase III clinical trial. Siegel EL, Rosenblum JD, Eckard DA, Leef J, Bergh J, Parsa MB, Redick ML. Acad Radiol 1996 Sep; 3 Suppl 3, pp. S507–13.

Adverse Reactions/Safety and Tolerability
Iodixanol/Ioxaglate

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.

Background Information: Iodixanol is an iso-osmolar non-ionic dimeric hydrophilic contrast agent that has a level of diagnostic efficacy comparable to other iodinated contrast media. Because of its physical properties, iodixanol would be expected to produce a lower incidence of adverse events than other non-dimeric contrast media. Indeed, pharmacodynamic studies indicate that iodixanol has fewer cardiovascular effects, causes less renal damage and is associated with similar or smaller changes to the blood-brain barrier and neurological function when compared with non-dimeric non-ionic contrast media.
Application: Iodinated radiographic contrast agents are applied to detect anatomical abnormalities within fluid body compartments.
Interpretation and Analysis: In clinical trials, iodixanol has demonstrated a similar tolerability profile relative to other non-ionic contrast media but induces fewer adverse events than ioxaglate. Iodixanol appears to have an advantage over other contrast media in that it generally causes less frequent and less intense sensations of discomfort following administration by injection. However, in common with other newer and most non-ionic contrast media, iodixanol is expensive. Studies investigating other non-ionic contrast media (but not iodixanol) have shown that it is not cost-effective to replace older, usually ionic, contrast media with the more costly newer alternatives. Nonetheless, in selected patients who are considered at increased risk of contrast medium-associated adverse events, non-ionic agents should be used. Iodixanol, with its lower intensity (and possibly frequency) of discomfort, may be a preferred option under such conditions.

Iodixanol. A review of its pharmacodynamic and pharmacokinetic properties and diagnostic use as an x-ray contrast medium. Spencer CM, Goa KL. Drugs 1996 Dec; 52 (6), pp. 899–927.

Adverse Reactions/Toxicological Profile: Contrast Media
Iobitridol

Cellular/Molecular Mechanism of Action: Iodinated contrast media are radiodense and are traditionally applied as passive liquid marker systems that enhance the accuracy and sensitivity of radiographic imaging techniques.
Application: Iobitridol is a new non-ionic low-osomolality contrast medium utilized to detect anatomical abnormalities within body cavities and fluid compartments.
Route of Administration (Research): Iobitridol (intravenous [mouse, rat, dog]; oral [mouse]; intracisternal [rats]).
Implementation: Characterization of the toxicity of iobitridol following acute or repeated intravenous administration in several different species (mouse, rat, dog); single oral administration in the mouse and intracisternal injection in rats. Complementary evaluations include delineation of teratogenicity and mutagenicity in rats and rabbits in concert with potential local perivenous toxicity in rabbits.
Animal Model: Murine, rat and canine.
Interpretation and Analysis: Acute toxicity of iobitridol in mice is equivalent to iohexol (reference agent). Chronic administration (daily intravenous injections over 4 weeks) in the rat and dog do not demonstrate any particular toxicity for iobitridol. Unlike iohexol, iobitridol does not provoke any vacuolization of the renal tubular cells in the rat following repeated injections. Furthermore, iobitridol does not induce any detectable teratogenic or mutagenic properties. The typical local inflammatory signs observed following perivenous injection in the rabbit are low in intensity and reversible. In summary, the toxicologic profile of iobitridol appears to be favorable and does not show any particular risk for clinical use under the usual indications of water-soluble iodinated contrast agents.

Toxicologic profile of iobitridol, a new non-ionic low-osmolality contrast medium. Donandieu AM, Idee JM, Doucet D, Legros A, Penati S, Nain-Dit-Ducret M, Marmion F, Bonnemain B. Acta Radiol Suppl 1996; 400, pp. 17–24.

Adverse Reactions/Trans-Placental Contrast Media Transport/Fetal Omphalomesenteric Duct Cysts
Iohexol

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.
Application: Iohexol is an iodinated, low-molecular weight postive contrast imaging enhancing media that can be utilized in angiography procedures.
Route of Administration: Iohexol can be administered intravascularly.
Interpretation and Analysis: Iohexol can be identified in the intestines of twin neonates after administration to pregnant mothers during the course of angiography procedures. Non-ionic contrast agents cross the human placenta and enter the fetus in significant concentrations to the extent that they can facilitate the identification of fetal omphalomesenteric duct cysts.

Transplacental passage of iohexol. Moon AJ, Katzberg RW, Sherman MP. J Pediatr. 2000 Apr; 136 (4), pp. 548–9.

Agents: General Concept/Contrast Agent Properties and Tissue Concentration
Iohexol/[^{14}C]-Labeled Inulin

Background Information: Computed tomography (CT) provides accurate measurement of blood iodine concentration *in vivo*, as well as in phantoms simulating tissue; however, its ability to measure radiopaque agents in biologic tissues in comparison with a standard technique has not been well demonstrated.
Application: Validate the performance of CT imaging for *in vivo* quantification of contrast media in a variety of biologic tissues by evaluating comparisons between CT imaging with an iodinated contrast agent (iohexol) utilizing a reference tracer quantification technique (storage-phosphor autoradiography with [^{14}C]-labeled inulin).
Implementation: Intravenous injection of a cocktail containing iohexol and quantification of [^{14}C]-labeled inulin formulated at different dose ratios. Sacrifice (e.g., rabbit) is performed immediately following injection in order arrest blood flow at different stages of tissue tracer distribution [Baseline = no iohexol-inulin]. Liver, spleen, kidneys, testis, and heart are excised and rapidly frozen. Each organ is subsequently scanned with CT (1-mm contiguous sections) to determine tissue iodine distribution. Twenty-micrometer tissue slices are prepared in planes that correspond with the orientation of CT images. Storage-phosphor screen autoradiography is performed to quantify [^{14}C]-labeled inulin distribution. Digital image analysis of CT images and autoradiograms is performed on spatially matched regions, and resultant tracer concentrations compared.
Animal Model: Rabbit (n = 6 New Zealand White breed).
Interpretation and Analysis: Tracer concentrations are highly correlated, with resultant R2 values exceeding 0.9 in all tissues. The high correlation of results for iodinated tracer quantification in tissues for CT compared to those obtained with the reference technique validate the performance of CT as an accurate means of measuring concentration of radiopaque agent in tissue, independent of tracer dose.

Indicator measurement in tissues: CT with iohexol vs storage-phosphor autoradiography with carbon-14-labeled inulin. Whiteman KR, Wolf GL. Acad Radiol 1998 Nov; 5 (11), pp. 799–803.

Agents: General Concepts/Contrast Agent Properties/Hydrophobicity/Stability/Toxicity/ Function of Molecular Configuration and Chemical Composition
Iobitridol

Background Information: The chemotoxicity of iodinated contrast agents is essentially related to the spatial accessibilty of lipophilic and polarizable iodine atoms.
Laboratory Analysis: Spatial accessibility of lipophilic and polarized iodine atoms in iobitridol can be delineated applying high-performance liquid chromatography (HPLC) analysis and ^{1}H- and ^{13}C-NMR spectroscopy with the static distribution of the hydrophilic groups around the triiodinated benzene ring, and especially the dynamic modulation of this distribution both taken into account. The purpose of addressing the dynamic modulation of distribution parameter is to prevent distortion of the hydrophilic sphere of non-ionic agents when exposed to a hydrophobic environment.
Interpretation and Analysis: Iobitridol is characterized by 2 tertiary carbamoyl substituents whose high rotation barriers (deltaG*353 = 27.6 kcal for E/Z-rotation and deltaG*345 = 17.3 kcal for syn/antirotation) stabilize the hydrophilic sphere. The 3rd dihydroxylated anilide substituent does not undergo SMILES rearrangement and provides iobitridol with its even hydrophilic distribution. Iobitridol possesses remarkable chemical solubility (> 140% m/v) and stability. The iobitridol molecule has been specifically designed with the aim of stabilizing the hydrophilic sphere around the triiodinated benzene ring, therefore permanently masking access to the iodine atoms. This new concept represents a further step forward toward the synthesis of new iodinated contrast agents, which should be totally inert vis-à-vis biological membranes and proteins.

Stabilization of the hydrophilic sphere of iobitridol, a new non-ionic iodinated contrast agent. Meyer D, Petta M, Fouchet MH, Vadel M, Schaefer M, Dugast-Zrihen M, Guillemot M. Acta Radiol Suppl 1996; 400, pp. 8–16.

Agents: General Concepts/Contrast Imaging Agents Properties/ Pharmacokinetics/Renal Clearance (Age-Related Differences)
Iodixanol

Application: Iodixanol is an iso-osmolar iodinated radiocontrast agent.
Route of Administration: Iodixanol (intravascular).
Dosage: Iodixanol.
Implementation: Iodixanol is administered by cardiac catheterization and then plasma samples collected at 0.75 to 1.25 hours, 2 to 4 hours, 8 to 12 hours, and 16 to 32 hours postinjection (e.g., n = 41 cases: newborn to < 2 months; 2 to < 6 months; 6 months to < 1 year; 1 to < 3 years; and 3 to ≤ 12 years). Plasma concentrations of iodixanol can subsequently be determined using high performance liquid chromatography. The primary pharmacokinetic end point to be applied is the terminal elimination rate constant (K_{el}).
Interpretation and Analysis: Mean K_{el} is significantly lower in newborns ≤ 2-month-old cases in contrast to older subjects: (h-1, mean ± standard deviation [SD]): newborn to < 2 months 0.185 ± 0.060, 2 to < 6 months, 0.256 ± 0.046, 6 months to < 1 year 0.299 ± 0.042, 1 to < 3 years 0.322 ± 0.058, and 3 to ≤ 12 years 0.307 ± 0.071; with increasing age, excretion is more rapid, as shown by each age group's elimination half-life ($T_{1/2}$ beta; 4.14 ± 1.41 hours, 2.79 ± 0.55 hours, 2.36 ± 0.37 hours, 2.23 ± 0.51 hours, and 2.36 ± 0.52 hours, respectively). Elimination of iodixanol in children > 6 months of age is comparable to normal adults. Prolonged elimination in children < 6 months of age is related to renal immaturity.

Iodixanol pharmacokinetics in children. Johnson WH Jr, Lloyd TR, Victorica BE, Zales VR, Epstein ML, Leff RD, Ardinger RH Jr, Slovis TL, Johnson JA, Marsters PA. Pediatr Cardiol 2001 May–Jun; 22 (3), pp. 223–7.

Agents: General Concepts/Contrast Imaging Agents/Pharmacokinetics/Iodine Concentrations/ Plasma Clearance
Iohexol

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.
Application: Iodine can be used as a postive radiographic contrast imaging agent.
Dosage: Iohexol (300 mg iodine/kg in dog/cats).
Laboratory Analysis: Analysis of iodine contained in iohexol preparations utilizing plasma atomic emission spectroscopy. Measurement of iodine at 178.276 nm on the phosphorus 178.287 nm channel of the polychromator by utilization of spectrum shifter offset software, while correcting for P with the sequential P 214.914 nm emission line.
Implementation: Evaluation of glomerular filtration rate using an intravenous injected bolus of iohexol with plasma samples collected at T = 0.0 hours, 3.0 hours, and 7.0 hours.
Animal Model: Canine and feline.
Interpretation and Analysis: Determination of iodine on a polychromator provides excellent precision in the measurement of serum iodine, even with interelement correction of P with a sequential P line. Total imprecision (CV) (n = 13) is 16% (at 13.7 mg/L I), 8.6% (28.7 mg/L), 3.6% (59.0 mg/L), 2.6% (120.5 mg/L), 1.7% (237.8 mg/L), 1.2% (478.7 mg/L), and 1.8% (597 mg/L). The linear range is approximately 15–600 mg/L. Iohexol added to serum (mg/L iodine) equivalent to 15, 30, 60, 120, 240, 480, and 600 produce percent recoveries of approximately (91.3%), (95.7%), (98.3%), (100.4%), (99.1%), (99.7%), and (99.5%), respectively.

A single intravenous iohexol injection is sufficient to measure glomerular filtration rate using a single compartment model for plasma clearance calculated using plasma samples drawn at T = 0.0 hours, 3.0 hours, and 7.0 hours (dog and cat). Using this experimental protocol, correlation coefficients are > 0.99 for the beta phase of the plasma disappearance curve.
Instrumentation: Plasma-atomic emission spectroscopy.

Measurement of serum iohexol by determination of iodine with inductively coupled plasma-atomic emission spectroscopy. Braselton WE, Stuart KJ, Kruger JM. Clin Chem 1997 Aug; 43 (8 Pt 1), pp. 1429–35.

CARDIOVASCULAR SYSTEM

Angiography: Arterial and Venous
Carbon Dioxide (CO_2)

Cellular/Molecular Mechanism of Action: Carbon dioxide functions as a compound with radioleucent properties.
Application: Contrast agent in angiogam procedures.
Route of Administration: Intravascular.
Implementation: Evaluation of the capacity and limitations of CO_2 to function as a contrast agent to guide vascular interventional procedures in scenarios limited by pre-existing renal insufficiency or allergic reaction. Examples of arterial procedures capable of being performed include renal angioplasty or stent (e.g., n = 6), iliac angioplasty or stent (e.g., n = 5), infrainguinal angioplasty (e.g., n = 5), arterial bypass graft angioplasty (n = 3), and thrombolysis (e.g., n = 2). Examples of venous procedures include trans-jugular intrahepatic portosystemic shunt recanalization (e.g., n = 3), angioplasty

of the venous anastomosis of a thigh dialysis graft (e.g., n = 1), and angioplasty of the inferior vena cava (e.g., n = 1).

Human Model: Clinical angiography procedures (e.g., n = 26; n = 21/26 arterial; n = 5/26 venous) in cases with pre-existing renal insufficiency (e.g., n = 21/26; mean creatinine level, 2.8 mg/dl), or allergic reaction (e.g., n = 1/26).

Interpretation and Analysis: The rate of success applying CO_2 facilitated angiography is relatively high (e.g., n = 25/26). Approximately 31% of cases (e.g., n = 8/26) require no iodinated contrast material, while about 42% (e.g., n = 11/26) require less than or equal to 20 ml of contrast material. Alternatively, CO_2 is inadequate in approximately 27% of diagnostic procedures performed (e.g., n = 7/26). Iliac artery angioplasty or stent placement requires an average of 9 ml of iodinated contrast material; infrainguinal angioplasty requires an average of 22 ml of iodinated contrast material. Therefore in the application of CO_2, it can be successfully used as a contrast agent in a variety of vascular interventional procedures. Such diagnostic methods can usually be performed in the iliac and infrainguinal arteries using minimal supplemental iodinated contrast material. However, CO_2 fails to provide satisfactory guidance in approximately 50% of intra-abdominal procedures.

Carbon dioxide as a contrast agent to guide vascular interventional procedures. Eschelman DJ, Sullivan KL, Bonn J, Gardiner GA Jr. AJR Am J Roentgenol 1998 Nov; 171 (5), pp. 1265–70.

Angiography/Contrast Media Comparison (Iodine vs Gadolinium-Based Formulations)/ Digital Subtraction Procedures

Gadolinium Diethylenetriamine Pentaacetic Acid ([Gd]-DTPA)

Application: [Gd]-DTPA can function as an alternative contrast agent for digital subtraction angiography (DSA) in patients with renal insufficiency or previous anaphylactic reaction to iodinated contrast agents.

Route of Administration: [Gd]-DTPA (intravascular).

Dosage: [Gd]-DTPA 0.5-M solution without exceeding a total amount of 0.4 mmol/kg body weight (Magnevist, Schering, Berlin, Germany). Injection rate is identical for iodinated contrast reagents.

Implementation: Angiography procedures performed with power-injected or hand-injected [Gd]-DTPA (e.g., n = 34 digital subtraction angiography studies). Application of this diagnostic contrast agent's provides the flexibility of being able to be utilized as the sole contrast reagent (e.g., n = 18/34) or in combination with carbon dioxide (CO_2: n = 9/34). Validation can be achieved by performing restricted non-ionic contrast medium injections.

Interpretation and Analysis: Vascular anatomical structures that can be successfully imaged include cerebral and carotid arteries, superior limbs, abdominal aorta, renal arteries, renal transplants, iliac arteries, and inferior limbs. Additional examples include endovascular intervention procedures (e.g., n = 10/34) such as transjugular intrahepatic percutaneous stent shunts (e.g., n = 3/10). The incidence of side effects is very low to non-existent. Diagnostic angiographic images can be obtained in a large percentage of cases with the exception of some distal run-off studies (e.g., n = 5/8). Gadolinium-based contrast can produce clinically useful angiograms in patients with a contraindication to iodine who must undergo angiography.

Gadolinium dimeglumine: An alternative contrast agent for digital subtraction angiography. Hammer FD, Goffette PP, Malaise J, Mathurin P. Eur Radiol 1999; 9 (1), pp. 128–36.

Angiography/Contrast Imaging Agents: Relative Effectiveness

Gadolinium Chelates/Iodinated Contrast Imaging Agents/Carbon Dioxide Contrast Agent

Application: Imaging of vascular structures applying digital subtraction angiography (DSA) analyses.

Dosage: Gadolinium chelates (0.5 mol/L solutions; 34 ± 19 mL/case). Carbon dioxide (CO_2; 212 ± 226 mL).

Implementation: Diagnostic angiographies (e.g., n = 15) and percutaneous trans-luminal angioplasties (e.g., n = 15). Digital subtraction angiography performed in cases with contraindications to iodinated contrast media (e.g., n = 30 images; n = 22 cases, n = 5/22 females, n = 17/22 males; renal insufficiency: n = 28; hyperthyroidism: n = 1; contrast allergy: n = 2; mean age 64.9 years). Gadolinium chelates can be applied as the sole contrast agent (e.g., n = 17 images) or applied in combination with CO_2. Some cases will allow the combined applications of these image-enhancing agents with the restricted use of non-ionic iodinated contrast (mean 12.8 ± 4.7 mL; e.g., n = 6 images).

Interpretation and Analysis: The use of gadolinium chelates allows the acquisition of diagnostic angiographic images in the vast majority of cases (e.g., n = 30/30). However, the quality of angiograms is inferior compared with that obtained with iodinated contrast agents and superior compared with CO_2 as the contrast material. Adverse events are rarely recognized. Mean serum creatinine is approximately 2.6 ± 1.5 mg/dL before and 2.3 ± 1.0 mg/dL after DSA and contrast-induced nephropathy is rarely detected. Gadolinium chelates produce an x-ray DSA intermediate in image quality between iodinated contrast and CO_2. Digital subtraction angiography with intra-arterial gadolinium chelate administration may offer an alternative to iodinated contrast material in situations where iodine-containing agents are contraindicated.

The use of gadolinium chelates for x-ray digital subtraction angiography. Wagner HJ, Kalinowski M, Klose KJ, Alfke H. Invest Radiol 2001 May; 36 (5), pp. 257–65.

Angiography/Contrast Media Relative Effectiveness/Vasculature Architecture Malformation/Collateral Circulation/Arteriovenous Shunts/Residual Postembolization Disease

Iodinated Contrast Imaging Agent/Carbon Dioxide (CO_2) Contrast Imaging Agent

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.

Application: Angiography procedures.

Implementation: Evaluation of the diagnostic usefulness of CO_2 as a radiologic contrast medium in pre- and postembolization of hemodynamically active vascular malformations (HAVM).

Pre- and postembolization angiographies using sequentially iodinated contrast medium and CO_2 are performed in cases of HAVM (e.g., n = 8 studies in 5 cases). Images are then assessed for relative uptake by malformations based on the parameters of quality; filling in of the contrast agent in afferent artery of the HAVM; caliber and number of vessels; and existence of pathologic communications in HAVM. Such characteristics are evaluated both before and after embolization.

Interpretation and Analysis: The CO_2 angiographic results are compared to those obtained using iodinated contrast material. Relative to CO_2, iodinated contrast media provide superior image quality. The filling of arterial afferents of HAVM is well defined with both contrast media. In essentially all instances with CO_2 imaging, the

malformations reveal a larger number of vessels. No immediate or subsequent complications can usually be appreciated with CO_2 injections. Exceptions include the development of an intense sensation of cramps in the lower limbs.

As a diagnostic and assessment agent, CO_2 appears to be useful before and especially during the embolization of hemodynamically active vascular malformations. It improves quantification and uptake of the malformation's vascular architecture, detecting collateral circulation and arteriovenous shunts. It also detects residual postembolization disease when iodinated contrast agent is unsuccessful.

Instrumentation: Procedures can be performed aided by the use of Philips Integris V equipped with specific software to process images obtained with CO_2 as contrast medium and with a purpose-built gas injector pump.

CO_2 as a contrast medium in endoluminal treatment of high flow vascular malformations. Gorriz E, Carreira JM, Reyes R, Gallardo L, Pulido JM, Romero A, Maynar M. Eur J Radiol 1999 Sep; 31 (3), pp. 182–7.

Angiography/Contrast Agent Comparative Radiographic Image Enhancement
Iodipamide Ethyl Ester (IDE)

Cellular/Molecular Mechanism of Action: Iodinated compounds have radiopaque properties.

Application: The iodinated particulate contrast agent IDE can be applied in diagnostic angiography procedures. Because it is excreted slowly in bile and is isotonic, iodipamide ethyl ester may prove useful in cases with renal insufficiency, diabetes, multiple myeloma, or severe coronary disease.

Route of Administration: Iodinated particulate contrast agent IDE can be infused intravascularly for angiography procedures.

Dosage: Iodipamide ethyl ester (40–100 mg I/kg).

Implementation: Iodipamide doses are diluted to a total volume of 5 to 20 mL and injected to perform digital subtraction angiography. Reference procedures are performed applying iohexol as a water-soluble contrast medium. All images are reviewed blinded and graded subjectively on a 5-point scale.

Animal Model: Canine (n = 9 anesthetized dogs given iodipamide; and n = iohexol and water-soluble contrast media reference controls).

Interpretation and Analysis: Angiographic studies of multiple vascular territories performed with Iodipamide ethyl ester yield images of slightly lower overall quality compared with images obtained with iohexol ($p = 0.14$, Mann-Whitney U test). Arterial phase images are subjectively superior with iohexol when compared with iodipamide ethyl ester ($p < 0.0001$, chi^2).

Depiction of the corresponding veins during the venous phase on iodipamide ethyl ester angiograms is superior to iohexol angiograms in a large percentage of cases (e.g., n = 12/21), but is not statistically significant ($p > 0.05$ chi^2). Images of the renal vein and portal vein acquired with iodipamide ethyl ester are of a superior grade compared to a large percentage of those performed utilizing iohexol (e.g., n = 8/10). Angiography procedures are feasible with iodipamide ethyl ester as a contrast image-enhancing agent. Compared with iohexol, iodipamide ethyl ester produces images that are of a lesser quality during the arterial phase, but of equal or superior quality in the venous phase depending on the type of vessel imaging procedure.

Preclinical evaluation of an iodinated particulate contrast agent for use during angiography: Work in progress. Sproat IA, Lee FT Jr, Rappe AH, Chosy SG. J Vasc Interv Radiol 1996 Nov–Dec; 7 (6), pp. 889–95.

Angiography/Contrast Imaging Agents/ Pharmacokinetic Profiles/Coagulation Pathways: Potential Influences/Histamine and Leukotriene B_4: Influence on Release
P743 (Monodispersed Iodinated Contrast Agent)/ Iobitridol (Non-Ionic Contrast Agent)

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.

Application: Iodinated contrast imaging agent that can potentially be used in angiography procedures.

Route of Administration: P743 (intravascular).

Dosage: P743 (300 mg I/kg).

Implementation: Synthesis, molecular modeling, and pharmacokinetic profiling of an iodinated macromolecule (P743). Complementary evaluations include delineation of acute toxicity (mice), renal tolerance (normal rabbits), and renal tolerance in uninephrectomized conditions with superimposed dehydration and evaluated by selective intrarenal injection (rats). Permeability effects can also be evaluated *in vitro* applying isolated mastocytes populations along with evaluation of alterations in coagulation pathway function. Computed tomography vascular image analysis are performed after intravenous injection of P743 (300 mg I/kg in rabbits) and compared with the non-specific non-ionic agent iobitridol.

Animal Model: Murine, rat, and rabbit.

Interpretation and Analysis: The monodispersed macromolecular iodinated contrast agent P743 displays pharmacokinetic profiles in both rabbits and rats consistent with that of a rapid-clearance blood-pool agent. Diffusion *in vitro* through the endothelium is low, thus confirming early confinement of this macromolecule, unlike non-specific contrast media. In both species, P743 is excreted by glomerular filtration. Acute toxicity produces no mortality at the highest volume that could be injected into mice, leading to a calculated median lethal dose of greater than 8.9 g I/kg. Renal tolerance is good in euvolemic rabbits and uninephrectomized, dehydrated rats. No histamine or leukotriene B4 release can be detected in populations of isolated RBL-2H3 mastocytes. Coagulation pathways appear to be unaffected by P743 when evaluated at clinically relevant concentrations. Imaging experiments confirm that P743 remains within the vascular compartment for a longer period of time compared to iobitridol, thus allowing vascular enhancement that is twice as high as that of iobitridol during the recirculation phase. The pharmacokinetic and imaging profiles of P743, a new, monodisperse, macromolecular blood-pool iodinated contrast medium, are consistent with those of a rapid-clearance blood-pool agent. Its initial safety profile is satisfactory. Further experimental imaging studies are required to define the clinical interest in such molecules.

Preclinical profile of the monodisperse iodinated macromolecular blood-pool agent P743. Idee JM, Port M, Robert P, Raynal I, Prigent P, Dencausse A, Le Greneur S, Tichkowsky I, Le Lem G, Bourrinet P, Mugel T, Benderbous S, Devoldere L, Bourbouze R, Meyer D, Bonnemain B, Corot C. Invest Radiol 2001 Jan; 36 (1), pp. 41–9.

Angiography/Portal Vein Imaging/Postintrahepatic Injection Pathology/Trans-Jugular Intrahepatic Portosystemic Shunt Placement (TIPS)/ Percutaneous Trans-Hepatic Cholangiography (PTC)
Iohexol (Non-Ionic)/Ditrizoate (Ionic)

Application: Iohexol and CO_2 for direct hepatic injection imaging procedures.

Route of Administration: Iohexol (300 mg I, non-ionic) and ditrizoate (60% ionic) can be injected directly into the pyrenchyma of a hepatic lobe (intrahepatic).
Dosage: Iohexol (300 mg I, non-ionic) and ditrizoate (ionic) each injected at a volume of between 2 and 5 ml (intrahepatic).
Implementation: Delineation of approaches for optimum contrast agent selection and technique for localization of portal veins during TIPS placement or PTC. Parameters evaluated include comparisons of gross anatomic and histologic appearance associated with effects caused by parenchymal injections of iodinated contrast agents and carbon dioxide.

Contrast agents iohexol (300 mg I, non-ionic) or ditrizoate (ionic) are injected into 1 hepatic lobe in combination with injection of the same volume of CO_2 into another lobe. Gross pathology and histologic evaluation of liver tissue is performed at days 2 to 7 postinjection.

Animal Model: Rabbit (e.g., n = 18 New Zealand White rabbits).
Interpretation and Analysis: At the time of administration, anatomical sites of diatrizoate and iohexol injection show persistent dark discoloration, whereas CO_2 sites showed minimal visible changes. On postmortem gross examination, all diatrizoate sites show severe scarring and also commonly show areas of necrosis. Iohexol and CO_2 injection sites show only minimal discoloration and needle-puncture scars ($p < 0.0001$). The histologic grade for injury caused at diatrizoate sites is significantly more severe than for paired CO_2 sites ($p < 0.016$). Iohexol sites have mild histologic changes similar to paired CO_2 sites ($p = 0.375$). Iohexol and CO_2 therefore appear to produce less severe hepatic damage and are preferred to meglumine diatrizoate for direct hepatic injection procedures.

Comparison of hepatic damage from direct injections of iodinated contrast agents and carbon dioxide. Culp WC, Mladinich CR, Hawkins IF Jr. J Vasc Interv Radiol 1999 Oct; 10 (9), pp. 1265–70.

Angiography/Portal Venography/Fine-Needle Percutaneous Trans-Hepatic Parenchymal Portal Venography/Fluoroscopic and B-Mode Ultrasonography (US) Guided Catheter Delivery
Carbon Dioxide (CO_2)

Application: Magnetic resonance colonography.
Implementation: Negative contrast imaging agent for characterization of anatomical features of the portal vein facilitated by fine-needle percutaneous trans-hepatic parenchymal portal venography using injected CO_2 preparations. Under fluoroscopic and B-mode US guidance, right or left lobes of liver are punctured with a 22-G Chiba needle, through which CO_2 is injected with a dedicated CO_2 injector at an injection rate of 20 ml/s for 20 ml, 40 ml/s for 40 ml, 40 ml/s for 60 ml, and 40 ml/s for 80 ml, respectively. The portal venograms can be obtained by digital subtraction angiography (DSA) system with animals maintained in a supine position. Reference controls used for comparisons and validation include the administration of iodinated contrast media to perform trans-arterial portal venography.

Animal Model: Porcine (e.g., n = 3 Belgian landrace pigs).
Interpretation and Analysis: The portal vein can almost invariably be visualized during venography imaging procedures. Optimal images of portal tree structure up to 4-order branches can be obtained in all those receiving injected CO_2 at a rate of 40 ml/sec and appear to be of a much better quality than those obtained by cranial mesenteric arteriography with iodinated contrast agent. Extravasation of CO_2, liver laceration, or any other complication usually does not occur during diagnostic procedures. The technique described demonstrates optimal portography and appears to be safe, minimally invasive, less time-consuming, cost-effective, and easy to perform, with great potential for clinical application.

Fine-needle percutaneous trans-hepatic parenchymal portal venography by using carbon dioxide: A pilot study in pigs. Sun F, Hernandez J, Crisostomo V, Pineda LF, Lima JR, Uson J, Maynar M. Eur Radiol 2003 Feb; 13 (2), pp. 244–50. Epub 2002 May 09.

Angiography/Renal Artery Imaging
Carbon Dioxide (CO_2) Contrast/Nephrotoxicity: Iodinated Contrast Media

Background Information: Use of iodinated contrast for vascular imaging can be associated with nephrotoxicity and hypersensitivity reactions. Renal injury following conventional angiography is more likely to manifest in conditions of pre-existing renal dysfunction. In the setting of suboptimal renal allograft function, these considerations are particularly relevant. Recently, CO_2 has received attention as a non-toxic, injectable, rapidly absorbed gas that is a cost-effective alternative to standard contrast agents in high-risk patients, such as renal transplant recipients.
Implementation: Angiographs and percutaneous trans-luminal angioplasty using CO_2 in cases of transplant renal artery stenosis (serum creatinine 2.8 mg/dl).
Interpretation and Analysis: Vascular imaging of cases with suboptimal renal function requiring definitive vascular imaging or therapy can be achieved with CO_2 as a contrast agent.

CO_2 angiography—A technique for vascular imaging in renal allograft dysfunction. Kuo PC, Petersen J, Semba C, Alfrey EJ, Dafoe DC. Transplantation 1996 Feb 27; 61 (4), pp. 652–4.

Angiography/Renal Function (Compromised)/ Contraindicated Iodinated Contrast Media
Gadopentetate Dimeglumine ([Gd]-DTPA)/Carbon Dioxide (CO_2)

Background Information: Hemodialysis grafts and native fistulas are frequently evaluated angiographically utilizing iodinated contrast material to determine the cause of malfunction. Occasionally, patients are not able to receive iodinated contrast material due to a history of previous severe allergic reaction or concern that iodinated contrast material could worsen existing conditions of altered renal function requiring premature initiation of permanent dialysis.
Application: Diagnostic administration of [Gd]-DTPA with or without CO_2 as imaging enhancing angiography contrast agents, especially in cases with renal abnormalities where iodinated contrast agents are contraindicated (hemodialysis grafts and native fistulas).
Implementation: Characterization of malfunctioning hemodialysis graft and native fistula using carbon dioxide and [GD]-DTPA. An analogous approach involves the application of balloon angioplasty using [GD]-DTPA alone as the alternative contrast agent.
Interpretation and Analysis: In conditions of a malfunctioning hemodialysis graft and native fistula, a high percentage of cases can be successfully evaluated and treated through the diagnostic application of [GD]-DTPA either alone or in combination with CO_2 angiography (e.g., 100% or n = 6/6). Approximately 66% of affected cases are successfully diagnosed using carbon dioxide in combination with [GD]-DTPA as angiographic contrast agents (e.g., n = 5/6). Angiograms using [GD]-DTPA identifies arterial anastomosis lesions and more clearly identifies stenotic lesions and venous outflow anatomy compared to carbon dioxide angiograms. Gadopentetate dimeglumine is useful as an alternative contrast agent in conjunction with

CO_2 in patients with malfunctioning hemodialysis grafts and fistulas, that have a contraindications for the administration of iodinated contrast material.

CO_2 and gadopentetate dimeglumine as alternative contrast agents for malfunctioning dialysis grafts and fistulas. Spinosa DJ, Angle JF, Hagspiel KD, Schenk WG 3rd, Matsumoto AH. Kidney Int 1998 Sep; 54 (3), pp. 945–50.

Angiography:/Renal Function/Diabetic-Induced Pathology
Gadopentetate Dimeglumine ([GD]-DTPA)/ Gadolinium-Based Contrast Medium

Application: Contrast imaging agent for performing angiography image analyses using digital subtraction instrumentation. Gadopentetate dimeglumine is an alternative and safe radiographic contrast agent for angiography and interventional procedures in patients with severe pre-existing renal impairment. In this population with a high risk for contrast-induced acute renal failure, it is less nephrotoxic than iodinated contrast media.
Route of Administration: Gadopentetate dimeglumine (intravenous).
Dosage: Gadopentetate dimeglumine mean dose = 0.34 ± 0.06 mmol/kg body weight.
Implementation: Injection of [GD]-DTPA as a radiographic contrast agent in conditions of severe renal insufficiency. Gadopentetate dimeglumine can be applied either alone (e.g., n = 20/32) or in conjunction with carbon dioxide (n = 12/32). Examples include (i) diagnostic procedures such as selective renal arteriographies (e.g., n = 11), angiographies of the iliac arteries and lower extremities (e.g., n = 6), and venous angiographies of the upper extremity and central veins (e.g., n = 7); in addition to (ii) interventional procedures, including percutaneous trans-luminal renal angioplasties with stenting (e.g., n = 2), percutaneous peripheral vascular interventions (e.g., n = 4), and balloon angioplasties of a dialysis fistula (e.g., n = 2).

Human Model: Cases with pre-existing severe renal insufficiency subjected to angiographic procedures (e.g., n = 32 angiograms, n = 24/32 diagnostic angiographies, n = 8 interventional angiographies; n = 29 cases, n = 17/29 diabetics; mean serum creatinine = 3.6 ± 1.4 mg/dl).
Interpretation and Analysis: Development of postprocedure contrast material–induced renal failure (e.g., n = 1/29 with serum creatinine > 0.5 mg/dl within 72 hours) and other types of complications are relatively rare in occurrence. Cases that experience alterations in renal function sometimes display increases in serum creatinine after percutaneous trans-luminal renal angioplasty and stenting that are probably due to cholesterol embolism. Gadopentetate dimeglumine has a level of radiographic density that is sufficient to allow adequate diagnostic visualization with digital subtraction equipment in all of the diagnostic procedures described.

Gadolinium as an alternative contrast agent for diagnostic and interventional angiographic procedures in patients with impaired renal function. Rieger J, Sitter T, Toepfer M, Linsenmaier U, Pfeifer KJ, Schiffl H. Nephrol Dial Transplant 2002 May; 17 (5), pp. 824–8.

Angiography/Vascular Permeability: Contrast Imaging Agents/Relative Contrast Imaging Agent Endothelial Permeability
Triiodinated Non-Ionic Monomer (Iversol)/Iron Oxide Nanoparticle (Sinerem)/Iodinated Dextran Polymer (P604)

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.
Background Information: The efficiency of contrast agents in medical imaging depends on their distribution into vascular and interstitial compartments.
Application: Radiopaque contrast imaging agent.
Implementation: Compare the *in vitro* endothelial permeability of different classes of contrast agents with various vascular persistence properties (e.g., triiodinated non-ionic monomer [ioversol]; an iodinated dextran polymer [P604]; and an iron oxide nanoparticle [Sinerem]). Permeability studies are performed through collagen-coated filters (with or without porcine aortic endothelial cell monolayer) by placing each filter-ring luminal chamber into a beaker containing culture medium (abluminal chamber). Contrast media, diluted in the culture medium, is then added to the luminal chamber. Aliquots are sampled from the abluminal chamber for contrast agent measurements. The volume that is cleared of the compound is calculated from the luminal side to the abluminal side. Parallel permeability tests for $[^3H]$-H_2O and Evans blue albumin are performed as reference controls. Finally, the modulatory effect of bradykinin on endothelial permeability to albumin or to contrast agents can also be evaluated.
Interpretation and Analysis: The volume cleared of ioversol, P604, and Sinerem through membrane filters is decreased by 19.6%, 32.1%, and 52.0%, respectively, in the presence of a cell monolayer. Bradykinin (10^{-6} M) significantly increases permeability to albumin, ioversol, and Sinerem. Ioversol and Sinerem induce a significant decrease in albumin permeability. A relation appears to exist between contrast agent molecular size and their endothelial permeability when evaluated in certain *in vitro* models.

In vitro evaluation of vascular permeability to contrast media using cultured endothelial cell monolayers. Martin-Chouly CA, Youmine H, Saiag B, Hentsch AM, Corot C, Legrand A. Invest Radiol 1999 Nov; 34 (11), pp. 663–8.

Angiography/Vena Cava (Inferior) Cavography/ Inferior Vena Cava Diameter/Assessment Prior to Filter Placement/Carbon Dioxide (CO_2) Negative Contrast
Iodinated Postive Contrast Media/ CO_2 Negative Contrast

Cellular/Molecular Mechanism of Action: Carbon dioxide possesses radioleucent properties that can be detected when infused into a liquid medium.
Application: Carbon dioxide can be applied as a negative contrast image-enhancing agent.
Route of Administration: Carbon dioxide (intravascular).
Implementation: Inferior vena cavography applying both CO_2 (negative) and iodinated (positive) contrast materials performed prior to filter placement. The diameter of the IVC is measured and compared in the same 4 locations for both contrast agents. The diameter is corrected for magnification and "pin-cushion" distortion. Ability of CO_2 to correctly classify inferior vena caval (IVC) diameter as ≤ 28 mm or > 28 mm, based on the IVC diameter with iodinated contrast material is established. Blood pressure and arterial oxygen saturation are measured immediately before and after CO_2 injection.

Interpretation and Analysis: There is no significant difference in the measured diameter of the IVC with CO_2 compared to iodinated contrast material after correction for magnification and pincushion distortion (e.g., n = 30 cases). A low percentage of cases may be misclassified as having an IVC $\leq$ 28 mm with CO_2 when, in fact, the IVC diameter is $>$ 28 mm based on iodinated contrast material. Such considerations could be clinically significant for certain IVC filters. Nearly half of renal veins identified on contrast venography can be identified by CO_2 vena cavography (e.g., 47%). No significant differences can be appreciated in blood pressure or oxygen saturation values measured before and after CO_2 injection. A small percentage of cases with pulmonary artery hypertension experience transient, symptomatic hypotension after CO_2 injection (e.g., n = 1/30). Vena cavography with CO_2 in most instances accurately evaluates IVC diameter prior to filter placement.

Discrepancy in measurements between CO_2 and iodinated contrast material can be clinically significant in some cases (e.g., 3.3%) depending on the type of filter placed. Carbon dioxide (CO_2) is less accurate than iodinated contrast material in identifying renal veins. Although CO_2 vena cavography is safe in the majority of patients, it should be used with caution in patients with pulmonary hypertension.

Accuracy and safety of carbon dioxide inferior vena cavography. Boyd-Kranis R, Sullivan KL, Eschelman DJ, Bonn J, Gardiner GA. J Vasc Interv Radiol 1999 Oct; 10 (9), pp. 1183–9.

Angiography/Vena Cava (Inferior) Cavography
Carbon Dioxide (CO_2)

Background Information: The use of iodinated contrast in the critically ill trauma patient has been associated with the development of acute renal failure. The low incidence of nephrotoxicity associated with CO_2 makes it an ideal contrast agent for cavography. However, the use of CO_2 has been limited, because it reportedly underestimates the diameter of the inferior vena cava (IVC).
Application: Angiography, including cavography of the IVC.
Implementation: Delineation of the luminal diameter of the IVC and renal veins utilizing CO_2 and iodinated medias as contrast agents for cavagram procedures.

Human Model: Trauma cases examined over a period of 6 months that required IVC filter placement (e.g., n = 25).
Interpretation and Analysis: The diameter of the IVC and anatomy of renal vein structures can be successfully achieved utilizing injected CO_2 as a negative contrast agent in most diagnostic examinations (e.g., n = 25). Images acquired applying CO_2 cavography compared with those obtained with iodinated positive contrast media reveal very small variations in IVC diameter estimates (e.g., $<$ 1 mm).

Therefore, CO_2 cavagrams appear to accurately reflect the diameter of the IVC and the renal vein anatomy. Additionally, CO_2 cavagrams can be safely performed in the intensive care unit during bedside placement of IVC filters.

Comparison of carbon dioxide and iodinated contrast for cavography prior to inferior vena cava filter placement. Holtzman RB, Lottenberg L, Bass T, Saridakis A, Bennett VJ, Carrillo EH. Am J Surg 2003 Apr; 185 (4), pp. 364–8.

CENTRAL NERVOUS SYSTEM

Myelography/Image Quality/Adverse Reactions: Relative Frequency/Pharmakinetics
Iomerprol/Iohexol/Iotrolan

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.
Application: Iomeprol is a non-ionic iodinated contrast medium that can be applied to perform myelogram procedures (conventional radiography and myelo-computed tomography [CT]). Other iodinated compounds like iohexol and iotrolan can be applied in a similar fashion.
Route of Administration: Iomeprol (intrathecal).
Dosage: Iomeprol.
Implementation: Evaluation of pharmacokinetic, tolerability, safety, and efficacy of iomeprol following intrathecal injection (e.g., n = 600 cases).
Interpretation and Analysis: Pharmacokinetic study results reveal that after intrathecal administration iomeprol is completely absorbed from the cerebrospinal fluid compartment (once absorbed into the systemic circulation, it is rapidly excreted, unmetabolized, by glomerular filtration). Dose-finding studies show that the opacification produced by iomeprol depends on the injected dose. Although a dose-dependent increase in efficacy is observed, no differences in neurotolerability and safety are detected between the doses tested. Doses of iomeprol greater than 3 g iodine do not cause a greater incidence of adverse events and produce significantly better contrast efficacy. Comparative clinical trials demonstrate that iomeprol and iopamidol, iohexol, and iotrolan always provide adequate opacification of the subarachnoid space, both in conventional myelography and myelo-CT, with adequate delineation of normal structures and pathologic processes. No serious adverse events occur up to a total dose of 4.5 g of iodine. Almost invariably, no differences between the agents with regard to tolerance, adverse events, and effects on vital signs, physical examination, and neurologic examination can be appreciated. Therefore, iomeprol is safe and effective and can be recommended for myelography and myelo-CT.

Clinical experience with iomeprol in myelography and myelo-CT: Clinical pharmacology and double blind comparisons with iopamidol, iohexol, and iotrolan. Katayama H, Heneine N, van Gessel R, Taroni P, Spinazzi A. Invest Radiol 2001 Jan; 36 (1), pp. 22–32.

GASTROINTESTINAL SYSTEM

Esophogeal Leakage/Postoperative Complications/ Esophagogastrectomy/Gastrectomy/Total Laryngectomy
Barium Sulfate/Iodinated Contrast Media

Cellular/Molecular Mechanism of Action: Barium containing preparations and iodinated compounds possess radiopaque properties.
Application: Can be utilized as positive contrast image-enhancing agents in conventional radiography procedures for the detection of esophageal "leaks" in cases subjected to esophagogastrectomy, total gastrectomy, or total laryngectomy.
Implementation: Identify and review radiographic imaging procedures performed with water-soluble contrast agent alone or a water-soluble contrast agent followed by barium that demonstrate "leaks" in cases that have undergone esophagogastrectomy, total gastrectomy, or total laryngectomy (e.g., n = 46; single institution radiology database search between 1998 and 2001).
Interpretation and Analysis: Approximately 50% of the "leaks" detected on radiographic images can be identified with the aid of water-soluble contrast agents (e.g., n = 23/46), while the other 50% can be detected only with high-density barium (e.g., n = 23/46). Of the 23 leaks visualized with water-soluble contrast media, 26% (n = 67/23) can be characterized by blind-ending tracks, 61% (n = 14/23) by sealed-off collections, and 13% (n = 3/23) by extravasations of free contrast material into the mediastinum or neck.

Of the 23 leaks visualized only with high-density barium, 83% (n = 19/23) can be characterized by blind-ending tracks and 17% (n = 4/23) by sealed-off collections. Thus, leaks detected only on images obtained with high-density barium are significantly more likely to be characterized by blind-ending tracks than those detected on images obtained with a water-soluble contrast agent (p = 0.0007). Of patients with clinical follow-up (e.g., n = 33), the findings seen on these imaging studies ultimately affects management in 86% (e.g., n = 12/14) of patients with leaks depicted by water-soluble contrast media and in 53% (e.g., n = 10/19) with leaks depicted only by high-density barium. Observations noted in this report support the use of high-density barium as part of the routine postoperative radiographic examination when no leaks are detected on images obtained with a water-soluble contrast agent.

Usefulness of high-density barium for detection of leaks after esophagogastrectomy, total gastrectomy, and total laryngectomy. Swanson JO, Levine MS, Redfern RO, Rubesin SE. AJR Am J Roentgenol 2003 Aug; 181 (2), pp. 415–20.

Gastrointestinal (GI) Tract
17 (1,3,5-Tri-n-Hexyl-2,4,6-Triiodobenzene)/ Barium Sulfate Alternative

Cellular/Molecular Mechanism of Action: The compound 17 (1,3,5-tri-n-hexyl-2,4,6-triiodobenzene) possesses radiopaque properties.
Background Information: Examination of the GI tract has been performed for decades using barium sulfate. Although this agent has many recognized limitations, including extreme radiopacity, poor intrinsic affinity for the GI mucosa, and very high density, no alternative contrast agents have emerged that produce comparable or better contrast visualization. In fact, the various techniques of the GI radiologic examination (i.e., single contrast, double contrast, biphasic) were developed to compensate for its limitations. Each of these techniques requires complex patient manipulation to achieve adequate mucosal coating or compression to overcome the marked radiopacity of barium sulfate in order to obtain a diagnostically useful examination.
Application: Detection and characterization of anatomical and physiological abnormalities affecting the gastrointestinal tract.
Route of Administration: Gastrointestinal tract.
Implementation: Administration of the compound 17 (1,3,5-tri-n-hexyl-2,4,6-triiodobenzene) to determine how well it is tolerated following intraperitoneal injection.

Animal Model: Rodent (mice, hamsters, rats) with 17 (1,3,5-tri-n-hexyl-2,4,6-triiodobenzene) administered intraperitoneally at 4 times (4X) the anticipated human clinical dosage.

Animal Model: Canine intestinal imaging studies.

***Ex Vivo* Model:** Hepatic microsomes harvested from rat, hamster, canine, monkey and human hepatic tissues applied to delineate how extensively 17 (1,3,5-tri-n-hexyl-2,4,6-triiodobenzene) is metabolized by liver microsomal enzyme systems.
Interpretation and Analysis: The class of radiopaque oils known as the 1,3, 5-trialkyl-2,4,6-triiodobenzenes can improve the efficacy, stability, and safety of barium formulations. The compound 17 (1,3,5-tri-n-hexyl-2,4,6-triiodobenzene), formulated as an oil-in-water emulsion, is well tolerated in rodents (mice, hamsters, rats) following acute oral and/or intraperitoneal administrations at 4 times the anticipated human clinical dose. No metabolism of 17 (1,3,5-tri-n-hexyl-2,4,6-triiodobenzene) can be detected in rat, hamster, dog, monkey, or human hepatic microsomes, suggesting the lack of oral toxicity is a consequence of poor absorption. Image analysis in dogs reveals that emulsions of 17 (1,3,5-tri-n-hexyl-2,4,6-triiodobenzene) provides excellent mucosal coating and improved radiodensity relative to barium sulfate suspensions. On the basis of the preliminary imaging and toxicity data, compound 17 (1,3,5-tri-n-hexyl-2,4,6-triiodobenzene) is selected as a potential development candidate.

1,3,5-Trialkyl-2,4,6-triiodobenzenes: Novel x-ray contrast agents for gastrointestinal imaging. Estep KG, Josef KA, Bacon ER, Illig CR, Toner JL, Mishra D, Blazak WF, Miller DM, Johnson DK, Allen JM, Spencer A, Wilson SA. J Med Chem 2000 May 18; 43 (10), pp. 1940–8.

Pharyngeal Perforation
Iodinated Aqueous Contrast Agents/Barium Suspension (50% Weight/Volume)/Barium Suspension (100% Weight/Volume)

Cellular/Molecular Mechanism of Action: Iodinated compounds and barium preparations possess radiopaque properties.
Application: Diagnostic imaging of gastrointestinal system.
Route of Administration: Oral.
Implementation: Evaluate visual *in vitro* comparisons of an iodinated aqueous contrast agent, a 50% weight/volume barium suspension, and a 100% weight/volume barium suspension in procedures including pharyngography. In cases of detectable pharyngeal perforation, clinical monitoring is performed to exclude complications associated with barium administration.
Interpretation and Analysis: As opposed to the 100% weight/volume barium suspension, *in vitro* comparison between the aqueous contrast agent and the 50% weight/volume barium suspension reveals no substantial differences. Pharyngeal perforations can be detected with the aqueous contrast agent, but in approximately 59% of such cases, diagnostic visualization is superior with 100% weight/volume barium suspension (e.g., n = 10/17) and a small percentage of pharyngeal perforation cases cannot be detected with the latter preparation (e.g., n = 2/17). Because of a higher radiopacity, 100% weight/volume barium suspensions may more sharply delineate perforations. However, in contrast to aqueous contrast media, narrow pharyngeal perforations can be missed. Thus, the use of a 100% weight/volume barium suspension does not improve the detection of pharyngeal perforation.

Detection of pharyngeal perforation: Comparison of aqueous and barium-containing contrast agents. Keberle M, Wittenberg G, Trusen A, Hoppe F, Hahn D. AJR Am J Roentgenol 2000 Nov; 175 (5), pp. 1435–8.

HEPATOBILIARY SYSTEM

Cholangiopancreaticography/Iodine Load
Iopamidol

Background Information: Hyperthyroidism induced by contrast agents is a major problem in patients with pre-existing thyroid disease, particularly in patients with functional thyroid autonomy.
Application: Iopamidol is a non-ionic contrast media in procedures including endoscopic retrograde cholangiopancreaticography.
Dosage: Iopamidol (total iodine load = 57.4 ± 22.8 mmol [7.3 ± 2.9 g]).
Implementation: Determination of the extent iodinated contrast media administered during endoscopic retrograde cholangiopancreaticography influences total and free iodine concentrations within the plasma compartment and excreted in the urine (e.g., n = 15 cases; day 0–day 21).
Interpretation and Analysis: Endoscopic retrograde cholangiopancreaticography procedures utilizing iodinated contrast media promote highly significant increases in total serum iodine levels from 0.8 ± 0.5 to 85.2 ± 116.9 μmol/l at 4 hours postadministration

(e.g., iopamidol). In parallel, serum iodide levels increase from 0.06 ± 0.04 to 5.42 ± 6.09 μmol/l, and urinary iodine excretion increases from 71.1 ± 35.7 μmol/mol creatinine to 621,620.9 ± 636,492.2 μmol/mol creatinine. Peak concentrations of serum iodine are closely related to the total amount of iodine administered ($p < 0.05$). During follow-up, iodine levels return to pre-exposure levels within 2 to 3 weeks. Levels of thyrotropin, free thyroxine, and free triiodothyronine remain unchanged during follow-up monitoring periods. The full clinical significance of elevations in total and free iodine and their urinary excretion associated with the application of iodinated contrast agents in endoscopic procedures remains to be fully established.

Systemic iodine absorption during endoscopic application of radiographic contrast agents for endoscopic retrograde cholangiopancreaticography. Mann K, Rendl J, Busley R, Saller B, Seybold S, Hoermann R, Sauerbruch T, Borner W. Eur J Endocrinol 1994 May; 130 (5), pp. 498–501.

MONOCYTES AND MACROPHAGES

Macrophage Imaging Agent/Liver and Spleen/ Vascular Compartment Imaging Agent
Cyclic Carbonate of Ioxilan (IXC)/Ioxilam Nanoparticles/Ioxilam Microparticles/ Biodegradable Radiopaque Particles

Cellular/Molecular Mechanism of Action: Cyclic carbonate of ioxilan is a biodegradable radiopaque particle preparation that is a prodrug of the non-ionic water-soluble contrast agent ioxilan.
Application: Cyclic carbonate of ioxilan is the prodrug form of non-ionic water-soluble ioxilan contrast agent. This contrast agent enhances liver attenuation and is cleared from the body as ioxilan.
Route of Administration: Ioxilan (intravenous: rats n = 2).
Dosage: Ioxilan (50 mg I/kg body weight).
Implementation: Determination of the influence of particle physical characteristics on IXC particle biodistribution. Formulations of IXC nanoparticles (average diameter = 290 nm) and IXC microparticles (average diameter = 1.7 mm) are prepared and characterized prior to intravenous injection (rats n = 2). The sensitive, reproducible analytic methods, inductively coupled plasma-mass spectrometry (ICP-MS) and high-performance liquid chromatography (HPLC) can be applied to quantify tissue iodine and ioxilan concentrations.
Animal Model: Rat (n = 2).
Interpretation and Analysis: Ioxilan nanoparticles and microparticles are both assimilated by the liver and spleen. The IXC nanoparticles remain in the liver at high concentrations for 6 hours and are then slowly eliminated. Each agent also produces high blood iodine concentrations within the 1st 5 minutes following intravenous injection, suggesting their potential use as a blood-pool imaging agent. Unlike nanoparticles, the microparticles have a significantly lower uptake by the kidney. Because of reduced renal uptake, microparticles are a preferred macrophage imaging agent. Biodegradable radiopaque particles may be used either as blood-pool imaging agents or as macrophage imaging agents depending on their size and distribution characteristics. The ICP-MS and HPLC methods are useful for biodistribution studies of iodinated contrast agents.
Instrumentation: Inductively coupled plasma-mass spectrometry and HPLC.

Biodistribution of cyclic carbonate of ioxilan: A radiopaque particulate macrophage imaging agent. Li C, Yu D, Kan Z, Yang DJ, Tansey W, Kuang LR, Wallace S. Acad Radiol 1996 Jun; 3 (6), pp. 500–6.

RENAL SYSTEM

Renal Clearance (Age-Related Differences)/ Pharmacokinetics
Iodixanol

Application: Iodixanol is an iso-osmolar iodinated radiocontrast agent.
Route of Administration: Iodixanol (intravascular).
Dosage: Iodixanol.
Implementation: Iodixanol is administered by cardiac catheterization and then plasma samples collected at 0.75 to 1.25 hours, 2 to 4 hours, 8 to 12 hours, and 16 to 32 hours postinjection (e.g., n = 41 cases: newborn to < 2 months; 2 to < 6 months; 6 months to < 1 year; 1 to < 3 years; and 3 to ≤ 12 years). Plasma concentrations of iodixanol can subsequently be determined using high performance liquid chromatography. The primary pharmacokinetic end point to be applied is the terminal elimination rate constant (K_{el}).
Interpretation and Analysis: Mean K_{el} is significantly lower in newborns ≤ 2-month-old cases in contrast to older subjects: (iodixanol/hr, mean ± standard deviation [SD]): newborn to < 2 months 0.185 ± 0.060, 2 to < 6 months, 0.256 ± 0.046, 6 months to < 1 year 0.299 ± 0.042, 1 to < 3 years 0.322 ± 0.058, and 3 to ≤ 12 years 0.307 ± 0.071; with increasing age, excretion is more rapid, as shown by each age group's elimination half-life ($T_{1/2}$ beta; 4.14 ± 1.41 hours, 2.79 ± 0.55 hours, 2.36 ± 0.37 hours, 2.23 ± 0.51 hours, and 2.36 ± 0.52 hours, respectively). Elimination of iodixanol in children > 6 months of age is comparable to normal adults. Prolonged elimination in children < 6 months of age is related to renal immaturity.

Iodixanol pharmacokinetics in children. Johnson WH Jr, Lloyd TR, Victorica BE, Zales VR, Epstein ML, Leff RD, Ardinger RH Jr, Slovis TL, Johnson JA, Marsters PA. Pediatr Cardiol 2001 May–Jun; 22 (3), pp. 223–7.

Renal Failure
Iodinated Contrast Media/Gadolinium

Renal failure due to iodinated contrast media is a serious complication of peripheral angiography in patients with impaired renal function. Gadolinium-based agents that are widely used in magnetic resonance imaging have no adverse renal toxicity at recommended doses. These agents have sufficient radiographic density to be seen using digital subtraction equipment. In this context, undiluted [GD]-DTPA can be applied as a radiographic contrast agent (e.g., n = 2 case reports).

Gadopentate dimeglumine as an alternative contrast agent for use in interventional procedures. Hatrick AG, Jarosz JM, Irvine AT. Clin Radiol 1997 Dec; 52 (12), pp. 948–52.

Renal Failure/Diabetes/Metformin: Contrast Media Drug Interaction

Intravascular administration of iodinated contrast media to patients who are receiving metformin, an oral antidiabetic agent, can result in lactic acidosis. However, this rare complication occurs only if the contrast medium causes renal failure, and the patient continues to take metformin in the presence of renal failure. Because metformin is excreted primarily by the kidneys, continued intake of metformin after the onset of renal failure results in a toxic accumulation of this drug and subsequent lactic acidosis. To avoid this complication, metformin must be withheld after the administration of the contrast agent for 48 hours, during which the contrast-induced renal failure becomes clinically apparent. If renal function is normal at 48 hours,

the metformin can be restarted. There is no scientific justification for withholding metformin for 48 hours before administration of the contrast medium, as currently recommended in the package insert. Reviews have been described regarding the pharmacology of metformin and institutional policies for managing patients with diabetes who receive metformin and who require intravascular administration of iodinated contrast media.

Metformin and contrast media: Where is the conflict? Rasuli P, Hammond DI. Can Assoc Radiol J 1998 Jun; 49 (3), pp. 161–6.

Urography: Excretory/Comparison: Image Quality, Vital Signs, Clinical Pathology, Reactions
Iodixanol/Iohexol

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties. Iodixanol is a non-ionic dimeric iodinated contrast agent, while iohexol is a monomeric agent.
Application: Iodixanol and iohexol can be used as positive contrast agents for enhancing radiographic imaging during excretory urography procedures.
Route of Administration: Intravascularly.
Implementation: Evaluation of image quality, vital signs, laboratory values, and adverse reactions (e.g., n = 75 cases). Iodixanol at a dose of 1ml/kg consisting of preparations formulated at either 270 mg I/ml, 320 mg I/ml, or 300 mg I/ml (e.g., n = 25 cases for each concentration). In situations where comparisons are being made between different groups, no important differences in demographics should exist. The radiographs are interpreted and evaluated for overall quality.
Study Design: Randomized, double blind, parallel comparison.
Interpretation and Analysis: Evaluation of each phase of the radiographic study reveals almost uniform good-to-excellent opacification, with no significant differences among the 3 agents. No significant differences exist for the 3 groups in terms of vital signs, hematology, blood and urine chemistry, and injection discomfort. Death or serious reactions are overall a very rare occurrence. There is no statistically significant difference between the numbers of adverse events for each of the 3 contrast imaging agents. Iodixanol at both 270 and 320 mg I/ml has proven to be a safe and effective contrast material for intravenous urography and its profile is essentially indistinguishable from that of iohexol at 300 mg I/ml.

Comparison of iodixanol with iohexol in excretory urography. Siegle RL, Gavant ML. Acad Radiol 1996 Sep; 3 Suppl 3, pp. S524–7.

Urography/Image Enhancement
Iopromide/Iotrolan/Urea/Iloprost/Nifedipine/ Papaverine/Sodium Nitroprusside

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties. Certain molecular additives influence the excretion rate of iodinated contrast agents during urography imaging procedures.
Application: Enhancement of the diagnostic quality of urography images produced with iodinated contrast-enhancing agents, including iopromide and iotrolan (conventional radiography and computed tomography [CT]).
Route of Administration: Iopromide (300 mg/mL) and iotrolan preparations (280 mg/mL) are each administered intravenously.
Dosage: Iopromide (plain films = 300 and 600 mg iodine/kg) and iotrolan preparations (plain films = 300 and 600 mg/kg) in dogs and rabbit. Alternatively, iopromide (CT scans = 50 mg iodine/kg) and iotrolan preparations (CT scans = 50 mg/kg) in rabbit.
Implementation: Conventional plain-film radiography urograms utilizing urea (52 mg/mL), iloprost (10, 20, 50, and 100 ng/mL), nifedipine (0.02 mg/mL), papaverine (0.625 mg/mL) and sodium nitroprusside (0.05 μg/mL) added to commercial iopromide (300 mg/mL) and iotrolan preparations (280 mg/mL). Images are obtained at different time points after contrast injection of iodine preparations (e.g., rabbits and dogs). Image analysis is then repeated using CT and iopromide or iotrolan plus urea (52 mg/mL) or iloprost (20 ng/mL) and iodine doses of 50 mg/kg body weight (rabbits).
Interpretation and Analysis: Urea and iloprost at low concentrations (10 and 20 ng/mL) increase image quality both in plain film and in CT urography. Iloprost at high concentrations (50 and 100 ng/mL), nifedipine, papaverine and sodium nitroprusside decreases image quality. An increase in image quality is accompanied by faster renal elimination of the contrast agent. Therefore, image quality in plain film and CT urography can potentially be improved by additives to the contrast medium.

Use of additives to contrast media to improve imaging in plain film and computed tomography urography. Krause W, Schromm M. Invest Radiol 2003 Jan; 38 (1), pp. 17–26.

REPRODUCTIVE SYSTEM

Hysterosalpingography
Hexabrix/Diatrizoate Meglumine

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.
Application: Hexabrix is applied as a monoacidic dimeric iodinated contrast material.
Route of Administration: Diatrizoate meglumine (Renografin 60) and Hexabrix can both be infused directly for hysterosalpingography procedures.
Interpretation and Analysis: Serious adverse reactions are relatively rare with the application of either Hexabrix or diatrizoate meglumine. Discomfort during and after the procedure is not statistically different between cases administered either contrast reagent. Furthermore, no differences in radiographic quality can usually be appreciated despite the reduced osmolality and increased viscosity of Hexabrix. Both contrast agents appear to be safe and acceptable contrast agents for hysterosalpingography imaging.

Hexabrix as a contrast agent for hysterosalpingography. Winfield AC, Maxson WS, Harding DR, Diggs J, Wentz AC. Radiology 1984 Jul; 152 (1), pp. 232–3.

COMPUTED TOMOGRAPHY (CT) RADIOGRAPHY IMAGE-ENHANCING AGENTS

Adverse Effects/Sequellae: Bronchospam Induction
Iomeprol (Non-Ionic and Triiodinated)/Iopamidol (Non-Ionic and Triiodinated)/Iohexol (Non-Ionic and Triiodinated)/Diatrizoate (Ionic and Triiodinated)/ Iotrolan (Non-Ionic and Hexaiodinated)/Iocarmate (Ionic and Hexaiodinated)/Ioxaglate (Ionic and Hexaiodinated)/ Lysine Acetylsalicylate/Indomethacin

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.
Application: Administered intravenously as contrast agents to enhance computed tomography (CT) angiography imaging analyses.

Route of Administration: Preparations of iomeprol (400 mg I/ml), iopamidol (370 mg I/ml), iohexol (350 mg I/ml), diatrizoate (370 mg I/ml), iotrolan (300 mg I/ml), iocarmate (280 mg I/ml), and ioxaglate (320 mg I/ml) can each be delivered intravenously (IV) as iodinated contrast agents for CT angiography imaging.
Dosage: Administration of the iodinated contrast agents (i) non-ionic, triiodinated iomeprol (400 mg I/ml), iopamidol (370 mg I/ml), and iohexol (350 mg I/ml); (ii) ionic, triiodinated diatrizoate (370 mg I/ml); (iii) non-ionic, hexaiodinated iotrolan (300 mg I/ml); and (iv) ionic hexaiodinated iocarmate (280 mg I/ml) and ioxaglate (320 mg I/ml) at a dose of 2 g I/kg. (Note: Anesthetized guinea pigs.)
Implementation: Evaluation of alterations in pulmonary airway resistance following intravenous administration of pharmaceutical formulations of iomeprol (400 mg I/ml), iopamidol (370 mg I/ml), and iohexol (350 mg I/ml), diatrizoate (370 mg I/ml), iotrolan (300 mg I/ml), iocarmate (280 mg I/ml), and ioxaglate (320 mg I/ml). Changes in pulmonary airway resistance are evaluated by measuring intratracheal pressure at the moment of maximum insufflation, or maximal insufflation pressure (MIP).

Animal Model: Guinea pig (anesthetized and subjected to forced ventilation).
Interpretation and Analysis: All contrast media except ioxaglate cause mean increases in MIP of no more than 20%. By contrast, ioxaglate causes a marked bronchoconstrictor effect, and increases in MIP of 242% ± 46%. In the evaluation of pharmaceuticals for antagonistic action on increases in MIP, salbutamol inhibits almost completely the increase in MIP for the 1st 40 minutes post-treatment. Similarly, lysine acetylsalicylate and indomethacin consistently reduce MIP after contrast media administration to levels only 30% and 14% above those of baseline precontrast media, respectively. Promethazine has only a minor inhibitory effect, and the response to prednisolone varies. There is no apparent relationship between the size of the increase in airway resistance and the charge or molecular weight of contrast agents or the pharmaceutical formulation. The increase induced by ioxaglate must be attributed to inherent molecular toxicity mediated through a direct action on the production of bradykinin and/or the prostanoid products of the cyclo-oxygenase pathway, rather than through a direct action on the release of histamine.

Effects of iodinated contrast media on pulmonary airway resistance in anesthetized guinea pigs. Cipolla P, Castano M, Kirchin MA, de Haen C, Tirone P. Acad Radiol 1995 Apr; 2 (4), pp. 306–12.

Adverse Effects/Sequellae Incidence/Discomfort and Sensations/Relative Safety
Iodixanol/Iohexol

Cellular/Molecular Mechanism of Action: Non-ionic iodinated compound that has radiopaque properties.
Background Information: Non-ionic iodinated contrast media have proved effective for computed tomography (CT) of the head and have demonstrated greater tolerability than their ionic counterparts. Phase I safety, tolerance, and pharmacokinetic studies have indicated that iodixanol may be associated with fewer adverse effects than iohexol, while it provides equivalent diagnostic information.
Application: Liquid non-ionic iodinated contrast media applied in CT to detect anatomical abnormalities in body fluid compartments. Iodixanol is also formulated as an isosmolar preparation, which has a distinct advantage over contrast agents like iohexol (iodixanol 50% the osmolality of iohexol). Each of these agents can be applied as an intracranial contrast agent to enhance CT imaging analysis.
Dosage: Iodixanol 270 mg I/ ml (IOD-270) and at 320 mg I/ml (IOD-320) compared to iohexol 300 mg I/ml (IOH-300).
Implementation: Comparison of the safety and diagnostic efficacy of iodixanol to iohexol.
Interpretation and Analysis: No statistically significant differences in the quality of images or in the occurrence of adverse events can be appreciated between the applications of iodixanol and iohexol (270 mg I/ ml & 320 mg I/ml) or iohexol (300 mg I/ml). Pairwise comparisons of injection-associated discomfort reveals that significantly more sensations of discomfort are associated with iohexol (300 mg I/ml) compared to iodixanol (270 mg I/ ml or 320 mg I/ml). Iodixanol at 270 or 320 mg I/ml therefore appears to be safe and effective when administered intravenously at a volume of 100 ml for intracranial CT scans in adult patients.

A randomized comparison of iodixanol and iohexol in adult intracranial computed tomography scanning. Grossman RI, Modic MT. Acad Radiol 1996 Sep; 3 Suppl 3, pp. S488–94.

Agents: General Concepts/Artifact Reduction
Lanthanice-Based Compounds: Gadolinium Diethylenetriamine Pentaacetic Acid ([Gd]-DTPA)/ Iodinated Contrast Media Comparison

Background Information: Recent experiments using computed tomography (CT) an transmission radiography show that [Gd] agents can increase image contrast agent by up to a factor of 2 relative to more commonly used iodinated agents on an equimolar basis. The use of [Gd] has been proposed to reduce beam hardening artifacts.
Application: Lanthanide-based compounds such as [Gd]-DTPA are currently used as contrast agents in magnetic resonance imaging (MRI).
Implementation: Analysis of 3 different CT scanners using a circular water equivalent phantom with contrast-filled tube inserts.
Interpretation and Analysis: Artifacts are a factor of 1.3 to 1.8 more pronounced with an iodinated contrast agent compared with [Gd]-DTPA. A theoretical model that uses an experimentally derived photon energy spectrum is proposed that relates the strength of beam hardening artifacts to the variance (over the energy spectrum) of the attenuation coefficient of the contrast agent. This allows easy assessment of the relative magnitudes of the artifact for different contrast agents

A comparison of beam-hardening artifacts in x-ray computerized tomography with gadolinium and iodine contrast agents. Med Phys 1995 Dec; 22 (12), pp. 1977–1982.

Agents: General Concepts/Contrast Imaging Agents/Computed Tomography (CT) Applications

Background Information: Computed tomography is a reliable, widely available imaging modality with high spatial resolution. Except for trauma detection, in practically all cases contrast agents are administered for improving image quality. The presently available agents are non-specific compounds that distribute into the extracellular space. Specificity (i.e., high contrast in selected tissues) is only possible when the pharmacokinetic behavior (peak levels at the region of interest) is followed on a time scale that counts in seconds. If the peak time is missed, a 2nd injection of contrast material is necessary. The objective of extensive research efforts has therefore been the search for tissue-specific contrast agents that should result both in higher and in longer-lasting local concentrations. For the tissue targets, liver, spleen, lymph nodes, and the blood-pool, efficient contrast-enhancing compounds have been described utilizing different

active transport systems or passive diffusion-limiting molecular sizes. The agents include water-soluble metal chelates, iodinated polymeric compounds and contrast agent-carrying liposomes. The remaining task for the future will be to improve the tolerability of the contrast agents to such an extent that the side-effect incidence and severity is low enough to allow for the use of these agents in patients.

Delivery of diagnostic agents in computed tomography. Krause W. Adv Drug Deliv Rev 1999 Apr 5; 37 (1), pp. 159–73.

Agents: General Concepts/Contrast Imaging Agents/Renal Clearance: Age-Related Differences
Iodixanol

Application: Iodixanol is an iso-osmolar iodinated radiocontrast agent.
Route of Administration: Iodixanol (intravascular).
Implementation: Iodixanol is administered by cardiac catheterization, and then plasma samples are collected at 0.75 to 1.25 hours, 2 to 4 hours, 8 to 12 hours, and 16 to 32 hours postinjection (e.g., n = 41 cases: newborn to < 2 months; 2 to < 6 months; 6 months to < 1 year; 1 to < 3 years; and 3 to ≤ 12 years). Plasma concentrations of iodixanol can subsequently be determined using high-performance liquid chromatography. The primary pharmacokinetic end point to be applied is the terminal elimination rate constant (K_{el}).
Interpretation and Analysis: Mean K_{el} is significantly lower in newborn to < 2-month-old cases vs older subjects: (iodixanol, mean ± standard deviation [SD]): newborn to < 2 months 0.185 ± 0.060, 2 to < 6 months 0.256 ± 0.046, 6 months to < 1 year 0.299 ± 0.042, 1 to < 3 years 0.322 ± 0.058, and 3 to ≤ 12 years 0.307 ± 0.071; with increasing age, excretion is more rapid, as shown by each age group's elimination half-life ($T_{1/2}$ beta; 4.14 ± 1.41 hours, 2.79 ± 0.55 hours, 2.36 ± 0.37 hours, 2.23 ± 0.51 hours, and 2.36 ± 0.52 hours, respectively). Elimination of iodixanol in children > 6 months of age is comparable to normal adults. Prolonged elimination in children < 6 months of age is related to renal immaturity.

Iodixanol pharmacokinetics in children. Johnson WH Jr, Lloyd TR, Victorica BE, Zales VR, Epstein ML, Leff RD, Ardinger RH Jr, Slovis TL, Johnson JA, Marsters PA. Pediatr Cardiol 2001 May–Jun; 22 (3), pp. 223–7.

CARDIOVASCULAR SYSTEM

Angiogenesis: Neoplastic Disease

Background Information: Tumor angiogenesis has significant implications in the diagnosis and treatment of various solid tumors. With the advent of fast, multislice computed tomography (CT) scanners, CT imaging techniques capable of qualitative and quantitative analysis of tumor angiogenesis have been the subject of extensive investigation for several decades. The fundamental basis for CT imaging of angiogenesis includes transport by blood flow of intravenously administered iodinated contrast material to tissue and subsequent exchange by diffusion of contrast molecules between the intravascular space and the extravascular interstitial space. With current fast CT scanners both tissue and vascular enhancement can be measured and traced over time at small time intervals to allow detailed modeling of the distribution of contrast agent in tissue. Both compartmental and distributed parameter models for contrast transport and exchange have been developed to quantify from the CT data the following angiogenesis related parameters: tissue blood flow, blood volume, mean transit time, contrast arrival time, capillary permeability surface area product, and hepatic arterial fraction in the case of the liver.

CT imaging of angiogenesis. Lee TY, Purdie TG, Stewart E. Q J Nucl Med 2003 Sep; 47 (3), pp. 171–87.

Angiography
Gadopentetate Dimeglumine ([Gd]-DTPA)

Application: In subsets of cases with contraindications to iodinated contrast medium and for whom magnetic resonance angiography is inappropriate, [GD]-DTPA can function as an alternative contrast medium for computed tomography angiography (CTA).
Dosage: Gadopentetate dimeglumine, 0.5 mol/l (Berlex Laboratories, Wayne, NJ),
Implementation: Characterization of the cervical vessels for presurgical assessment of neck vascular anatomy (e.g., n = 3 cases) after 1st establishing proof of principle.
Animal Model: Canine (beagle 12.2 kg BW).
Human Model: Cases subjected to 3D CT scanning angiography (n = 3).
Interpretation and Analysis: Sufficient enhancement for CTA of the thoracic aorta, cervical vessels, and abdominal vessels can readily be achieved. Cervical vessels can be clearly defined in the vast majority of human cases (e.g., n = 3/3).
Instrumentation: Computed tomography: LightSpeed QX/i CT (General Electric Medical Systems, Milwaukee, WI), and an Ultra Sparc II (SUN Microsystems, Santa Clara, CA) running Advantage Windows 3.1 (General Electric Medical Systems).

Gadopentetate dimeglumine is potentially an alternative contrast agent for 3-dimensional computed tomography angiography with multidetector-row helical scanning. Gupta AK, Alberico RA, Litwin A, Kanter P, Grossman ZD. J Comput Assist Tomogr 2002 Nov–Dec; 26 (6), pp. 869–74.

Angiography/Abdominal Vasculature
Gadobutrol/Iopromide/Continuous Spiral Computed Tomography (CT)

Application: Angiography of abdominal vascular structures.
Route of Administration: Gadobutrol (intravenous); iopromide (intravenous).
Dosage: Gadobutrol (2 mmol/kg BW; 1 mol/L gadobutrol); iopromide (2 mmol/kg BW; 300 mg I/mL).
Implementation: Continuous spiral CT imaging of the chest and abdomen can be performed using either gadobutrol or iopromide (slice 5 mm, table feed 7.5 mm, reconstruction increment 5 mm). Comparisons can be made 1 week later, utilizing the same protocol and employing other contrast agents of interest. Serial CTs are performed at the same level using gadobutrol or iopromide on day 1 and the alternate agent on day 8 in order to determine contrast media kinetics, peak enhancement, and time-enhancement product in important vascular regions and parenchymal organs (abdominal aorta, inferior vena cava, liver, and renal parenchyma). Peak enhancement (net increase compared with non-enhanced baseline values) is measured in Hounsfield units (HU) in defined anatomical regions of interest.
Experimental Animal Model: Domestic pigs (n = 8; 35 ± 4 kg body weight).
Interpretation and Analysis: The mean *in vivo* peak enhancement at 5, 15, 30, and 120 seconds in the abdominal aorta after injection of 2 mL/kg BW gadobutrol and iopromide is 200 ± 11, 224 ± 10, 261 ± 13, and 95 ± 9 HU vs 232 ± 10, 298 ± 10, 152 ± 11, and 123 ± 10 HU, respectively. Differences in enhancement of vascular structures are statistically significant ($p < 0.05$) in carotid arteries (235 ± 20 HU for gadobutrol and 264 ± 19 HU for iopromide) and the aortic arch (261 ± 14 HU for gadobutrol and 279 HU ± 13 HU

for iopromide). No statistical significance can be appreciated in any other measured vascular structures and parenchymal organs. Contrast-enhanced CT with 1 mol/L gadobutrol at a dose of 2 mmol/kg body weight provides excellent enhancement of vascular structures and parenchymal tissues in most vascular regions and parenchymal organs similar to an equivalent volume of 300 mg/mL iodinated contrast media.

1-molar gadobutrol as a contrast agent for computed tomography: Results from a comparative porcine study. Kalinowski M, Kress O, Wels T, Alfke H, Klose KJ, Wagner HJ. Invest Radiol 2003 Apr; 38 (4), pp. 193–9.

Angiography: Arteriography/Abdominal Aorta and Renal Arteries/Digital Subtraction Arteriography (DSA)
Gadodiamide (Full-Strength)/Iodinated Contrast Imaging Agents (Half-Strength)

Cellular/Molecular Mechanism of Action: Iodinated compounds and gadodiamide possess radiopaque properties.
Application: Angiography procedures.
Route of Administration: Intra-arterial.
Dosage: Equal volumes (32 mL) of either half-strength (300 mg/mL iodine) iodinated contrast material or full-strength gadodiamide (0.11–0.25 mmol/kg).
Implementation: Conduction of DSA of the abdominal aorta and renal arteries utilizing gadodiamide for comparison with half-strength iodinated contrast media (equal volumes). The abdominal aorta, left and right renal main renal artery, and 1st and 2nd order segmental branches are graded separately as either diagnostic or non-diagnostic (e.g., blinded study, 4 angiographers).
Interpretation and Analysis: Images of the abdominal aorta are (i) diagnostic 100% of the time when using iodine and gadodiamide; (ii) 76% and 80% diagnostic for iodine and gadodiamide in the left main renal artery, respectively; and (iii) 100% and 80% diagnostic for iodine and gadodiamide in the right main renal artery, respectively. First-order segmental branches of the right and left renal arteries are graded diagnostic (i) 72% and 56% of the time, respectively, for dilute iodinated contrast material, and (ii) 40% and 28% of the time, respectively, for gadodiamide. Second-order segmental branches of the right and left kidney are graded diagnostic (i) 24% of the time for iodinated contrast, and (ii) 8% and 4% of the time, respectively, for gadodiamide. Full-strength, intra-arterial gadodiamide at doses smaller than 0.3 mmol/kg can produce diagnostic images of the abdominal aorta and main renal arteries. However, images of the intrarenal branches are usually not diagnostic.

Feasibility of gadodiamide compared with dilute iodinated contrast material for imaging of the abdominal aorta and renal arteries. Spinosa DJ, Angle JF, Hagspiel KD, Bissonette E, Conaway MR, Hartwell GD, Matsumoto AH. J Vasc Interv Radiol 2000 Jun; 11 (6), pp. 733–7.

Angiography: Arteriography/Selective Intra-Arterial Administration/X-Ray Digital Subtraction Angiography (DSA)
Gadobutrol/Gadolinium Diethylenetriamine Pentaacetic Acid ([Gd]-DTPA)

Cellular/Molecular Mechanism of Action: Gadolinium preparations and iodinated compounds possess radiopaque properties.
Application: Selective arterial angiography using x-ray DSA as an imaging modality.
Route of Administration: Gadolinium-DTPA (intra-arterial), gadobutrol (intra-arterial), iopromide (intra-arterial).
Dosage: Gadolinium-DTPA (0.5 mol/L), gadobutrol (1 mol/L), iopromide (300 mg I/mL).
Implementation: Flush arteriograms (ascending, descending, abdominal aorta, iliac, and femoral arteries) and selective angiograms (carotid, renal, and visceral arteries) are obtained utilizing bilateral femoral arterial access (5 F sheaths). Digital subtracted angiograms are obtained during injection of undiluted gadobutrol, iopromide, and gadopentetate with the injection parameters of volume and velocity maintained in a similar manner for each of the 3 contrast agents. In paired arteries, 2 different contrast media are used during the same angiographic run. Diagnostic quality and accuracy of the angiograms are evaluated on a 3-step scale.
Animal Model: Porcine (n = 10, 70 kg total BW).
Interpretation and Analysis: Sufficient non-selective angiographic images can be obtained in 90% of cases using iodinated contrast material (swine). Gadobutrol can achieve sufficient non-selective angiograms in 64% of acquired images Alternatively, selective angiograms are of sufficient diagnostic quality in 98% of the procedures using iodinated contrast material compared to 90% for 1 mol/L gadobutrol and 48% using 0.5 mol/L [Gd]-DTPA. Adverse reactions for any of the reagents is rarely appreciated. One mol/L gadobutrol solution allows x-ray DSA with a diagnostic accuracy equivalent to 300 mg/mL iodinated contrast media, if a selective injection technique is performed. Flush aortograms produce images of inferior quality compared to iodinated contrast material.

X-ray digital subtraction angiography with 1 mol/L gadobutrol: Results from a comparative porcine study With iodinated contrast agents. Kalinowski M, Kress O, Wels T, Alfke H, Klose KJ, Wagner HJ. Invest Radiol 2002 May; 37 (5), pp. 254–62.

Angiography: Arteriography/Catheter-Based Digital Subtraction Arteriography (DSA)
Gadolinium (Gadodiamide)

Cellular/Molecular Mechanism of Action: Gadolinium possesses radiopaque properties.
Application: Catheter-based DSA image-enhancing contrast agent.
Dosage: Gadolinium (gadodiamide, 287 mg/mL formulation).
Implementation: Catheter-based DSA studies performed in cases suffering from azotemia using gadolinium (gadodiamide, 287 mg/mL) as a contrast agent to evaluate renal arterial circulation characteristics (e.g., n = 25 images; n = 21 cases). Quantities of gadolinium administered range between 40 and 264 mL (mean = 124 ± 74 mL). Serial determinations of renal function are performed in cases as a comparative monitoring parameter. Example case population: Arteriography performed in cases prior renal revascularizations (e.g., n = 20); routine postoperative follow-up study (e.g., n = 7); increasing azotemia (e.g., n = 9); worsening hypertension (e.g., n = 3); evaluation of a known renal artery stenosis and abdominal aortic aneurysm (e.g., n = 1); evaluation of suspected renovascular hypertension (e.g., n = 3); and known aortic aneurysms in whom renal artery stenosis is suspected.
Human Model: Cases suffering from azotemia (n = 21 cases for n = 25 images).
Interpretation and Analysis: Adverse changes in renal function are infrequently appreciated following gadolinium arteriography. Prearteriography serum creatinine values can range between 1.6 to 9.1 mg/dL (3.0 ± 1.4 mg/dL), compared with postangiography values varying between 1.2 and 8.4 mg/dL (2.9 ± 1.3 mg/dL). Comparable blood urea nitrogen values range from 23 to 71 mg/dL (40.1 ± 13.5 mg/dL) before arteriography and from 21 to 68 mg/dL

(36.5 ± 13.3 mg/dL) after arteriography. Renal arteries can be successfully imaged in a high percentage of cases (e.g., n = 38/38). First-order and 2nd-order branches are well visualized on selective renal studies. Image evaluations reveal alterations, including renal artery stenosis, renal artery occlusion, renal artery thrombosis, renal artery dissecting pathology, and aortorenal bypass graft. Catheter-based arteriography in patients with azotemia with gadolinium as a contrast agent is a safe and effective means to evaluate the renal arterial circulation. Gadolinium should be considered as 1 of the preferred contrast agents for catheter-based arteriography procedures because it is a relatively safe alternative to nephrotoxic iodinated contrast agents in cases suffering from azotemia.

Gadolinium as a non-nephrotoxic contrast agent for catheter-based arteriographic evaluation of renal arteries in patients with azotemia. Ailawadi G, Stanley JC, Williams DM, Dimick JB, Henke PK, Upchurch GR Jr. J Vasc Surg 2003 Feb; 37 (2), pp. 346–52.

Angiography/Attenuation of Positive Contrast Imaging Enhancing Agents
Gadolinium (Gadobutrol)/Iopromide

Cellular/Molecular Mechanism of Action: Gadolinium and iodinated compounds possess radiopaque properties.
Application: Gadobutrol is a neutral lanthanide macrocyclic chelate containing gadolinium that is applied as a positive contrast agent for diagnostic imaging modalities, including computed tomography (CT). Iopromide is an iodinated compound that is utilized as a positive contrast agent.
Dosage: Gadolinium/gadobutrol (0.7, 1.0, and 1.5 mmol [Gd]/kg; rabbits). Iodine/iopromide (1.0 and 2.4 mmol I/kg; rabbits).
Implementation: Measurement of the degree of attenuation in Hounsfield units (HU) of increasing concentrations of aqueous gadolinium ([Gd] from gadobutrol) and iodine (I from iopromide) formulations by CT at 80 kV, 120 kV, and 137 kV. Peak enhancement (net increase in CT attenuation compared with baseline) and the time-enhancement product in the aorta and in the renal parenchyma of the outer and inner cortex are measured over a 5-minute period following the administration of a single intravenous injection of gadolinium or iopromide
Animal Model: Rabbit.
Interpretation and Analysis: The *in vitro* CT attenuation of gadolinium is approximately 40% higher than that of iodine at equivalent mass concentrations (120 kV). The mean peak enhancements in the aorta after injections of 0.7, 1.0, and 1.5 mmol [Gd]/kg and 1.0 and 2.4 mmol I/kg is 216, 313, 591, 224, and 498 Hounsfield units, respectively. In addition, a 30-second injection of high-dose gadobutrol creates an attenuation profile that is suitable for 3-dimensional reconstructions of the aorta and the renal vasculature. Due to the higher CT attenuation of gadolinium compared with that of iodine, gadobutrol is a more effective contrast agent than iopromide for CT at lower doses of the imaging atom.

Evaluation of gadobutrol in a rabbit model as a new lanthanide contrast agent for computed tomography. Schmitz SA, Wagner S, Schuhmann-Giampieri G, Wolf KJ. Invest Radiol 1995 Nov; 30 (11), pp. 644–9.

Angiography: Blood-Pool Imaging
Iopromide-Containing Liposomes/[Iopromide-Containing Soy Phosphatidyl Glycerol Liposomes]

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties. Liposomes protect agents from degradation or dilution and can under certain scenarios facilitate selective delivery.
Application: Soy phosphatidyl glycerol liposomes containing iopromide can be utilized as blood-pool imaging agents for computed tomography (CT) (non-human primates).
Route of Administration: Iopromide-containing soy phosphatidyl glycerol liposomes (intravenous).
Dosage: Iopromide-containing soy phosphatidyl glycerol liposomes (300 mg total iodine per kilogram).
Semi-Synthetic Methods: Incorporation of iopromide into soy phosphatidyl glycerol liposomes with a mean diameter of 195 nm (46% encapsulation).
Implementation: Evaluation of the diagnostic efficacy of intravenously injected iopromide contained within soy phosphatidyl glycerol liposomes.
Animal Model: Primate. Anesthetized adult baboons (15–21 kg).
Interpretation and Analysis: Injections of iopromide-containing soy phosphatidyl glycerol liposomes are well tolerated without any measurable changes in electrocardiographic parameters. Recoveries from anesthesia is uneventful. Sequential helical CT scans from the base of the skull to the symphysis pubis acquired up to 40 minutes after injection show persistent blood-pool enhancement. Maximum mean enhancement of major vascular structures is 106 Hounsfield units (HU) at 1 minute after contrast medium injection. Mean blood-pool enhancement is 76, 72, and 67 HU at 10, 20, and 40 minutes after injection, respectively. Liver and spleen can be enhanced by 40 and 41 HU, respectively, 40 minutes after injection. No significant enhancement can be measured in the brain and pancreas. Soy phosphatidyl glycerol liposomes containing iopromide therefore appear to have potential utility as blood-pool agents due to their ability to produce prolonged enhancement of CT generated images of vascular structures (non-human primates).

CT blood-pool enhancement in primates with lopromide-carrying liposomes containing soy phosphatidyl glycerol. Schmiedl UP, Krause W, Leike J, Sachse A. Acad Radiol 1999 Mar; 6 (3), pp. 164–9.

Angiography/Blood-Pool Imaging/Aorta/Liver/Renal Cortex
Liposomal Iohexol

Cellular/Molecular Mechanism of Action: Iohexol is an iodine-containing compound that possesses radiopaque properties. Liposomes protect encapsulated compounds from excessively rapid elimination (renal excretion), metabolic degradation, and sometimes faciltate selective delivery.
Background Information: Although soluble non-ionic iodine compounds with low systemic toxic effects have been developed for use in computed tomography (CT), they have short residence times of only a few minutes or mere seconds, and therefore last for an insufficient time period for blood-pool imaging, even with high-speed multidetector row spiral CT. Moreover, potential renal toxic effects preclude repeated administration of these contrast agents during imaging, as well as their use in patients with compromised renal function.
Application: Potential blood-pool agent that can be applied for cardiovascular imaging purposes.
Route of Administration: Liposomal iohexol (intravascular).
Dosage: Liposomal iohexol (475 mg of iodine per kilogram of body weight).
Implementation: Development and evaluation of a CT contrast agent for blood-pool imaging that remains in the blood for more than 3 hours and that is relatively non-toxic to the kidneys. One strategy for achieving this objective can entail liposomal encapsulation of iohexol formulations. Relevant properties and characteristics that need to be assessed for such preparations include (i) encapsulation efficiency in terms of milligrams of iodine per milliliter of lipid for-

mulation; (ii) stability *in vitro* in phosphate buffer solution and in human plasma; and (iii) *in vivo* stability, residence time, and enhancement of contrast on images of various organ systems.

Animal Model: Rabbit (*in vivo* investigations).

Interpretation and Analysis: Formulations that contained 34.8 mg of iodine per milliliter of liposomal iohexol solution, remain stable in blood plasma in both *in vitro* and *in vivo* environments, after intravascular injection (e.g., rabbit). An intravenous dose of 475 mg I/kg produces contrast enhancement of approximately 130 Hounsfield units (HU) in the aorta and liver cortex and approximately 100 HU in the renal cortex. Contrast enhancement is maintained for 3 hours after injection, and minimal clearance of the contrast agent via the kidneys is observed. Liposomal iohexol formulation may therefore have sufficient residence time for blood-pool imaging in a rabbit model. Future experiments with long-residence-time iohexol formulations may lead eventually to applications in cardiac imaging and in early tumor detection.

Long-residence-time nano-scale liposomal iohexol for x-ray-based blood-pool imaging. Kao CY, Hoffman EA, Beck KC, Bellamkonda RV, Annapragada AV. Acad Radiol 2003 May; 10 (5), pp. 475–83.

Angiography/Central Nervous System (CNS) Blood-Brain Barrier (BBB)/Monitoring BBB Disruption/ Monitoring CNS Chemotherapeutic Delivery
Meglumine Iothalamate/Metrizamide/Methotrexate

Background Information: Enhanced computed tomography (CT) is a non-invasive means of monitoring BBB disruption.

Application: Meglumine iothalamate and metrizamide can be applied as contrast-enhancing agents for the detection and characterization of vascular anomalies. Related examples include their utilization to monitor the degree, distribution, extent, and reversibility of osmotic BBB disruption.

Route of Administration: Meglumine iothalamate (intravascular), metrizamide (intravascular).

Dosage: Meglumine iothalamate.

Implementation: Intravenous and intracarotid injection of meglumine iothalamate and metrizamide for CT imaging of cranial vasculature and assessment of the integrity of the BBB (canine animal model).

Interpretation and Analysis: The timing of iodinated contrast agent administration is crucial to achieving optimal enhancement by CT of disruptions in the integrity of the BBB. Intravenous administration of meglumine iothalamate produces excellent levels of enhancement on CT scan images, while intracarotid infusions are less satisfactory. Under similar conditions, enhancement provided by metrizamide is less marked and more transient than that observed with meglumine iothalamate. Systemically administered methotrexate after osmotic BBB disruption results in increased brain levels of the agent in areas that closely correlated with CT scan enhancement. Based on these observations, CT can be utilized as an effective non-invasive approach to monitoring both BBB disruption and the delivery of chemotherapeutic agents to the brain.

Use of enhanced computerized tomography to evaluate osmotic blood-brain barrier disruption. Neuwelt EA, Maravilla KR, Frenkel EP, Barnett P, Hill S, Moore RJ. Neurosurgery 1980 Jan; 6 (1), pp. 49–56.

Angiography/Central Nervous System (CNS)/Mean Cerebral Blood Flow Volume/Regional Brain Perfusion
Iodinated Contrast Agents

Application: Synchrotron radiation computed tomography (CT) allows the *in vivo* measurement of absolute contrast-agent concentrations with high accuracy and precision, and absolute cerebral blood volume or flow can be derived from these measurements using tracer kinetic methods.

Implementation: Acquisition of CT images following intravenous bolus injection of an iodinated contrast agent in order to follow the temporal evolution of the contrast material within the intravascular compartment (blood circulation). The 1st images are acquired before iodine infusion and subtracted to obtain CT slices expressed in absolute iodine concentrations. Cerebral blood volume and cerebral blood flow maps are obtained after correction for partial volume effects.

Animal Model: Rat (e.g., $n = 7$ healthy animals).

Interpretation and Analysis: Mean cerebral blood volume and flow values are approximately 2.1 ± 0.38 mL/100 g and 129 ± 18 mL/(100 g/min) in the parietal cortex; and 1.92 ± 0.32 mL/100 g and 125 ± 17 mL/(100 g/min) in the caudate putamen, respectively. Synchrotron radiation CT has the potential to assess these 2 brain-perfusion parameters.

Absolute cerebral blood volume and blood flow measurements based on synchrotron radiation quantitative computed tomography. Adam JF, Elleaume H, Le Duc G, Corde S, Charvet AM, Tropres I, Le Bas JF, Esteve F. J Cereb Blood Flow Metab 2003 Apr; 23 (4), pp. 499–512.

Angiography/Central Nervous System (CNS) Neurovasculature/Anatomical Model of the Cerebrovascular System / Cranial Model for Instructional Imaging/Cranial Model of Anatomical Dissection
Tomographic Contrast Imaging Agent/Silicone

Application: Production of a physical anatomical model suitable for imaging and manual dissection of vascular structures of the cranium for instructional purposes.

Implementation: Volumetric ratios of computed tomographic contrast agent and a silicone preparation are formulated in a manner that creates a final mixture that is optimally suited as an imaging compound. The resultant mixture is injected into the cerebrovascular systems of 6 fresh human cadaver heads for the purpose of acquiring digital virtual exposures performed in parallel with laboratory dissection. The specimens are analyzed by computed tomography (CT) with static and dynamic 3-dimensional images of the cadaver vascular tree obtained as viewed through surgical corridors of various skull base approaches.

Interpretation and Analysis: A contrast agent to silicone rubber volumetric ratio of 1:8 creates a preparation that is most appropriate for both CT and subsequent laboratory dissection of specimens. The blood vessels in computed tomographic scans demonstrate a higher attenuation than surrounding soft tissues. The opacity consistency of injected vessels is a critical parameter for a clear 3-dimensional rendering of the vascular structures in the natural surroundings of the skull base. Preparations of cadaver skulls in the manner described are suitable models for both imaging and manual dissection. The model allows for static and dynamic 3-dimensional examination of the surgical anatomy from a neurosurgeon's perspective. Preparation of biological specimens in this manner can therefore facilitate the study of cerebrovascular system morphology/pathology in relation to the skull base as a tool for designing surgical approaches and methodologies.

Imaging the cerebrovascular tree in the cadaveric head for planning surgical strategy. Zhao JC, Chen C, Rosenblatt SS, Meyer JR, Edelman RR, Batjer HH, Ciric IS. Neurosurgery 2002 Nov; 51 (5), pp. 1222–7; discussion 1227–8.

Angiography/Contrast Agent Artifact/Computed Tomography (CT) Imaging/Positron Emission Tomography (PET)
Iodinated Contrast Imaging Agents

Application: Enhancement of PET/CT imaging.
Route of Administration: Intravenous (most frequently).
Implementation: Intravenous and oral iodinated contrast agent administered to oncology cases (e.g., n = 30) combined with whole-body PET/CT. Computed tomography images acquired in the presence of intravenous and oral iodinated contrast agent are used for PET attenuation correction. Positron emission tomography images are assessed for the presence of artifact, defined as a region of high count rate on attenuation-corrected images in accurate co-registration with a contrast-enhanced blood vessel. Intravascular enhancement of thoracic veins is quantified by application of regions of interest, and quantities in cases with artifact (Group 1) and without artifact (Group 2) correlated. Body surface area is calculated for all patients.
Interpretation and Analysis: Contrast-induced PET artifact can be appreciated in approximately 13% of cases (e.g., n = 4/30 patients). Mean density differences in intravascular enhancement are highly significant ($p < 0.001$) compared to case groups with artifact (2,262 ± 304 Hounsfield units [HU]) and without artifact (1,058 ± 209 HU). Body surface area is significantly lower ($p = 0.035$) in cases with artifact (1.67 ± 0.11 m^2) than in cases without artifact (2.01 ± 0.18 m^2). Contrast-enhanced dual-modality PET/CT examinations may result in a PET artifact that is due to the transient bolus passage of undiluted intravenous contrast agent.

Focal tracer uptake: A potential artifact in contrast-enhanced dual-modality PET/CT scans. Antoch G, Freudenberg LS, Egelhof T, Stattaus J, Jentzen W, Debatin JF, Bockisch A. J Nucl Med 2002 Oct; 43 (10), pp. 1339–42.

Angiography: Hepatic and Abdominal Vasculature
Iohexol/Non-Ionic Computed Tomography (CT) Contrast Agent

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.
Application: Iohexol can be applied as a non-ionic contrast agent in spiral CT to enhance image analysis of hepatic and abdominal vascular structures.
Route of Administration: Iohexol (intravenous injection).
Dosage: Iohexol formulated at 240 mg I/ml and 350 mg I/ml injected at a rate of 2 ml/sec (New Zealand rabbits).
Implementation: Evaluation of the relative effectiveness of iohexol contrast agent (iodinated/non-ionic) formulated at 240 mg I/ml and 350 mg I/ml as contrast agents for enhancing the imaging of hepatic and abdominal vascular structures applying spiral CT. Each animal is evaluated using both concentrations of iohexol using 4 different contrast volumes: 2.3, 1.7, 1.1, and 0.57 ml/kg. Enhancement values of the aorta, hepatic veins, inferior vena cava, and hepatic parenchyma are measured using a region-of-interest cursor.
Animal Model: Rabbit (e.g., n = 10 New Zealand male rabbits).
Interpretation and Analysis: At all contrast doses, equal volumes of contrast iohexol-350 results in statistically higher hepatic ($p \leq 0.003$, paired Student's t test) as well as vascular ($p < 0.04$) enhancement compared with iohexol-240. The slopes and intercepts of the enhancement curves for iohexol-350 and iohexol-240 are not statistically different ($p > 0.05$) when enhancement is plotted as a function of total grams of iodine administered. In the application of spiral CT scanning, appropriate contrast doses and relative costs per dose of iohexol should be considered on the basis of total iodine load administered rather than total volume administered.

Effect of contrast concentration on abdominal enhancement in the rabbit: Spiral computed tomography evaluation. Bluemke DA, Fishman EK, Anderson JH. Acad Radiol 1995 Mar; 2 (3), pp. 226–31.

Angiography/Neoplasia/Perfusion Characteristics of Hepatic Metastatic Lesions
EOE-13/[^{99m}Technetium] ([^{99m}Tc]) Macroaggregated Albumin or [^{99m}Tc]-MAA

Cellular/Molecular Mechanism of Action: Biological preparation that is passively retained within the intravascular compartment for a prolonged period of time following intravenous injection due to its relatively large molecular weight.
Application: Assessment of vascular perfusion of organs and tissue structures in a manner that can detect hepatic metastatic lesions.
Route of Administration: Intravenous (catheter infusion at a rate of 0.66 ml/min.)
Implementation: Evaluation of hepatic perfusion patterns applying both nuclear scintigraphy and computed tomography imaging methodologies.
Interpretation and Analysis: Computed tomography with EOE-13 yields more precise anatomic detail and is unique in demonstrating the perfusion status of each hepatic metastasis. Further evaluation of EOE-13 for this purpose is warranted.
Instrumentation: Computer-integrated nuclear medicine scintigraphy camera imaging (CT with EOE-13 used as a validating procedure).

Assessment of perfusion patterns during hepatic artery infusion chemotherapy: EOE-13 CT and [^{99m}Tc]-MAA scintigraphy. Miller DL, Schneider PD, Gianola FJ, Willis M, Vermess M, Doppman JL. AJR Am J Roentgenol 1984 Oct; 143 (4), pp. 827–31.

Angiography/Pulmonary Artery Embolism/ Warning: Potential Risk of Cardiac Arrest
Carbon Dioxide (CO_2)/Multidetector Row Spiral Computed Tomography (CT) Image Analysis

Cellular/Molecular Mechanism of Action: Carbon dioxide possesses radioleucent properties.
Application: Carbon dioxide can be applied as a negative contrast agent in CT imaging procedures.
Route of Administration: Carbon dioxide (intravascular).
Dosage: Carbon dioxide (120 or 180 mL).
Implementation: Serial CT scanning is performed in the supine and prone positions utilizing different scan delays (10, 15, and 20 seconds) and different volumes of CO_2 (60, 120, 180, and 240 mL) that are hand-infused over a duration of 10 to 15 seconds (e.g., n = 4 swine). In pulmonary embolism models (e.g., n = 5 swine), scanning is performed with iodinated contrast medium and then rescanned utilizing CO_2 (120 or 180 mL) as a negative contrast agent. The supine and prone CT scans and the number and location of thrombi depicted in the CO_2- and contrast material-enhanced CT scans are then compared.
Animal Model: Creation of pulmonary emboli in swine (e.g., n = 7) followed by delineation of their anatomical characteristic using multidetector row spiral CT image analysis.
Interpretation and Analysis: Because the position of the pulmonary artery in swine, the prone position is more effective than the supine position with CO_2 enhancement. An infusion of 120 mL of CO_2 is sufficient to enhance the entire pulmonary artery, and scan-

ning can be timed to coincide with the completion of infusion, thereby creating the most effective results. Both the CO_2- and contrast-enhanced CT scans can aid in the detection of the vast majority of pulmonary thrombi (e.g., n = 7/7). Thrombi are more apparent using CO_2-enhanced CT scans compared to contrast-enhanced scans because of the high contrast interface between soft tissue and gas. However, a number of cases may not be able to be resuscitated after the occurrence of abrupt cardiac arrest following CO_2-enhanced scanning procedures (e.g., n = 2/7 swine). The CT depiction of pulmonary emboli is feasible with CO_2 gas as a negative contrast agent and may even be superior to that with iodinated contrast media. Further studies are required to evaluate the safety of this method and to develop an improved delivery of CO_2 gas for this application.

CO_2-enhanced CT imaging for the detection of pulmonary emboli: Feasibility study in a porcine model. Bae KT, Hong C, Becker CR, Prasad S, Nolte MA, Eisenbeis PE, Heiken JP. Acad Radiol 2003 Mar; 10 (3), pp. 313–20.

Angiography/Pulmonary Vasculature/ Pharmacokinetic Profile
Iodinated Macromolecule Contrast Agent Prototype (P743)/Iobitridol

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.
Application: Imaging of vascular structures utilizing spiral computed tomography (CT) pulmonary angiography in rabbits.
Route of Administration: Iobitridol (intravascular) and P743 (intravascular).
Dosage: Iobitridol (iodine dosage = 250 mg I/kg), P743 (iodine dosage = 150 mg I/kg).
Implementation: Evaluation of the relative pharmacokinetic profiles for the iodinated macromolecular contrast medium P743 compared to the standard contrast agent iobitridol pertaining to their relative capacity to enhance imaging of vascular structures in both 1st-pass and delayed CT scans (manual and power injected delivery). Protocols can be applied that facilitate comparison of vessel enhancement in both 1st-pass and delayed scans for both P743 and iobitridol contrast agents with the help of a power injector.
Animal Model: Rabbit.
Interpretation and Analysis: In instances of manual-fast injection, the 1st pass of iobitridol can be observed only on proximal scans. Conversely, opacification of vessels is maintained during 3 spiral scans with P743 under the same injection conditions. Utilization of optimal bolus timing provides for higher vessel enhancement that can be appreciated during bolus 1st pass with iobitridol compared with P743 prototype. However, during the post-bolus phase, the decrease in attenuation values is markedly faster with iobitridol than with P743. Therefore, P743 remains within the intravascular compartment to a greater extent than does iobitridol, which may have clinical diagnostic implications (e.g., pulmonary embolism).

CT pulmonary angiography with a macromolecular contrast medium: A comparative study vs iobitridol in rabbits. Wiart M, Corot C, Berthezene Y, Violas X, Canet E. Invest Radiol 2001 Sep; 36 (9), pp. 547–53.

Angiography: Vena Cava (Inferior): Cavography/ Diagnostic Accuracy and Sensitivity
Iodinated Contrast Media/Gadolinium/Carbon Dioxide (CO_2)

Cellular/Molecular Mechanism of Action: Carbon dioxide has radioleucent properties, while gadolinum and iodinated compounds possess radiopaque properties.
Application: Carbon dioxide, gadolinium, and iodinated contrast medias can be applied as imaging enhancing contrast medias for the identification and characterization of vascular anomalies.
Route of Administration: Carbon dioxide, gadolinium, and iodinated contrast medias are utilized as intravascular contrast agents.
Implementation: Injection of CO_2, gadolinium, and iodinated contrast media into catheterized vascular structures for achieving enhanced imaging analysis of anatomical abnormalities within the inferior vena cava. Caval diameter is determined utilizing calibrating software applied in combination with visual evaluations based on measurements of the distance from the superior image border to the inferior margin of the renal veins and from the inferior image border to the iliac bifurcation. Measurements of anatomical structures using CO_2 and gadolinium can then be compared to those obtained with iodinated contrast materials in addition to establishing their relative sensitivity in detecting the presence or absence of caval thrombus formation and vascular anomalies.
Experimental Model: Cases suspected of suffering from various vascular anomalies (e.g., n = 40 injected with iodinated contrast material, CO_2, and gadolinium).
Interpretation and Analysis: Caval diameter measurements differ by 0.4 mm or less for all 3 agents. Measurements with all agents are within 2 mm of each other for all individual cases. Measurements acquired utilizing gadolinium and CO_2 are not significantly different from one another pertaining to estimates of caval diameter. At initial reading, compared with iodinated contrast material, gadolinium has greater mean inter-observer error in measuring the distance to the iliac bifurcation and both renal veins (range, 1.6–1.8 mm) than CO_2 (range, 0.2–1.4 mm). This finding, although statistically significant for gadolinium ($p < 0.05$), is doubtful to be of any clinical relevance. Inter-observer correlation is significantly worse for CO_2 at the levels of the iliac bifurcation ($p = 0.02$) and right renal vein ($p = 0.008$). Inter-observer correlation for gadolinium is similar to that for iodinated contrast material at all levels. At repeat reading, there are significantly inferior intra-observer correlations with use of CO_2 for both renal veins ($p < 0.05$) compared to iodinated contrast material and for the left renal vein ($p < 0.05$) compared to gadolinium. Renal vein anomalies can often be easier to detect with gadolinium and iodinated contrast media (e.g., n = 3/3) compared to negative CO_2 contrast enhancement (e.g., n = 1/3). Therefore, CO_2 and gadolinium appear to have limitations when compared with iodinated contrast material. Gadolinium provides superior consistency in identifying relevant landmarks for filter placement. Alternatively, CO_2 demonstrates significantly greater mean correlative error than gadolinium for initial and repeat readings.

Gadolinium, carbon dioxide, and iodinated contrast material for planning inferior vena cava filter placement: A prospective trial. Brown DB, Pappas JA, Vedantham S, Pilgram TK, Olsen RV, Duncan JR. J Vasc Interv Radiol 2003 Aug; 14 (8), pp. 1017–22.

Cardiovascular: Ventricular (Left) Heart Failure/ Atypical Hounsfield Attenuation in Cardiac Failure/ Unacceptable Screening Methods for Cardiopulmonary Function
Lopromid

Cellular/Molecular Mechanism of Action: Lopromid is a compound that possesses radiopaque properties.
Background Information: Bolus tracking systems have been developed that can improve the timing of intravenous contrast media application in helical computed tomography (CT).

Application: Contrast-enhancing agent for use in helical CT image analysis.

Dosage: Lopromid (75 ml; 300 mg/ml; 2 ml/sec).

Implementation: Evaluation of bolus tracking systems for improving the timing of intravenous contrast media delivery applied in CT imaging assessement of cardiac function. The displayed increase of vascular density over time after peripheral lopromid contrast media injection is classified according to 3 categories, including (Type A) rapid increase, (Type B) deceleration before a 100 HE threshold was reached, and (Type C) 1 or more peaks. The findings of the invasive investigation of the heart are correlated to findings of the bolus-tracking measurements.

Human Model: Cases subjected to bolus triggered contrast enhanced helical CT and invasive investigation of the heart within 1 week (n = 64).

Interpretation and Analysis: Examinations can have slightly different category distributions: Type A = 19; Type B = 34; Type C = 11 cases. A highly significant correlation exists between the type of the Hounsfield attenuation and systolic pressure in the left ventricle. There is no correlation between the type of the Hounsfield attenuation and the diastolic pressure in the left ventricle, pressures related to the right ventricle or the ejection fraction. The bolus-tacking system shows a sensitivity of 53%, a specificity of 82%, an accuracy of 70%, a positive predictive value of 70% and a negative predictive value of 70% in detection of left heart failure. The bolus tracking system C.A.R.E.-bolus often shows atypical Hounsfield attenuation in cases of cardiac failure but is not suitable as a screening method for cardiopulmonary function.

Instrumentation: CT scanner Somatom Plus 4 Volume Zoom (Siemens Corp., Forchheim, Germany) using the C.A.R.E. Bolus software that performs repetitive low-dose test scans (e.g., for the abdomen: 140 kV, 20 mA, T_1 0.5 sec) and measures the Hounsfield attenuation (increase over the baseline) in a preselected region of interest.

Observing the density increase curve after intravenous contrast medium administration using a bolus triggering system: A method for detection cardiovascular disorders. Stückle CA, Kickuth R, Kirchner EM, Liermann D, Kirchner J. Radiologe 2002 Jun; 42 (6), pp. 480–4.

CENTRAL NERVOUS SYSTEM (CNS)

Adenosine A2A Receptor Complexes (Central Nervous System [CNS])/A2A and A1 Selectivity *Styrylxanthine Derivatives/[7-Methyl-[^{11}C]-(E)-3,7-Dimethyl-8-(3-Iodostyryl)-1-Propargylxanthine or [^{11}C]-IS-DMPX/[7-Methyl-[^{11}C]-(E)-8-(3-Bromostyryl)-3,7-Dimethyl-1-Propargylxanthine or [^{11}C]-BS-DMPX/KF15372 A1 Antagonist/KF17837 A2A Antagonist*

Background Information: Previous investigations have evaluated the potential of iodinated and brominated styrylxanthine derivatives labeled with [^{11}C] as *in vivo* probes.

Application: Detection and characterization of the distribution patterns for adenosine A2A receptor complexes within the CNS (striatum) applying positron emission tomography (PET) or single photon emission computed tomography (SPECT) imaging modalities.

Semi-Synthesis: [7-methyl-[^{11}C]-(E)-3,7-dimethyl-8-(3-iodostyryl)-1-propargylxanthine ([^{11}C]-IS-DMPX) and [7-methyl-[^{11}C]-(E)-8-(3-bromostyryl)-3,7-dimethyl-1-propargylxanthine ([^{11}C]-BS-DMPX) can be prepared by the [^{11}C]-methylation of corresponding 7-demethyl derivatives.

Implementation: Evaluation of the diagnostic efficacy of [^{11}C]-BS-DMPX and [^{11}C]-IS-DMPX for delineating the distribution and relative binding avidity for A1 and A2A receptor complexes. Determination of the diagnostic efficacy of these agents can therefore be validated by performing *in vivo* imaging studies and *in vitro* membrane binding analyses.

Animal Model: Murine (CNS).

Interpretation and Analysis: Membrane binding studies performed *in vitro* show a high affinity (K_i values) of [^{11}C]-IS-DMPX and [^{11}C]-BS-DMPX ligands for A2A receptor: 8.9 nM for IS-DMPX and 7.7 nM for BS-DMPX, and a high A2A/A1 selectivity: $>$ 1,100 for IS-DMPX and 300 for BS-DMPX. In mice, [^{11}C]-IS-DMPX and [^{11}C]-BS-DMPX is taken up slightly more in the striatum than in the reference regions such as the cortex and cerebellum. The uptake ratios of striatum-to-cortex and striatum-to-cerebellum gradually increases but are very small: 1.6–1.7 for the striatum-to-cortex ratio and 1.2 for the striatum-to-cerebellum ratio at 60 minutes postinjection. The uptake by these 3 regions is reduced by co-injection of an excess amount of carrier or an A2A antagonist KF17837, but not by an A1 antagonist KF15372. The blocking effects in the 3 regions is greater for [^{11}C]-BS-DMPX (32–57%) than for [^{11}C]-IS-DMPX (6–29%). *Ex vivo* autoradiography analysis confirms that the 2 ligands are slightly concentrated in the striatum. [^{11}C]-BS-DMPX shows more selective affinity for adenosine A2A receptors than does [^{11}C]-IS-DMPX, but the 2 tracers are not suitable as *in vivo* ligands because of low selectivity for the striatal A2A receptors and a high level of non-specific binding.

Evaluation of iodinated and brominated [^{11}C]-styrylxanthine derivatives as *in vivo* radioligands mapping adenosine A2A receptor in the central nervous system. Ishiwata K, Shimada J, Wang WF, Harakawa H, Ishii S, Kiyosawa M, Suzuki F, Senda M. Ann Nucl Med 2000 Aug; 14 (4), pp. 247–53.

Alzheimer's Disease (AD): General Perspective *Amyloid Plaque Ligands/Computed Tomography (CT)/Positron Emission Tomography (PET)*

Alzheimer's disease, a progressive neurodegenerative disorder, is the most common cause of dementia in the elderly. Current consensus statements have emphasized the need for early recognition and the fact that a diagnosis of AD can be made with high accuracy by using clinical, neuropsychologic, and imaging assessments. Magnetic resonance (MR) or CT imaging is recommended for the routine evaluation of AD. Coronal MR images can be useful to document or quantify atrophy of the hippocampus and entorhinal cortex, both of which occur early during the course of the disease process. Both volumetric and subtraction MR techniques can be used to quantify and monitor dementia progression and rates of regional atrophy. MR measures are also increasingly being used to monitor treatment effects in clinical trials of cognitive enhancers and antidementia agents. Positron emission tomography and single photon emission CT (SPECT) offer value in the differential diagnosis of AD from other cortical and subcortical dementias and may also offer prognostic value. In addition, PET studies have demonstrated that subtle abnormalities may be apparent in the prodromal stages of AD and in subjects who carry susceptibility genes. Positron emission tomography ligands are in late-stage development for demonstration of amyloid plaques, and human studies have already begun. Functional MR-based memory challenge tests are in development as well.

Neuroimaging and early diagnosis of Alzheimer's disease: A look to the future. Petrella JR, Coleman RE, Doraiswamy PM. Radiology 2003 Feb; 226 (2), pp. 315–6.

Myelography: Image Quality/Adverse Reactions: Relative Frequency
Iomeprol/Iohexol/Iotrolan/Iopamidol

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.
Application: Iomeprol is a non-ionic iodinated contrast medium that can be applied in myelogram procedures (conventional radiography and myelo-computed tomography [CT]). Other iodinated compounds that can be applied in a similar fashion include iohexol and iotrolan.
Route of Administration: Iomeprol (intrathecal).
Dosage: Iomeprol (3 g total iodine reference dose with doses as high as 4.5 g of total iodine).
Implementation: Evaluation of pharmacokinetics, tolerability, safety, and efficacy of iomeprol following intrathecal injection (e.g., n = 600 cases).
Interpretation and Analysis: Pharmacokinetics study results reveal that after intrathecal administration iomeprol is completely absorbed from the cerebrospinal fluid compartment (once absorbed into the systemic circulation, it is rapidly excreted, unmetabolized, by glomerular filtration). Dose-finding studies show that the opacification produced by iomeprol depends on the injected dose. Although a dose-dependent increase in efficacy is observed, no differences in neurotolerability and safety are detected between the doses tested. Doses of iomeprol greater than 3 g iodine do not cause a greater incidence of adverse events and produce significantly better contrast efficacy. Comparative clinical trials demonstrate that iomeprol and iopamidol, iohexol, and iotrolan always provided adequate opacification of the subarachnoid space, both in conventional myelography and myelo-CT, with adequate delineation of normal structures and pathologic processes. No serious adverse events occur up to a total dose of 4.5 g of iodine. Almost invariably, no differences between the agents with regard to tolerance, adverse events, and effects on vital signs, physical examination, and neurologic examination can be appreciated. Therefore, iomeprol is safe and effective and can be recommended for myelography and myelo-CT.

Clinical experience with iomeprol in myelography and myelo-CT: Clinical pharmacology and double blind comparisons with iopamidol, iohexol, and iotrolan. Katayama H, Heneine N, van Gessel R, Taroni P, Spinazzi A. Invest Radiol 2001 Jan; 36 (1), pp. 22–2.

GASTROINTESTINAL SYSTEM

Gastrointestinal/Abdominal and Pelvic Organs
Gastrografin (Oral)/Antiperistaltic Agents

Background Information: The oral administration of a dilute positive iodinated contrast agent such as gastrografin (2%) is usually necessary to achieve optimal delineation of abdominal and pelvic organs. The amount of contrast agent administered and the timing of its administration depends on the site of the suspected disease state. The simultaneous intravenous administration of antiperistaltic agents is generally unnecessary when utilizing modern fast computed tomography (CT) scanners. However, contrast agent-induced artifact may at times be troublesome, so it is therefore suggested by some radiologists that lesions in the left lobe of the liver be scanned without positive contrast in the stomach. Negative contrast may also be useful in delineating disease: gas (carbon dioxide) has been shown to be useful in evaluating bladder tumors. Air insufflation has also been utilized to facilitate the evaluation of small rectal tumors. Intravenous administration of contrast agent aids in the characterization of various disease entities and also facilitates the recognition of vascular structures (such as veins and arteries in the peripancreatic region). Both the infusion and bolus modes of contrast material administration have their place in the evaluation of abdominal and pelvic lesions evaluated by CT. Newer techniques such as dynamic CT scanning is a valuable diagnostic modality for both delineating and characterizing disease states.

Positive and negative contrast agents in CT evaluation of the abdomen and pelvis. Hamlin DJ, Burgener FA. J Comput Tomogr 1981 Jun; 5 (2), pp. 82–90.

Intestinal Opacification/Combined Abdominal/Pelvic Helical Computed Tomography (CT)
Oral Intravenous Contrast Media

Application: Enhancement of abdominal/gastrointestinal imaging studies.
Implementation: Dilution of intravenous contrast agents in water to a total volume of 400 ml and oral ingested 60 minutes prior to, in addition to 400 ml of water immediately before helical CT imaging (e.g., n = 19 cases).
Interpretation and Analysis: The distal small bowel is opacified by the positive contrast agent, and the stomach by the negative contrast agent in all patients. Gastric contents are homogenous, and the density is a mean ± standard deviation 2.5 ± 7.3 Hounsfield units (HU). The difference between the densities of the gastric contents and of the gastric wall (mean ± standard deviation 80.8 ± 20.9 HU) is statistically significant ($p < 0.05$). Applying the described protocol (diluted iodine solution 1st followed by water) can be used as a method for the oral administration of contrast agents for combined abdominal and pelvic helical CT with intravenous contrast media.

Positive and negative oral contrast agents for combined abdominal and pelvic helical CT: First iodinated agent and 2nd water. Matsuoka Y, Masumoto T, Koga H, Suzuki K, Ushimi T, Terada H, Tamura A, Yokoyama Y, Abe K, Kamata N. Radiat Med 2000 May–Jun; 18 (3), pp. 213–6.

HEPATIC SYSTEM

Hepatocyte Selective Contrast Agent/Arterial Portography/Carcinoma Lesions
Iodinated Tryglyceride/Iohexol

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties. Iodinated tryglycerides are rather selectively assimilated by hepatocytes.
Application: Iodinated tryglycerides can be injected as a radiodense contrast agent that is subsequently assimilated relatively selectively by hepatocytes in a manner that can provide enhance computed tomography (CT) images of the liver.
Route of Administration: Iodinated tryglycerides can be selectively injected directly into specific (catheterized) vascular structures (e.g., arterial portography).
Dosage (Rabbit): Iohexol-enhanced CT (600 mg iodine per kilogram of body weight [mg I/kg]); CT arterial portography (iohexol [600 mg I/kg]); triglyceride-enhanced computer tomograpy (126 mg I/kg); and dual-contrast-enhanced CT (triglyceride plus iohexol [425 mg I/kg]).
Implementation: Comparison of the relative effectiveness of iodinated tryglyceride (hepatocyte-selective contrast agent) and/or iohexol to function as CT image-enhancing agents during arterial portography procedures. Such an evaluation can be performed

utilizing livers (e.g., rabbit) directly inoculated with VX2 carcinoma. Results are compared for 5 helical CT examinations: (i) unenhanced CT; (ii) iohexol-enhanced CT; (iii) CT arterial portography; (iv) triglyceride-enhanced CT; (v) and dual-contrast-enhanced CT. Attenuation of normal liver and neoplastic lesions can be assessed using analysis of variance techniques and blinded-reader evaluation protocols.

Interpretation and Analysis: Normal liver attenuation is greatest at CT arterial portography (127.3 Hounsfield units [HU] ± 5.3 [mean ± standard error of the mean]), followed by dual-contrast-enhanced CT (112.4 HU ± 1.2), iohexol-enhanced CT (97.9 HU ± 2.2), triglyceride-enhanced CT (82.3 HU ± 1.1), and unenhanced CT (54.9 HU ± 1.8). Liver-to-lesion attenuation difference at triglyceride-enhanced CT is significantly greater than at iohexol-enhanced CT ($p < 0.05$), and attenuation differences at dual-contrast-enhanced CT are comparable to those at CTAP. Detection of tumors is not improved with triglyceride-enhanced CT, which increases conspicuity. Sensitivity values for lesion detection at dual-contrast-enhanced CT are greater than those with iohexol-enhanced CT or CT arterial portography ($p < .05$). Computed tomography imaging enhanced with triglyceride preparations (especially when combined with iohexol) produces sensitivity values and liver-to-lesion attenuation differences that are greater with lower iodine doses than with iohexol or with CT arterial portography methods.

CT depiction of experimental liver tumors: Contrast enhancement with hepatocyte-selective iodinated triglyceride vs conventional techniques. Lee FT Jr, Chosy SG, Naidu SG, Goldfarb S, Weichert JP, Bakan DA, Kuhlman JE, Tambeaux RH, Sproat IA. Radiology 1997 May; 203 (2), pp. 465–70.

Hepatic Biodistribution Profile/Emulsion Particle Diameter and Dose/Organ Radioactive Dosimetry
[^{125}I]-Radioiodinated Polyiodinated Triglyceride (ITG)-Lipid Emulsion (LE)/(Potential Computed Tomography [CT] Agent)

Physiological Mechanism of Action: Polyiodinated triglyceride lipid emulsions are rather selectively assimilated intracellularly by hepatocytes.

Application: Novel LE formulations can be applied as a delivery moiety for the development for hepatoselective contrast agents. Radioiodinated polyiodinated triglyceride can be used as an indicator/signal molecule. The production of a LE-ITG conjugated complex can therefore be utilized as a potential contrast image-enhancing agent for application in CT.

Route of Administration: [^{125}I]-ITG-LE (intravenous).

Semi-Synthetic Methods: The signal molecule polyiodinated triglyceride is covalently cross-linked to LE (carrier molecule) to create a biologically functional conjugate.

Implementation: Delineation of the *in vivo* biodistribution of radioactivity associated with intravenously administered [^{125}I]-ITG-LE as a function of (i) mean particle size; (ii) total administered dose; (iii) formulation composition; and (iv) time after injection. Computed tomography imaging studies of the abdomen can be applied to evaluate the extent of hepatic enhancement after ITG-LE administration.

Animal Model: Rat.

Interpretation and Analysis: Mean emulsion particle diameter and total administered dose exert the greatest effect on ITG-LE biodistribution profiles. In optimal delivery scenarios, > 70% of the administered dose localizes to the liver 30 minutes after injection. Liver enhancement profiles in CT imaging studies are consistent with biodistribution profiles. Therefore, an appropriately formulated and administered dose of ITG-LE provides tissue-selective localization of contrast material that can be effectively used in CT procedures.

Polyiodinated triglyceride lipid emulsions for use as hepatoselective contrast agents in CT: Effects of physicochemical properties on biodistribution and imaging profiles. Bakan DA, Weichert JP, Longino MA, Counsell RE. Invest Radiol 2000 Mar; 35 (3), pp. 158–69.

Hepatic Neoplastic Disease/Hepatocellular Carcinoma: Arteriography/Vascularity Pattern of Hepatocellular Carcinoma/Trans-Catheter Arterial Chemoembolization Response/Arteriography Prognostic Variables
Arterial Phase Computed Tomography (CT) Contrast Image-Enhancement Agents

Application: Hepatic arterial-phase helical CT can be utilized to assess tumor vascularity and predict the likelihood of response to trans-catheter arterial chemoembolization in patients with hepatocellular carcinoma.

Implementation: Classification of helical CT image results in conditions of hepatocellular carcinoma into 3 patterns of vascularity on the basis of the degree of tumor or liver enhancement during the hepatic arterial phase. Cases in which hypervascular lesions predominate are classified as a Type 1 pattern. In cases that primarily display hypovascular lesions are classified as a Type 2 patterns. Conditions can further be classified as responders or non-responders on the basis of changes in tumor size detected on CT images after 3 trans-catheter arterial chemoembolization treatments.

Human Model: Hepatocellular carcinoma (e.g., n = 57 cases).

Interpretation and Analysis: Approximately 65% of hepatocellular carcinoma cases subjected to 3 trans-catheter arterial embolization treatments can be classified as responders (e.g., n = 37/57), while 35% are classified as non-responders (e.g., n = 20/57). There is a statistically significant correlation between Type 1 hypervascular patterns and response to trans-catheter arterial chemoembolization. Conversely, Type 2 hypovascular patterns correlate with non-response to trans-catheter arterial chemoembolization ($chi^2 = 7.85$, $p = 0.02$). Patients classified as responders live significantly longer than those classified as non-responders with 12-, 24-, and 36-month survival rates of 90%, 67%, and 36%, respectively, for responders and 70%, 17%, and 10%, respectively, for non-responders. Therefore, patients that respond to trans-catheter arterial chemoembolization have a prolonged survival period ($p < 0.01$). Response correlates closely with tumor vascularity as shown on hepatic arterial phase helical CT images.

Prognostic significance of arterial phase CT for prediction of response to trans-catheter arterial chemoembolization in unresectable hepatocellular carcinoma: a retrospective analysis. Katyal S, Oliver JH, Peterson MS, Chang PJ, Baron RL, Carr BI. AJR Am J Roentgenol 2000 Dec; 175 (6), pp. 1665–72.

INFLAMMATION AND SEPSIS

Abscess: Focal Hepatic Lesions
Ethyl Ester of Diatrizoic Acid (EEDA)

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.

Background Information: Ethyl ester of diatrizoic acid is an iodinated (89 mg I/ml) nanoparticulate (200 nm) contrast agent that has undergone preclinical evaluation.

Application: Contrast agent for enhancement of computed tomography (CT) imaging of focal hepatic disease.

Route of Administration: Ethyl ester of diatrizoic acid (intravenous).

Dosage: Ethyl ester of diatrizoic acid is an iodinated (89 mg I/ml) nanoparticulate (200 nm).
Implementation: Evaluation of EEDA administered in conditions of focal liver abscesses (e.g., n = 11 New Zealand White rabbits). On different days EEDA and iohexol are individually administered. CT scanning is performed at intervals following contrast agent administration. Liver and abscess enhancement are measured and compared. Dynamic imaging experiments in normal animals are also performed using both agents.
Interpretation and Analysis: Preparations of EEDA result in a significantly greater enhancement of liver and liver-to-abscess contrast imaging compared to iohexol at all time points beyond 5 minutes at approximately 25% of the total iodine load. During dynamic imaging, liver and aortic enhancement is greater with EEDA than with iohexol, except during a 20- to 40-second period immediately following contrast agent administration. The contrast agent EEDA therefore is superior to iohexol for imaging liver abscesses. Liver-directed agents such as EEDA may prove to be more efficacious than currently available extracellular agents designed for liver CT scanning.

Hepatic imaging with iodinated nanoparticles: A comparison with iohexol in rabbits. Gazelle GS, Wolf GL, McIntire GL, Bacon ER, Na G, Halpern EF, Toner JL. Acad Radiol 1995 Aug; 2 (8), pp. 700–4.

LYMPH NODES AND LYMPHATICS

Lymphography/Percutaneous Computed Tomography (CT) Imaging
Iodinated Chylomicron Microemulsions

Application: Enhanced imaging of lymphoid structures.
Implementation: An iodinated chylomicron remnant-like microemulsion is formulated with a mean particle size of 91.3 nm and an iodine concentration of 91 mg I/mL. Contrast material (2 mL) can be injected into the subcutaneous tissues of the metatarsus and metacarpus (e.g., n = 6 normal dogs) to enhance visualization of popliteal and cervical lymph nodes, respectively. Computed tomography images are then acquired at 0, 15, 30, 45, 60, 240, 480, and 1,440 minutes.
Interpretation and Analysis: Significant lymph node enhancement occurs in as little as 15 minutes postinjection and persists for at least 8 hours. Node opacification is most pronounced at 1 to 4 hours postinjection and exceeds 200 HU in some nodes (precontrast attenuation = 45 HU). Marked enhancement of popliteal efferent lymphatics and of iliac and sacral node groups also occurs, indicating distribution to 2nd-order nodes. Attenuation of enhanced nodes reverts to precontrast levels by 24 hours. The new surface-modified, chylomicron remnant-like emulsion provides marked, selective enhancement of targeted lymph nodes after subcutaneous administration. Moreover, the formulation produces significant opacification of more distant node groups from a single injection.

A surface-modified chylomicron remnant-like emulsion for percutaneous computed tomography lymphography: synthesis and preliminary imaging findings. Wisner ER, Weichert JP, Longino MA, Counsell RE, Weisbrode SE. Invest Radiol 2002 Apr; 37 (4), pp. 232–9.

Lymphography: Regional Lymph Nodes
Iodinated Nanoparticle

Application: Computed tomography (CT) lymphography of the craniocervical and thoracic lymph nodes.
Route of Administration: Iodinated nanoparticulate suspension injected subcutaneously, submucosally, and intraperitoneally.
Dosage: Iodinated nanoparticulate suspension (2–4 ml of 15% wt/vol preparation).
Implementation: Evaluation of the imaging characteristics of iodinated particulate contrast agents administered interstitially or intraperitoneally for CT lymphography of the craniocervical and thoracic lymph nodes. Suspensions of iodinated nanoparticle are injected subcutaneously, submucosally, or intraperitoneally (e.g., n = 8 dogs). Computed tomography and plain radiographic images are obtained prior to contrast administration and 4 hours, 24 hours, and 7 days after injection. Correlations are then made by detailed postmortem assessment.
Animal Model: Canine (e.g., n = 8 dogs).
Interpretation and Analysis: Computed tomography images reveal enhancement of regional nodes draining injection sites. Mean attenuation of opacified nodes is approximately 313 ± 297 (mean ± standard deviation), 536 ± 453, and 492 ± 372 Hounsfield units at 4 hours, 24 hours, and 7 days postinjection, respectively. Lymph node opacification on CT images correlates well with node location found at postmortem. It is therefore feasible to effectively opacify craniocervical and thoracic lymph nodes with iodinated nanoparticulate contrast agent following interstitial or intraperitoneal delivery.

Iodinated nanoparticles for indirect computed tomography lymphography of the craniocervical and thoracic lymph nodes in normal dogs. Wisner ER, Katzberg RW, Koblik PD, Shelton DK, Fisher PE, Griffey SM, Drake C, Harnish PP, Vessey AR, Haley PJ, et al. Acad Radiol 1994 Dec; 1 (4), pp. 377–84.

Lymphography: Subdiaphragmatic Lymph Nodes
Iodinated Nanoparticles

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.
Application: Computed tomography (CT) lymphography of lymph nodes (e.g., subdiaphragmatic).
Dosage: Iodinated nanoparticles (4 ml of a 15% [wt/vol]; n = 10 dogs [beagles]).
Implementation: Evaluation of the imaging characteristics of iodinated particulate contrast media for indirect CT lymphography of normal subdiaphragmatic lymph nodes (canine). Iodinated nanoparticle suspensions can be injected into the gastric, colonic, rectal, or cervical submucosa, loose paraprostatic fascia, or metatarsal subcutaneous tissues. Endoscopic, CT, or ultrasound guidance is used when necessary to facilitate contrast agent delivery. Computed tomography and radiographic images are obtained prior to contrast administration and at 4 hours, 24 hours, and 7 days postcontrast injection. Postmortem examinations are then performed as a validation procedure.
Interpretation and Analysis: Computed tomography images show enhancement of regional lymph nodes draining the various injection sites. The mean attenuation of opacified nodes is 678 ± 463 Hounsfield units 24 hours after injection, which remains elevated at 7 days postinjection. Lymph node opacification on CT images correlates well with node location observed on postmortem examinations. Subdiaphragmatic lymph nodes can be effectively opacified using an iodinated nanoparticle contrast agent for indirect CT lymphography.

Indirect computed tomography lymphography of subdiaphragmatic lymph nodes using iodinated nanoparticles in normal dogs. Wisner ER, Katzberg RW, Koblik PD, McGahan JP, Griffey SM, Drake CM, Harnish PP, Vessey AR, Haley PJ. Acad Radiol 1995 May; 2 (5), pp. 405–12.

NEOPLASIA

Neoplastic Disease/Hepatic Tumor Detection Enhancement
Vascular Endothelial Growth Factor (VEGF)/ Water-Soluble Contrast Imaging Agents

Application: Vascular endothelial growth factor may be a biopharmaceutical agent that can be applied to enhance the detection of hepatic neoplasia using water-soluble contrast agents and computed tomography (CT) imaging analyses.
Route of Administration: Vascular endothelial growth factor theoretically would most often be administered intravascularly in either a selective or non-selective manner.
Dosage: Vascular endothelial growth factor.
Implementation: Hepatic tumors (e.g., n = 11 hepatocellular carcinomas; 3 metastatic malignant lesions) are evaluated applying dual-phase dynamic helical computed tomography, or computed tomographic hepatic arteriography. The attenuation of each mass is classified as hyper-attenuation, isoattenuation or hypoattenuation with respect to the normal adjacent parenchyma. Gun-needle biopsy can be done for each tumor, and paraffin sections immunostained with anti-VEGF antibody by the avidin-biotin-peroxidase complex method. The pathologic grade is assigned according to intensity (1+, 2+, 3+) and area (±, 1+, 2+). Tumor size ranges are approximately 2.0–14.0 cm (mean, 5.8 cm).
Interpretation and Analysis: In the arterial phase, the intensity does not correlate with the degree of enhancement ($p = 0.086$). However, the correlation between the attenuation value of hepatic arterial phase and the area of positive tumor cells is statistically significant ($p = 0.002$). Vascular endothelial growth factor may be a biopharmaceutical agent that can be utilized to enhance hepatic mass with water-soluble iodinated contrast agent in computed tomography imaging methodologies.

Correlation of VEGF with contrast enhancement on dual-phase dynamic helical CT in liver tumors: Preliminary study. Kwak BK, Shim HJ, Park US, Lee TJ, Paeng SS, Lee CJ, Lim HK, Park CK. J Korean Med Sci 2001 Feb; 16 (1), pp. 83–7.

Neoplastic Disease: Hepatic VX2 Implants
Dy-EOB-DTPA/Iopromide

Application: Dy-EOB-DTPA is a liver-specific contrast imaging agents that can be applied for the detection of hepatic neoplastic cell implants using spiral computed tomography (CT) image analysis.
Route of Administration: Dy-EOB-DTPA (intravenous); iopromide (intravenous).
Dosage: Dy-EOB-DTPA (0.5 mmol/kg); iopromide (600 mg iodine/kg).
Implementation: The agent Dy-EOB-DTPA is injected intravenously as a hepatic image-enhancing agent. At 15, 30, 45, 60, and 90 minutes after administration spiral CT images are obtained and attenuation within the liver determined. Other studies involve the evaluation of neoplastic lesions (e.g., rabbits with VX2 tumor implants) receive in a random crossover design either Dy-EOB-DTPA, or 1 day later, iopromide contrast agent. At 60 minutes following injection of Dy-EOB-DTPA administration and both the arterial and portal-venous phases occur after iopromide injection, CT images are then acquired. Livers are subsequently harvested and histopathology examinations performed on hepatic neoplastic lesions. In tumor-bearing animals, 14 implanted tumors are 3–20 mm in diameter with 65% of the tumors were below 10 mm in diameter.
Animal Model: Rabbits (normal) and tumor-bearing rabbits (e.g., n = 14 VX2 tumor implants; 3–20 mm in diameter with 65% of the tumors below 10 mm in diameter). All rabbits are anesthetized during scanning procedures.
Interpretation and Analysis: In normal animals, 0.5 mmol/kg Dy-EOB-DTPA results in a liver enhancement of 30 HU during an entire 90-minute observation period. Dy-EOB-DTPA is able to detect 93% of the total number of neoplastic lesions present within the liver compared to 79% level of detection for iopromide both in the arterial and in the portal-venous phase (histopathology analysis serving as a comparative reference). Differences between the 2 agents is not statistically significant. Alternatively, plain CT image analysis detects approximately 50% of the total number of neoplastic lesions present ($p < 0.01$ vs iopromide and Dy-EOB-DTPA). Scar tissue and sites of necrosis are also detected by each of the methods. Dy-EOB-DTPA injection at a dose of 0.5 mmol/kg results in a long-lasting detectability of 93% of all implanted tumors vs 79% found with iopromide.

Efficacy of the iodine-free computed tomography liver contrast agent, Dy-EOB-DTPA, in comparison with a conventional iodinated agent in normal and in tumor-bearing rabbits. Krause W, Handreke K, Schuhmann-Giampieri G, Rupp K. Invest Radiol 2002 May; 37 (5), pp. 241–7.

Neoplastic Disease/Hepatic Metastasis Animal Model
Radioiodinated Polyiodinated Triglyceride (ITG)-Poly(Ethylene) Glycol (PEG): Blood-Pool Contrast Agent/ITG-Lipid Emulsion (LE): Hepatocyte-Selective Contrast Agent

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties.
Application: Combined formulation of ITG-PGE and ITG-LE for detection of hepatic metastatic neoplastic lesions (e.g., small [< 10 mm] VX2 tumors in rabbit liver).
Route of Administration: Iohexol (intravascular).
Dosage: Iohexol (600 mg I/kg iohexol); ITG-LE (200 mg I/kg).
Implementation: Evaluate the effectiveness of combining (i) lipid-based blood-pool contrast agent (ITG-PEG); with a (ii) hepatocyte-selective agent (ITG-LE) for accurate computed tomography (CT) detection of small neoplastic metastatic lesions within the liver parenchyma, in addition to determining the relative capacity of (iii) an iodinated lipid-based blood-pool contrast agent to remain within the intravascular compartment for extended periods of time compared to conventional water-soluble contrast agents.

One approach to achieving this investigation objective can involve conducting pharmacokinetic analyses utilizing injected preparations of either [^{125}I]-labeled ITG-PEG or [^{125}I]-labeled ITG-LE followed by subsequent blood collection and quantification of radioactivity. Computed tomography imaging is then performed in both normal reference control and tumor-bearing *in vivo* models. Scanning CT image analysis is then performed at 10 days with multiple imaging techniques, including non-contrast and helical intravenous enhanced (iohexol), and then 24 hours later using both ITG-PEG and ITG-LE. Tissue density measurements (Hounsfield units [HU]) of liver, tumor, and blood (descending aorta) are acquired in each case for comparison. Tumor morphology is verified by evaluation of gross pathological changes.

Animal Model: Rat (n = 12 SD rats) and rabbits (e.g., n = 3 normal New Zealand White rabbits and n = 2 New Zealand White rabbits with < 10 mm VX2 liver tumors). Tumor-bearing rabbits are laparotomized and VX2 cells injected directly into the hepatic parenchyma to produce a total of 8 focal lesions (2–10 mm diameter).

Interpretation and Analysis: Pharmacokinetic analysis in rats as well as CT studies in normal rabbits reveals that ITG-PEG remains in the blood-pool phase for more than 2 hours following intravenous administration. In fact, blood density in normal rabbits obtained with ITG-PEG is 95.1 HU ± 5.8 at 120 minutes compared to 90.7 HU ± 6.1 immediately after injection. Although liver enhancement is greater with iohexol (67 HU within 1 minute of injection), than for ITG-PEG/ITG-LE (32 HU, 60 minutes postinjection), liver-to-lesion ratios favor ITG-PEG/ITG-LE due to significant enhancement of tumors with iohexol (+40 HU). Tumor enhancement is minimal with ITG-PEG/ITG-LE. Lesions are subjectively much better defined with ITG-PEG/ITG-LE with sharper edge definition. The iodinated lipid-based contrast agent composed of both blood-pool and hepatocyte-selective components affords favorable CT imaging results compared to conventional urographic agent, albeit at one-third the total iodine dose.

Lipid-based blood-pool CT imaging of the liver. Weichert JP, Lee FT Jr, Longino MA, Chosy SG, Counsell RE. Acad Radiol 1998 Apr; 5 Suppl 1, pp. S16–9; discussion S28–30.

Neoplastic Disease/Hepatic Metastases: Carcinoma of the Colon/Improved Sensitivity of Detection: Computed Tomography (CT) Scan
Hepatic-Specific Lipid Emulsion (FP 736-03) Iohexol

Cellular/Molecular Mechanism of Action: Compound FP 736-03 is an iodinated lipid emulsion that has radiopaque properties.
Application: Hepatocyte-specific iodinated lipid emulsion applied to perform CT liver imaging (FP 736-03).
Implementation: Evaluation of multiple hepatic metastases of human colonic cancer (e.g., nude rat model). Animals are examined 3 weeks after intraportal tumor cell injection. Plain image examinations, and iohexol- and FP-736-03-enhanced CT are then performed. The rate of detection is determined on a lesion-by-lesion basis. Metastatic diameters measured on CT images are compared with corresponding macroscopic evaluation of serially collected liver specimens.
Animal Model: Rat (nude rat with human colon cancer transplants).
Interpretation and Analysis: In a lesion-by-lesion analysis (e.g., n = 140 metastases), the CT imaging detection rates when utilizing FP-736-03 are significantly greater than observed with plain images, or iohexol-enhanced imaging (e.g., 16.4% and 30.7% for native examination, 12.9% and 17.9% for iohexol-enhanced CT, and 53.6% and 72.1% for FP-736-03-enhanced CT, respectively [e.g., n = 2 diagnosticians]). Detection rates tend to increase with lesion diameter. The hepatocyte-specific contrast medium FP 736-03 improved the detection rate significantly in comparison with both plain non-contrast enhanced and iohexol-enhanced CT images.

An iodinated lipid emulsion for CT of the liver. Comparison with iohexol in the detection of experimental hepatic metastases. Bergman A, Sundin A, Magnusson A. Acta Radiol 1997 Jan; 38 (1), pp. 55–60.

RENAL SYSTEM

Urography: Image Enhancement Contrast Agents
Iopromide/Iotrolan/Urea/Iloprost/Nifedipine/ Papaverine/Sodium Nitroprusside

Cellular/Molecular Mechanism of Action: Iodinated compounds possess radiopaque properties. Certain molecular additives can be applied to influence the excretion rate of iodinated contrast agents during urography imaging procedures.
Application: Enhancement of the diagnostic quality of urography images produced with iodinated contrast-enhancing agents including iopromide and iotrolan (conventional radiography and computed tomography).
Route of Administration: Iopromide (300 mg/mL) and iotrolan preparations (280 mg/mL) are each administered intravenously.
Dosage: Iopromide (plain films = 300 and 600 mg iodine/kg) and iotrolan preparations (plain films = 300 and 600 mg/kg) in dogs and rabbit. Alternatively, iopromide (computed tomography [CT] scans = 50 mg iodine/kg) and iotrolan preparations (CT scans = 50 mg/kg) in rabbit.
Implementation: Conventional plain-film radiography urograms utilizing urea (52 mg/mL), iloprost (10, 20, 50, and 100 ng/mL), nifedipine (0.02 mg/mL), papaverine (0.625 mg/mL), and sodium nitroprusside (0.05 μg/mL) added to commercial iopromide (300 mg/mL) and iotrolan preparations (280 mg/mL). Images are obtained at different time points after contrast injection of iodine preparations (e.g., rabbits and dogs). Image analysis is then repeated using CT and iopromide or iotrolan plus urea (52 mg/mL) or iloprost (20 ng/mL) and iodine doses of 50 mg/kg body weight (rabbits).
Interpretation and Analysis: Urea and iloprost at low concentrations (10 and 20 ng/mL) increases image quality both in plain film and in CT urography. Iloprost at high concentrations (50 and 100 ng/mL), nifedipine, papaverine, and sodium nitroprusside decrease image quality. An increase in image quality is accompanied by faster renal elimination of the contrast agent. Therefore, image quality in plain film and CT urography can potentially be improved by the application of additives formulated with contrast medium preparations.

Use of additives to contrast media to improve imaging in plain film and computed tomography urography. Krause W, Schromm M. Invest Radiol 2003 Jan; 38 (1), pp. 17–26.$eref4

RESPIRATORY SYSTEM

Neoplasia/Lung Cancer Staging/Lymph Node Metastasis Detection
Iodinated Nanoparticles

Background Information: Lung cancer continues to be a leading cause of death around the world. Staging of this disease is critically dependent upon the involvement or non-involvement of the lymph nodes that drain the region of lung containing the lesion/tumor. Palpation, unenhanced computed tomography (CT), and lymph node excision (i.e., mediastinectomy) are currently used to ascertain the status of these regional draining lymph nodes.
Application: Detection and staging of lung cancer and metastatic lesions within regional lymph nodes.
Route of Administration: Iodinated nanoparticles (inhalation).
Implementation: Pulmonary instillation of iodinated nanoparticles for contrast-enhanced CT of lung draining lymph nodes.
Animal Model: Canine (beagles).
Interpretation and Analysis: The variables of dose, time post installation, and formulation type (surfactant) have an impact upon enhanced CT images of the tracheobronchial lymph nodes. Pulmonary instillation of small volumes of iodinated nanoparticles can be successfully used to aid in staging forms of lung cancer by CT imaging.

Pulmonary delivery of nanoparticles of insoluble, iodinated CT x-ray contrast agents to lung draining lymph nodes in dogs. McIntire GL, Bacon ER, Toner JL, Cornacoff JB, Losco PE, Illig KJ, Nikula KJ, Muggenburg BA, Ketai L. J Pharm Sci 1998 Nov; 87 (11), pp. 1466–70.

Pulmonary Arterial Embolism/Warning: Potential Risk of Cardiac Arrest
Carbon Dioxide (CO_2)/Multidetector Row Spiral Computed Tomography (CT) Image Analysis

Cellular/Molecular Mechanism of Action: Carbon dioxide possesses radioleucent properties.
Application: Carbon dioxide can be applied as a negative contrast agent in CT imaging procedures.
Route of Administration: Carbon dioxide (intravascular).
Dosage: Carbon dioxide (120 or 180 mL).
Implementation: Serial CT scanning can be performed in the supine and prone positions utilizing different scan delays (10, 15, and 20 seconds) and different volumes of CO_2 (60, 120, 180, and 240 mL) that are manually infused over a duration of 10 to 15 seconds (e.g., n = 4 swine). In pulmonary embolism models (e.g., n = 5 swine), scanning can be performed with iodinated contrast medium and then rescanned with CO_2 (120 or 180 mL). The supine and prone CT scans and the number and location of thrombi recognized in the CO_2- and contrast material-enhanced CT scans are then compared.

Experimental Model: Creation of pulmonary emboli in swine (e.g., n = 7) followed by delineation of their anatomical characteristics using multidetector row spiral CT image analysis.
Interpretation and Analysis: Because of the position of the pulmonary artery in swine, the prone position is more effective than the supine position with CO_2 enhancement. An infusion of 120 mL of CO_2 is sufficient to enhance the entire pulmonary artery, and scanning timed to coincide with the completion of infusion is the most effective. Both the CO_2- and contrast-enhanced CT scans can aid in the detection of the vast majority of pulmonary thrombi (e.g., n = 7/7). Thrombi are more apparent using CO_2-enhanced CT scans compared to contrast-enhanced scans because of the high contrast interface between soft tissue and gas. However, a number of cases cannot be resuscitated after the occurance of abrupt cardiac arrest following CO_2-enhanced scanning procedures (e.g., n = 2/7). The CT depiction of pulmonary emboli is feasible with CO_2 gas as a negative contrast agent and may even be superior to iodinated contrast media. Further studies are required to evaluate the safety of this method and to develop an improved delivery of CO_2 gas for this application.

CO_2-enhanced CT imaging for the detection of pulmonary emboli: Feasibility study in a porcine model. Bae KT, Hong C, Becker CR, Prasad S, Nolte MA, Eisenbeis PE, Heiken JP. Acad Radiol 2003 Mar; 10 (3), pp. 313–20.

TECHNIQUE

Computed Tomography: X-Ray Micro-Computed Tomography (CT)/Quantitative Imaging Enhancemet of Molecular Transport
Heavy Metal Chelates: Iodine Devoid/Radiopaque Indicators

Application: Utilized in x-ray micro-CT primarily for the purpose of (i)acquiring 3D microarchitecture images and their correlation with associated functional characteristics; and (ii) regional distribution of administered radiopaque indicators, within intact rodent organs or biopsies from large animals and humans.
Implementation: Current use of x-ray micro-CT can be extended in 3 ways to increase the quantitative imaging of molecular transport processes and accumulation within such tissue/organ specimens. Examples in this regard include: (i) Use of heavy elements, other than iodine, attached to molecules of interest or to surrogates for those molecules for detection of accumulation patterns of the indicator in physiological compartments, and their transport to and from such compartments, which can be quantitated from the imaged spatial distribution of the contrast agents. (ii) High spatial resolution of conventional x-ray attenuation-based CT images to improve the quantitative nature of radionuclide-based tomographic images (single photo emission computed tomography [SPECT] and positron emission tomography [PET]) by providing correction for the attenuation of emitted gamma rays and the accurate delineation of physiological spaces known to selectively accumulate those indicators. Similarly, other imaging modalities that also localize function in 2D images (such as histological sections subsequently obtained from the same specimen), can be used in synergistic combination with CT-based 3D microstructure. (iii) Increasing the sensitivity and specificity of x-ray CT image contrast by use of methods such as: K-edge subtraction imaging, x-ray fluorescence imaging, imaging of the various types of scattered x-ray and the consequences of the change in the speed of x-rays through different tissues, such as refraction and phase shift. These other methods of x-ray imaging can increase contrast by more than an order of magnitude over that from conventionally-used attenuation of x-ray. To fully exploit their potentials, much development of radiopaque indicators, scanner hardware and image reconstruction and analysis software are needed.

Molecular imaging in small animals—Roles for micro-CT. Ritman EL. J Cell Biochem Suppl 2002; 39, pp. 116–24.

FLUOROSCOPIC IMAGING

Angiography: Fluoroscopic Imaging/Dosimetry Performance: Comparisons
Iodine-Based Vascular Contrast Agents (Gadolinium Filter)/Gadolinium-Based Vascular Contrast Agents (Tungsten Filter)

Application: Fluoroscopic imaging.
Implementation: Evaluation of fluoroscopic imaging and dosimetric analyses utilizing iodine-based and gadolinium-based vascular contrast agents in combination with K-absorption edge filters with atomic numbers between 50 (tin) and 82 (lead). Such combinations are studied using a theoretical model for a range of diagnostic x-ray spectra (55–100 kVp) and for water phantoms representative of thin and thick anatomical structures. Performance can be characterized according to radiographic contrast patterns, a derived image quality index, patient integral and entrance skin doses, and x-ray tube load. For a given thickness of anatomical structures, an optimum combination of spectrum kVp, contrast agent, and supplemental filter is defined by maximum imaging performance for a minimum or tolerable x-ray tube load and patient dose.
Interpretation and Analysis: Improvement of both imaging performance and reduced dose is possible through the use of an appropriate combination of spectrum kVp and filter. For gadolinium-based contrast, performance is optimized with tungsten filtration at 90 kVp for both thin and thick anatomies. It is not possible, however, to optimize the iodinated contrast performance with a single combination of supplemental filter and spectrum kVp. The optimal performance for iodinated contrast is achieved with gadolinium filtration at 60 kVp for thin anatomical structures and with ytterbium filtration at 80 kVp for thick anatomical structures. The best performance for thin anatomies is observed with a combination of iodinated contrast/gadolinium filter at 60 kVp and the best performance for thick anatomy can be observed with a combination of gadolinium-based contrast/tungsten filter at 90 kVp.

X-ray image intensifier performance and patient doses for combinations of supplemental beam filters and vascular contrast agents. McParland BJ, Boyd MM. Phys Med Biol 2001 Jan; 46 (1), pp. 227–44.

21 Ultrasonography

GENERAL CONSIDERATIONS AND CONCEPTS

Acoustic Parameters
Optison/Definity/SonoVue/Sonazoid

Implementation: Evaluation of the acoustic properties of 4 ultrasonic contrast agents (Optison, Definity, SonoVue, and Sonazoid) at 30 MHz. A range of contrast agent concentrations can be studied using either saline or glucose as a diluent of choice. Mean backscatter power is measured over regions-of-interest (ROIs) at distances of 1, 1.5, 2, 3, 4, and 5 mm from the center of the intravascular probe and normalized to the ultrasound (US) data collected from a standard glass reflector.
Interpretation and Analysis: For all of the agents, the mean backscatter power at 30 MHz varies in a linear manner with concentration between 0.01 million microbubbles/mL and 1 million microbubbles/mL. Furthermore, for 2 of the agents, mean backscatter enhancement is detectable at concentrations as low as 2 microbubbles/sample volume.
Instrumentation: Boston Scientific ClearView Ultra intravascular US scanner modified to allow access to the unprocessed US data.

In vitro acoustic characterization of 4 intravenous ultrasonic contrast agents at 30 MHz. Moran CM, Watson RJ, Fox KA, McDicken WN. Ultrasound Med Biol 2002 Jun; 28 (6), pp. 785–91.

Contrast Image-Enhancing Agents

The concept of contrast imaging was introduced to ultrasound almost 30 years ago. The development of ultrasound contrast agents (USCAs), initially slowed by technical limitations, has become more dynamic during the past decade. The ideal USCA should be nontoxic, injectable intravenously, capable of crossing the pulmonary capillary bed after a peripheral injection, and stable enough to achieve enhancement for the duration of the examination. While satisfying cost-benefit requirements, it should provide not only Doppler but also gray-scale enhancement. Doppler examinations can be improved by using USCAs when studying deep and small vessels, vessels with low or slow flow, or vessels with a non-optimal insonation angle. Ultrasound contrast agents also enhance detection of flow within abnormal vessels, including tumor vascularization and stenotic vessels, and provide better delineation of ischemic areas. Research has focused on the development of specific contrast imaging sequences that allow detection of tissue enhancement similar to that obtained with computed tomography (CT) or magnetic resonance imaging (MRI). These sequences take advantage of the non-linear behavior of microbubbles within ultrasound fields, bringing real-time perfusion imaging for liver, kidney, and the myocardium into reach. New objectives include targeted agents that could further widen USCA applications to the specific delivery of active drugs such as anticoagulants or cytotoxic compounds. The combination of new generations of USCAs and new ultrasound image sequences appears to be very promising and currently represents a significant part of ultrasound research.

Ultrasound contrast agents: Properties, principles of action, tolerance, and artifacts. Correas JM, Bridal L, Lesavre A, Mejean A, Claudon M, Helenon O. Eur Radiol 2001; 11 (8), pp. 1316–28.

Contrast Image-Enhancing Agents
Microbubbles

Various applications of contrast-assisted ultrasound, including blood vessel detection, perfusion estimation, and drug delivery, require controlled destruction of contrast agent microbubbles. The lifespan of a bubble depends on the properties associated with the bubble shell, the gas core, and the acoustic waveform impinging on the bubble. At least 3 mechanisms of microbubble destruction can occur within a biological system, including fragmentation, acoustically driven diffusion, and static diffusion. Fragmentation is responsible for rapid destruction of contrast agents on a microsecond time scale. The primary characteristics of fragmentation are a very large expansion and subsequent contraction that results in bubble instability. Optical studies using a novel pulsed-laser optical system show the expansion and contraction of ultrasound microbubble contrast agents have a ratio of maximum diameter to minimum diameter greater than 10. Fragmentation is dependent on the transmission pressure, occurring in over 55% of bubbles insonified with a peak negative transmission pressure of 2.4 MPa and in less than 10% of bubbles insonified with a peak negative transmission pressure of 0.8 MPa. The echo received from a bubble decorrelates significantly within 2 pulses when the bubble becomes fragmented, creating an opportunity for rapid detection of bubbles via a decorrelation-based analysis. Preliminary findings observed in mouse tumor models have verified the occurrence of *in vivo* fragmentation. A much slower mechanism of bubble destruction is diffusion, which is driven by both a concentration gradient between the concentration of gas in the bubble compared with the concentration of gas within the liquid, as well as convective effects of motion of the gas-liquid interface. The rate of diffusion increases during insonation, because of acoustically driven diffusion, producing changes in diameter on the time scale of the acoustic pulse length, thus on the order of microseconds. Gas bubbles diffuse while they are not being insonified (referred to as static diffusion). An air bubble with initial diameter of 2 microns in water at 37° C is predicted to fully dissolve within a 25-ms timeframe. Clinical ultrasound contrast agents are often designed with a high molecular weight core in an attempt to decrease the diffusion rate. C3F8 and C4F10 gas bubbles of the same size are predicted to fully dissolve within 400 ms and 4,000 ms, respectively. Optical experiments involving gas diffusion of a contrast agent support the theoretical predictions; however, shelled agents diffuse at a much slower rate without insonation, on the order of minutes to hours. Shell properties play a significant role in the rate of static diffusion by blocking the gas-liquid interface and decreasing the transport of gas into the surrounding liquid. Static diffusion decreases the diameter of albumin-shelled agents to a greater extent than lipid-shelled agents after insonation.

Mechanisms of contrast agent destruction. Chomas JE, Dayton P, Allen J, Morgan K, Ferrara KW. IEEE Trans Ultrason Ferroelectr Freq Control 2001 Jan; 48 (1), pp. 232–48.

Contrast Image-Enhancing Agents/Adverse Effect of Soluble Radiographic Contrast Media (RCM)

The pulmonary adverse effects of intravascular administered water-soluble RCM include bronchospasm, pulmonary edema, and increases in pulmonary arterial blood pressure (Ppa). Symptomatic bronchospasm is rare but subclinical increase in airways resistance is common after intravascular injection of RCM. Experimental studies have demonstrated that the low osmolar ionic dimer ioxaglate can induce significant bronchospasm in comparison with other types of RCM. Histamine and endothelin, which are potent bronchoconstrictors and released in response to the administration of RCM, do not seem to mediate the bronchospastic effect of RCM. Pretreatment with corticosteroids or antihistamine does not appear to prevent RCM-induced bronchospasm, but the administration of β_2-adrenergic agonist can abolish this adverse effect. RCM-induced pulmonary edema can be secondary to endothelial injury causing an increase in the permeability of the microcirculation. It may also occur in cases with incipient cardiac failure, when large doses of RCM particularly of the high osmolar type are used. A rise in Ppa induced by RCM seems to be secondary to an increase in pulmonary vascular resistance through direct effects on the pulmonary circulation. Low osmolar non-ionic monomers induce the least noticeable changes in the pulmonary circulation and should be the contrast media of choice for intravascular use in cases with pulmonary hypertension. The mechanisms responsible for the effects of RCM on airway resistance and pulmonary circulation remain unclear. Intrabronchial administration of high osmolar water-soluble RCM is dangerous and can induce severe bronchial irritation and pulmonary edema. Low osmolar RCM are well tolerated by the lungs following aspiration with minimal histological reaction.

Effects of radiographic contrast media on the lung. Morcos SK. Br J Radiol 2003 May; 76 (905), pp. 290–5.

Contrast Image-Enhancing Agents/Adverse Effects to Endothelium Injury/Endothelial Cell Viability: *Ex Vivo*/[Local Delivery] *Microbubbles/Propidium Iodine*

Background Information: Microvascular endothelial cells (EC) may be subject to the bioeffects induced by contrast ultrasound (US) because of their proximity to circulating microbubbles.
Application: Potential modality for the selective delivery of diagnostic or therapeutic pharmaceutical agents contained with microbubble preparations and subsequently liberated by ultrasound-induced disruption (lysis).
Route of Administration: Intravascular.
Implementation: Evaluation of EC injury produced in mesentery microvessel sections (e.g., arteriole, capillary, or venule) by exposure of ultrasound microbubble contrast agents to ultrasound energy. Assessment of such phenomenon can involve injection of microbubble preparations followed by ultrasound exposure at a 1-Hz or 30-Hz frame rate. Propidium iodide (PI), a fluorescent indicator of cell injury, can then be employed to visualize impaired endothelial cell integrity. Note: PI-positive nuclei should be equally few among the 3 control preparations.

Animal Model: Rat (mesenteric vasculature) divided into 5 experimental groups including 3 controls (sham operation, microbubble injection alone, US exposure with saline injection); and 2 contrast ultrasound groups (1-Hz or 30-Hz frame rates).
Interpretation and Analysis: Contrast-US increases the number of PI-positive cells in capillaries (1-Hz frame rate, 2.4 ± 2.2 cells per 0.1-mm vessel length, $p = 0.09$; 30-Hz frame rate, 4.3 ± 1.8 cells, $p < 0.01$) and in venules (1-Hz frame rate, 4.1 ± 2.5 cells, $p < 0.05$; 30-Hz frame rate, 13.8 ± 3.6 cells, $p < 0.01$) compared with sham preparations (0.10 ± 0.22 cells). Such findings indicate that diagnostic contrast ultrasound potentially causes endothelial injury, particularly within venules and capillaries.

Endothelial cell injury in venule and capillary induced by contrast ultrasonography. Kobayashi N, Yasu T, Yamada S, Kudo N, Kuroki M, Kawakami M, Miyatake K, Saito M. Ultrasound Med Biol 2002 Jul; 28 (7), pp. 949–56.

Contrast Image-Enhancing Agents/Adverse Effects of Renal Hemorrhage: Transducer Power vs Frequency/Renal Hemorrhage: Intermittent vs Continuous Insonification *Microbubbles*

Background Information: The generation of ultrasound (US) bioeffects using a clinical imaging system is controversial.
Route of Administration: Intravascular.
Implementation: Evaluation of the hypothesis that the presence of microbubbles in the US field of a medical imager induces biologic effects. One approach to detecting such effects includes insonification of the kidneys for 5 minutes using a medical imaging system after the administration of microbubbles. One kidney is insonified using a continuous mode (30 Hz) while the opposite kidney is insonified using an intermittent (1 Hz) technique. The microbubbles are exposed to 3 different transducer frequencies and 4 transducer output powers. After insonification, the animals are euthanized, the kidneys removed, and their gross appearance scored under "blinded" conditions using a defined pathology scale.

Animal Model: Rat (anesthetized).
Interpretation and Analysis: Following the administration of microbubbles, ultrasound imaging of the kidney induces hemorrhage in the renal tissue. The severity and area of hemorrhage increases with increases in the transducer power and a decrease in the transducer frequency. Intermittent insonification in the presence of microbubbles produces a greater degree of renal hemorrhage than continuous imaging techniques.

Microbubbles induce renal hemorrhage when exposed to diagnostic ultrasound in anesthetized rats. Wible JH Jr, Galen KP, Wojdyla JK, Hughes MS, Klibanov AL, Brandenburger GH. Ultrasound Med Biol 2002 Nov–Dec; 28 (11–12), pp. 1535–46.

Constrast Image-Enhancing Agents/Adverse Effects/ Gastrointestinal Inflammation, Necrosis, Mucosal Ulceration *Gas-Carrying Ultrasound Contrast Agents/Sonazoid*

Cellular/Molecular Mechanism of Action: Gas-carrying agents interact with ultrasound energy in a manner that impedes their transmission and reflects a portion of the "wave energy" back toward the probe/detector.
Application: Enhanced detection and characterization of physiological conditions and pathological anomalies affecting tissues, organ systems, vascular structures, and body fluids utilizing ultrasound-based diagnostic modalities.
Route of Administration: Gas-carrying ultrasound contrast image-enhancing agents (usually intravenous but theoretically can be utilized in any body fluid compartment). However, please note findings described in the Interpretation and Analysis section.
Implementation: Evaluation of the potential for gas-carrying ultrasound contrast image-enhancing agents to create pathological changes within tissues and organs.

Animal Model: Dogs, guinea pigs, mice, rats injected intravenously with gas-carrying ultrasound contrast image-enhancing agents.

Interpretation and Analysis: Single intravenous administration of different gas-carrier contrast agents used in ultrasound imaging (e.g., n = 3 mice) cause inflammation, necrosis, and ulceration of cecum and proximal colon (cecocolonic area) and focal necrosis in the liver of mice. Similar intestinal lesions are also found in rats after treatment with a single intravenous administration of a gas-carrier contrast agent. Strain differences in the incidences of these lesions can be appreciated in both rats and mice. HsdHan:NMRI mice are among the most sensitive of the mouse strains evaluated to date. Even at the lowest dose of Sonazoid technically possible to inject in HsdHan:NMRI mice, lesions can be identified and a no-effect dose cannot be determined. In time-course experiments in HsdHan:NMRI mice, lesions begin to develop in the cecum and colon within 15 to 30 minutes after dosing. Lesions in the liver are 1st observed 120–240 minutes after dosing. Interestingly, diet plays a role in the etiology of the lesions, as HsdHan:NMRI mice given a diet with reduced amounts of cellulose and starch have reduced incidences of lesions, and when glucose is the only carbohydrate source, no lesions can be observed. No intestinal or hepatic lesions can be found in guinea pigs or rabbits after repeated intravenous administrations of Sonazoid. In dogs, minimal to mild granulocytic inflammation of the cecum and/or colon is found after daily repeated intravenous injections for 28 days, but not after daily repeated administration for 14 days nor after a single administration. Intestinal and hepatic lesions in rats and mice after a single intravenous injection of gas-carrier contrast agents have been proposed to be caused by a common mechanism: intravascular growth of gas-carrier agents in tissues with gas supersaturation, as occurs in the cecal wall of rats and mice. In this particular environment the growing gas bubbles cause ischemia and necrosis in the cecal and colonic wall and liver. Such a proposed mechanism of action is consistent with the absence of clinical reports indicative of intestinal and/or hepatic lesions in humans after administration of gas-carrier contrast agents.

Intestinal and hepatic lesions in mice, rats, and other laboratory animals after intravenous administration of gas-carrier contrast agents used in ultrasound imaging. Dirven HA, Rasmussen H, Johnsen H, Videm S, Walday P, Grant D. Toxicol Appl Pharmacol 2003 May 1; 188 (3), pp. 165–75.

Contrast Imaging Agent Stability/Microbubble Formulations/Saline in Plastic vs Glass Vials/Saline in Vacuum vs Non-Vacuum Vials/Bladder Contrast-Enhanced Voiding Urosonograpy

Microbubbles (Galactose-Based Formulations: Levovist)

Background Information: The sonographic diagnosis of vesicoureteral reflux with intravesical administration of ultrasound contrast media is increasingly more frequent.

Application: Lower urinary tract examination.

Route of Administration: Urethral catheter.

Considerations: Rapid dissolution of microbubbles in the bladder filled with normal saline can occasionally be appreciated during the course of ultrasound examinations.

Implementation: Evaluate the degree of interaction between normal saline and ultrasound contrast media in concert with elucidating any potential causes for such interactions. Such an objective can be addressed applying an *in vitro* experimental model to characterize normal saline solution and a galactose-based ultrasound contrast medium (Levovist) formulated at gradient concentrations and then scanned utilizing predefined parameters. As a point of reference, the oxygen concentration of the solutions can also be measured (pO_2 and O_2 mg/l).

Interpretation and Analysis: Ultrasound contrast medium has a significantly longer contrast duration when mixed with normal saline from plastic containers rather than glass containers. The contrast duration difference is even more marked between normal saline from containers sealed under vacuum and those not sealed under vacuum (e.g., 0.7 and 12 minutes, respectively). The oxygen concentration in normal saline from vacuum-sealed containers is one-third or less that from non-vacuum-sealed containers. The high concentration of dissolved oxygen in normal saline seems to prevent the diffusion of air from microbubbles into the solution and thus their collapse. Desaturated normal saline has a detrimental effect on microbubbles of galactose-based US contrast agents. For the purpose of filling the bladder during contrast-enhanced voiding urosonography only normal saline solution from non-vacuum-sealed containers should be used. For practical purposes, normal saline from plastic containers is safest.

Interaction of normal saline solution with ultrasound contrast medium: Significant implication for sonographic diagnosis of vesicoureteral reflux. Darge K, Bruchelt W, Roessling G, Troeger J. Eur Radiol 2003 Jan; 13 (1), pp. 213–8.

Echocardiography/Myocardial Contrast Imaging

Microbubbles

Myocardial contrast echocardiography (MCE) has undergone many advances in the past several years through remarkable developments in contrast agent and ultrasound equipment technology. Microbubble ultrasound contrast agents can now safely transit the pulmonary circulation to provide opacification of the left ventricular cavity and improved endocardial border definition and to detect myocardial perfusion. The role of contrast echocardiography in enhancing technically difficult images is now well established in clinical practice and has proven especially useful in the stress and intensive care unit settings. Major progress has been made in the application of MCE for myocardial perfusion assessment in acute and chronic ischemic heart disease syndromes. Advances in novel applications of contrast echocardiography, including targeted delivery of genetic and pharmaceutical materials, have also occurred but remain in a preclinical phase. In summary, the combination of recent innovations in ultrasound equipment, and microbubble acoustics, allows for exciting exploration of the expanding role of contrast echocardiography in clinical practice.

Recent advances in myocardial contrast echocardiography. Gunda M, Mulvagh SL. Curr Opin Cardiol 2001 Jul; 16 (4), pp. 231–9.

Oxygen-Carrying Compounds/Vasculature/Liver or Spleen and Associated Neoplasia

Perflurochemicals (PFCs)

Cellular/Molecular Mechanism of Action: Perfluorochemicals possess oxygen-carrying properties. The characteristics that make them unique diagnostic agents pertain to their lack of hydrogen atoms, immiscibility with water, low surface tension, compressibility, and long intravascular persistence when emulsified and given intravenously.

Application: Perfluorochemicals can function as versatile contrast agents with important applications related to radiology (x-ray), ultrasound, and magnetic resonance imaging (MRI) modalities. When made radiopaque, they are visible with x-ray computed tomography (CT) and standard radiography.

Interpretation and Analysis: Because the neat liquid is inert it can be ingested, instilled in the lung, or introduced into any hollow organ to image the lumen without untoward effects. The long intravascular persistence allows imaging of blood vessels and vascularized

tissues. Small or deep vessels become visible with color Doppler imaging, and on angiographic images of any vascular tree including the coronary arteries, which can be rendered from serial CT images. As PFCs accumulate within reticuloendothelial system (RE) cells, specific liver and spleen enhancement can be achieved allowing the detection of small tumors within these organs. When injected interstitially, the particles find their way to draining (regional) lymph nodes providing detail of the internal architecture to detect the presence or absence of tumor involvement using both CT and sonography. Applying 19F MR, tissue perfusion and tissue pO_2 measurements can be obtained. The applications of PFC for diagnostic purposes are vast, unique, and important. These new capabilities will advance radiological tools to new horizons.

Pharmaceutical Delivery/Ultrasound-Triggered Focal Delivery/Acoustic Power: Optimization/Signal Intensity Maximization/Bulk Modulus/Influence of Difference in Shell Characteristics
Microbubbles/Acoustic Lability

Background Information: Low mechanical index perfusion imaging relies on the detection of signals produced by microbubble oscillation at low acoustic powers that results in minimal microbubble destruction.
Route of Administration: Intravascular.
Consideration: Localized ultrasound-mediated disruption of microbubble preparations containing encapsulated pharmaceutical agents has been employed as a modality for selective delivery.
Implementation: Evaluation of the hypothesis that the optimal acoustic power for real-time imaging differs for microbubbles with different shell characteristics. One approach for pursuing this hypothesis can involve the evaluation of 3 microbubble agents with varying shell elastic properties according to their polymer composition. Differences in the elastic properties of these microbubbles can be demonstrated by (i) measurement of their bulk modulus, and (ii) evaluation of their acoustic lability by microscopic visualization of microbubble destruction during insonification at incremental acoustic powers. The ultrasound signal generated by these microbubbles at various mechanical indexes and the degree of microbubble destruction during continuous imaging is then determined both in an *in vitro* flow system and during *in vivo* open-thorax imaging procedures.
Animal Model: Canine (open-thorax preparations).
Interpretation and Analysis: Optimal power for achieving maximal signal intensity with minimal microbubble destruction is influenced by the shell elastic properties. Acoustic power for maximizing acoustic signal without destroying microbubbles during low mechanical index imaging varies according to specific shell characteristics.

Influence of microbubble shell properties on ultrasound signal: Implications for low-power perfusion imaging. Leong-Poi H, Song J, Rim SJ, Christiansen J, Kaul S, Lindner JR. J Am Soc Echocardiogr 2002 Oct; 15 (10 Pt 2), pp. 1269–76.

Phase Aberration Correction: Acoustic Imaging
Droplet Emulsion

Application: Potentially useful for phase aberration correction in acoustic imaging.
Route of Administration: Intravascular.
Considerations: Acoustic pressure thresholds exist, above which droplets vaporize into bubbles approximately 25 times the original diameter. For frequencies between 1.5 and 8 MHz, the threshold decreases from 4.5 to 0.75 MPa peak rarefactional pressure.
Semi-Synthetic Methods: Droplet emulsion (90% < 6 microm diameter) are produced by mixing saline, bovine albumin, and dodecafluoropentane.
Implementation: Evaluation of droplet preparations pertaining to their evaporation as a function of applied acoustic pressure and frequency, as well as simulations of gas bubble lifetime based on gas diffusion. Simulation of *in vivo* environments can be effectively achieved by the evaporation of droplets in blood flowing under attenuating material.
Interpretation and Analysis: The droplet emulsion agent may be potentially useful for tissue occlusion in cancer treatment, as well as for phase aberration corrections in acoustic imaging.

Acoustic droplet vaporization for therapeutic and diagnostic applications. Kripfgans OD, Fowlkes JB, Miller DL, Eldevik OP, Carson PL. Ultrasound Med Biol 2000 Sep; 26 (7), pp. 1177–89.

Stability of Contrast Preparations/Concentration and Preparation Time
Galactose-Based Ultrasound Contrast Agents (USCA)

Application: Galactose-based USCA (Levovist) can be applied as an ultrasound contrast agent for the detection of physiological alterations and pathological anomalies affecting tissues, organ systems, and vascular structures.
Route of Administration: Galactose-based USCA (intravascular).
Dosage: Galactose-based USCA (volumetric doses = 0.1 ml, 0.5 ml, and 1 mL; formulated at concentrations of 200, 300, and 400 mg/mL administered at various times since reconstitution = 2 minutes, 12 minutes, 22 minutes, and 32 minutes).
Implementation: Characterization (*in vitro*) of changes in microbubble population formulated as a galactose-based USCA (Levovist) based on, or a function of attenuation measurements. Additional parameters evaluated include dose-effect, formulation concentrations, and time, because reconstitution is evaluated using 2 broadband pulses at different peak negative pressures (0.39 and 0.49 MPa; n = 72 injections).
Analysis and Interpretation: Two minutes after reconstitution, a linear relationship can be appreciated between attenuation measurements and the amount of USCA (slope 0.92 dB × mg/cm/ml, r = 0.86). For a given dose and concentration, microbubble stability is significantly reduced with an increase in time between reconstitution and administration, particularly at lower concentrations. The persistence (image duration) and contrast effect of Levovist can be improved by administering the agent within the recommended time period following reconstitution, and by the injection of maximum suggested concentrations.

Optimizing an ultrasound contrast agent's stability using *in vitro* attenuation measurements. Correas JM, Kurtisovski E, Bridal SL, Amararene A, Helenon O, Berger G. Invest Radiol 2002 Dec; 37 (12), pp. 672–9.

CARDIOVASCULAR SYSTEM

Anatomical and Physiological Anomalies/Solid Organ Lesions
Fluorocarbon Microbubble/C_3F_8 Microbubbles/ SF_6 Microbubbles

Cellular/Molecular Mechanism of Action: Gas microbubbles resonate when impacted by ultrasound frequencies and there-

fore reflect a fraction of the ultrasound energy they come in contact with.

Background Information: Ultrasonography has, until recently, lacked effective contrast-enhancing agents. Micrometer-sized gas bubbles that resonate at a diagnostic frequency are ideal reflectors for ultrasound. However, simple air bubbles, when injected into the blood stream, disappear within seconds through the combined effects of Laplace pressure, blood pressure, and exposure to ultrasound energy.

Semi-Synthetic Methods: Production of microbubbles containing fluorocarbon vapor (C_3F_8 or SF_6).

Implementation: Positive contrast media for performing ultrasonographic imaging of fluid-filled body compartments.

Analysis and Interpretation: Fluorocarbon vapor extends the *in vivo* persistence of microbubbles from seconds to minutes in a manner that substantially improves their level of clinical utility. Imaging techniques that selectively suppress tissue, but not microbubble signals, further increase image contrast. Approved products consist of C_3F_8 or SF_6 microbubbles and N_2 microbubbles osmotically stabilized with C_6F_{14}. These agents allow the detection and characterization of cardiovascular abnormalities and solid organ lesions, such as tumors. By providing higher quality images, they improve the accuracy and confidence of disease diagnosis and can play a decisive role in clinical decision making. New objectives include agents that target specific cells for the molecular imaging of disease, and drug and gene delivery, including ultrasound-triggered delivery.

Injectable microbubbles as contrast agents for diagnostic ultrasound imaging: The key role of perfluorochemicals. Schutt EG, Klein DH, Mattrey RM, Riess JG. Angew Chem Int Ed Engl 2003 Jul 21; 42 (28), pp. 3218–35.

Angina/Typical Stress-Induced Angina
Microbubbles/Levovist and Optison

Cellular/Molecular Mechanism of Action: Microbubbles variably impede, absorb, and reflect the unidirectional flow of ultrasound energy, causing a portion of the "waves" to be directed back toward the transducer sensor (detector).

Background Information: Power Doppler harmonic imaging (PDHI) is normally performed in a triggered mode.

Application: Potential detection of hypoperfusion events utilizing myocardial contrast echocardiography (MCE) performed with PDHI modalities.

Route of Administration: Intravascular.

Considerations: Microbubbles are destroyed by ultrasound energy in the myocardium, requiring refilling of the myocardium with microbubbles within the time interval between the ultrasound pulses to obtain repetitive information about perfusion. Using the contrast agent Levovist, however, real-time PDHI also results in myocardial opacification presumably due to perfusion signals of the arteriolar microbubble passage.

Implementation: Evaluation of coronary artery integrity and patency.

Human Model: Typical stress-induced angina (e.g., female 45 years old).

Interpretation and Analysis: Prior to angiography a conventional echocardiogram may show normal left ventricular function. By contrast, however, tissue Doppler may demonstrate postsystolic longitudinal shortening of the septal, anterior, and lateral wall regions. Myocardial contrast echocardiography with triggered PDHI can reveal complete opacification of the myocardium at rest. Using real-time PDHI with Levovist, the septum can lack opacification. It is possible with consecutive angiography studies to document the presence of pathological conditions, including severe unprotected main coronary artery stenosis. After angioplasty and stent implantation, MCE measurements can be repeated. Repetitive intravenous bolus injections of Optison during triggered PDHI may reveal no difference relative to images acquired prior to angioplasty. Using real-time PDHI with Levovist, however, there may be a marked difference in comparisons to the preinterventional analyses. Complete opacification of the apical septum may be observed. Evaluation of some cases may suggest that different MCE techniques can analyze different compartments of the myocardial vasculature in clinical practice. Such methodological comparisons between triggered and real-time PDHIs show obvious differences in the Doppler intensity (DI) signal detection due to different microbubble behaviors. Clinicians should be aware of the potentials of MCE to improve non-invasive diagnostic procedures in patients with ischemic heart disease.

Instrumentation: Echocardiographic instrumentation.

Myocardial contrast echocardiography for assessment of myocardial perfusion at rest in a patient with left main coronary artery stenosis. Hagendorff A, Pfeiffer D, Rother T, Becher H. Z Kardiol 2003 Oct; 92 (10), pp. 876–83.

Angiography/Blood Flow and Vascular Patency/ Ultrasound Contrast-Enhancing Agents
C_3F_8 Microbubbles/N_2 Microbubbles/SF_6 Microbubbles

Cellular/Molecular Mechanism of Action: Use of fluorocarbon vapor extends the persistence of microbubbles *in vivo* from seconds to minutes and has greatly facilitated the application of contrast ultrasonography into clinical practice.

Application: Imaging techniques and reagents that selectively suppress the intensity of signal from tissue structures, but not injected microbubbles, serve to further enhance image contrast. Approved products consist of C_3F_8 or SF_6 microbubbles, and N_2 microbubbles osmotically stabilized with C_6F_{14}. These agents allow the detection and characterization of cardiovascular abnormalities and solid organ lesions, such as tumors. By providing higher quality images, they improve the accuracy and confidence of disease diagnosis and can play a decisive role in clinical decision making. New objectives include the design of agents that target specific cells for the molecular imaging of disease, and drug and gene delivery, including ultrasound-triggered delivery.

Route of Administration: Preparations of C_3F_8 microbubbles, SF_6 microbubbles, and N_2 microbubbles osmotically stabilized with C_6F_{14} are administered intravenously.

Dosage: C_3F_8 microbubbles, SF_6 microbubbles, and N_2 microbubbles osmotically stabilized with C_6F_{14} are administered at dosages commensurate with the diagnostic procedure being performed.

Considerations: Ultrasonography has, until recently, lacked effective contrast-enhancing agents. Micrometer-sized gas bubbles that resonate at a diagnostic frequency are ideal reflectors for ultrasound. However, simple air bubbles, when injected into the blood stream, disappear within seconds through the combined effects of Laplace pressure, blood pressure, and exposure to ultrasound energy.

Analysis and Interpretation: These agents allow the detection and characterization of cardiovascular abnormalities and solid organ lesions, such as tumors. By providing higher quality images, they improve the accuracy and confidence of disease diagnosis and can play a decisive role in clinical decision making. New design objectives include development agents that target specific cells for the molecular imaging of disease, and drug and gene delivery, including ultrasound-triggered delivery.

Injectable microbubbles as contrast agents for diagnostic ultrasound imaging: The key role of perfluorochemicals. Schutt EG, Klein DH, Mattrey RM, Riess JG. Angew Chem Int Ed Engl 2003 Jul 21; 42 (28), pp. 3218–35.

Angiography/Blood Flow Quantification
Microbubble Contrast Image-Enhancing Agent

Application: Enhanced detection and characterization of physiological conditions and pathological anomalies affecting tissues, organ systems, vascular structures, and body fluids utilizing ultrasound-based diagnostic modalities.
Route of Administration: Microbubble contrast image-enhancing agents (intravascular).
Implementation: Evaluate changes in destruction-replenishment curves (*in vitro* and *in vivo*) that result from microbubble destruction in feeding vessels that pass through the imaging plane before microbubbles enter the region-of-interest (ROI). Establishing the nature of such parameters can be applicable to the assessment of renal perfusion applying a microbubble contrast media. Such investigations can entail performing continuous injection of an ultrasonographic contrast agent, in concert with non-linear gray-scale image analysis obtained *in vitro* in the longitudinal plane of a renal dialysis cartridge flow phantom (flow rates of 100, 200, and 400 mL/min) and *in vivo* in the coronal plane of the left kidneys (n = 2 left kidneys). Destruction-replenishment curves are obtained for the dialysis cartridge in the form of ROIs located immediately after the entrance of microbubbles into the image plane and further from the entrance, after microbubbles have traveled across the complete length of the imaging plane. Replenishment curves are also obtained from ROIs corresponding to the kidneys at the level of segmental arteries, distal interlobar arteries, and the cortex.

Animal Model: Rabbit renal preparations (n = 2 left kidneys, n = 2 rabbits).
Analysis and Interpretation: The ROIs immediately after the entrance of the microbubbles in the image plane of the dialysis cartridge and in the segmental artery of the kidney follow a typical exponential function, represented as $A^{1-e\text{-}alphat}$. Early portions of curves for ROIs representing large number of microbubbles that have already passed through the image plane of the dialysis cartridge or reside within the renal cortex are not well described by such a function. The shape of the curve and the variations as a function of flow rate can be explained by means of a mathematical model based on indicator-dilution theory. Therefore, when the "feeding" vessels of an ROI travel across the ultrasound field before they reach the measurement region, the typical shape of the replenishment curve is modified (reduced velocity parameter and plateau).

Blood flow quantification with contrast-enhanced US: "Entrance in the section" phenomenon-phantom and rabbit study. Lucidarme O, Franchi-Abella S, Correas JM, Bridal SL, Kurtisovski E, Berger G. Radiology 2003 Aug; 228 (2), pp. 473–9. Epub 2003 Jun 11.

Angiography/Carotid Artery (Internal): Occlusion vs Pseudoocclusion/High-Grade Stenosis: Maximal Narrowing/Extracranial Vertebral Artery/Trans-Cranial Arteriovenous Malformation/Trans-Cranial Thrombosis of Cerebral Veins/Sinuses/Trans-Cranial Intracranial Aneurysms
Echo-Contrast Agents

Application: Enhanced detection and characterization of physiological conditions and pathological anomalies affecting tissues, organ systems, vascular structures, and body fluids utilizing ultrasound-based diagnostic modalities.
Route of Administration: Echo-contrast agents (intravascular).
Implementation: Utilization of echo-contrast agents to differentiate internal carotid artery occlusion and pseudoocclusion; better delineate the maximal narrowing in high-grade stenoses; and better visualize the extracranial vertebral artery and its collaterals. Trans-cranial applications include assessment of insufficient foraminal or temporal window, assessment of arteriovenous malformations, thrombosis of cerebral veins and sinuses, and intracranial aneurysms.
Analysis and Interpretation: The use of echo-contrast can have direct diagnostic and therapeutic consequences. Harmonic imaging, perfusion imaging, stimulated acoustic emission, and drug delivery are possible future domains of the technique. Besides the support of conventional neurovascular ultrasound in poor examination conditions due to variations in anatomy or pathology, echo-contrast agents may allow for novel applications in the diagnosis and treatment of cerebrovascular disease states.

Ultrasound contrast-enhancing agents in neurosonology: Principles, methods, future possibilities. Droste DW, Kaps M, Navabi DG, Ringelstein EB. Acta Neurol Scand 2000 Jul; 102 (1), pp. 1–10.

Angiography: Central Nervous System/Stimulated Acoustic Emission/High-Acoustic Disintegration of Microbubbles/Insonation of Echo-Contrast Agents
Microbubbles/Non-Moving Microbubbles (SHU 563 A)/Levovist (SHU 508 A)

Background Information: Experimental and clinical data suggest that insonation of echo-contrast agents with high acoustical power produces disintegration of microbubbles, resulting in a pseudo-Doppler phenomenon called stimulated acoustic emission (SAE).
Application: Potential measurement of cerebral vascular perfusion applying trans-cranial Doppler image detection of SAE signals.
Implementation: Evaluation of non-moving microbubbles (SHU 563 A) insonated *in vitro* through the temporal parts of a human cadaver skull, and contrast signals detected by velocity-coded color Doppler and power Doppler recordings. Complementary investigations can include the trans-cranial color Doppler and power Doppler imaging (e.g., n = 10 normal controls) utilizing the echo-contrast agent Levovist (SHU 508 A).
Analysis and Interpretation: Color Doppler signals reveal that SAE can be observed *in vitro* and in trans-cranial human investigations. These signals are characterized as a mosaic of color Doppler pixels ranging over a full color scale. Apparent velocity information and spatial distribution of SAE signals changes from image frame to image frame. In experimental models, the intensity of SAE signals decreases exponentially over time. With an increase of acoustic power, there is a significant increase in the maximum signal intensity ($p < 0.01$) and they are significantly shorter in signal duration ($p < 0.01$), consistent with stronger and more rapid disintegration. In humans, SAE signals can be clearly detected in cerebral tissue regions. The intensity of SAE signals in these regions (e.g., temporal cortex, 3.7 ± 1.2 dB) is approximately 8 times lower than the signal enhancement in the major cerebral arteries (e.g., 29.5 ± 5.6).

Stimulated acoustic emission detected by trans-cranial color Doppler ultrasound: A contrast-specific phenomenon useful for the detection of cerebral tissue perfusion. Pohl C, Tiemann K, Schlosser T, Becher H. Stroke. 2000 Jul; 31 (7), pp. 1661–6.

Angiography/Endothelium: ICAM-1 Expression/Optimization of Binding/Antibody-Density/Wall Shear Rate
Anti-ICAM 1 Microbubbles/Lipid-Based Perfluorobutane-Filled Microbubble

Background Information: The early stages of atherosclerosis are characterized by increased endothelial cell (EC) surface expression of leukocyte adhesion molecules (LAMs). Ultrasound detection

of acoustically active LAM-targeted microbubbles might provide a means to non-invasively assess the functional status of the endothelium.

Application: Non-invasive ultrasound assessment of the functional status of the endothelium.

Route of Administration: Intravascular.

Semi-Synthetic Methods: Production of a lipid-based perfluorobutane-filled microbubble synthesized with various densities of anti-ICAM 1 monoclonal antibodies conjugated to the bubble shell (1%, 5%, 10%, 50%, 75%, and 100% of maximum coverage) and possessing various wall shear rates (100, 175, 250, 350, and 500/s).

Implementation: Evaluation of the hypothesis that modulating the surface antibody density can permit regulation of the endothelial adhesion characteristics of microbubbles, and that microbubble adhesion is dependent on local wall shear rate. Such a hypothesis can be addressed by exposing coronary artery ECs to microbubbles produced with different surface antibody densities and various wall shear rates in a parallel plate perfusion chamber.

***Ex Vivo* Model:** Human coronary artery ECs cultured on coverslips. Endothelial cells are either normal or activated by interleukin-1 beta (IL-1β) in a manner that induces ICAM-1 overexpression.

Interpretation and Analysis: Immunomicrobubble adhesion is greater in the presence of activated vs normal endothelial cells ($p < 0.001$); increases with increasing surface antibody density ($p < 0.01$); and decreases with increasing wall shear rate ($p = 0.02$). In conclusion, shell antibody density and wall shear rate are critical parameters controlling differential microbubble adhesion. This phenomenon might ultimately permit imaging of clinically relevant (*in vivo*) LAM expression.

Modulating targeted adhesion of an ultrasound contrast agent to dysfunctional endothelium. Weller GE, Villanueva FS, Klibanov AL, Wagner WR. Ann Biomed Eng 2002 Sep; 30 (8), pp. 1012–9.

Angiography: Pulmonary Veins (Right and Left)
Optison (FS069)

Background Information: Pulmonary vein spectral Doppler signals to characterize ventricular diastolic and systolic function, though often difficult to obtain, can be enhanced using contrast imaging agents.

Application: Optison can be used as a positive contrast image-enhancing agent for application in diagnostic ultrasound procedures where it has the ability to improve Doppler-generated images in scenarios of poor signal transmission during 2-dimensional echocardiography procedures.

Dosage: Gradient injection volumes of 0.2, 0.5, 3.0, and 5.0 ml.

Implementation: Evaluation of the relative enhancement of pulmonary venous flow applying various injection volumes (e.g., $n = 191$ cases).

Analysis and Interpretation: Greatest contrast enhancement for right and left pulmonary veins is observed at the highest doses. At 0.5 ml, conversion from inadequate to adequate can be observed in right and left pulmonary veins in 48.0% and 79.3% of injection studies, respectively while the degree of improvement is 54.4% and 65.8%, respectively. The adverse event rate (6.5%) is similar to a 1st-generation agent. Optison is a safe and effective contrast agent for improving the visualization of pulmonary Doppler signals, especially the left pulmonary vein.

Intravenous Optison (FS069) enhances pulmonary vein flow velocity signals: A multicenter study. Ellahham S, Hausnerova E, Gottdiener J. Clin Cardiol 2000 Feb; 23 (2), pp. 91–5.

Angiography: Trans-Cranial Color-Coded Sonography (TCCS)/Duration of Contrast Enhancement
Levovist

Background Information: Since the introduction of contrast media, TCCS has become increasingly important for the examination of intracranial vessels. However, the widely practiced bolus injection of these agents leads to the initial creation of blooming artifacts and thereafter the level of contrast enhancement decreases rapidly, reducing the effective time of enhancement.

Application: Trans-cranial color-coded sonography examination of intracranial vessel structure, integrity, and function.

Route of Administration: Levovist (antecubital vein.)

Dosage: Levovist (300 mg/ml; 4 g at a constant infusion rate of 60 ml/hr).

Implementation: Trans-cranial color-coded sonography examination of intracranial vessels using a 2.25-MHz phased-array transducer during administration of Levovist contrast agent. The degree of enhancement is graded chronologically over time.

Human Model: Normal subjects ($n = 26$).

Analysis and Interpretation: During continuous administration, a constant level of contrast enhancement is achieved after 60.1 ± 26.2 seconds and lasts approximately 663.4 ± 55.8 seconds (evaluator 1 = 66.6 ± 26.2 seconds; evaluator 2 = 664.3 ± 55.9 seconds). The limits of interobserver agreement ranges from -10.1% to 9.9%. No major blooming effect is seen in the initial phases of the examinations.

Continuous administration of contrast medium for trans-cranial color-coded sonography. Schminke U, Motsch L, Bleiss A, von Smekal U, Griewing B, Kessler C. Neuroradiology 2001 Jan; 43 (1), pp. 24–8.

Angiography: Vascular Blood Flow Characterization/Aorta/Renal Artery and Vein/Portal Vein/Vena Cava
SHU 508 Microbubbles (Levovist)/Indocyanine Green (ICG)

Cellular/Molecular Mechanism of Action: Indocyanine green and microbubbles can be infused into the intravascular compartment, where they disperse throughout the blood volume.

Application: Indocyanine green and microbubbles can be applied to characterize blood flow through vascular structures.

Route of Administration: Indocyanine green and microbubbles are both administered intravascularly.

Dosage: Indocyanine green (1.25 mg/mL at 0.1 mL/kg); SHU 508 A (300 mg/mL at 0.1 mL/kg).

Considerations: SHU 508 A microbubbles (Levovist) can be detected by Doppler ultrasound.

Implementation: Evaluation of blood flow in the vena cava, aorta, renal artery, renal vein, and portal vein. The kinetics of ICG can be evaluated by measuring absorbance values using a photodiode, while SHU 508 A microbubbles (Levovist) can be detected using Doppler ultrasound.

Animal Model: Rabbit ($n = 5$).

Interpretation and Analysis: Peak signal intensity is observed immediately after injection of SHU 508 A, followed by a biphasic decay pattern. The rates of biphasic decay are similar in all vessels. A 2nd peak of the signal that represents microbubble recirculation can be observed within the vena cava. The circulation and recirculation times of the microbubbles after injection of SHU 508 A are similar to that of ICG. These findings suggest that majority of SHU 508 A microbubbles circulate through the body similarly to blood flow, without retention in microvasculature structures.

In vivo kinetics of microbubbles of SHU 508 A (Levovist): Comparison with indocyanine green in rabbits. Uchimoto R, Niwa K, Eguchi H, Kamiyama N, Mine Y, Miyazawa T, Brautigam M. Ultrasound Med Biol 1999 Nov; 25 (9), pp. 1365–70.

Angiography/Thrombosis
[Lys-Gla-Ala-Gly-Asp-Val]-Aerosomes-Entrapped Microbubbles

Cellular/Molecular Mechanism of Action: Microbubbles can function as a means for delaying excretion, suppressing biological degradation, and enhancing site-specific accumulation of diagnostic and therapeutic pharmaceutical agents.
Application: Ultrasound can be used as a primary diagnostic technique for the detection of deep venous thrombosis. Microbubble preparations can potentially enhance the detection and characterization of intravascular thrombi.
Route of Administration: Intravascular.
Semi-Synthetic Methods: In the 1st phase of production, synthetic linear hexapeptide (lysine-glutamine-alanine-glycine-aspartate-valine) can be coupled to a lipid moiety. The targeted lipid moiety is then incorporated into a lipid blend, followed by the entrapment of Aerosomes contrast agent (ImaRx) yielding perfluorobutane-entrapped microbubbles. Prior to administration microbubble preparations are then sized for uniformity.
Implementation: Evaluation of the *in vitro* capacity of sized perfluorobutane-entrapped microbubbles to (i) retain high levels of acoustic stability; (ii) recognize (bind) to blood clots; and (iii) enhance ultrasound image analysis of intravascular thromboses (blood clots).
Interpretation and Analysis: Experimental results reveal that the mean size of the specific ultrasound contrast agent (MRX-408) is about 2.0 microm. Microbubbles appear as smooth spherical structures. Microscopic analysis reveals that targeted bubbles bind to blood clots, whereas control, non-targeted bubbles do not bind to blood clots. *In vitro* acoustic studies reveal similar levels of stability for modified microbubbles compared with control microbubbles. Targeted microbubbles enhance *in vitro* blood clot visualization, whereas non-targeted microbubbles do not increase clot detection. Therefore, thrombus-specific ultrasound contrast agents could potentially improve the detection of thrombosis by ultrasound and may be useful for distinguishing between new and old thrombosis. Investigations performed *in vivo* have been initiated to further characterize the applicability of these preparations.

In vitro studies of a new thrombus-specific ultrasound contrast agent. Unger EC, McCreery TP, Sweitzer RH, Shen D, Wu G. Am J Cardiol 1998 Jun 18; 81 (12A), pp. 58G–61G.

Arrythmias
Microbubble Echosonography Contrast Media/ Contrast-Enhanced Pulsed Ultrasound

Dosage: Microbubble preparations (0.25 ml in rats).
Implementation: Conduction of contrast-enhanced pulsed ultrasound imaging to acquire conduction complex and heart lesion recording data. The volume of the contrast agent administered is based on body weight and the mechanical index (ultrasonic pressure) exceeding those used in echocardiography by 14 to 345 and 3 to 29 times, respectively.
Animal Model: Development of an experimental protocol suitable for characterizing electrocardiographic arrhythmias in rat hearts exposed to ultrasound after injection of a microbubble contrast agent.
Analysis and Interpretation: Premature atrial complexes, premature ventricular complexes, or polymorphic ventricular tachycardia can be detected in about 50% of rats (e.g., n = 10/20). Cessation of ultrasound image analyses results in a termination of arrhythmia patterns; however, such alterations can reoccur (e.g., n = 4/20) when ultrasound exposure is resumed. Myocardial degeneration identified by histochemical staining (hematoxylin-basic fuchsinpicric acid) can be appreciated *in vivo* in a large percentage of test model subjects (e.g., n = 16/20) with a smaller percentage of these actually displaying arrhythmias (e.g., n = 10/20). There is no significant difference in the amount of histochemical staining in hearts from *in vivo* preparations with arrhythmias when compared to scenarios when arrhythmias are not detected.

Because arrhythmias are induced principally when the contrast agent interacts with ultrasound energy during exposure, the presence of myocardial degeneration alone is not a sufficient explanation for ectopic electrical activity. Under these extreme exposure conditions, the data suggest that pulsed ultrasound through its biomechanical interactions with contrast agents has the potential to induce arrhythmias.
Instrumentation: Pulsed ultrasound examination (frequency, 3.1 MHz; pulse duration, 1.3 microseconds; pulse repetition frequency, 1,700 Hz; and *in situ* peak rarefactional pressure, 15.9 MPa).

Arrhythmias in rat hearts exposed to pulsed ultrasound after intravenous injection of a contrast agent. Zachary JF, Hartleben SA, Frizzell LA, O'Brien WD Jr. J Ultrasound Med 2002 Dec; 21 (12), pp. 1347–56.

Arteriography: Aortic Stenosis/Aortic Valve Replacement (AVR)/Coronary Flow Reserve (CFR)
Dipyridamole

Physiological Mechanism of Action: Dipyridamole induces vasodilatory responses.
Background Information: In patients with aortic stenosis and a normal coronary angiogram, CFR is impaired.
Route of Administration: Dipyridamole (intravascular).
Dosage: Dipyridamole (0.56 mg/kg for 4 minutes).
Implementation: Evaluate the effect of AVR on the CFR after a long-term follow-up. In part, this can be assessed by measuring CFR 123 ± 137 days before and 497 ± 167 days after aortic valve replacement. Coronary flow reserve measurements are performed according to a standardized protocol, with a vasodilator stimulus (e.g., dipyridamole) and peak diastolic velocity measurements recorded at 6 minutes.
Human Model: Cases of aortic stenosis with normal coronary angiogram images (e.g., n = 30). Cases with AVR (e.g., n = 21).
Interpretation and Analysis: The initial average peak gradient of aortic stenosis is 89.5 ± 22.4 mm Hg. After AVR, it decreases to 26.2 ± 9 mm Hg. Left ventricular mass is significantly lower after AVR: 354.9 ± 107.9 g vs 223.8 ± 73.6 g ($p < 0.001$). The average baseline diastolic velocity measured by pulsed Doppler in the left anterior descending coronary artery amounts to 62.2 ± 25.5 cm/s before and 40.1 ± 13.6 cm/s after AVR. The difference is statistically significant ($p < 0.01$). The average diastolic velocity at maximum stress equals 117 ± 42.8 cm/s pre- and 91.5 ± 34 cm/s postoperatively ($p < 0.005$). Calculated CFR before AVR amounts to 1.96 ± 0.5 and increases to 2.37 ± 0.8 postoperatively. The difference is statistically significant ($p < 0.05$). Prosthetic AVR is of considerable benefit concerning the CFR in cases with a normal coronary angiogram after a long-term follow-up.

The effect of aortic valve replacement on coronary flow reserve in patients with a normal coronary angiogram. Nemes A, Forster T, Kovács Z, Thury A, Ungi I, Csanády M. Herz 2002 Dec; 27 (8), pp. 780–4.

Arteriography: Aortic Stenoses and Atherosclerotic Plaques
Microbubbles (AF0150)

Cellular/Molecular Mechanism of Action: The microbubble agent AF0150 absorbs and reflects ultrasound energy.
Application: Detection and characterization of vascular anamalies, including atherosclerotic plaque deposits in the coronary arteries.
Route of Administration: AF0150 (intravenous).
Dosage: AF0150 (0.3 ml in rabbits and 1.0/L porcine blood for *ex vivo* vascular preparations).
Implementation: Evaluation of contrast media pertaining to (i) testing the hypothesis that filling the arterial lumen with echoes at B-mode ultrasound (US) enables the assessment of wall and luminal abnormalities, and (ii) comparing contrast material-enhanced B-mode US with color and power Doppler US angiography. Such diagnostic procedures can be performed to delineate the presence of aortic atherosclerotic lesions utilizing AF0150 as an ultrasound contrast image-enhancing agent applied in combination with color Doppler and B-mode ultrasound. Radiopaque plastic casts of the rabbit aortas and contact radiographs of the plastic replicas can serve as standard reference controls.

Animal Model: Rabbit (created atherosclerotic aorta lesions).

Human *Ex Vivo* Preparation: Replicas of diseased human carotid arteries immersed in a tissue-mimicking phantom (e.g., $n = 4$).
Interpretation and Analysis: Although color and power Doppler US allow immediate localization of the lumen, precise estimation of stenoses and reliable visualization of surface irregularities is not possible. After AF0150 administration, angiogram-like images of the lumen can be created with B-mode US, allowing rapid assessment of the entire vessel lumen and wall. Consequently, luminal stenoses can be more accurately measured than with unenhanced B-mode US ($r^2 = 0.94$, $p < 0.0001$ vs $r^2 = 0.21$, $p = 0.25$) or Doppler ($r^2 = 0.42$, $p < 0.03$). In addition, plaques and ulcerations are visible only with contrast-enhanced B-mode US. Microbubbles fill the arterial lumen with echoes at B-mode US, creating an angiogram-like image. The ability to visualize the inner and outer surfaces of the vascular wall improves the evaluation of luminal and wall abnormalities

Contrast-enhanced B-mode US angiography in the assessment of experimental *in vivo* and *in vitro* atherosclerotic disease. Sirlin CB, Lee YZ, Girard MS, Peterson TM, Steinbach GC, Baker KG, Mattrey RF. Acad Radiol 2001 Feb; 8 (2), pp. 162–72.

Arteriography: Aortic Stent Graft Monitoring/ Cost-Effectiveness: Relative Expense
Contrast Duplex Ultrasound/Computed Tomography (CT) Angiography

Background Information: The use of endovascular stent graft repair for aortic aneurysmal disease has become increasingly common, with the added requirement for close postoperative surveillance to detect the presence of endoleaks or graft migration. The most commonly used technique for surveillance is CT angiography, with the need for intravenous contrast posing one limitation in those cases with renal dysfunction and the cost of such testing posing an economic limitation.
Analysis and Interpretation: Early results of duplex imaging using an intravenous ultrasound contrast agent have shown sensitivity and specificity equivalent to CT angiography, with no evidence of any related morbidity. The difference in cost-effectiveness for using duplex ultrasound imaging as the primary surveillance technique for postoperative follow-up in cases with aortic stent grafts is substantial. Surveillance protocols now require performing 8 follow-up examinations during the 1st 3 years after stent graft placement. The charges for CT angiography in some institutions average $2,779 per study, for a 3-year total of $22,232 per patient. The charges for aortic duplex ultrasound average $525 per study, with a 3-year total of $4,200 per patient. Adding the cost of routine abdominal radiographs to confirm stent graft position ($147 per study) would bring this 3-year total to $5,376, a savings of $16,856 per case. For every 100 patients that are monitored after stent graft placement, this represents a 3-year savings of more than $1.6M. Promising early results of duplex ultrasound imaging with an intravenous contrast agent show sensitivity and specificity equivalent to those of CT angiography in detecting aneurysm size and graft endoleaks or other hemodynamic abnormalities. If these results can be demonstrated in larger patient series, this technique should become the method of choice for stent graft surveillance, for it offers very significant economic advantages and avoids the complications of intravenous contrast-induced renal dysfunction.

Duplex ultrasound imaging with an ultrasound contrast agent: The economic alternative to CT angiography for aortic stent graft surveillance. Bendick PJ, Zelenock GB, Bove PG, Long GW, Shanley CJ, Brown OW. Vasc Endovascular Surg 2003 May–Jun; 37 (3), pp. 165–70.

Arteriography: Arterial Disease (Peripheral)/ Relative Sensitivity and Specificity
Ultrasound Contrast-Enhancing Agents/Digital Subtraction Arteriography (DSA)

Application: Ultrasound contrast-enhancing agents can be utilized to improve the diagnostic ability of duplex-ultrasound and increase agreement with DSA when examining difficult arterial segments in conditions of peripheral arterial disease.
Route of Administration: Ultrasound contrast agent (intra-arterial).
Implementation: Conduction of a duplex-ultrasound scan and DSA for the evaluation of vascular trifurcation structures. In situations when duplex-ultrasound scans are inconclusive, the procedure can be repeated during continuous ultrasound contrast agent infusion. Digital subtraction arteriography findings serve as a master reference control.

Human Model: Cases suffering from peripheral arterial disease (PAD: $n = 60$; $n = 15$ inconclusive duplex-ultrasound scan of the trifurcation; $n = 8/15$ male; $n = 15$; DSA exam $n = 15$ candidates for vascular surgery (20% or $n = 3/15$ due to claudication; 33% or $n = 5/15$ due to rest pain; and 47% or $n = 7/15$ due to tissue loss).
Analysis and Interpretation: Following contrast agent administration, the number of inconclusively diagnosed segments is significantly reduced by 26 (70%), from 37 to 11 ($p < 0.001$). In 19 segments (73%), contrast agent infusion changes the diagnosis in accordance with the DSA ($p < 0.05$). Values of sensitivity and positive predictive value are improved from 0.20 (0.04–0.62) to 0.47 (0.26–0.69) and 0.50 (0.10–0.91) to 0.80 (0.49–0.93), respectively. Specificity and negative predictive value are unchanged. Agreement between duplex-ultrasound and DSA are improved from poor (kappa = 0.18 [95% CI: 0–0.82]) to moderate (kappa = 0.45 [0.17–0.74]) ($p = 0.44$). Ultrasound contrast agents improve the diagnostic ability of duplex-ultrasound when scanning difficult arterial segments in patients suffering from PAD.

Ultrasound contrast agent improves imaging of lower limb occlusive disease. Eiberg JP, Hansen MA, Jensen F, Rasmussen JB, Schroeder TV. Eur J Vasc Endovasc Surg 2003 Jan; 25 (1), pp. 23–8.

Arteriography: Arterial Function (Peripheral: Brachial Artery Vasodilation)
Nitroglycerin

Cellular/Molecular Mechanism of Action: Nitroglycerin activates guanylate cyclase, thereby increasing the synthesis of guanosine 3′5′ monophosphate (cGMP) within smooth muscle tissue. In part this is mediated by increasing nitric oxide production that in turn increases cGMP levels. Ultimately light chain myosin is dephosphorylated, which functions in the contractile process. Analogs of cGMP also relax vascular and bronchial smooth muscle.
Physiological Mechanism of Action: Nitroglycerin promotes primarily venodilation properties at lower dosages compared to its effect on arterioles.
Application: Echocardiography/pharmaceutical provocative test procedures designed to detect and characterize physiological and pathological anomalies affecting vascular structures.
Route of Administration: Nitroglycerin (multiple).
Dosage: Nitroglycerin (variable).
Implementation: Investigate the effects of non-ECG-triggered imaging during ultrasound studies of endothelial function. Brachial artery diameters can be measured throughout the cardiac cycle at rest, during reactive hyperemia, and after nitroglycerin administration. Cardiac cycle-related variations are computed as the maximum percent change from the end-diastolic diameter. The range of possible errors in flow-mediated dilation (FMD) and nitroglycerin-mediated vasodilation that may result from ignoring cyclic variations in diameter are determined for each condition.

Human Model: n = 24 subjects.
Interpretation and Analysis: True FMD, true nitroglycerin-mediated vasodilation, and the maximum and minimum values that can be erroneously calculated for FMD if timing is ignored all differ dramatically ($p < 0.05$). The range of apparent FMD values that can be measured is nearly 3 times the true FMD value. Ignoring temporal position within the cardiac cycle artifactually increases calculated FMD into the normal range, despite truly impaired FMD. Peak arterial dilation occurs before end-systole and greater baseline vessel compliance is associated with greater FMD. Brachial arterial diameters vary significantly throughout the cardiac cycle. The magnitude of this variation is similar to the arterial dilation induced by reactive hyperemia and nitroglycerin, making ECG-triggered imaging mandatory for accurate and reproducible clinical and research measurements of artery diameters and FMD. Measurement of diameters at end-diastole may be preferred to other time points in the cardiac cycle.
Instrumentation: 7.5-MHz ultrasound transducer (R-wave-triggered imaging with acquisition every 41.7–66.7 ms).

Effect of cardiac cycle on ultrasound assessment of endothelial function. Chuang ML, Douglas PS, Bisinov EA, Stein JH. Vasc Med 2002 May; 7 (2), pp. 103–8.

Arteriography: Athrosclerosis Imaging by Ultrasonography/Atheroma: Regions of Fibrous Content/Atheroma: Regions of Early Phase Deposition
Anti-Fibrinogen-Liposomes/Anti-ICAM-Liposomes

Background Information: Previous reports have demonstrated the development of acoustically reflective liposomes that can be conjugated for site-specific acoustic enhancement.
Application: Detect and characterize (*in vivo*) atherosclerotic plaque deposits affecting vascular structures, including the coronary artery.
Semi-Synthetic Methods: Liposomes can be prepared with phospholipids and cholesterol using a dehydration/rehydration method. Antibodies are thiolated for liposome conjugation with *N*-succinimidyl 3-(2-pyridyldithio) propionate resulting in the generation of a thioether linkage between the protein molecule and the phospholipid. As a synthesis test model, liposomes can be conjugated to antifibrinogen or anti-intercellular adhesion molecule 1 (anti-ICAM 1).
Implementation: Evaluate the ability of acoustically reflective liposomes coupled to antibodies specific for different components of atherosclerotic plaques and thrombi to target and enhance *in vivo* ultrasonic image analysis. One approach to achieving this objective can involve assessing arterial plaques imaged (20-MHz intravascular ultrasound catheter and 7.5-MHz trans-vascular linear probe) after injection of saline, unconjugated liposomes, and antibody conjugated liposomes.

Animal Model: Swine (Yucatan "mini-hogs" for atherosclerosis developed by crush injury of 1 carotid and 1 femoral artery in concert with the ingestion of a hypercholesterolemic diet).
Interpretation and Analysis: Conjugated liposomes retain their acoustically reflective properties and provide ultrasonic image enhancement of their targeted structures. Liposomes conjugated to antifibrinogen attach to thrombi and fibrous portions of atheromas, whereas liposomes conjugated to anti-ICAM 1 attach to early atheroma. Such conjugated acoustic agents can therefore provide varying targeting with different antibodies with retention of intravascular and trans-vascular acoustic properties.

In vivo targeting of acoustically reflective liposomes for intravascular and trans-vascular ultrasonic enhancement. Demos SM, Alkan-Onyuksel H, Kane BJ, Ramani K, Nagaraj A, Greene R, Klegerman M, McPherson DD. J Am Coll Cardiol 1999 Mar; 33 (3), pp. 867–75.

Arteriography/Atherosclerotic Plaque Deformation
Acetylcholine/Isosorbide Dinitrate (Vasodilation)

Cellular/Molecular Mechanism of Action: Acetylcholine functions as a parasympathetic/cholinergic neurotransmitter by physically binding to and activating its corresponding receptor complex.
Physiological Mechanism of Action: Isosorbide dinitrate promotes vasodilation, while acetylcholine promotes vasoconstriction.
Application: Visualize ultrasonic deformations of atherosclerotic plaques in human coronary arteries during vasoconstriction and vasodilatation.
Route of Administration: Acetylcholine (selective intravascular); isosorbide dinitrate (intracoronary injection).
Considerations: The cross-sectional area of the atherosclerotic plaque appears to be constant during vasomotion of human coronary arteries.
Interpretation and Analysis: Intravascular ultrasound can detect occult atherosclerosis in angiographically normal coronary arteries in instances of chest pain at rest (n = 8). During the acetylcholine provocative tests, intravascular ultrasound can be used to monitor deformations of the atherosclerotic plaques. During the last phase of evaluations, vasodilation can be promoted with the intracoronary injection of isosorbide dinitrate. Under control, acetylcholine-treated, and isosorbide dinitrate-treated conditions, the cross-sectional areas of sonolucent circle and vessel lumen can be measured to establish the area of atherosclerotic plaques. In the process of vasoconstriction and vasodilation, the plaque area does not change significantly.

Intravascular ultrasonic evidence by constant cross-sectional area of atherosclerotic plaques during coronary vasomotion in humans. Matsu-ura Y, Kijima Y, Hashimura K, Kato Y, Ueda T, Yasuda T, Mori I, Hoshida S, Hori M. Eur Heart J 1997 Jun; 18 (6), pp. 949–53.

Arteriography/Coronary Artery Blood Flow in Athletes
Microbubbles (Levovist)

Application: Quantitative myocardial contrast echocardiography imaging.
Route of Administration: Intravascular (selective intra-arterial delivery).
Implementation: Characterization of coronary artery blood flow in atheletes.
Interpretation and Analysis: Coronary microcirculation patterns in athletes are similar, but at higher levels compared to "control" cases. Training influences the development of physiologic left ventricular hypertrophy that counterbalances the dilatation in the left ventricular chambers because of the higher blood volume in athletes compared with control participants. Angiogenesis and several functional adaptations (relaxation of small coronary arteries, increased production of nitric oxide by the coronary endothelium, or both) represent the potential mechanisms that allow an optimal distribution of oxygen and of nutrient substrates to the hypertrophied myocardium of athletes.
Instrumentation: Harmonic power Doppler analysis using background subtraction. Quantitative analysis of echo-contrast can be performed off-line with PC software, obtaining the transit curves of microbubbles through the coronary capillary system.

The role of quantitative myocardial contrast echocardiography in the study of coronary microcirculation in athlete's heart. Di Bello V, Giorgi D, Bertini A, Talini E, Mengozzi G, Palagi C, Nardi C, Paterni M, Mariani M. J Am Soc Echocardiogr 2002 Jul; 15 (7), pp. 678–85.

Arteriography/Endothelium: ICAM-1 Expression/ Endothelial Dysfunction: Coronary Ischemia
Microbubbles

Background Information: Clinical signs and symptoms of coronary artery disease are predated in decades by endothelial dysfunction, an aberration in the vascular lining that permits the development and propagation of atherosclerotic lesions and vasomotor dysfunction in the arterial circulation. These ultimately lead to acute and chronic coronary ischemic syndromes. Other pathophysiologic scenarios encountered in clinical cardiology practice, such as cardiac transplant rejection and the period following coronary angioplasty or cardiac surgery, also are associated with endothelial dysfunction. Endothelial dysfunction parallels coronary risk factors and is potentially reversible, rendering early identification of the phenomenon a clinically important end point. Current methods for detecting endothelial dysfunction are limited.
Application: Characterization of vascular endothelial integrity based on the detection of alterations in the expression of surface membrane complexes, including intracellular adhesion molecule 1 (ICAM-1) using targeted ultrasound imaging techniques.
Route of Administration: Intravascular.
Considerations: Implications pertain to other disease processes beside coronary ischemia and encompass both diagnostic and therapeutic delivery strategies.
Implementation: Evaluation of endothelial cell viability and biology as a function of unique surface marker expression (e.g., ICAM-1).
Interpretation and Analysis: Myocardial contrast echocardiography using microbubbles targeted to bind to cell surface markers uniquely expressed by dysfunctional endothelial cells may offer an approach for the non-invasive detection of endothelial disease using clinical ultrasound imaging techniques.

Microbubble-endothelial cell interactions as a basis for assessing endothelial function. Villanueva FS, Klibanov A, Wagner WR. Echocardiography 2002 Jul; 19 (5), pp. 427–38.

Arteriography: Coronary Artery Microcirculation Regulation/Vasodilative and Perfusion Reserve
Colored Microspheres/Adenosine Phosphate

Cellular/Molecular Mechanism of Action: Adenosine phosphate promotes relaxation of vascular smooth muscle. Colored microspheres impede the transmission and reflect a fraction of ultrasound wave energy back in the direction of the detector/probe.
Application: Evaluate and characterize microvascular perfusion parameters.
Route of Administration: Adenosine phosphate (intravenous/rat), colored microspheres (intravenous).
Dosage: Adenosine phosphate (3 mg/kg/min).
Implementation: Measurement of perfusion parameters based on perfusion-sensitive T1 relaxation after magnetic spin labeling of water protons. Regional blood volume (RBV) is determined from steady state measurements of T1 before and after administration of an intravascular contrast agent. A colored microsphere technique can be used as a reference method for perfusion measurements. Regional blood volume and perfusion maps are obtained at rest and during administration of adenosine phosphate (3 mg/kg of body weight per minute).
Animal Model: Rat.
Interpretation and Analysis: At magnetic resonance imaging (MRI), perfusion during resting conditions is 3.5 mL/g/min $\pm$ 0.1 (standard error of measurement [SEM]), while RBV is 11.6% $\pm$ 0.6 (SEM). Adenosine phosphate significantly increases perfusion to 4.5 mL/g/min $\pm$ 0.3 (SEM) and decreases mean arterial pressure from 120 mm Hg to 65 mm Hg, which implies a reduction of coronary resistance of 40% relative to baseline values. Regional blood volume increases consistently to 23.8% $\pm$ 0.6 (SEM). Quantitative mapping of perfusion and regional blood volume can therefore be performed non-invasively *in vivo* by means of MRI. Such methods allow determination of vasodilative and perfusion reserve, which reflects the *in vivo* regulation of coronary microcirculation in response to a given stimulus.

Myocardial perfusion and intracapillary blood volume in rats at rest and with coronary dilatation: MR imaging *in vivo* with use of a spin-labeling technique. Waller C, Kahler E, Hiller KH, Hu K, Nahrendorf M, Voll S, Haase A, Ertl G, Bauer WR. Radiology 2000 Apr; 215 (1), pp. 189–97.

Arteriography: Coronary Artery/Myocardial Contrast Echocardiography (MCE)
SonoVue

Background Information: Myocardial contrast echocardiography has become a major field of clinical research in echocardiography in the last decade. The introduction of new contrast agents has been accompanied by a large variety of new contrast specific imaging techniques.
Route of Administration: SonoVue (intravascular).
Implementation: Intravascular injection of ultrasound contrast media (e.g., SonoVue) for visualization of vascular anatomical abnormalities affecting vessel structures, including disease affecting the coronary artery.
Analysis and Interpretation: Myocardial echocardiography imaging can be performed utilizing SonoVue as an enhancing agent for improved characterization of coronary artery disease (CAD) in clinical environments.

Clinical value of myocardial contrast echocardiography in chronic coronary artery disease. Tiemann K. Echocardiography 2002 Oct; 19 (7 Pt 2), pp. 635–9.

Arteriography: Coronary Artery/Myocardial Perfusion/Contrast Media Formulation for Echocardiography
Albumin/Dextrose/Deca-Fluorobutane

Route of Administration: Albumin/dextrose/deca-fluorobutane gas contrast media (PESDA: continuous intravascular infusion at 1 to 2 ml/min and titrated for best myocardial contrast); adenosine (intravenous bolus).
Dosage: PESDA contrast media (dependent upon diagnostic procedure of interest); adenosine (6–18 mg).
Semi-Synthetic Methods: Ultrasound contrast media formulation (PESDA: sonocated solution composed of albumin 20% [1 ml]; dextrose 5% [1 ml]; deca-fluorobutane gas [8 ml]).
Implementation: Utilization of PESDA as a positive contrast agent in (i) echocardiography for the evaluation of myocardial perfusion at rest and after bolus injection of adenosine; and (ii) coronary angiography (1 month lag phase between procedures; n = 81 cases; n = 64 males). Diagnostically, the left ventricular perfusion beds can be evaluated; they are usually of prime clinical interest in conditions of cardiac disease (e.g., n = 208 territories analyzed). Acquisition of images is established with triggered (1:1) 2nd harmonic.
Analysis and Interpretation: Coronary angiography is capable of detetecting flow limiting (> 75%; e.g., n = 70); and no-flow limiting lesions (e.g., n = 138). At rest, obvious myocardium contrast enhancement can be appreciated in at least 1 segment of a territory in all cases. After adenosine injection an unquestionable further increase in myocardial contrast can be observed in territories related to no-flow limiting lesions lasting < 10 seconds (e.g., 99% or n = 138 territories); and myocardial perfusion defects detected in territories related to flow limiting lesions (e.g., 97% or n = 68 territories). Usually false results are very low, as is the incidence of serious complications. Myocardial perfusion study with PESDA and adenosine protocol is a practical, safe, and accurate method for analyzing coronary flow reserve.

Study of coronary flow reserve with intravenous use of microbubbles (contrast echocardiography) and adenosine: Protocol for clinical application in patients suspected of having coronary heart disease. Morcerf F, Moraes A, Carrinho M, Dohmann HJ. Arq Bras Cardiol 2002 Mar; 78 (3), pp. 281–98.

Arteriography: Coronary Artery Stenosis/Myocardial Ischemia/Wall Motion
Levovist (Ultrasound Contrast Media)/Dipyridamole Stress Test/[^{99m}Tc]-SestaMIBI

Background Information: Power Doppler imaging is a method that can be used to perform myocardial contrast echocardiography (MCE) analysis. It can selectively evaluate signals coming from an ultrasound contrast agent, allowing myocardial perfusion studies.
Application: Detection and characterization of coronary artery stenosis and myocardial ischemia/perfusion.
Implementation: Evaluation of the relative accuracy of the noninvasive imaging modalities of power Doppler MCE, stress-echo wall motion, and nuclear scan imaging (single photon emission computed tomography [SPECT]) employed to assess (i) coronary artery stenosis; (ii) myocardial ischemia/perfusion; and (iii) responses during pharmacological stress, using coronary angiography as a reference standard. Power Doppler MCE images are acquired using continuous intravenous infusion of Levovist contrast agent. Echo wall motion images are acquired. Complementary diagnostic procedures can involve the injection of [^{99m}Tc]-sestaMIBI at peak stress in concert with the acquisition of stress SPECT images 30 minutes after diagnostic agent administration.
Human Model: Dipyridamole stress test (e.g., n = 25 subjects).
Analysis and Interpretation: Power Doppler MCE and SPECT show an 84% concordance (e.g., n = 21/25 cases; kappa = 0.67) for the detection of ischemia. Concordance based on coronary artery territories for normal perfusion vs fixed defects vs reversible defects is 92% (69% of 75; kappa = 0.81), with 100% for left anterior descending, 92% for right coronary artery, and 84% for circumflex. Power Doppler MCE has a lower sensitivity than SPECT (89% vs 100%) but higher specificity (100% vs 88%) for identifying stenotic (≥ 70%) coronary arteries as assessed by angiography. Echo wall motion analysis displays the lowest sensitivity (68%) with 100% specificity. Accuracy is 94% for both power Doppler MCE and SPECT, and 83% for wall motion analysis. Based on the nature of such findings, power Doppler MCE can function as a sensitive and specific method for identifying myocardial perfusion during pharmacological stress. Accuracy of power Doppler MCE for stenotic coronary arteries appears to be slightly higher than stress-echo wall motion and similar to SPECT.

Non-invasive detection of coronary artery stenosis: A comparison among power Doppler contrast echo, [^{99m}Tc]-sestaMIBI SPECT and echo wall motion analysis. Rocchi G, Fallani F, Bracchetti G, Rapezzi C, Ferlito M, Levorato M, Reggiani LB, Branzi A. Coron Artery Dis 2003 May; 14 (3), pp. 239–45.

Arteriography: Neoplasia/Hepatocellular Carcinoma: Response to Percutaneous Radio Frequency Abalation/Relative Effectiveness: 3-Phase Dynamic Computed Tomography (CT) vs Coded Harmonic Angiography
Levovist Microbubbles

Cellular/Molecular Mechanism of Action: Microbubbles have a different level of acoustic impedance compared to homogenous biological fluids. Upon contact, transmission of ultrasound energy is slowed, absorbed, and/or reflected away from the microbubbles, a fraction of which is detected by the probe/detector.
Application: Microbubbles can be utilized in contrast-enhanced coded phase-inversion harmonic sonography to assess the therapeutic response of percutaneous radio frequency ablation in conditions of hepatocellular carcinoma.
Route of Administration: Microbubbles (e.g., Levovist given by intravenous injection).
Implementation: Evaluation of hepatocellular carcinoma nodules applying coded harmonic angio involving coded phase-inversion harmonic sonography facilitated by the application of microbubble contrast image-enhancing agents before and after percutaneous radio frequency ablation. The intratumor blood vessels and tumor parenchymal can be detected in the early arterial phase and the late vascular phase, respectively. The results of contrast-enhanced imaging with coded harmonic angio can be compared with those of 3-phase dynamic CT.
Human Model: Cases of hepatocellular carcinoma nodules (e.g., n = 67 cases, n = 107 exams; n = 91 nodular lesions).
Analysis and Interpretation: A vast majority of hepatocellular carcinoma nodules are found to be hypervascular on contrast-enhanced imaging with coded harmonic angiography (e.g., n = 107/107). Following radio frequency ablation, contrast-enhanced coded harmonic angiography detects persistent signal enhancement of nodules (e.g., n = 41/107 or 38.3%), whereas the technique shows

no intratumoral enhancement in greater than half of examined nodules (e.g., n = 66/107 or 61.7%). Compared with dynamic CT, the sensitivity, specificity, and diagnostic accuracy of contrast-enhanced coded harmonic angio is approximately 95.3%, 100%, and 98.1%, respectively. With contrast-enhanced coded harmonic angio, it is difficult to identify the safety margin that can be detected on dynamic CT. Contrast-enhanced imaging with coded harmonic angio may provide an alternative approach that has high diagnostic agreement with dynamic CT in assessing the therapeutic effect of radio frequency ablation in hypervascular hepatocellular carcinomas, in spite of having limitations in identifying the safety margin.

Radio frequency ablation of hepatocellular carcinoma: Therapeutic response using contrast-enhanced coded phase-inversion harmonic sonography. Wen YL, Kudo M, Zheng RQ, Minami Y, Chung H, Suetomi Y, Onda H, Kitano M, Kawasaki T, Maekawa K. AJR Am J Roentgenol 2003 Jul; 181 (1), pp. 57–63.

Arteriography: Neoplasia/Prostatic Carcinoma (PC-3m)/Vascular Structures: Vascular Density
Contrast Agent/[Protamine]

Cellular/Molecular Mechanism of Action: Influences the transmission of ultrasound energy by creating changes in impedance, absorption, or reflectance in a manner that is detectably different from most biological fluids (echogenic properties).
Application: Contrast media can be utilized to enhance Doppler ultrasound image quality and sensitivity for the purpose of detecting and characterizing tumor vascularity patterns.
Route of Administration: Intravenous.
Implementation: Evaluation of tissue density and vascular structures perfusing neoplastic lesions applying color flow signal-pixel rate (SPR) of images calculated using the number of pixels showing color Doppler signals as a ratio of total pixel number associated with the entire lesion.

Animal Model: Mice (BALB/c nude mice; n = 48) receiving subcutaneous transplants of human prostate carcinoma PC-3m tumor followed by protamine injections (SQ) as an angiogenesis inhibitor. Animals are randomly divided into 3 groups according to protamine dose.
Analysis and Interpretation: The SPR of the high- and low-dose groups is significantly lower than that of control groups ($p < 0.01$). Mean SPR ± standard deviation (SD) is 0.09 ± 0.05, 0.11 ± 0.05, and 0.22 ± 0.10 for different treatment groups, respectively. The SPR parameters correlate significantly with the density of microvessel structure ($r = 0.86–0.94$, $p < 0.01$). Contrast agent-enhanced Doppler ultrasound imaging can effectively reveal changes in vascularity in neoplastic lesions (e.g., ± protamine). In addition to microvessel density, contrast agent-enhanced Doppler ultrasound imaging may become 1 of several independent prognostic indexes of angiogenesis inhibitor therapy.

Evaluation of the effect of protamine on human prostate carcinoma PC-3m using contrast-enhanced Doppler ultrasound. Tang J, Li S, Li J, Zhang Y, Li X, Dong B, Shi H, Zhang G. J Urol 2003 Aug; 170 (2 Pt 1), pp. 611–4.

Arteriography: Splanchnic Hemodynamics
Levovist

Application: Enhancement of Doppler ultrasound acquired images of splanchnic hemodynamic properties.
Route of Administration: Levovist infused as an intra-arterial bolus.
Dosage: Levovist at 2.5 g/dose.
Implementation: Doppler ultrasound examination of portal vein and branches of the hepatic, splenic, and superior mesenteric arteries before and 5–8 and 12–15 minutes after the initiation of an 8-minute long infusion of image-enhancing contrast media (e.g., Levovist). Mean velocity and mean diameter are calculated for the portal vein. Resistance indexes are determined for individual arteries.

Human Model: Cases suffering from hepatic cirrhosis (e.g., n = 12) and healthy normal reference controls (e.g., n = 12).
Analysis and Interpretation: A significant increase in resistance index can be observed in the hepatic (0.80 ± 0.07 vs 0.71 ± 0.06; $p < 0.01$) and splenic arteries (0.72 ± 0.06 vs 0.64 ± 0.06; $p < 0.01$) 5–8 minutes after contrast agent injection in conditions of cirrhosis but not in controls. Neither portal vein diameter nor portal flow mean velocity change during test challenges in both controls and cirrhosis cases. This effect may be related to a selective trapping of microbubbles in the altered hepatic and splenic microvasculature in cirrhosis conditions rather than being an imaging artifact. Such phenomena may have implications regarding harmonic ultrasound protocols designed to image cirrhotic liver tissue in the early arterial phase.

Effect of Levovist on splanchnic hemodynamics in cirrhotic patients. Gaiani S, Serra C, Piscaglia F, Celli N, Rasciti L, Miglioli M, Bolondi L. Ultrasound Med Biol 2003 May; 29 (5), pp. 643–8.

Capillary Retention/Myocardial and Pulmonary Retention
Neutral vs Anionic Microbubbles (± Poly(Ethylene Glycol) [PEG])

Cellular/Molecular Mechanism of Action: Microbubbles do not transmit ultrasound energy to the same extent (degree) as do "homogeneous" biological fluids due to partial impedance, absorption, and reflectance phenomena ultimately detected by the ultrasound sensor/probe/detector.
Background Information: Interactions between serum proteins and lipid membranes are greater with anionic compared to neutral membranes. Such interactions may influence the microvascular behavior of anionic lipid microbubbles. Lipid microbubbles with a net negative charge can be retained within capillaries via complement-mediated attachment to the external membrane surface of vascular endothelium. This property may be useful for the development of ultrasound contrast agents that can be imaged late after venous injection.
Application: Enhanced detection and characterization of physiological conditions and pathological anomalies affecting tissues, organ systems, vascular structures, and body fluids utilizing ultrasound-based diagnostic modalities.
Route of Administration: Lipid-shelled microbubbles (bolus intravenous injection).
Semi-Synthetic Methods: Lipid-shelled microbubbles with either a neutral or a negative charge can be prepared either with or without a protective surface layer of PEG. Complement attachment to microbubbles can be assessed by flow cytometry with flourescein isothiocyanate-conjugated anti-C3b monoclonal antibody.
Implementation: Intravascular administration to delineate the influence of microbubble charge on microvascular retention of microbubble contrast agents.

Intravital microscopy can be performed on the cremaster muscle wild-type and C3-deficient mice during the intravenous injection of either anionic/negative or neutral-charged PEG lipid-shelled microbubbles. Pulmonary and myocardial retention of lipid-shelled microbubbles can be established by myocardial contrast echocardiography.

Analysis and Interpretation: Size-independent capillary retention of microbubbles, occurring for a few seconds to > 10 minutes, is frequently observed with anionic, but rarely with neutral, microbubbles (4.3 ± 0.3 mm^{-3} vs 0.4 ± 0.1 mm^{-3}, $p < 0.01$). Anionic microbubble retention is reduced by 70% by surface PEG and also markedly reduced in C3-deficient mice (1.4 ± 0.1 mm^{-3}, $p < 0.05$ vs wild-type). Flow cytometry demonstrates that complement binds only to anionic microbubbles. Contrast echocardiography reveals both pulmonary and myocardial retention of only anionic microbubbles, the latter appreciated as a function of persistent opacification > 10 minutes after bolus intravenous injection. Lipid microbubbles with a net negative charge can be retained within capillaries due to complement-mediated attachment to endothelial cell populations. Such properties may be useful for the development of ultrasound contrast agents that can be imaged late after venous injection.

Influence of microbubble surface charge on capillary transit and myocardial contrast enhancement. Fisher NG, Christiansen JP, Klibanov A, Taylor RP, Kaul S, Lindner JR. J Am Coll Cardiol 2002 Aug 21; 40 (4), pp. 811–9.

Cardiac Failure: Chronic/Inotropic Activity/Cardiac Output/Pressor Effect/Inotropic Agent Selection
Dobutamine/Carvedilol/Metoprolol

Cellular/Molecular Mechanism of Action: Dobutamine functions as a positive adrenergic (sympathomimetic) agent. Metoprolol is a selective β_1-adrenoreceptor antagonist (blocker), while carvedilol is a non-selective β-adrenoreceptor blocker.
Physiological Mechanism of Action: Dobutamine promotes positive cardiac inotropic responses while also promoting increases in cardiac output and increases in systemic blood pressure.
Application: Enhance the accuracy and sensitivity of stress echocardiography procedures and serve as a guide during the process of selecting (therapeutic) inotropic agents.
Route of Administration: Dobutamine (intravenous).
Dosage: Carvedilol and metoprolol CR/XL (target dose 50 mg twice daily and 200 mg once daily, respectively) for 8 weeks. Dobutamine (5 μg/kg/min and high-dose 15 μg/kg/min).
Implementation: Evaluation of carvedilol and metoprolol CR/XL as potential adjunct forms of intervention during dobutamine-stress echocardiography procedures performed at the end of each maintenance period. Parameters evaluated include determining if conditions of congestive heart failure display different hemodynamic responses during dobutamine challenge in the presence of β-adrenoreceptor blocking agents.

Human Model: Cases with stable chronic congestive heart failure (ejection fraction < 40%) on chronic treatment with metoprolol CR/XL (n = 10 subjects).

Study Design: Single center, single blind, randomized, 2-period crossover study comparing carvedilol with metoprolol CR/XL.
Interpretation and Analysis: No significant hemodynamic differences can be seen at rest after 2 treatments. There is a more pronounced increase in heart rate and cardiac output that occurs during dobutamine infusion when cases are given metoprolol compared to carvedilol. Mean arterial pressure increases significantly with carvedilol Cardiac output increases during low-dose dobutamine, without further changes being appreciated with high-dose dobutamine administration. During infusions of dobutamine, there is no significant difference in ejection fraction between carvedilol and metoprolol treatment. Therefore, during conditions of congestive heart failure on a non-selective β-adrenoreceptor blocker or β_1-selective blocker respond differently to the inotropic drug dobutamine. Selective β_1 blockade with metoprolol can be counteracted by dobutamine, whereas with carvedilol a low dose of dobutamine increases cardiac output, and a higher dose of dobutamine initiates a pressor effect. These findings may be clinically relevant when choosing an inotropic pharmaceutical agent.

Different responses to dobutamine in the presence of carvedilol or metoprolol in patients with chronic heart failure. Bollano E, Täng MS, Hjalmarson A, Waagstein F, Andersson B. Heart 2003 Jun; 89 (6), pp. 621–4.

Cardiac Shunts: (Right to Left)
Echovist 200/Echovist 300

Cellular/Molecular Mechanism of Action: Echovist 200 and Echovist 300 are agents that impede/absorb/reflect ultrasound energy.
Background Information: Cardiac right-to-left shunts (RLS) can be identified by trans-esophageal echocardiography (TEE) as well as by trans-cranial Doppler ultrasound (TCD) using contrast agents, such as Echovist 200 or Echovist 300, in conjunction with a Valsalva maneuver (VM) as a provocation procedure. Both Echovist preparations are in clinical use. Currently, the appropriate timing of the VM is controversial.
Application: Characterization of cardiac RLS.
Route of Administration: Intravascular.
Implementation: Evaluation of TEE and bilateral TCD as modalities for characterizing the middle cerebral arteries. One approach for objective assessment can entail the application of randomized protocols including (i) no utilization of VM; (ii) VM for 5 seconds starting with the beginning of Echovist 300 injection; (iii) VM for 5 seconds starting 5 seconds after the beginning of Echovist 300 injection; (iv) VM for 5 seconds starting 10 seconds after the beginning of Echovist 300 injection; and (v) VM for 5 seconds starting 5 seconds after the beginning of Echovist 200 injection.

Human Model: Cases with right-to-left shunts (n = 64).
Interpretation and Analysis: Cardiac RLS can be demonstrated by both TEE and contrast TCD in a relatively large percentage of cases (n = 27/64 shunt-positive cases).

Conversely, a relatively large number of cases are negative for both TEE and TCD analyses (e.g., n = 22/64). A very small percentage of cases are TEE positive, but TCD negative (e.g., n = 0/64). Alternatively, a considerable number of cases will be only positive on at least 1 TCD investigation but negative on TEE (e.g., n = 15/64). Evaluation of methods employing VM for 5 seconds starting 5 seconds after the beginning of Echovist 300 injection, or VM for 5 seconds starting 5 seconds after the beginning of Echovist 200 injection, are diagnostically the most appropriate with the former procedures being slightly superior. Trans-cranial Doppler ultrasound using Echovist 300 or Echovist 200 is a sensitive method to identify TEE proven cardiac RLS. To achieve the best diagnostic accuracy, the VM should be performed for a duration of 5 seconds starting at 5 seconds following the beginning of contrast injection.

Contrast trans-cranial Doppler ultrasound in the detection of right-to-left shunts: Comparison of Echovist 200 and Echovist 300, timing of the Valsalva maneuver, and general recommendations for the performance of the test. Droste DW, Jekentaite R, Stypmann J, Grude M, Hansberg T, Ritter M, Nabavi D, Nam EM, Dittrich R, Wichter T, Ringelstein EB. Cerebrovasc Dis 2002; 13 (4), pp. 235–41.

Cardiomyopathy: Idiopathic Dilated (IDCM)/ Prognostic Parameters
Dobutamine/Low-Dose Dobutamine Echocardiography

Physiological Mechanism of Action: Dobutamine exerts adrenergic agonist properties.

Background Information: Dobutamine echocardiography is widely used for the evaluation of myocardial contractile reserve.
Application: The response of the left ventricle to low-dose dobutamine infusion adds clinically valuable prognostic information for the evaluation of IDCM.
Dosage: Dobutamine (10 μg/kg/min for 5 minutes).
Implementation: Evaluate the prognostic value of low-dose dobutamine echocardiography in conditions of IDCM. Image analysis can entail measurement of 2-dimensional and Doppler echocardiographic variables before and after the infusion of dobutamine.

Human Model: Cardiovascular disease (n = 77 consecutively diagnosed cases of IDCM; left ventricular (LV) ejection fractions of < 40%; age range = 49 ± 9 years mean ± standard deviation [SD]; men = 82%; n = 30/77 died; n = 5/77 successful heart transplant over a 63 ± 7-month follow-up period within a 49- to 75-month range).
Interpretation and Analysis: Using multivariate regression analysis, the only significant factors related to fatal outcome or the need for cardiac transplantation include the following: (i) LV end-systolic volume of > 150 mL after low-dose dobutamine infusion (odds ratio [OR], 2.2; confidence interval [CI], 1.2 to 4.1; p = 0.011); (ii) no decrease of LV end-diastolic volume after dobutamine infusion (OR, 1.9; CI, 1.1–3.4; p = 0.031); (iii) atrial fibrillation (OR, 2.7; CI, 1.4–5.3; p = 0.003); and (iv) male gender (OR, 2.6; CI, 1.2–5.5; p = 0.017). A scoring system has been proposed with 1 point assigned for each of the above-mentioned factors. The mortality rates for total scores of 0, 1, 2, 3, and 4 are approximately 0%, 19%, 48%, 83%, and 100%, respectively. The response of the LV to low-dose dobutamine infusion adds clinically valuable prognostic information to the evaluation of IDCM conditions.

Prognostic value of low-dose dobutamine echocardiography in patients with idiopathic dilated cardiomyopathy. Drozdz J, Krzemińska-Pakula M, Plewka M, Ciesielczyk M, Kasprzak JD. Chest 2002 Apr; 121 (4), pp. 1216–22.

Cardiomyopathy: Ischemic/Low-Dose Wall Motion Scores: Risk Stratification/Prediction of Benefit from Revascularization
Dobutamine

Physiological Mechanism of Action: Dobutamine exerts adrenergic/sympathetic agonist properties.
Application: Evaluation of dobutamine low-dose wall motion scores for estimating risk stratification of ischemic cardiomyopathy conditions and identification of those who do and do not benefit from revascularization.
Route of Administration: Dobutamine (intravascular).
Dosage: Dobutamine (low-dose = 10 μg/kg/min and high-dose/maximal dose 50 μg/kg/min) infusion.
Implementation: Delineation of the value of wall motion scores at rest and with low- and high-dose dobutamine infusion for predicting the outcome and benefit associated with revascularization in conditions with ischemic cardiomyopathy. Complementary follow-up evaluation entails assessment of ischemic cardiomyopathy cases utilizing echocardiography analyses acquired at rest and during low-dose and high-dose/maximum dobutamine infusion.

Human Model: Cases of ischemic cardiomyopathy (n = 139).
Interpretation and Analysis: Both rest and low-dose wall motion scores are multivariate predictors of cardiac death, but ischemia and peak dose scores are not appropriate predictors. Cases can be classified into resting condition scores that have been risk stratified into 3 groups, including (i) score (1.00–1.99) with 11% cardiac death; (ii) score (2.00–2.49) with 30% death; and (iii) score ≥ 2.50 with 47% death. One-third of cases with rest scores ≥ 2.50 have improvement in scores to < 2.50 with low-dose dobutamine. Frequency of cardiac death is reduced to 23% compared with 60% (p = 0.04) in those that remain with low-dose scores ≥ 2.50. Low-dose scores also can identify those cases who benefited from revascularization. In casess with low-dose scores (1.00–1.99), the frequency of cardiac death is marginally lower in revascularized than in non-revascularized conditions (10% vs 21%, p = 0.28). In cases with scores (2.00 to 2.49), revascularized conditions have a significantly lower frequency of cardiac death than non-revascularized cases (15% vs 41%, p < 0.05). The frequency of death in those with low-dose scores ≥ 2.50 is very high in both revascularized (75%) and non-revascularized (56%, p = 0.42) conditions.

Usefulness of rest and low-dose dobutamine wall motion scores in predicting survival and benefit from revascularization in patients with ischemic cardiomyopathy. Sawada SG, Lewis SJ, Foltz J, Ando A, Khouri S, Kaser S, Gradus-Pizlo I, Gill W, Fineberg N, Segar D, Feigenbaum H. Am J Cardiol 2002 Apr 1; 89 (7), pp. 811–6.

Cardiovascular Functional Reserve/Global Ventricular Function/Tei Index
Dobutamine-Stress Echocardiography

Cellular/Molecular Mechanism of Action: Dobutamine exerts adrenergic/sympathomimetic properties.
Background Information: Dobutamine stress echocardiography has become an accepted approach for the assessment of cardiac functional reserve. Although the Doppler-derived index of combined systolic/diastolic myocardial performance (Tei index) has been described as being easily obtainable and useful for predicting left ventricular performance, the effect of dobutamine on the Tei index has not been thoroughly established in children.
Application: Dobutamine can be applied in combination with diagnostic ultrasound to characterize various aspects of cardiac physiology (e.g., ventricular function).
Route of Administration: Dobutamine (infusion).
Dosage: Dobutamine (5 μg/kg per minute).
Implementation: Assess the effect of dobutamine on the Tei index in cases of postoperative ventricular septal defect and Kawasaki disease. Echocardiographic recordings are obtained before and after dobutamine infusion. Variables measured include trans-mitral flow velocities (E, A, E/A), rate-corrected mean velocity of circumferential fiber shortening (rate-corrected Vcf), and idiopathic mitral prolapse (IMP). Isovolumic contraction time (ICT), isovolumic relaxation time (IRT), and ejection time (ET) are measured and then applied to calculate the Tei index using the following formula: Tei index = (ICT + IRT)/ET.

Human Model: Postoperative ventricular septal defect (n = 8 cases); and cases of Kawasaki disease (n = 7).
Interpretation and Analysis: Dobutamine infusion increases rate-corrected Vcf (29%, p < 0.01), peak E (7%, p < 0.05), and peak A (13%, p < 0.05). E/A ratios do not change during dobutamine infusion. ET, ICT, and IRT decrease during dobutamine infusion. The magnitude of the change in ICT (−21%, p < 0.01) is greater than that in IRT (−12%, p < 0.01) and ET (−8%, p < 0.05). The decrease in Tei index (−16%, p < 0.01) results in a decrease in ICT/ET (−21%, p < 0.01) and a slight decrease in IRT/ET (−12%, p < 0.05). The Tei index has potential as a sensitive indicator of the effects of inotropic stimulation on global left ventricular function.

Effect of dobutamine on a Doppler echocardiographic index of combined systolic and diastolic performance. Harada K, Tamura M, Toyono M, Yasuoka K. Pediatr Cardiol 2002 Nov–Dec; 23 (6), pp. 613–7.

Cardiovascular Thrombi
Ligand-Targeted Lipid-Encapsulated Perfluorodichlorooctane/Perfluorohexane (PFH)/ Perfluorooctane (PFO)/Perfluorooctyl Bromide (PFOB)/ Perfluorodichlorooctane (PFDCO)/Perfluorodecalin (PFD)

Background Information: Targeted acoustic contrast agents offer the potential for sensitive ultrasonic detection of pathologic tissues. Previous reports have described the development of a ligand-targeted, lipid-encapsulated, liquid PFDCO ultrasonic contrast system with a small nominal particle size (approximately 250-nm diameter). Perfluorocarbon nanoparticles substantially increase reflectivity when bound to targeted surfaces, and it has been proposed that such a system can be approximated physically as a simple, thin layer, acoustic transmission line.
Application: Ultrasound detection of intravascular thrombi (reference model).
Route of Administration: Intravascular.
Implementation: Evaluate the ultrasonic reflectivity of different perfluorocarbon formulations with widely varying acoustic impedances that have been "targeted" to either nitrocellulose membranes or *in vitro* plasma thrombi. Examples of 5 perfluorocarbons include PFH, PFO, PFOB, PFDCO, while PFD. Ultrasonic reflection can be measured by acoustic microscopy (17 MHz to 35 MHz).
Interpretation and Analysis: Acoustic reflectivity is increased ($p < 0.05$) by all targeted perfluorocarbon formulations, and the magnitude of the contrast effect is inversely correlated with the perfluorocarbon acoustic impedance. Perfluorohexane nanoparticles exhibit the greatest enhancement, while PFD nanoparticles show the least. The acoustic transmission line model effectively predicts the relative differences in acoustic reflectivity and frequency dependence among different perfluorocarbon formulations. For future clinical applications, PFO nanoparticles may provide the best combination of acoustic enhancement, *in vivo* physical stability, and safety.

Improvements in the ultrasonic contrast of targeted perfluorocarbon nanoparticles using an acoustic transmission line model. Marsh JN, Hall CS, Scott MJ, Fuhrhop RW, Gaffney PJ, Wickline SA, Lanza GM. IEEE Trans Ultrason Ferroelectr Freq Control 2002 Jan; 49 (1), pp. 29–38.

Catheter Placement Validation
Levovist Microbubble Contrast Agent

Background Information: Intraperitoneal port catheter systems for local delivery of cytotoxic drugs require imaging prior to chemotherapy to confirm homogenous distribution of an injected fluid in the entire peritoneal cavity.
Application: Image analysis to validate correct placement of intraperitoneal port catheter systems such as those applied in the delivery of cytotoxic pharmaceuticals.
Route of Administration: Levovist (infusion as a bolus).
Implementation: Ultrasound examinations are performed after bolus injection of microbubble contrast medium (e.g., Levovist). Distribution of the contrast medium in the peritoneal cavity is imaged using B-mode ultrasound (US) and color-stimulated acoustic emission imaging (SAE). Contrast-enhanced computed tomography (CT) imaging can be used as a validation reference control for evaluating the accuracy of ultrasound images.

Human Model: Peritoneal carcinoma ($n = 12$ cases) implanted with intraperitoneal port catheter system prior to the initiation of chemotherapy administration.
Analysis and Interpretation: Distribution of microbubbles in the peritoneal cavity can be easily detected by both US methods. Free distribution in all abdominal quadrants can be visualized with both US techniques in most cases (e.g., $n = 10/12$). In a small number of cases, CT and US reveal contrast medium limited to the perihepatic area (e.g., $n = 2/12$, requiring surgical catheter repositioning). Ultrasound after intraperitoneal injection of a microbubble contrast agent provides reliable information about the distribution of intraperitoneally injected fluid in the peritoneal cavity. This method is therefore well suited for imaging port catheter systems prior to chemotherapy.

Intraperitoneal distribution of ultrasound contrast medium imaged with B-mode ultrasound and color-stimulated acoustic emission imaging. Puls R, Gebauer B, Hildebrandt B, Riess H, Herrmann M, Hosten N, Albrecht T. Eur Radiol 2003 Apr; 13 (4), pp. 695–9. Epub 2002 Sep 07.

Myocardial Akinesis Postinfarction
Perflutren Microbubbles: Myocardial Contrast Echocardiography (MCE)/Dobutamine Echocardiography (DE)

Background Information: Akinesia after acute myocardial infarction (AMI) may be reversible or irreversible. Distinguishing these 2 entities early after AMI is difficult, but clinically important. Previous studies have shown that MCE and low-dose DE may both be useful in this setting. However, there are few data regarding the relative and combined value of these techniques.
Implementation: Evaluate and compare the utility of real-time intravenous MCE and low-dose DE in the early prediction of akinetic myocardial functional recovery following an AMI episode. Real-time MCE can be performed using perflutren microbubbles followed immediately by performing low-dose DE analysis. Contrast opacification and wall motion are determined by experienced observers blinded to clinical data. Repeat echocardiograms are obtained 51 ± 19 days later and wall motion at rest is scored by an observer blinded to clinical data.

Human Model: Cases of AMI ($n = 37$ at 3 ± 2 days after AMI).
Interpretation and Analysis: Normal contrast opacification can predict functional recovery with a positive predictive value of 63%, a negative predictive value of 73%, and an accuracy of 66%. Residual contractility during low-dose DE can have a positive predictive value of 82%, a negative predictive value of 72%, and a predictive accuracy of 76%. When the 2 tests are concordant (64%), they have a positive predictive value of 81%, a negative predictive value of 85%, and a predictive accuracy of 83%. Low-dose DE is superior to intravenous MCE in the prediction of functional recovery of akinetic myocardium after AMI, but the combination of both maximizes prediction accuracy.

Comparison of intravenous myocardial contrast echocardiography and low-dose dobutamine echocardiography for predicting left ventricular functional recovery following acute myocardial infarction. Hillis GS, Mulvagh SL, Pellikka PA, Hagen ME, Gunda M, Wright RS, Oh JK. Am J Cardiol 2003 Sep 1; 92 (5), pp. 504–8.

Myocardial Akinesis (Post–Acute Infarction)/ Independent Predictor of Functional Recovery/ Left Anterior Descending Coronary Artery Segment
Octafluoropropane Microbubbles/Myocardial Contrast Echocardiography (MCE)

Background Information: Akinesia after acute myocardial infarction (MI) may be reversible, secondary to stunning, or irreversible, as a result of extensive myocyte necrosis. Distinguishing these 2 entities soon after MI is difficult but has important clinical implications.

Application: Myocardial contrast echocardiography.
Route of Administration: Intravenous infusion.
Implementation: Evaluation of the effectiveness of MCE (real-time mode) in combination with the intravenous infusion of octafluoropropane microbubbles to assess myocardial perfusion. Repeated echocardiograms can be reevaluated 56 (± 29) days following initial MI episodes.

Human Model: Cases of myocardial infarction (n = 35 at 2 ± 1 days after an acute episode [e.g., n = 31/35 or 91% underwent myocardial revascularization]).
Interpretation and Analysis: Development of normal perfusion profiles predicts functional recovery with a positive predictive value of 66% and a negative predictive value of 81%. The accuracy of the technique is superior in myocardial segments supplied by the left anterior descending coronary artery (positive and negative predictive value: 70% and 90%, respectively). In multivariable analysis, the mean MCE perfusion score in akinetic segments is the most powerful independent predictor of functional recovery (odds ratio 8.6, p = 0.02). Such findings suggest that real-time intravenous MCE is a useful predictor of functional recovery of akinetic myocardium after acute MI.

Contrast echocardiography using intravenous octafluoropropane and real-time perfusion imaging predicts functional recovery after acute myocardial infarction. Hillis GS, Mulvagh SL, Gunda M, Hagen ME, Reeder GS, Oh JK. J Am Soc Echocardiogr 2003 Jun; 16 (6), pp. 638–45.

Myocardial/Border Detection of Endocardium Postischemia/Fundamental and Harmonic Imaging/ Stress Echocardiography
Sulfur Hexafluoride Microbubbles: (Stabilized)/ Dobutamine Stress

Background Information: Although stress echocardiography has been established as a diagnostic technique for the detection and assessment of ischemia, there are still a number of limitations to the application of the technique. These are related to suboptimal image quality with poor visualization of endocardial borders. Because assessment of wall motion is fundamental to the diagnostic value of stress echocardiography (both pharmacologic and exercise), endocardial border visualization is of the utmost clinical importance. Furthermore, interinstitutional observer agreement for image interpretation can approach 100% in cases that have high-quality images, compared to a cumbersome 43% level of agreement for cases that have images of a lower quality.
Application: Decreasing the number of redundant diagnostic tests used in the evaluation of myocardial function (e.g., postischemic insult).
Route of Administration: Intravascular.
Considerations: Harmonic imaging improves visualization of endocardial borders at rest and during dobutamine stress tests. However, there is room for improvement. Since the introduction of ultrasound contrast agents, contrast has been increasingly used for better endocardial border visualization. Data from centers that conduct a large number of stress echocardiography tests have shown that the addition of contrast agents decreases redundant diagnostic testing.
Implementation: Evaluation of myocardial dynamic function.
Interpretation and Analysis: Data obtained by some centers from subsets of clinical cases administered SonoVue (stabilized sulfur hexafluoride microbubble contrast agent; SF_6 = inert gas) show an improvement in the number of evaluatable segments with fundamental and harmonic imaging, and in endocardial border detection during dobutamine stress echocardiography. Contrast also enables future quantitative analysis using acoustic quantification (AQ) and color kinesis. These studies should be carried out now since the contrast agent has been approved for clinical application.

Usefulness of ultrasound contrast for image enhancement during stress echocardiography. Ten Cate FJ. Echocardiography 2002 Oct; 19 (7 Pt 2), pp. 621–5.

Myocardial Contrast Echocardiography (MCE)

Myocardial contrast echocardiography has undergone many advances in the past several years through remarkable developments in contrast agent and ultrasound instrumentation/technology. Microbubble ultrasound contrast agents can now safely transit the pulmonary circulation to provide opacification of the left ventricular cavity, improve endocardial border definition, and detect myocardial perfusion. The role of contrast echocardiography in enhancing technically difficult images is now well established in clinical practice and has proven especially useful in the stress and intensive care unit settings. Major progress has been made in the application of MCE for myocardial perfusion assessment in acute and chronic ischemic heart disease syndromes. Advances in novel applications of contrast echocardiography, including targeted delivery of genetic and pharmaceutical materials, have also occurred, but remain in a preclinical phase. The combination of recent innovations in ultrasound equipment and microbubble acoustics allows for exciting exploration of the expanding role of contrast echocardiography in clinical practice.

Recent advances in myocardial contrast echocardiography. Gunda M, Mulvagh SL. Curr Opin Cardiol 2001 Jul; 16 (4), pp. 231–9.

Myocardial Function/Ventricular Physiology
Dobutamine/Nitroglycerin

Cellular/Molecular Mechanism of Action: Dobutamine is an adrenergic agonist/sympathomimetic agent.
Physiological Mechanism of Action: Nitroglycerin exerts vasodilatory properties.
Background Information: Dobutamine-inducible left ventricular obstruction lacks a sound clinical meaning. This phenomenon may be related to an abnormal response of the heart to the sympathetic stimulation, and head-up tilt test would elicit intraventricular obstruction in cases known to develop it during dobutamine administration, through the synergistic effects of reduced preload, hypercontractility, and reflex increase in the cardiac sympathetic tone.
Application: Dobutamine echocardiography analyses for the evaluation of ventricular function.
Route of Administration: Dobutamine (infusion) and nitroglycerin (infusion).
Dosage: Dobutamine and nitroglycerin (0.3 mcg/kg/min).
Implementation: Evaluation of dobutamine stress-echocardiography and 60° head-up tilt on echocardiographic and electrocardiographic monitoring in drug-free and nitroglycerin infusion (0.3 mcg/kg/min) protocols. Doppler echocardiographic measurements of left ventricular diameters, function, and outflow tract flow velocity can be acquired in addition to assessment of power heart rate variability analyzed on short electrocardiographic recordings (low/high frequency ratio). In addition, plasma catecholamines can be determined at baseline and during tilt maneuvers.

Human Model: Normal coronaries (n = 21; of which n = 12 cases with left ventricular obstruction during dobutamine stress-echocardiography [n = 7/12 males, aged 61 ± 7 years]; n = 9 failed to develop complications [n = 3 males, aged 60 ± 9 years]).

Interpretation and Analysis: Intraventricular obstruction does not develop in cases with complications during dobutamine stress electrocardiography. Baseline differences can be appreciated in ventricular dimensions and mitral early-to-late velocity ratio between cases that have or have not developed complications during dobutamine stress electrocardiography procedures. However, hemodynamic behavior during either tilt maneuver is similar. The low/high frequency ratio, that is similar at baseline and similarly increased on head-up tilt, increases significantly less on nitroglycerin-tilt in cases that develop complications during dobutamine electrocardiography procedures. Differences in plasma catecholamines can usually not be appreciated.

Dobutamine-inducible left ventricular obstruction: Head-up tilt and autonomic balance. Barletta G. Int J Cardiol 2003 Feb; 87 (2–3), pp. 245–52.

Myocardial Function/Ventricular (Left) Dysfunction: Chronic/Ventricular Wall Motion Score Index
Glucose-Insulin-Potassium (GIK)/Dobutamine

Background Information: Glucose-insulin-potassium infusion improves cardiac function and outcome during acute ischemia.
Application: Characterization of chronic left ventricular dysfunction as a function of ventricular wall motion score index parameters.
Route of Administration: Dobutamine (intravenous) and GIK (4-hour intravenous infusion).
Implementation: Evaluation of the capacity for GIK infusion to benefit conditions of chronic ischemic left ventricular dysfunction and determination of whether there is a relationship to the presence and integrity of viable myocardium. In this manner dobutamine echocardiography can be combined with a 4-hour infusion of GIK. Segmental responses are quantified by improvement in wall motion score index (WMSI) and peak systolic velocity using tissue Doppler. Global responses are assessed by left ventricular volume and ejection fraction, measured using 3-dimensional reconstruction methods. Myocardial perfusion is also determined using contrast echocardiography.

Human Model: Chronic ischemic left ventricular dysfunction ($n = 30$ cases).
Interpretation and Analysis: Ventricular WMSI (mean $\pm$ standard deviation [SD]) improves with dobutamine (from 1.8 ± 0.4) to 1.6 ± 0.4), $p < 0.001$) and with GIK (from 1.8 ± 0.4 to 1.7 ± 0.4, $p < 0.001$); there is a similar increment for both. Improvement in wall motion score with GIK may be observed in 55% of the 62 segments classed as viable by dobutamine echocardiography, and in 5% of 162 classed as non-viable. There can be an increment in peak systolic velocity after both dobutamine echocardiography (from 2.5 ± 1.8 to 3.2 ± 2.2 cm/s, $p < 0.01$) and GIK (from 3.0 ± 1.6 to 3.5 ± 1.7 cm/s, $p < 0.001$). The GIK effects are not mediated by changes in pulse, mean arterial pressure, lactate, or catecholamines, nor do they correlate with myocardial perfusion. End systolic volume improves after GIK ($p = 0.03$), but only in cases that have a viable myocardium detected by dobutamine echocardiography. Therefore, in cases with a viable myocardium and chronic left ventricular dysfunction, GIK improves wall motion score, myocardial velocity, and end systolic volume, independent of effects on hemodynamics or catecholamines. Such a response to GIK is observed in areas of normal and abnormal perfusion assessed by contrast echocardiography.

Effects of glucose-insulin-potassium infusion on chronic ischaemic left ventricular dysfunction. Khoury VK, Haluska B, Prins J, Marwick TH. Heart 2003 Jan; 89 (1), pp. 61–5.

Myocardial Function/Ventricular (Left) Dysfunction: Halothane-Induced/Acute Coronary Occlusion/ Pericardial Effusion/Echocardiography-Calculated Ejection Fractions
Optison/Phased-Array Intracardiac Echocardiography/ Ultrasound (ICE) Catheter

Application: Phased-array ICE catheter may be a useful clinical tool for the diagnosis of heart failure, ischemia, tamponade, and pulmonary embolism.
Route of Administration: Optison (intracardiac/intravascular applying an ICE catheter system).
Implementation: ICE catheter-facilitated images are obtained from the right atrium during (i) acute left ventricular dysfunction; (ii) acute coronary occlusion; (iii) pericardial effusion and tamponade; and (iv) pulmonary embolism.

Experimental Model: Halothane-induced left ventricular dysfunction and pericardial effusion induced by direct injection/ infusion of saline into the pericardium.
Analysis and Interpretation: In experimental halothane-induced left ventricular dysfunction, echocardiography-calculated ejection fractions reveal declines from $47\% \pm 11\%$ to $25\% \pm 10\%$ ($p < 0.01$). Regional contraction abnormalities after acute coronary occlusion are identified without and with ultrasound contrast agent (e.g., Optison). Pericardial effusion produced by saline infusion into the pericardium can be detected in amounts as small as 15 mL. Right ventricular and atrial compression and respiratory variation in right ventricular inflow during tamponade can be demonstrated on images. After injection of intravenous thrombin to create venous thromboembolism, right ventricular dilatation/dysfunction and thrombi attached to the tricuspid and pulmonary valves and within the pulmonary artery can be identified.

Phased-array intracardiac echocardiographic imaging of acute cardiovascular emergencies: Experimental studies in dogs. Yamada E, Zhang Y, Davies R, Coddington W, Kerber RE. J Am Soc Echocardiogr 2002 Oct; 15 (10 Pt 2), pp. 1309–14.

Myocardial Function/Ventricular (Left) Function/ Poor Thoracic Window Visualization: Chronic Obstructive Pulmonary Disease (COPD)/ Mechanical Ventilation/Positioning
Ultrasound Contrast Media

Application: Enhancement of echocardiographic imaging in cases with a poor thoracic window to cardiovascular structures due to COPD, mechanical ventilation, or suboptimal positioning.
Dosage: Contrast media (1–2 mls).
Implementation: Echocardiographic evaluation of left ventricular function. Outcome measure: The total scores for the left ventricle (LV) in the 2-chamber and 4-chamber views are calculated at baseline and following injection of 1 to 2 mL of a contrast agent. The mean numbers of segments visualized in all cases at baseline and after injection of contrast agent are compared to assess any improvements in anatomical visualization of the heart (e.g., $n = 40$ cases).
Analysis and Interpretation: The endocardium can be adequately visualized to assess LV function in a relatively small percentage of cases admitted to an intensive care unit (ICU) service (e.g., 37% or $n = 15/40$ cases). In population subgroups where the endocardium is only poorly visualized, the simultaneous administation of contrast media is necessary in efforts to acquire suitable diagnostic images (e.g., 63% or $n = 25/40$). Such cases display a rela-

tively low average baseline segmental score of approximately 4.5 compared to a value of 11.6 in cases receiving the benefit of contrast image-enhancement media. Of the population of cases with poor image acquisitions, a relatively large percentage have average baseline segmental scores of 3.9 (e.g., n = 19/25) and display non-diagnostic images. However, the vast majority of these cases following the administration of IV contrast media will convert and display diagnostic images with an average of 11.6 segments visualized. Use of echocardiographic contrast agents in selected patients with poor baseline echocardiographic windows in the ICU setting significantly enhances segmental LV visualization and yields 100% conversion from non-diagnostic to diagnostic studies.

Contrast microbubbles improve diagnostic yield in ICU patients with poor echocardiographic windows. Nguyen TT, Dhond MR, Sabapathy R, Bommer WJ. Chest 2001 Oct; 120 (4), pp. 1287–92.

Myocardial Function/Left Ventricular (LV) Opacification
Octafluoropropane-Filled Human Albumin Microbubbles/Air-Filled Human Albumin Microbubbles

Cellular/Molecular Mechanism of Action: Microbubbles variably impede, absorb, and reflect ultrasound energy in a manner that is different from surrounding tissues or biological fluids.

Background Information: Echocardiographic contrast enhancement of the LV has diagnostic value in the assessment of regional and global LV function. The efficacy of both octafluoropropane-filled human albumin microbubbles (OCTA) and of air-filled human albumin microbubbles (AIR) for LV endocardial delineation and qualitative LV opacification has been reported. However, pulmonary disease, obesity, impaired LV function, and decreased echogenicity may diminish the efficacy of contrast agents for LV opacification.

Application: Octafluoropropane-filled human albumin microbubbles (OCTA: 0.5 mL) and air-filled human albumin microbubbles can be applied as positive contrast image-enhancing agents for ultrasonography procedures.

Dosage: Octafluoropropane-filled human albumin microbubbles (OCTA: 0.5 mL); air-filled human albumin microbubbles (AIR: 0.22 mL/kg).

Implementation: Compare quantitative LV opacification provided by octafluoropropane-filled human albumin microbubbles (OCTA: 0.2, 0.5, 3.0, 5.0 mL) vs air-filled human albumin microbubbles (AIR: 0.08 mL/kg, 0.22 mL/kg) during videodensitometry procedures. Changes in videodensity from non-contrast to contrast agent with the same gain settings can be determined at end diastole and end systole (gray scale 0–255 U) for 2 regions of interest: LV apex-to-mid-cavity; and mid-cavity-to-base. The relative influence of clinically evident pulmonary disease, impaired LV function on echocardiography, and echogenicity on LV opacification produced by both contrast agents can be determined by multivariate analysis.

Human Model: (i) n = 199 cases of suspected cardiac dysfunction; 59.2 ± 13.3 years, n = 157/199 or 79% males; (ii) n = 74 with impaired LV function, pulmonary disease, or both; (iii) n = 70 obese with a body mass index > 30 kg/m^2; (iv) n = 45 non-echogenic (≥ 4 of 6 endocardial segments not seen in the apical 4-chamber view).

Analysis and Interpretation: Significant videodensity increases ranging from 67% to 143% are observed with both agents. At the recommended initial doses (0.5 mL for OCTA, 0.22 mL/kg for AIR), OCTA produces greater opacification than AIR in both regions of interest and at both phases of the cardiac cycle. Poor LV function is associated with decreases in LV opacification for AIR but not for OCTA. Diminished echogenicity is more strongly associated with impaired opacification for AIR than for OCTA. Obesity and clinically evident pulmonary disease are associated with diminished chamber opacification with both OCTA and AIR. In addition to the superiority of octafluoropropane-filled microspheres to air-filled microspheres for LV opacification, the efficacy of OCTA is relatively unaffected by impaired LV function and is less susceptible to the effects of poor echogenicity than AIR.

Differing susceptibility of echocardiographic contrast agents to adverse effects of biologic factors: Multicenter, videodensitometric comparison of octafluoropropane-filled microspheres with air-filled microspheres for left ventricular opacification. Hausnerova E, Gottdiener JS, Gould JJ, Pezzullo JC, Callahan JD, Cohen JL, Bruns DE, Kuvelas MT, West HE, Dittrich HC. J Am Soc Echocardiogr 1999 Nov; 12 (11), pp. 957–66.

Myocardial Function/Ventricular Wall Motion: Post–Heart Transplant/Myocardial Contractile Response
Dipyridamole

Background Information: Coronary allograft vasculopathy (CAV) remains a major factor limiting long-term survival after heart transplantation (HTX). The diagnosis of CAV is still based on serial coronary angiography.

Application: Evaluation of coronary allograft vasculopathy applying combined dipyridamole administration with echocardiography image analysis. Dipyridamole echocardiography is a simple, non-invasive test that after heart transplantation may identify cases with altered wall motion that will subsequently require stricter surveillance.

Dosage: Dipyridamole (high dose).

Implementation: Evaluation of the prognostic value of high-dose dipyridamole echocardiography in heart transplant cases. Coronary allograft vasculopathy is defined as CAV 1 (focal or diffuse stenosis < 50%) or CAV 2 (focal or diffuse stenosis ≥ 50%). The wall motion score index (WMSI) is measured at rest and after dipyridamole administration.

Human Model: Heart transplant cases (n = 68) 48 hours prior to scheduled annual coronary angiography.

Interpretation and Analysis: Results of coronary angiography imaging are normal in a large number of cases (e.g., n = 43/68 or 63%); approximately 16% show CAV 1 (e.g., n = 11/68) and CAV 2 in about 21% of cases (e.g., n = 14/68). Similarly, rest wall motion is normal in a large percentage of cases (e.g., n = 39/68 normal; n = 29/68 abnormal). Following dipyridamole administration, wall motion remains unchanged in normal cases (e.g., n = 39/39; Group 1, no CAV in n = 34 and CAV 1 in n = 5). In cases with rest wall motion abnormalities (e.g., n = 29), dipyridamole promotes no change or worsening in most instances (e.g., n = 21/29; Group 3, CAV 2 in n = 14 and no CAV or CAV 1 in n = 7) but can reverse to normal in a modest number of cases (e.g., n = 8/29; Group 2, no CAV in n = 7, and CAV 1 in n = 1). During a 6-year (± 3 years) monitoring period, a large number of cases may experience a major cardiac event (e.g., n = 15; n = 11 Group 3, n = 4 Groups 1 and 2). Wall motion at rest and after dipyridamole administration and CAV is an independent predictor for cardiac events; only dipyridamole WMSI > 1 remains significant ($p < 0.0001$) when assessed by multivariate analysis.

Prognostic value of contractile response during high-dose dipyridamole echocardiography test in heart transplant recipients. Ciliberto GR, Parodi O, Cataldo G, Mangiavacchi M, Alberti A, Parolini M, Frigerio M. J Heart Lung Transplant 2003 May; 22 (5), pp. 526–32.

Myocardial Function/Ventricular (Left) Wall Segment
Optison Contrast Agent/Dobutamine Stress Echocardiography

Application: A 2nd-generation echocardiogaphic contrast agent (e.g., Optison).
Route of Administration: Optison (intravascular).
Implementation: Determine the effectiveness and quality of left ventricular wall segment images, image quality, and confidence of interpretation with and without the use of Optison as an intravenous contrast agent during rest and peak dobutamine stress echocardiography tests (e.g., n = 300 cases).
Analysis and Interpretation: At rest and at peak stress, the percentage of wall segments visualized, image quality, and confidence of interpretation is superior with the use of contrast agent compared with non-contrast imaging. No significant decrease can be seen in wall segment visualization, image quality, or confidence of interpretation from rest to peak stress in images obtained with contrast, unlike the images obtained without contrast from rest to peak stress. The use of intravenous echocardiographic contrast agents like Optison during dobutamine stress echocardiography significantly improves wall segment visualization and image quality at rest and at peak stress, resulting in improved confidence of interpretation.

Contrast dobutamine stress echocardiography: Clinical practice assessment in 300 consecutive patients. Rainbird AJ, Mulvagh SL, Oh JK, McCully RB, Klarich KW, Shub C, Mahoney DW, Pellikka PA. J Am Soc Echocardiogr 2001 May; 14 (5), pp. 378–85.

Myocardial Infarction: Akinesia of the Myocardial Wall
Perflutren Microbubbles/Dobutamine Echocardiography (DE)

Background Information: Akinesia after acute myocardial infarction (AMI) may be reversible or irreversible. Distinguishing these 2 entities early after AMI is difficult but clinically important. Previous studies have shown that myocardial contrast echocardiography (MCE) and low-dose DE may both be useful in this setting. However, minimal data exists regarding the relative and combined value of these techniques.
Route of Administration: Intravascular.
Implementation: Evaluate and compare the utility of real-time intravenous MCE and low-dose DE in the early prediction of functional recovery of akinetic myocardium after AMI. Real-time MCE is performed using perflutren microbubbles. Subsequently, low-dose DE is immediately performed. Contrast opacification and wall motion are determined by experienced observers blinded to clinical data. Repeat echocardiograms are obtained 51 ± 19 days later and wall motion at rest is scored blinded to clinical data.
Human Model: Cases of AMI (n = 37 at 3 ± 2 days after AMI).
Interpretation and Analysis: Normal contrast opacification predicts functional recovery with a positive predictive value of 63%, a negative predictive value of 73%, and an accuracy of 66%. Residual contractility during low-dose DE has a positive predictive value of 82%, a negative predictive value of 72%, and a predictive accuracy of 76%. When the 2 tests are concordant (64%), they have a positive predictive value of 81%, a negative predictive value of 85%, and a predictive accuracy of 83%. Low-dose DE is superior to intravenous MCE for the prediction of functional recovery of akinetic myocardium after AMI, but the combination of both maximizes predictive accuracy.

Comparison of intravenous myocardial contrast echocardiography and low-dose dobutamine echocardiography for predicting left ventricular functional recovery following acute myocardial infarction. Hillis GS, Mulvagh SL, Pellikka PA, Hagen ME, Gunda M, Wright RS, Oh JK. Am J Cardiol 2003 Sep 1; 92 (5), pp. 504–8.

Myocardial Infarction/Coronary Artery Disease
Contrast Echocardiography

The application of non-invasive imaging techniques to assess myocardial viability has become an important part of routine management of acute myocardial infarction and chronic coronary artery disease. Information regarding the presence and extent of viability may help identify patients likely to benefit from revascularization or therapy directed at attenuating left ventricular remodeling. Myocardial contrast echocardiography (MCE) is capable of defining the presence and extent of viability by providing an accurate assessment of microvascular integrity needed to maintain myocellular viability. It is especially suited for the spatial assessment of perfusion, even when myocardial blood flow is reduced substantially in the presence of severe epicardial stenoses or in a vascular bed dependent on collateral perfusion. The routine use of MCE to evaluate viability in conditions of acute and chronic coronary artery disease is now feasible with the advent of new imaging technologies and microbubble agents capable of myocardial opacification from venous injections. The utility of this technique for determining treatment strategies has not been established but is forthcoming.

Assessment of myocardial viability with myocardial contrast echocardiography. Lindner JR. Echocardiography 2002 Jul; 19 (5), pp. 417–25.

Myocardial Infarction: Uncomplicated/Prediction of Favorable Outcome/High Negative Predictive Value Assessment
Dobutamine/Electropharmacology

Cellular/Molecular Mechanism of Action: Dobutamine is an adrenergic agonist/sympathomimetic.
Background Information: Risk stratification after uncomplicated myocardial infarction is a major clinical challenge. In particular, the prognostic value of residual inducible ischemia is still controversial.
Application: Electrocardiogram (ECG) and dobutamine stress echocardiography evaluation of cases with uncomplicated myocardial infarction.
Route of Administration: Intravenous.
Implementation: Evaluation of the relative prognostic value of exercise ECG and dobutamine stress echocardiography performed in the early postinfarction period. One approach to achieving this objective can entail assessment of maximal exercise ECG and dobutamine stress echocardiography within 10 days of an uncomplicated myocardial infarction off therapy and then prospectively monitored for 8.8 months. The variables of age, sex, diabetes, smoking habit, hypertension, dyslipidemia, infarct location, thrombolysis, and resting wall motion score index are taken into account as clinical variables. Prognostic correlations are then made vs spontaneous events (cardiac death, non-fatal reinfarction, and unstable angina requiring hospitalization) while cases undergo revascularization (by means of percutaneous trans-luminal coronary angioplasty or coronary artery bypass surgery).
Human Model: Cases of an uncomplicated myocardial infarction off therapy and prospectively monitored for 8.8 months (n = 406 with n = 53 females; age = 57 ± 9 years).

Interpretation and Analysis: A relatively high number of "events" can be anticipated to occur during the monitoring period (e.g., n = 127; n = 41 or 10% spontaneous [5 deaths; 12 reinfarctions; 24 unstable angina], n = 86 procedural related [27 angioplasty; 59 bypass surgery]). Spontaneous events cannot be predicted by any clinical, exercise ECG, or dobutamine stress echocardiography variable. However, the negative predictive value of both tests is excellent (91% and 90%, respectively). With a multivariate Cox analysis, male gender, positive low-workload (< 100 W) exercise ECG ($p < 0.0001$), positive low-dose dobutamine stress echocardiography ($p < 0.0001$), and rest-stress wall motion score index variation ($p < 0.001$) are capable of predicting cumulative cardiac events with an independent and additive value.

Dobutamine stress echocardiography is significantly more sensitive ($p < 0.05$) and less specific ($p < 0.01$) in predicting the outcome of anterior infarction conditions, while exercise ECG is significantly more sensitive ($p < 0.05$) in cases with non-Q wave infarction. The most valuable concepts related to these observations include (i) spontaneous events are poorly predicted by provocative tests in low-risk patients after uncomplicated myocardial infarction; (ii) however, both exercise ECG and dobutamine stress echocardiography can predict a favorable outcome with a very high negative predictive value; (iii) dobutamine stress echocardiography should be considered a secondary option in cases where the exercise ECG is equivocal or when the location of ischemia is a relevant issue; (iv) the possibility that the 2 tests have a differential utility depending on the infarct location and type (Q wave vs non-Q wave) may be clinically relevant and deserves further evaluation.

Prognostic value of residual ischemia assessed by exercise electrocardiography and dobutamine stress echocardiography in low-risk patients following acute myocardial infarction. Bigi R, Galati A, Curti G, Coletta C, Barlera S, Partesana N, Bordi L, Ceci V, Occhi G, Fiorentini C. Eur Heart J 1997 Dec; 18 (12), pp. 1873–81.

Myocardial Perfusion/Blood Flow and Chamber Volume
Microbubbles

Cellular/Molecular Mechanism of Action: Microbubbles do not propagate ultrasound energy as effectively as do homogeneous (biological) fluids or other types of liquid media.
Application: Microbubbles are excellent tracers for assessment of red blood cell kinetics.

In this fashion, microbubble contrast agents and ultrasound imaging modalities can facilitate the evaluation of various dynamic vascular processes, including the assessment of myocardial perfusion by echocardiography. Apart from providing a spatial assessment of myocardial perfusion, myocardial contrast echocardiography (MCE) can also be used to quantify the 2 specific components of myocardial blood flow-flow velocity and myocardial blood volume.
Implementation: One method that can be applied to quantify myocardial blood flow velocity is based on rapid destruction of microbubbles by ultrasound, and the subsequent assessment of the rate of replenishment of microbubbles into the myocardial microcirculation within the ultrasound beam elevation. Assessment of steady state myocardial video intensity (VI) provides a measure of myocardial or capillary blood volume.
Analysis and Interpretation: Perfusion defects that develop distal to a stenosis during hyperemia are due to capillary derecruitment. The degree of derecruitment (and therefore the severity of a perfusion defect) is proportional to stenosis severity. Because the capillary bed also provides the greatest resistance to hyperemic flow, decreases in capillary blood volume distal to a stenosis during hyperemia result in increases in microvascular resistance, which is the mechanism underlying the progressive decrease in flow reserve in the presence of a stenosis. Consequently, both the severity of a perfusion defect and quantification of abnormal myocardial blood flow reserve on MCE can be used to determine stenosis severity. As imaging methods with MCE continue to be refined, the optimal imaging algorithms for clinical practice still need to be determined. Myocardial contrast echocardiography, however, holds promise as a non-invasive, instantaneous, on-line method for the detection and quantification of coronary artery disease.

Detection and quantification of coronary stenosis severity with myocardial contrast echocardiography. Wei K. Prog Cardiovasc Dis 2001 Sep–Oct; 44 (2), pp. 81–100.

Myocardial Perfusion/Blood Flow Mismatch (Ischemic vs Normal)/Blood Flow Mismatch: Ischemic vs Normal Myocardium
NC 100100/Fluorescent Microspheres

Application: The ultrasound contrast agent NC 100100 can be applied to perform myocardial contrast echocardiography (MCE) imaging. Fluorescent microspheres can be utilized to determine regional myocardial blood flow parameters. The degree of blood flow mismatch between ischemic and normal myocardial regions during graded coronary stenoses can be estimated by quantitative assessment of myocardial perfusion produced by IV MCE (e.g., canine models).
Route of Administration: NC 100100 (intravenous).
Implementation: Coronary artery flow is measured with a transit time flowmeter during baseline, pharmacological-induced vasodilation, a non-flow-limiting stenosis at rest in conjunction with vasodilation, a flow-limiting stenosis, and total occlusion. Myocardial contrast echocardiography is then performed, facilitated by the injection of NC 100100 contrast agent. Time-intensity curves are obtained off-line for the left anterior descending (LAD) coronary artery risk area and the adjacent left circumflex (LCx) territory, and peak background-subtracted video intensity determined. Fluorescent microspheres are injected at each intervention for determination of regional myocardial blood flow.

Animal Model: Variable obstruction of the LAD coronary artery in dogs produced by a screw occluder.
Analysis and Interpretation: During non-flow-limiting stenosis, flow-limiting stenosis, and total occlusion, LAD/LCx ratios of peak myocardial video intensity and blood flow decrease proportionately. Both LAD/LCx ratios of video intensity and blood flow identify the non-flow-limiting and flow-limiting stenoses as well as total occlusion of the LAD artery. A significant correlation exists between LAD/LCx video intensity and blood flow ratios ($r = 0.83$, $p < 0.0001$).

Quantitative assessment of myocardial perfusion during graded coronary artery stenoses by intravenous myocardial contrast echocardiography. Leistad E, Ohmori K, Peterson TA, Christensen G, DeMaria AN. J Am Coll Cardiol 2001 Feb; 37 (2), pp. 624–31.

Myocardial Perfusion/Blood Flow with Vasculature/Red Blood Cell Velocity
Microbubbles/Microbubble "Replenishment"

Background Information: The development of new microbubble agents and ultrasound imaging modalities now allow the assessment of myocardial perfusion with echocardiography.
Application: Evaluation of vascular blood flow.

Route of Administration: Intravascular (selective delivery).
Implementation: Microbubbles can be administered intravenously as constant infusions, thereby allowing their concentration in blood to reach a steady state. If the relation between microbubble concentration and video intensity is within the linear range, then myocardial video intensity will reflect the concentration of microbubbles in that region, which at steady state represents the myocardial blood volume.
Interpretation and Analysis: The ability to destroy microbubbles and measure their replenishment within the ultrasound beam provides an opportunity to evaluate microbubble (or red blood cell) velocity. The product of myocardial blood volume and red blood cell velocity reflects properties of myocardial blood flow.

Assessment of myocardial blood flow and volume using myocardial contrast echocardiography. Wei K. Echocardiography 2002 Jul; 19 (5), pp. 409–16.

Myocardial Perfusion/Coronary Flow Quantification/Myocardioviability/Bedside Diagnostic Capabilities
Echocardiography Contrast Media

Background Information: Contrast echocardiography can delineate myocardial perfusion and has the potential for quantitating coronary flow and assessing myocardial viability.
Application: Assessment of myocardial perfusion, quantifying coronary artery flow, and determination of myocardial viability.
Analysis and Interpretation: Utilization of contrast echocardiography for quantifying coronary artery blood flow and assessment of myocardial viability provides important physiologic information that complements the characterization of vascular anatomical anomalies. Because it can be rapidly performed at the bedside, contrast echocardiography may be a valuable tool for use in acute myocardial ischemia. When contrast echocardiography has been used after recanalization of occluded coronary arteries, the assessment of myocardial salvage conveys information concerning reflow, stunning, and prognosis, and in the case of angioplasty it provides immediate information regarding the success of the procedure. Contrast echocardiography can also assess myocardial areas at risk of irreversible damage and the presence or absence of collateral flow. Myocardial contrast echocardiography is a rapidly changing field and with the continued development of newer contrast agents and refinement of ultrasound imaging equipment, the applications of contrast echocardiography will continue to grow.

Assessment of myocardial perfusion by contrast echocardiography. Perez JE. Rev Port Cardiol 2001 Jan; 20 Suppl 1, pp. I49–56.

Myocardial Perfusion/Ischemia/Occulsion and Reperfusion Injury/Myeloperoxidase Score
Microsphere Contrast Image-Enhancing Agents/BR14

Cellular/Molecular Mechanism of Action: Microspheres when applied as an ultrasound contrast image-enhancing agent variably absorb, impede, and reflect ultrasound energy in a manner that is different than patterns observed for biological fluids.
Background Information: Ultrasound exposure may destroy the ultrasound imaging agent BR-14 and eliminate visualization of sustained myocardial opacification from retained microbubbles.
Application: Microsphere contrast image-enhancing agents can be applied to evaluate alteration in anatomical integrity and physiological function of vascular structures, including the assessement of myocardial perfusion parameters.
Route of Administration: Microsphere contrast image-enhancing agent (intra-arterial).
Implementation: Determine if delays in postinjection imaging with the ultrasound contrast agent BR-14 produce prolonged opacification and hyperenhancement of myocardium subjected to coronary occlusion/reperfusion.
Animal Model: Canine cardiac preparations (n = 8 open-thorax; 3 hours left anterior descending coronary artery occlusion followed by 3 hours of reperfusion). Myocardial contrast echocardiography (MCE) is performed before occlusion and 120 minutes after the onset of both occlusion and reperfusion events. Ultrasound imaging is initiated 15 minutes after injection of microspheres to assess myocardial blood flow (MBF).
Analysis and Interpretation: Preocclusion images reveal a uniform opacification of the left ventricular myocardium that is greater than that of the ventricular cavity, with a mean intensity of the left anterior descending (LAD) coronary artery bed of 8.66 $\pm$ 1.38 dB. During occlusion, MCE results in the appearance of a perfusion defect in the LAD risk area (intensity 2.08 $\pm$ 1.10 dB). After 120 minutes of reperfusion, the LAD risk-area myocardium develops dense opacification of a higher intensity ("hot spot") than baseline (13.7 vs 8.7 dB), but with reduced MBF consistent with accumulation of a high concentration of microbubbles. Increased MCE intensity is associated with a greater myeloperoxidase score. Contrast opacification by BR-14 may be selectively retained within the perfusion bed of a coronary artery subjected to occlusion/reperfusion. Such opacification exhibits defects with occlusion, manifests hyperenhanced intensity (hot spot) with reperfusion, is associated (correlates) with levels of myeloperoxidase activity, and conforms to the area of myocardium subjected to altered flow.

Visualization of risk-area myocardium as a high-intensity, hyperenhanced "hot spot" by myocardial contrast echocardiography following coronary reperfusion: Quantitative analysis. Kunichika H, Peters B, Cotter B, Masugata H, Kunichika N, Wolf PL, DeMaria AN. J Am Coll Cardiol 2003 Aug 6; 42 (3), pp. 552–7.

Myocardial Perfusion Post–Myocardial Infarction/ Reflow Patterns/Stress Echocardiography
Perfluorocarbon-Encapsulated Microbubbles/ [Adenosine Stress Echocardiography]/[Dipyridamole Stress Echocardiography]/[Dobutamine Stress Echocardiography]

Background Information: One of the major challenges facing the field of ultrasonography is the accurate interpretation of images.
Application: Enhancement of the diagnostic accuracy of adenosine, dypyridamole, and dobutamine stress echocardiography procedures.
Route of Administration: Intravascular.
Implementation: Assessment of myocardial contrast patterns (e.g., perfusion abnormalities) during dipyridamole, adenosine, and dobutamine stress echocardiography procedures.
Interpretation and Analysis: Myocardial contrast patterns can detect myocardial perfusion abnormalities during dipyridamole, adenosine, and dobutamine stress echocardiography. Validity of such findings remains to be established in larger multicenter clinical studies.

Clinical experience in the detection of coronary artery disease with myocardial contrast echocardiography. Porter TR, Xie F. Echocardiography 2002 Jul; 19 (5), pp. 399–407.

Myocardial Perfusion/Myocardial Contrast Echocardiography (MCE) Flow or No-Flow: Correlation with Cardiac Physiology Parameters (Pressure-Derived Collateral Flow Index [CFIp]) *Microbubbles*

Cellular/Molecular Mechanism of Action: Microbubble preparations transmit ultrasound energy to a much lesser extent than do relatively "homogenous" biological fluid mediums due to variable increased impedance, absorbance, and reflectance, which can be detected by ultrasound instrumentation.

Background Information: Higher CFIp values are associated with less severe myocardial ischemia during angioplasty in the noninfarcted heart. It remains unknown whether CFIp also identifies collateral function in acute myocardial infarction cases with and without no-reflow phenomenon.

Application: Acquisition of MCE images for the assessment of myocardial perfusion.

Route of Administration: Microbubble myocardial perfusion imaging (intracoronary artery).

Implementation: Following successful percutaneous transluminal coronary angioplasty (PTCA) stent, measurements are acquired for mean aortic pressure (Pa), central venous pressure (Pv), and coronary wedge pressure (Pcw) of the infarct-related artery to calculate: CFIp = (Pcw − Pv)/(Pa − Pv). Myocardial contrast echocardiography is performed with an intracoronary injection of microbubbles to assess myocardial perfusion. Left ventriculograms on day 1 and day 28 are evaluated for the measurement of regional wall motion (RWM, SD/chord).

Human Model: Acute myocardial infarction (e.g., n = 48 cases).

Interpretation and Analysis: There is no difference in CFIp among subsets based on angiographic collateral grades (grade 0, 1, 2, 3; 0.28 ± 0.07, 0.27 ± 0.09, 0.27 ± 0.08, 0.23 ± 0.08, p = NS). The CFIp is significantly higher in cases with MCE no-reflow (n = 16) than in those with MCE reflow (n = 32, respectively 0.34 ± 0.07 vs 0.23 ± 0.06, $p < 0.01$). There is a significant inverse correlation between the extent of functional improvement (DeltaRWM [28 d-1 d]) and CFIp ($r = 0.56$, $p < 0.01$), implying that higher CFIp is associated with worse functional improvement.

In AMI, CFIp is unlikely to reflect collateral function but seems to increase with the severity of microvascular dysfunction. Because higher CFIp is generally associated with a poorer functional recovery, it provides a simple and useful estimate of clinical outcomes in AMI.

Pressure-derived collateral flow index as a parameter of microvascular dysfunction in acute myocardial infarction. Yamamoto K, Ito H, Iwakura K, Shintani Y, Masuyama T, Hori M, Kawano S, Higashino Y, Fujii K. J Am Coll Cardiol 2001 Nov 1; 38 (5), pp. 1383–9.

Myocardial Perfusion Postinfarction *Microbubbles*

Background Information: Intense research efforts have been made to bring forth the use of myocardial contrast echocardiography (MCE) as a viable clinical procedure for the diagnosis and evaluation of coronary artery disease.

Implementation: Evaluation of myocardial perfusion parameters and characterize myocardial infarction and ischemia.

Interpretation and Analysis: A number of ultrasound contrast agents have been developed that act as red blood cell tracers and display myocardial perfusion profiles when imaged by dedicated ultrasound imaging modalities. A considerable amount of experimental and clinical research has shown that MCE can aid in the recognition of acute and chronic myocardial infarction, viable myocardium, and functionally significant coronary stenoses. Comparison of this diagnostic technique to nuclear imaging and coronary arteriography has demonstrated that an excellent level of diagnostic accuracy can be achieved in evaluating various coronary syndromes. Optimal practice of perfusion imaging requires a thorough knowledge of microbubble characteristics and imaging modalities, as well as experience with specific methodologies. In this context, techniques continue to evolve from intermittent gated examination to real-time perfusion imaging in a manner that allows evaluation of both perfusion and functional parameters. The opportunity to target sites of pathology with specially engineered microbubbles could also aid in many therapeutic applications besides diagnostic imaging.

Myocardial perfusion imaging using contrast echocardiography. Nesser HJ, Morcerf F, Teupe C, Pandian NG. Herz 2002 May; 27 (3), pp. 217–26.

Thrombosis: Intravascular *Perfluorooctylbromide/Perfluorooctane/Nanoparticles*

Cellular/Molecular Mechanism of Action: Perfluorooctylbromide and perfluorooctane impede/absorb ultrasound emissions.

Background Information: Complex molecular signaling heralds the early stages of pathologies such as angiogenesis, inflammation, unstable atherosclerotic plaques, and areas of remote thrombi. Acoustic enhancement of blood clot morphology has been demonstrated to be feasible with the use of a non-gaseous, fibrin-targeted acoustic nanoparticle emulsion delivered *in vitro* and *in vivo* to areas of thrombosis.

Application: Perfluorooctylbromide and perfluorooctane can be applied as acoustic contrast image-enhancing agents for the detection of intravascular thrombosis.

Route of Administration: Perfluorooctylbromide and perfluorooctane (intravenous).

Implementation: Design and construct a system that allows visualization of the evolution of acoustic contrast enhancement. To evaluate the system 2 targeting strategies can be utilized, including (i) avidin-complexed nitrocellulose membrane; and (ii) human plasma clots. The time evolution of enhancement can be visualized in 10-minute increments over a 1-hour time period.

Interpretation and Analysis: A monotonic increase can be observed in ultrasonic reflection enhancement from specially treated nitrocellulose membranes for targeted emulsions containing perfluorooctylbromide (1.30 ± 0.3 dB) and for perfluorooctane (2.64 ± 0.5 dB) within the 1st 60 minutes of imaging. In comparison, inherently non-echogenic plasma clots show a substantial increase of 12.0 ± 0.9 dB when targeted with a perfluorooctane emulsion and effectively demonstrate the concept of molecular imaging. The methodologies can quantify the time evolution of the binding of a site-targeted ultrasonic contrast agent. Moreover, with the incorporation of specific drug treatments into the nanoparticulate contrast agent, ultrasonic molecular imaging may yield reliable strategies for detecting and quantifying nascent pathologies and facilitate targeted drug therapy.

Time evolution of enhanced ultrasonic reflection using a fibrin-targeted nanoparticulate contrast agent. Hall CS, Marsh JN, Scott MJ, Gaffney PJ, Wickline SA, Lanza GM. J Acoust Soc Am 2000 Dec; 108 (6), pp. 3049–57.

Valve Structures: Mitral Regurgitation (MR): Quantification of Severity
Microbubbles/(Power Injected)

Cellular/Molecular Mechanism of Action: Microbubbles variably absorb, impede, and reflect ultrasound energy relative to normal tissues and biological fluids.
Background Information: There is no method of quantifying the severity of MR from the injection of tracer directly into the left ventricular (LV) cavity (common method used in the cardiac catheterization laboratory).
Application: Measurement of the severity of cardiac chamber mitral regurgitation. Apart from being quantitative, the methodology can be safely used during cardiac catheterization in cases where iodinated contrast agents may be potentially harmful.
Route of Administration: Microbubble formulations (power injected into catheterized cardiac chamber).
Dosage: Microbubble formulation (5 ml/LV chamber). Five milliliters of a microbubble mixture is power injected into the LV during simultaneously performed contrast echocardiography.
Implementation: Characterization of relative tracer washout from the left atrial (LA) and LV chambers facilitated by the use of a mathematical model that derives regurgitant fraction (RF) parameters (e.g., n = 39 cases). Relative changes in background-subtracted video intensity are measured within the LV and LA, and the resultant model-derived RF is correlated with the severity of mitral regurgitation on cineangiography.
Human Model: Diagnostic cardiac catheterization in conditions of possible mitral regurgitation.
Analysis and Interpretation: The severity of MR ranges between 0 and 4+ on cineangiography with a corresponding model-derived RF of 0 to 0.69 on contrast echocardiography. A close linear relation is noted between angiographic severity of MR and model-derived RF on contrast echocardiography ($y = 0.1x + 0.03$, $r = 0.89$, $p < 0.001$). Contrast echocardiography is more sensitive than cineangiography for detecting mild MR.

Quantification of mitral regurgitation in the cardiac catheterization laboratory with contrast echocardiography. Buckley RS, Kaul S, Jayaweera AR, Gimple LW, Powers ER, Dent JM. Am Heart J 2000 Jun; 139 (6), pp. 1109–13.

Valve Structures: Tricuspid Regurgitation (TR)/ Right Heart Function
Agitated Colloid/Levovist (Lev)/Saline (Sal)

Background Information: Doppler imaging spectrum of TR can be used to non-invasively assess right ventricular (RV) pressure. With mild TR, the native (Nat) TR envelope may not allow accurate pressure evaluation. Proprietary contrast agents such as Lev can be used to augment TR Doppler and opacify right-sided heart chambers, but they are expensive and their efficacy has not been objectively evaluated in cases with difficult baseline studies or compared with less expensive Sal or colloid solutions, such as Gelofusine (Gel).
Application: Agitated colloid, Lev, and Sal can be used to assess pulmonary systolic pressure and right-sided heart opacification. Note: Cost $0.10, $2.50, and $75.00 per study for Sal, Gel, and Lev contrast agents, respectively.
Route of Administration: Cardiac catheterization.
Implementation: Reexamination of poor quality Nat TR envelopes detected on trans-thoracic echocardiogram with serial intravenous injection of 3 contrast agents (Sal, Gel, and Lev). Doppler signals for each agent are recorded on video and digitally on optical disk to facilitate assessment of signal quality, estimate RV pressure, and approximate signal longevity. Quality of RV-right atrial (RV-RA) opacification is also determined for Sal and Gel, in addition to the measurement of pressures obtained from cardiac catheterization in order to independently evaluate pressure estimates from echocardiography.
Human Model: Trans-thoracic contrast echocardiogram (n = 25 cases); percutaneous right-sided heart cathetrization (e.g., n = 9/25). Pressures obtained from the catheterization are used to independently evaluate the pressure estimates from echocardiography.
Analysis and Interpretation: The 3 contrast agents Sal, Gel, and Lev all significantly improve the mean quality grade (grades 0–5) of TR envelopes (Nat 1.12, Sal 1.97, Gel 2.56, Lev 2.41, $p < 0.001$), decrease the number of uninterpretable envelopes (grade 0) (Nat 49%, Sal 12%, Gel 4%, Lev 12%, $p < 0.0001$ for comparison of each agent relative to Nat), and improve the correlation between echocardiographic and catheter-derived RV-RA pressure measurements (Nat $r = 0.65$, Sal $r = 0.75$, Gel $r = 0.90$, Lev $r = 0.88$). The persistence of enhanced Doppler signals of interpretable quality (> grade 1) is greater for Lev (15.8 seconds) and Gel (15 seconds) than for Sal (7.6 seconds) ($p = 0.002$). Opacification of RV and RA, measured as mean luminosity score during 2-dimensional harmonic imaging, is significantly higher for Gel than Sal (92.84 ± 31.2 vs 56.06 ± 25.6, respectively; $p = 0.0003$).

Agitated colloid is superior to saline and equivalent to levovist in enhancing tricuspid regurgitation Doppler envelope and in the opacification of right heart chambers: A quantitative, qualitative, and cost-effectiveness study. Tan HC, Fung KC, Kritharides L. J Am Soc Echocardiogr 2002 Apr; 15 (4), pp. 309–15.

CENTRAL NERVOUS SYSTEM

Angiography/Stimulated Acoustic Emission (SAE)/ High-Acoustic Disintegration of Microbubbles/ Insonation of Echo-Contrast Agents
Microbubbles/Non-Moving Microbubbles (SHU 563 A)/ Levovist (SHU 508 A)

Background Information: Experimental and clinical data suggest that insonation of echo-contrast agents with high acoustical power induces the disintegration of microbubbles, resulting in pseudo-Doppler phenomenon SAE.
Application: Potential measurement of cerebral vascular perfusion applying trans-cranial Doppler image detection of SAE signals.
Implementation: Evaluation of the feasibility for performing trans-cranial imaging analyses. One investigative approach for achieving this objective can involve the evaluation of non-moving microbubbles (SHU 563 A) insonated *in vitro* through the temporal parts of a human cadaver skull, and contrast signals detected by velocity-coded color Doppler and power Doppler recordings. Complementary investigations can include trans-cranial color Doppler and power Doppler imaging (e.g., n = 10 normal controls) utilizing the echo-contrast agent SHU 508 A (e.g., Levovist).
Analysis and Interpretation: Color Doppler signals reveal that SAE can be observed *in vitro* and in trans-cranial human investigations. Such signals are composed of a mosaic of color Doppler pixels ranging over the full color scale. Apparent velocity information and spatial distribution of SAE signals ultimately changes from image frame to image frame. In experimental models, the intensity of SAE signals decreases exponentially over time. With an increase of acoustic power, there is a significant increase of the maximum signal intensity ($p < 0.01$) and a significantly shorter signal duration ($p < 0.01$), consistent with stronger and more rapid disintegration. In humans, SAE signals can be clearly detected in cerebral tissue regions. The intensity of SAE signals in these regions (e.g., temporal

cortex, 3.7 ± 1.2 dB) is approximately 8 times lower than the signal enhancement in the major cerebral arteries (e.g., 29.5 ± 5.6).

Stimulated acoustic emission detected by trans-cranial color Doppler ultrasound: A contrast-specific phenomenon useful for the detection of cerebral tissue perfusion. Pohl C, Tiemann K, Schlosser T, Becher H. Stroke 2000 Jul; 31 (7), pp. 1661–6.

Angiography: Trans-Cranial Color-Coded Sonography/Duration of Contrast Enhancement
Levovist

Background Information: Since the introduction of contrast media, trans-cranial color-coded sonography (TCCS) has become increasingly important for the examination of intracranial vessels. However, the widely practiced bolus injection of these agents leads to initial blooming artifacts, and thereafter the level of contrast enhancement decreases rapidly, reducing the effective time of imaging enhancement.
Application: Trans-cranial color-coded sonography examination of intracranial vessel structure, integrity, and function.
Route of Administration: Levovist (antecubital vein).
Dosage: Levovist (300 mg/ml; 4 g at a constant infusion rate of 60 ml/h).
Implementation: Trans-cranial color-coded sonography examination of intracranial vessels using a 2.25-MHz phased-array transducer during administration of Levovist contrast agent. The degree of enhancement can be graded chronologically over time.
Human Model: Normal subjects (n = 26).
Analysis and Interpretation: During continuous administration, a constant level of contrast enhancement is achieved after 60.1 ± 26.2 seconds and lasts approximately 663.4 ± 55.8 seconds (evaluator 1 = 66.6 ± 26.2 seconds; evaluator 2 = 664.3 ± 55.9 seconds). The limits of interobserver agreement can range from −10.1% to 9.9%. No major blooming effect is seen in the initial phases of examination.

Continuous administration of contrast medium for trans-cranial color-coded sonography. Schminke U, Motsch L, Bleiss A, von Smekal U, Griewing B, Kessler C. Neuroradiology 2001 Jan; 43 (1), pp. 24–8.

Arteriography: Intracranial Arteries
Galactose-Based Microbubble Suspension (Levovist)

Cellular/Molecular Mechanism of Action: Microbubbles variably impede, absorb, and reflect ultrasound energy in a manner that is different from surrounding tissues or biological fluids.
Application: Contrast-enhanced trans-cranial ultrasound (TU) demonstrates a high sensitivity and specificity for detecting and characterizing intracranial stenosis.
Implementation: Evaluate the frequency at which the ultrasound contrast agent (UCA) Levovist is used in routine TU.

In this context, it has been utilized as a secondary imaging strategy for identifying intracranial arteries insufficiently characterized with combined trans-cranial color-coded duplex and trans-cranial Doppler examination. Trans-cranial ultrasound images can be compared with 3-dimensional time-of-flight magnetic resonance (MR) angiography as a validation procedure.
Human Model: Cases with intracranial arteries that could not be adequately visualized with combined trans-cranial color-coded duplex and trans-cranial Doppler examination (e.g., n = 61/687).
Analysis and Interpretation: A diagnostic result with ultrasound contrast agent can be achieved in approximately 75% of cases during trans-temporal and in 81% during trans-foraminal insonation. The sensitivity and specificity of TU in the diagnosis of intracranial stenosis is approximately 83% and 82%, respectively. Use of UCA is necessary in approximately 8.8% of cases. A diagnostic benefit of between 75% and 80% can be achieved in relevant case populations.

Echo-contrast-enhanced trans-cranial ultrasound: Frequency of use, diagnostic benefit, and validity of results compared with MRA. Zunker P, Wilms H, Brossmann J, Georgiadis D, Weber S, Deuschl G. Stroke 2002 Nov; 33 (11), pp. 2600–3.

Brain Blood Flow Measurements/Induction of Neurologic Pathology by Ultrasound (US) Contrast Agents
US Contrast Agent/Burst US

Cellular/Molecular Mechanism of Action: Microbubbles variably impede, absorb, and reflect US energy in a manner that is different from surrounding tissues or biological fluids.
Application: Burst US and US contrast agents have been used to acquire brain blood flow measurements.
Implementation: Evaluation of the potential for burst US in the presence of a US contrast agent to cause injury to central nervous system (CNS) tissues using parameters similar to those during the acquisition of brain blood flow measurements. One approach to achieving this objective involves the sonication of brains in 3 to 8 locations with 1.5-MHz, 10-microsecond bursts repeated at a frequency of 1 kHz at temporal peak acoustic pressure amplitudes ranging from 2 to 12.7 MPa. The total sonication time for each location is 20 seconds. Before each sonication, a bolus of US contrast agent is injected intravenously. Contrast-enhanced magnetic resonance (MR) images are then obtained after sonications to detect local enhancement in the brain. Whole brain histological evaluation is performed, and sections are stained with H & E, TUNEL (terminal deoxynucleotidyl transferase-mediated deoxyuridine triphosphate nick-end labeling), and vanadium acid fuchsin (VAF) to evaluate tissue effects, including apoptosis and ischemia.
Animal Model: Intact rabbit brains (e.g., n = 10).
Analysis and Interpretation: Both the magnetic resonance imaging (MRI) contrast enhancement and histology findings indicate that brain tissue damage is induced at a pressure amplitude level of 6.3 MPa. Induced pathological injury that can be detected includes vascular wall damage, hemorrhage, and, eventually, necrosis. Mild vascular damage can be observed localized in a few microscopic tissue volumes in about half of the sonicated locations at all pressure values tested (down to 2 MPa). However, these sonications do not induce any detectable tissue effects such as ischemia or apoptosis. Therefore, ultrasound exposure levels that are currently used for blood flow measurements within the brain are below the threshold of blood-brain barrier opening or brain tissue damage. However, it is important to note that brain damage can be induced if exposure levels are increased.
Instrumentation: Ultrasound instrumentation (1.5 MHz).

The threshold for brain damage in rabbits induced by bursts of ultrasound in the presence of an ultrasound contrast agent (Optison). Hynynen K, McDannold N, Martin H, Jolesz FA, Vykhodtseva N. Ultrasound Med Biol 2003 Mar; 29 (3), pp. 473–81.

Brain Parenchyma Acoustic Density/Influence of Dose
BR14 [Perfluorobutane-Based]/Trans-Cranial Gray-Scale Harmonic Imaging

Cellular/Molecular Mechanism of Action: The agent BR14 is a perfluorobutane-based compound that has an increased level of acoustic density compared to homogeneous biological fluids.

Application: BR14 is a perfluorobutane-based ultrasound contrast agent that can be used to image the brain parenchyma by transcranial gray-scale harmonic imaging (SONOS 5500, 1.8/3.6 MHz).
Route of Administration: BR14.
Dosage: BR14 (dose 1 = 0.05 ml/kg BW; dose 2 = 0.2 ml/kg BW).
Implementation: Trans-cranial gray-scale harmonic imaging of brain parenchyma facilitated by the administration of BR14 (perfluorobutane-based ultrasound contrast agent). Following bolus injection of 2 different doses of BR14, acoustic densitometry is performed to quantify changes in regional contrast intensity.

Animal Model: Canine (n = 6 beagles; sedated).
Analysis and Interpretation: In brain parenchyma (canine), the mean relative peak increase in acoustic intensity is +61% and +24% following the administration of high- and low-dose BR14, respectively. In the masticatory muscle, application of the higher dose results in a stronger increase in contrast intensity compared to lower dosage levels. Evaluation of the contralateral base of the skull shows a dose-dependent decrease in acoustic intensity. Bolus injection of BR14 produces an increase in acoustic intensity that can be used for visualization of contrast agent within the brain parenchyma. Using high dosages, a strong signal-enhancing effect in the regions near the ultrasound probe leads to a consecutive attenuation of signals from structures being located beyond ("shadowing effect"). This is the explanation for the paradoxical result that higher dosage levels lead to a lower peak signal increase within brain parenchyma.
Instrumentation: SONOS 5500, 1.8/3.6 MHz.

Harmonic imaging of the brain parenchyma using a perfluorobutane-containing ultrasound contrast agent. Seidel G, Meyer K, Algermissen C, Broillet A. Ultrasound Med Biol 2001 Jul; 27 (7), pp. 915–8.

Brain Perfusion/Neural Parenchyma
Contrast Echo-Enhanced Ultrasound

Advances in neurosonology have generated several techniques of ultrasonic perfusion imaging employing ultrasound echo-contrast agents (ECAs). Doppler imaging techniques cannot measure the low flow velocities that are associated with parenchymal perfusion. Ultrasonic perfusion imaging, therefore, is a combination of a contrast agent-specific ultrasound imaging technique (CAI) mode and a data acquisition and processing (DAP) technique that is suited to observe and evaluate perfusion kinetics. The intensity in CAI images is a measure of ECA concentration but also depends on various other parameters, (e.g., depth of examination). Moreover, ECAs can be destroyed by ultrasound, which is an artifact but can also be a desirable feature. Thus, many different DAPs have been developed for certain CAI techniques, ECAs and target organs. Although substantial progress in ECA and CAI technology can be foreseen, ultrasound contrast imaging has yet to reliably differentiate between normal and conditions associated with pathological levels of perfusion. Destructive imaging techniques, such as contrast burst imaging (CBI) or time variance imaging (TVI), in combination with new DAP techniques provide sufficient signal-to-noise ratios (SNR) for trans-cranial applications, and the potential to provide information regarding contrast agent kinetics and sufficient destruction to eliminate depth dependency and facilitate the calculation of semi-quantitative parameters. Because ultrasound machines are widely accessible and cost-effective, ultrasonic perfusion imaging techniques should become supplementary standard perfusion imaging techniques in acute stroke diagnosis and monitoring.

Brain perfusion and ultrasonic imaging techniques. Eyding J, Wilkening W, Postert T. Eur J Ultrasound 2002 Nov; 16, pp. 91–104.

Brain Perfusion: Cerebral/Physiological and Pathological Perfusion Differentiation in Brain Parenchyma Regions
Galactose-Based Microbubble Suspension (Levovist)

Cellular/Molecular Mechanism of Action: Microbubbles variably impede, absorb, and reflect ultrasound energy in a manner that is different from surrounding tissues or biological fluids.
Background Information: Contrast burst imaging (CBI) and time variance imaging (TVI) are new ultrasonic imaging modes that enable visualization of intravenously injected echo-contrast agents in brain parenchyma.
Application: Enhanced visual analysis of brain tissues utilizing echo-contrast agent-specific imaging modalities. Evaluation of cerebral perfusion in a capacity that may serve to differentiate physiological and pathological perfusion in different parenchymal regions of the brain.
Route of Administration: Galactose-based microbubble suspension (Levovist: intravenous).
Dosage: Galactose-based microbubble suspension (Levovist: 4 g dose; 400 mg/mg formulation).
Implementation: Evaluation of cerebral perfusion in a manner that may facilitate differentiation between physiological and pathological perfusion in different parenchymal regions of the brain. In this context, normal vascular structures can be characterized applying CBI and TVI ultrasound methodologies in concert with a galactose-based microbubble suspension (Levovist). Complementary evaluations include performing a dynamic susceptibility contrast magnetic resonance imaging (MRI) (e.g., p-MRI obtained for each case). In both ultrasound (US) methods and p-MRI, the time-intensity curves are calculated off-line. Absolute time to peak intensities (TPI), peak intensities (PI), and peak width (PW) of US investigations and TPI, relative cerebral blood flow (CBF), and relative cerebral blood volume (CBV) of p-MRI examinations are determined in the following regions-of-interest (ROIs): lentiform nucleus (LN), white matter (WM), posterior (PT), and anterior thalamus (AT). In addition, the M_2 segment of the middle cerebral artery (MCA) is evaluated by US, and the precentral gyrus (PG) can be examined in p-MRI examinations. In relation to a reference parenchymal ROI (AT), relative TPIs are compared between the US and p-MRI methods and relative PI of US investigations with the ratio of CBF (rCBF) of p-MRI examinations in identical ROIs.

Human Model: Cases with no vascular abnormalities examined applying CBI and TVI ultrasound imaging methodologies (e.g., n = 12).
Analysis and Interpretation: Mean TPI vary from 18.3 ± 5.0 (AT) to 20.1 ± 5.8 (WM) to 17.2 ± 4.9 (MCA) seconds in CBI examinations and from 19.4 ± 5.3 (AT) to 20.4 ± 4.3 (WM) to 17.3 ± 4.0 (MCA) seconds in TVI examinations. Mean PIs vary from 581.9 ± 342.4 (WM) to 1522.9 ± 574.2 (LN) to 3400.9 ± 621.7 arbitrary units (MCA) in CBI mode and from 7.5 ± 4.6 (WM) to 17.5 ± 4.9 (LN) to 46.3 ± 7.1 (MCA) arbitrary units in TVI mode. PW range from 7.3 ± 4.5 (AT) to 9.1 ± 4.0 (LN) to 24.3 ± 12.8 (MCA) seconds in CBI examinations and from 7.1 ± 3.9 (AT) to 8.7 ± 3.5 (LN) to 26.7 ± 18.2 (MCA) seconds in TVI examinations. Mean TPI is significantly shorter and mean PI and mean PW are significantly higher in the MCA compared with all other ROIs ($p < 0.05$). Mean TPI of the p-MRI examinations range from 22.0 ± 6.9 (LN) to 23.0 ± 6.8 (WM) seconds; mean CBF range from 0.0093 ± 0.0041 (LN) to 0.0043 ± 0.0021 (WM). There is no significant difference in rTPI in any ROI between US and p-MRI measurements ($p > 0.2$), whereas relative PIs are significantly higher in areas with lower insonation depth such as the LN compared with rCBF. Com-

pared to PI, TPI and rTPI in US techniques are robust parameters for the evaluation of cerebral perfusion and may help to differentiate between physiological and pathological perfusion patterns in different parenchymal regions of the brain.

Comparison between echo-contrast agent-specific imaging modes and perfusion-weighted magnetic resonance imaging for the assessment of brain perfusion. Meves SH, Wilkening W, Thies T, Eyding J, Holscher T, Finger M, Schmid G, Ermert H, Postert T; Ruhr Center of Competence for Medical Engineering. Stroke 2002 Oct; 33 (10), pp. 2433–7.

Brain Perfusion/Lentiform Nucleus/Thalamus/ Cerebral White Matter/Trans-Cranial Sonography *Optison*

Background Information: Perfusion trans-cranial sonography is a technique that can detect pathological alterations in brain tissue perfusion in conventional hospital environments (e.g., bedside).
Application: Imaging of cranial vascular structures applying methodologies such as perfusion trans-cranial sonography.
Implementation: Perfusion trans-cranial sonography (P-TCS) is performed in an axial insonation plane through the thalamus and 3rd ventricle. Signal increases induced by a bolus of an echo-contrast agent (Optison) are quantified within regions-of-interest (ROIs) corresponding with the thalamus (TH), lentiform nucleus (LN), and the cerebral white matter (WM).

Human Model: Cases suffering from Moyamoya disease and bilateral thalamic edema due to thrombosis of the internal cerebral veins, in addition to healthy negative reference controls (e.g., n = 10).
Analysis and Interpretation: In Moyamoya disease P-TCS is capable of demonstrating decreases in perfusion in the WM and LN as a result of bilateral, high-grade stenoses of the intracranial part of the internal carotid artery. Peak intensity can be increased in the TH due to collateral crossover flow from the vertebrobasilar system. Thalamus perfusion can be decreased in thrombosis of the internal cerebral vein thrombosis with normal LN perfusion. The extention of the thalamic edema into the white matter can also be demonstrated by decreased perfusion in the adjacent WM. Regions-of-interest ratios of different tissues can prove helpful in quantifying perfusion parameters.

Sonographic harmonic grey scale imaging of brain perfusion: Scope of a new method demonstrated in selected cases. Stolz E, Allendorfer J, Jauss M, Traupe H, Kaps M. Ultraschall Med 2002 Oct; 23 (5), pp. 320–4.

Cardiovascular/Artifact Reduction: Minimization (Color Blooming)/Echoscintigraphy *Microbubbles/SHU 563A*

Background Information: Echoscintigraphy is based on the recording and summation of low-intensity signals that are emitted during ultrasound (US)-induced destruction of microbubbles.
Application: Reduction of color blooming and acoustic shadowing in contrast sonography imaging analyses through the use of an alternative imaging modality (echoscintigraphy).
Route of Administration: Intravascular.
Implementation: Evaluation of a new imaging modality (echoscintigraphy) to reduce color blooming and acoustic shadowing in contrast sonography. One strategy that has been implemented to achieve this objective has involved the use of the prototype echo-contrast agent SHU 563A to enhance imaging using a flow phantom (artificial vessels) as a reference. Following the injection of various amounts of SHU 563A (700– 40,000 bubbles/mL), preparations are insonated in the intermittent harmonic-power Doppler imaging (H-PDI) mode. The amount of receive gain is varied from 50% to 75%. The cross-sectional area (CSA) of the tube can be assessed using a summation algorithm (echoscintigraphy) and a conventional single-frame analysis (S-FA) of the H-PDI signals.
Interpretation and Analysis: Application of the summation algorithm at low-contrast concentration allows a gain-independent automatic calculation of the CSA at medium and high gain settings. Using the S-FA method, assessment of vessel diameter and the CSA is gain dependent and allows correct measurements only from 60% to 65% gain. At a high receive gain and high contrast concentration, S-FA results in an overestimation of the CSA up to 35.5%. Echoscintigraphy allows correct display of contrast-filled vessels over a wide range of gain settings at low-contrast concentrations, where S-FA does not adequately display echo contrast. Thus, echoscintigraphy minimizes artifacts resulting from color blooming and acoustic shadowing.

Echoscintigraphy: A new imaging modality for the reduction of color blooming and acoustic shadowing in contrast sonography. Schlosser T, Pohl C, Kuntz-Hehner S, Omran H, Becher H, Tiemann K. Ultrasound Med Biol 2003 Jul; 29 (7), pp. 985–91.

Neurosonology: Trans-Cranial Doppler Sonography

Background Information: Temporal hyperostosis is the major limitation of trans-temporal insonation of the basal cerebral arteries in trans-cranial Doppler sonography. Alternative contrast agents capable of traversing the pulmonary bed offer new prospects for overcoming this limitation.
Application: Echo-contrast agents improve the diagnostic potentiality of ultrasound techniques, increasing the diagnostic accuracy of these methods in cerebrovascular diseases, vascular malformations, venous pathologies, and tumors, and may contribute to reducing the need for more invasive and expensive examinations.

Echo-contrast agents in neurosonology. Totaro R, Del Sette M, Marini C. Funct Neurol 1999 Oct–Dec; 14 (4), pp. 235–9.

GASTROINTESTINAL SYSTEM

Abdominal Mass Detection (Small)/Phlegmon and Abscess Differentiation/Crohn's Disease *Levovist*

Application: Contrast-enhanced power Doppler ultrasound performed with contrast media (e.g., Levovist) can be used to detect small inflammatory masses in Crohn's disease in addition to facilitating differentiation between phlegmon and abscess formation.
Route of Administration: Levovist (intravascular).
Implementation: Evaluation of abdominal inflammatory masses utilizing power Doppler ultrasound before and after intravenous administration of ultrasound contrast agent (e.g., Levovist). Particular focus is directed at characterizing the vascularity within and/or around inflammatory masses. Color Doppler flow images are categorized as clearly visible, minimally visible, or absent. Computed tomography images can serve as validation reference controls.

Human Model: Abdominal inflammatory masses (e.g., n = 28 cases).
Analysis and Interpretation: Power Doppler ultrasound performed after the administration of contrast medium can detect small inflammatory masses in Crohn's disease, particularly those under 2 cm in diameter (validated by computed tomography). Contrast-enhanced power Doppler ultrasound is a sensitive method for detecting small abdominal inflammatory masses and for differentiation between conditions of phlegmon and abscess formation.

Contrast-enhanced power Doppler ultrasound in the diagnosis and follow-up of inflammatory abdominal masses in Crohn's disease. Esteban JM, Aleixandre A, Hurtado MJ, Maldonado L, Mora FJ, Nogues E. Eur J Gastroenterol Hepatol 2003 Mar; 15 (3), pp. 253–9.

Microstructures of the Gastrointestinal System/ Enhanced Optical Coherence Tomography
Propylene Glycol

Cellular/Molecular Mechanism of Action: The contact of certain cell types and tissues with propylene glycol subtly modifies some of their individual physical properties.
Background Information: Optical coherence tomography (OCT) is a recently developed imaging technique that has the potential to advance the early diagnosis of diseases in the human gastrointestinal (GI) tract. However, the high scattering nature of GI tissue limits its imaging depth and contrast. For more effective diagnosis using OCT, a concurrent improvement of imaging depth and contrast is, therefore, needed.
Application: Enhancement of non-invasive imaging of the GI tract applying OCT.
Implementation: Evaluate the administration of chemical agents as a means of improving the capability of OCT imaging of clinically relevant microstructures of the GI tract. Tissue preparations are imaged with OCT within 0.5 to 2 hours of harvest. Immediately after the 1st OCT imaging of tissue specimens, about 0.5 ml of 80% propylene glycol solution is applied onto tissue surfaces and the tissue allowed to absorb the compounds for 20 minutes. Another image is then taken at the same position. The specimens are then embedded and stained in preparation for histologic evaluation. Co-registration of the images obtained using OCT before and after topical application of propylene glycol formulations and standard histopathologic processing provide a basis for comparison.

***Ex Vivo* Tissue Preparations:** Normal human GI tissues, including stomach and esophagus, were obtained from hospitalized patients.
Interpretation and Analysis: More detailed microstructures, including the basal layer position and the cellular composition of the mucosal layer of GI tract tissues, can be observed after the topical application of propylene glycol solution. These same structures are not resolvable with conventional OCT imaging methods. Propylene glycol could be used as a contrasting agent for OCT imaging of human GI tract tissues, allowing an increased capability of OCT for rapid *in vivo* clinical diagnoses.

Propylene glycol as a contrasting agent for optical coherence tomography to image gastrointestinal tissues. Wang RK, Elder JB. Lasers Surg Med 2002; 30 (3), pp. 201–8.

HEPATIC SYSTEM

Angiography/Liver Transplant: Postoperative Assessment/Angiography of Portal and Hepatic Venous Structures/Arteriography of Hepatic Arteries/Budd-Chiari Syndrome: Hepatic Vein Occlusion/Pretransplant: Portal Vein Patency ± Thrombus/Flow Direction/Cavernous Transformation/Posttransplantation: Hepatic Artery Thrombosis/Hepatic Artery Stenosis ± Pseudoaneurysm
Levovist Microbubbles

Background Information: Color Doppler ultrasound (US) is a well established technique for imaging of hepatic vessels in the assessment of pre- and post–liver transplant conditions. Unfortunately, a full-color Doppler US examination of the portal or hepatic venous and hepatic arterial systems is frequently precluded by technical factors.
Application: Ultrasound contrast agents are useful in enhancing vascular Doppler signal images and play an important role in liver transplantation assessment.
Route of Administration: Levovist microbubbles (intravascular).
Implementation: Evaluation of vascular abnormalities in the pretransplant candidate with specific emphasis on establishing aspects of (i) portal vein patency and direction of flow; (ii) presence of portal vein thrombus; and (iii) demonstration of cavernous transformations.
Analysis and Interpretation: Occlusion of hepatic veins in Budd-Chiari syndrome can be confidently confirmed. Following liver transplantation, contrast ultrasonography allows for comprehensive assessment of hepatic artery thrombosis, hepatic artery stenosis, and pseudoaneurysm formation. The need for further imaging is reduced or confidently deferred in many instances. Ultrasound contrast agents play an important role in liver transplant candidates.

Clinical use of Levovist, an ultrasound contrast agent, in the imaging of liver transplantation: Assessment of the pre- and posttransplant patient. Sidhu PS, Marshall MM, Ryan SM, Ellis SM. Eur Radiol 2000; 10 (7), pp. 1114–26.

Biliary Colic/(Sphincter of Oddi Spasm)
Codeine/(Ultrasound)

Cellular/Molecular Mechanism of Action: Codeine.
Application: Codeine can be a used as a provocative agent to improve ultrasound assessment of changes in common bile duct diameter and provides an effective approach in the diagnostic detection of sphincter of Oddi spasms.
Considerations: Biliary colic from spasm of the sphincter of Oddi is a condition that is relatively difficult to detect and characterize.
Analysis and Interpretation: Diagnosis can be established by (i) using a pharmacological provocative tests employing codeine to reproduce pain; (ii) detection of changes in liver and pancreatic serum enzymes; and (iii) ultrasound imaging to demonstrate a transient increase in common bile duct diameter. Implementation of such procedures prior to surgical sphincteroplasty reproduces symptoms and brings about marked elevations in pancreatic and liver enzyme fractions and increases in common bile duct diameter that can be measured by ultrasound examination (e.g., 0.4–1.0 cm). Such events often cannot be appreciated after sphincteroplasty.

Ultrasound in the diagnosis of sphincter of Oddi spasm. Berezny GM, Beck IT, DaCosta LR, O'Brien PG, Paloschi GB. J Clin Gastroenterol 1985 Dec; 7 (6), pp. 528–32.

Cirrhosis with Focal Lesions/Hepatocellular Carcinoma: Tumor Vessels/Hyperechoic and Hypoechoic Image Patterns
Levovist Microbubbles/Pulse Inversion Harmonic Imaging (PIHI)/Color Doppler and Power Doppler

Application: Detection and characterization of focal hepatic lesions in conditions of cirrhosis applying microbubbles (e.g., Levovist) as a hepatospecific contrast image-enhancing agent in combination with PIHI.
Route of Administration: Levovist (intravenous).
Implementation: Examination of cirrhosis cases with focal hepatic lesions initially utilizing conventional ultrasound (US), followed by evaluation using color Doppler (CD), power Doppler (PD)

with spectral analysis of tumoral vessels, and PIHI. The latter modality, PIHI, is performed 30 seconds (vascular phase) and 3–5 minutes (late phase) after Levovist injection.

Human Model: Cirrhosis cases with focal hepatic lesions (e.g., n = 25). To definitely characterize and evaluate focal hepatic lesions, helical-CT (HCT) enhancement patterns (e.g., n = 15 cases) and/or surgical/bioptic histologic findings (e.g., n = 10 cases) are utilized as reference procedures (e.g., n = 30 focal hepatic lesions classified as hepatocellular carcinoma [HCC]).

Analysis and Interpretation: In focal hepatic lesions classified as HCC by reference procedures, approximately 63% appear hypoechoic (e.g., n = 19/30); 17% appear isoechoic (e.g., n = 5/30); or 20% hyperechoic (e.g., n = 6/30) on conventional US and are accompanied by basket arterial patterns (e.g., n = 10/30), vessels within the tumor (e.g., n = 6/30), peripheral arterial patterns (e.g., n = 4/30), or no vascular pattern (e.g., n = 10/30) on CD and PD. On PIHI, acquired images appear hyperechoic (e.g., n = 26/30) or isoechoic (e.g., n = 4/30) in the vascular phase, if compared to the surrounding liver parenchyma, and hypoechoic (e.g., n = 23/30) or isoechoic (e.g., n = 7/30) in the late phase. Some lesions classified as regenerative nodules (RNs) by reference procedures appear hypoechoic on conventional US, with peripheral venous/arterial pattern (e.g., n = 1/4) or no vascular pattern (e.g., n = 3/4) on CD and PD. On PIHI, lesions appear hypoechoic (n = 3) or isoechoic (n = 1) in the vascular phase, and remain prevalently hypoechoic (n = 3) or isoechoic (n = 1) in the late phase. Hepatic lesions classified as hemangioma by reference procedures appear hyperechoic (e.g., n = 4/5) or hypoechoic (e.g., n = 1/5) on conventional US with few peripheral venous vessels on CD and PD. On PIHI, a progressive fill-in from the periphery toward the center during the vascular and late phase can be appreciated following microbubble (Levovist) injection. Pulse Inversion Harmonic Imaging seems to be a reliable technique to characterize focal lesions in cirrhotic patients.

Characterization of focal hepatic lesions in cirrhotic patients by Pulse Inversion Harmonic Imaging US contrast specific technique with Levovist. Quaia E, Forgacs B, Calderan L, Bertolotto M, Pozzi Mucelli R. Radiol Med (Torino) 2002 Oct; 104 (4), pp. 285–94.

Hepatic Lesion Characterization/Neoplasia: Hepatic Nodules (Malignant vs Benign)/Hepatic Cirrhosis vs Diffuse Parenchymal Liver Disease/ Backscatter Ultrasound
Microbubbles/Contrast Medium Transit Time

Cellular/Molecular Mechanism of Action: Modern ultrasound contrast media are gas-containing stabilized microbubble preparations that remain intact in the circulating blood for several minutes after intravenous injection and increase the intensity of backscattered ultrasound.

Background Information: When the microbubbles disappear from the blood, they can be detected in the parenchyma of the liver and the spleen for about 30 more minutes (late liver- and spleen-specific phase). The insonated microbubbles produce 2nd-harmonic ultrasound frequencies, whose detection requires non-conventional ultrasound modalities such as pulsed inversion imaging. Non-conventional ultrasound techniques can also be used without microbubbles because 2nd harmonics can be generated by ultrasound in tissues as well.

Application: Circulating microbubbles can be used not only to enhance weak Doppler signals but also to perform dynamic contrast studies. Contrast-enhanced dynamic ultrasound studies—similar to contrast-enhanced computed tomography (CT) and magnetic resonance imaging (MRI) examinations—have been used in humans to non-invasively characterize lesions (i.e., without biopsies) found during conventional ultrasound examinations. To map the distribution of contrast medium in a nodule or in an organ, specific scanning techniques such as stimulated acoustic emission have been developed. Stimulated acoustic emission occurs when high acoustic pressure ultrasonic waves disrupt the stationary or slowly moving microbubbles. This results in the release of a large amount of harmonic ultrasound frequencies. When the stimulated acoustic emission technique is used for dynamic studies, scanning must be interrupted several times to allow the microvasculature of the lesion to refill with microbubbles (interval delay imaging). The contrast patterns of malignant and benign hepatic nodules in humans have been the most intensively studied. Another type of dynamic study in humans measures the transit time of the contrast medium; that is, how fast the peripherally injected microbubbles reach the hepatic veins. Hepatic cirrhosis can be differentiated from other diffuse parenchymal liver diseases by a shorter transit time. Introducing non-conventional ultrasound techniques and ultrasound contrast media in veterinary diagnostic imaging may have potential value; however, intensive research should be carried out before ultrasound contrast agents can routinely be used in clinical practice.

A review of non-conventional ultrasound techniques and contrast-enhanced ultrasonography of non-cardiac canine disorders. Szatmári V, Harkányi Z, Vörös K. Vet Radiol Ultrasound 2003 Jul–Aug; 44 (4), pp. 380–91.

Kupffer Cell Phagocytic Function
Perfluorobutane Microbubbles: Sonazoid/ Radioiodinated Albumin

Cellular/Molecular Mechanism of Action: Perfluorobutane microbubbles (Sonazoid) are eliminated from the intravascular compartment by hepatic tissues (mononuclear phagocytic system or reticuloendothelial system).

Application: Detection and characterization of hepatic mononuclear phagocytic system integrity (sinusoidal macrophages).

Route of Administration: Perfluorobutane microbubbles (Sonazoid) can be infused intravascularly. In a research environment, they can also be infused *ex vivo* into fresh whole- liver preparations (e.g., rat).

Dosage: Perfluorobutane microbubbles (Sonazoid ≤ 20 times the anticipated clinical dose for hepatic imaging).

Implementation: Delineation of the cell type within the liver that is responsible for removing perfluorobutane microbubbles (Sonazoid) from the intravascular compartment and determination of their potential to disrupt the normal function of hepatic cell populations. Following intravascular injection of perfluorobutane microbubbles, hepatic tissue are harvested and analyzed by electron microscopy.

Animal Model: Administration of perfluorobutane microbubbles (Sonazoid) to rats intravascularly, and to perfused liver preparations.

Analysis and Interpretation: Electron microscopy reveals that perfluorobutane microbubbles (Sonazoid) are exclusively internalized within Kupffer cells (hepatic macrophages of the mononuclear phagocytic system) that line the liver sinusoids. The hepatic parenchymal, stellate, or endothelial cell populations do not appear to internalize the contrast agent. Uptake of perfluorobutane microbubbles (Sonazoid) by the Kupffer cells following injection of a dose corresponding to 20 times the anticipated clinical dose for liver imaging does not result in measurable changes in the uptake and degradation of radioactively labelled albumin microspheres previously shown to be a useful indicator marker for Kupffer cell phagocytosis.

Hepatic clearance of Sonazoid perfluorobutane microbubbles by Kupffer cells does not reduce the ability of liver to phagocytose or degrade albumin

microspheres. Kindberg GM, Tolleshaug H, Roos N, Skotland T. Cell Tissue Res 2003 Apr; 312 (1), pp. 49–54. Epub 2003 Feb 27.

Neoplasia: Hepatic Carcinoma Vascularity
Levovist

Cellular/Molecular Mechanism of Action: Microbubble preparations variably impede, absorb, and reflect ultrasound energy (acoustical impedance) in a manner that is different from surrounding tissues/organs and relatively homogenous biological fluids.
Application: Characterization of alterations is tissues, organ systems, vascular structures, and biological fluids.
Route of Administration: Microbubble preparations (e.g., Levovist) are most frequently administered intravascularly.
Implementation: Evaluate the usefulness of contrast-enhanced harmonic wideband gray-scale sonography to assess the therapeutic effects of trans-catheter arterial chemoembolization in conditions of hepatocellular carcinoma for comparison with findings from histopathological analysis. In this context, hepatocellular carcinoma lesion vascularity can be characterized before and 7 days after trans-catheter arterial chemoembolization. Imaging analysis is performed by contrast-enhanced harmonic wideband gray-scale sonography combined with the injection of an ultrasound contrast image-enhancing agent (Levovist). Biopsy specimens are obtained from the lesions evaluated, and the histologic findings compared with contrast-enhanced sonography images.

Human Model: Cases of hepatocellular carcinoma lesions (e.g., n = 29).
Analysis and Interpretation: Contrast-enhanced harmonic wideband gray-scale sonography performed after trans-catheter arterial chemoembolization can detect tumor vascularity in approximately half of hepatocellular carcinoma lesions evaluated (e.g., n = 16/29). Histopathology evaluation detects residual tumor in most lesions determined to have positive vascularity patterns (e.g., n = 13/16 lesions). In contrast, essentially all lesions without detectable tumor vascularity have no histologically evident tumor residue (e.g., n = 13/13). Some of these lesions may display tumor progression that can be detected by computed tomography (CT) imaging during 9 to 12-month follow-up periods (e.g., n = 3/13). Sensitivity and specificity of images for discerning viable and non-viable hepatocellular carcinoma after trans-catheter arterial chemoembolization is approximately 100% and 81%, respectively, based on comparisons between contrast-enhanced harmonic wideband gray-scale sonographic images compared with histopathology findings. Contrast-enhanced harmonic wideband gray-scale sonography is potentially useful for evaluating the therapeutic effects of trans-catheter arterial chemoembolization on hepatocellular carcinoma.

Contrast-enhanced harmonic gray-scale sonographic-histologic correlation of the therapeutic effects of trans-catheter arterial chemoembolization in patients with hepatocellular carcinoma. Morimoto M, Shirato K, Sugimori K, Kokawa A, Tomita N, Saito T, Imada T, Tanaka N, Nozawa A, Numata K, Tanaka K. AJR Am J Roentgenol 2003 Jul; 181 (1), pp. 65–9.

Neoplasia: Hepatic VX2 Tumor Carrier Model
Bubble Contrast Image-Enhancing Agent (Non-Destructive)/B-Mode Ultrasound/2nd-Harmonic Imaging (SHI)

Application: Enhanced detection and characterization of physiological conditions and pathological anomalies affecting tissues, organ systems, and vascular structures utilizing ultrasound-based diagnostic modalities.
Route of Administration: Ultrasound contrast image-enhancement agent (intravenous/rabbit ear vein).
Dosage: Ultrasound contrast image-enhancement agent (0.01 mL/kg for B-mode and 0.05 ml/kg for SHI).
Implementation: Hepatic VX2 tumors can be imaged with B-mode ultrasonography and by SHI (high mechanical index [MI] = 1.6 and low MI = 0.1). Echo agents can be intravenously injected through an ear vein (B-mode = 0.01 mL/kg; 0.05 ml/kg = high MI SHI). Venous channels are then evacuated with sterilized saline. Images are recorded by magnetic optics (MO) and analyzed further by direct visual inspection.

Animal Model: New Zealand rabbits (e.g., n = 6; mean = 2.7 ± 0.4 kg) developed as a construct hepatic VX2 tumor carrier model.
Analysis and Interpretation: Ultrasound (B-mode) is capable of detecting both hypoechoic and hyperechoic lesions with a mean size of about 2.1 ± 0.4 and are oval or round in shape. Such lesions appear to have a clear outline or a hypoechoic halo at their margin (e.g., n = 6 rabbits; n = 6 hypoechoic; n = 3 hyperechoic lesions). Ultrasound contrast agent does not change the echogenicity of the lesions under B-mode ultrasound and SHI under high acoustic pressure. However, contrast media greatly increases real-time visualization sensitivity of lesions with SHI under low acoustic pressure. Contrast-enhanced SHI with low MI and a bubble non-destructive method is a much more effective methodology for detecting and characterizing hepatic VX2 tumors than is conventional SHI for clinical applications.
Instrumentation: B-mode ultrasonography; SHI and MO.

Assessment of hepatic VX2 tumors of rabbits with 2nd-harmonic imaging under high and low acoustic pressures. Du WH, Yang WX, Wang X, Xiong XQ, Zhou Y, Li T. World J Gastroenterol 2003 Aug; 9 (8), pp. 1679–82.

Neoplasia: Hepatocellular Carcinoma (Angiography)/Response to Percutaneous Radio Frequency Abalation/Relative Effectiveness: 3-Phase Dynamic Computed Tomography (CT) vs Coded Harmonic Angiography
Levovist Microbubbles

Cellular/Molecular Mechanism of Action: Microbubbles variably impede, absorb, and reflect ultrasound energy in a manner that is different than surrounding tissues or biological fluids, which in turn are detected by imaging probes (detectors).
Application: Characterization of pathological conditions affecting organ systems (e.g., hepatic carcinoma) and vascular structures.
Route of Administration: Levovist microbubbles (intravenous).
Implementation: Evaluation of the capacity for microbubbles in contrast-enhanced coded phase-inversion harmonic sonography angiography to assess therapeutic responses to percutaneous radio frequency ablation of hepatocellular carcinoma lesions. The intratumoral blood vessels and tumor parenchymal stain are detected in the early arterial phase and the late vascular phase, respectively. The results of contrast-enhanced imaging with coded harmonic angiography are compared with those of 3-phase dynamic CT.

Human Model: Cases of hepatocellular carcinoma (e.g., n = 67 cases, n = 107 exams; n = 91 nodular lesions).
Analysis and Interpretation: The vast majority of hepatocellular carcinoma nodules are hypervascular on contrast-enhanced imaging with coded harmonic angiography (e.g., n = 107/107). Following radio frequency ablation, contrast-enhanced coded harmonic angiography detects persistent signal enhancement of nodules (e.g., n = 41/107 or 38.3%), whereas the technique shows no intratumoral enhancement in greater than half of examined nodules (e.g.,

n = 66/107 or 61.7%). Compared with dynamic CT, the sensitivity, specificity, and diagnostic accuracy of contrast-enhanced coded harmonic angio is approximately 95.3%, 100%, and 98.1%, respectively. With contrast-enhanced coded harmonic angiography, it is difficult to identify the safety margin that can be detected on dynamic CT. Contrast-enhanced imaging with coded harmonic angiography may provide an alternative diagnostic approach that has a high level of agreement with dynamic CT in assessing the therapeutic effect of radio frequency ablation in hypervascular hepatocellular carcinomas, in spite of having limitations in safety margin identification.

Radio frequency ablation of hepatocellular carcinoma: Therapeutic response using contrast-enhanced coded phase-inversion harmonic sonography. Wen YL, Kudo M, Zheng RQ, Minami Y, Chung H, Suetomi Y, Onda H, Kitano M, Kawasaki T, Maekawa K. AJR Am J Roentgenol 2003 Jul; 181 (1), pp. 57–63.

Neoplasia: Hepatocellular Carcinoma/ Hemangiosarcoma/Nodular Hyperplasia/Hepatic Metastases
Sulfur Hexafluoride Vapor Microbubbles

Cellular/Molecular Mechanism of Action: Microbubbles impede the unidirectional progression of ultrasound (US) energy through tissues, and therefore variably impede, absorb, and reflect a portion of the waves generated by the transducer.
Application: Enhancement of focal hepatic lesions.
Route of Administration: Intravascular.
Implementation: Determine if US performed with a microbubble contrast imaging agent (e.g., SonoVue), or a contrast agent containing microbubbles filled with sulfur hexafluoride (SF_6) vapor, produces differential patterns of contrast enhancement of focal hepatic lesions. Such an objective can be addressed by assessing hepatic lesions utilizing ultrasound, color Doppler ultrasound, and contrast-enhanced ultrasound performed in intermittent high-acoustic-power mode. Reference control procedures can consist of contrast-enhanced helical computed tomography (e.g., n = 11 cases) and US-guided fine needle aspiration (e.g., n = 28 cases). Contrast enhancement patterns are defined by means of both subjective and objective analysis. Baseline and contrast-enhanced ultrasound scans can be reviewed off-line.

Human Model: Focal hepatic lesions associated with various clinical conditions (n = 39 cases; n = 40 focal hepatic lesions; n = 15 hepatocellular carcinomas [HCCs]; n = 10 metastases; n = 11 hemangiomas; n = 4 focal nodular hyperplasias).
Interpretation and Analysis: Injection of SonoVue can correctly characterize a large number of conditions affecting the liver parenchyma (e.g., n = 13/15 HCCs; n = 8/10 metastases; and n = 4/4 hemangiomas) based on the appreciation of an atypical pattern (baseline ultrasound images). A low percentage of HCCs and metastases may remain "indeterminate" with no identification of characteristic baseline or contrast-enhanced patterns (e.g., n = 2/15 HCCs; n = 2/10 metastases).

Baseline ultrasound imaging analysis appears to be essential in characterizing all hemangiomas with a typical pattern (n = 7), and color Doppler ultrasound with spectral analysis of tumoral vessels is essential in characterizing focal nodular hyperplasia. The percent diagnostic agreement with reference procedures is significantly higher ($p < 0.001$) for contrast-enhanced US compared with baseline ultrasound. Therefore, characteristic patterns of ultrasound contrast enhancement with SonoVue help in characterizing and differentiating focal hepatic lesions.

US characterization of focal hepatic lesions with intermittent high-acoustic-power mode and contrast material. Quaia E, Bertolotto M, Calderan L, Mosconi E, Mucelli RP. Acad Radiol 2003 Jul; 10 (7), pp. 739–50.

Neoplasia: Malignant and Benign Mass Lesions/ Nodular Hyperplasia: Central Starlike Fill-In Patterns/Hemangioma
Levovist/Iminodiacetic Acid-Enhanced Scintigraphy

Cellular/Molecular Mechanism of Action: Microbubbles (e.g., Levovist) variably impede and absorb ultrasound energy. Because their acoustical impedance differs from surrounding tissues or more "homogenous" biological fluids, the properties can be detected by imaging probes.
Application: Detection and characterization of benign and malignant mass lesions affecting the liver, including conditions of nodular hyperplasia and hemangioma.
Route of Administration: Microbubbles (e.g., Levovist) are usually administered intravascularly.
Dosage: Levovist (2 g).
Implementation: Histopathology analysis can initially be performed on biopsy specimens collected from hepatic mass lesions. Complementary forms of diagnostic evaluation can entail the application of computed tomography or hepatic iminodiacetic acid-enhanced scintigraphy. Ultrasound images are then acquired after injection of Levovist injection and analysis performed in order to characterize the arrival of contrast media utilizing the interval delay imaging technique for 60 seconds.

Human Model: Cases with focal heptic lesions (e.g., n = 72; n = 42/72 malignant, n = 30 benign).
Analysis and Interpretation: The early arrival of Levovist at less than 30 seconds after injection can be used as an indicator for malignancy and has a specificity level of 67% and sensitivity of 60% ($p < 0.05$). The central starlike "fill-in" pattern as a sign for focal nodular hyperplasia has a level of specificity of 100% and sensitivity of 67% ($p < 0.001$). The rimlike pattern followed by centripetal fill-in as a sign for hemangioma has a specificity level of 100% and sensitivity of 18% ($p < 0.01$). Alternatively, the early diffuse stippled arrival pattern can be found in 60% of malignant lesions and also in 33% of cases of focal nodular hyperplasia and in some cases of adenoma (e.g., n = 1 case). Analysis of Levovist arrival time cannot distinguish between a malignant or benign lesion in individual cases. However, the central starlike arrival pattern is characteristic of focal nodular hyperplasia.

Pulse inversion sonography in the early phase of the sonographic contrast agent Levovist: Differentiation between benign and malignant focal liver lesions. von Herbay A, Vogt C, Haussinger D. J Ultrasound Med 2002 Nov; 21 (11), pp. 1191–200.

Neoplasia: Metastatic Cancer/Colorectal Carcinoma
Styrene Maleic Acid Neocarzinostatin [SMANCS/ Lipiodol (S/L)]

Background Information: Liver metastasis is the major cause of death in conditions of colorectal cancer. Surgical resection is at present the only curative option. Styrene maleic acid neocarzinostatin targets the unique vascular architecture of tumor blood vessels, which are hyperpermeable and lack a well-developed lymphatic system.
Implementation: Evaluation of changes in the tumor microvasculature associated with hepatic metastases detected by the application of scanning electron microscopy (SEM) of corrosion casts following S/L administation.

Animal Model: Murine (mice with hepatic metastatic lesions induced by intrasplenic injection of dimethylhydrazine-induced colon cancer cells). In this model tumor angiogenesis occurs at day 10, while exponential tumor growth occurs at day 16.
Analysis and Interpretation: Tumors treated with S/L at day 10 appear similar to day 10 controls. Tumor vessels, 50 ± 18 microm

in diameter, are easily identified from hepatic vessels. Within the hepatic sinusoids are avascular spaces, 144 ± 60 μm in diameter, that correspond to tumor cell aggregates at the initial stages of growth. Similarly, day 16 treated tumors appear comparable to day 16 controls. These vessels are narrower (84 ± 32 μm vs 150 ± 70 μm) than their control counterparts. This is in contrast to vessels (216 ± 36 μm in diameter) of a complex nature appreciated at 3 weeks.

S/L exerts a marked and immediate effect on the tumor microvessels at both the angiogenic and the exponential phases of tumor growth. This agent is effective at the microvascular level during inhibition of metastatic growth.

Changes in the microvascular architecture of colorectal liver metastases following the administration of SMANCS/lipiodol. Kuruppu D, Christophi C, Maeda H, O'Brien PE. J Surg Res. 2002 Mar; 103 (1), pp. 47–54.

Neoplasia: Metastatic Cancer/Detection Limits and Resolution/Comparisons with Contrast Helical Computed Tomography (CT) and B-Mode Ultrasound (US)
Levovist/Wideband Harmonic Imaging (WHI)

Application: Contrast-enhanced WHI can be applied to detect and characterize various types of hepatic metastases (nodules < 1 cm diameter).
Route of Administration: Microbubbles (Levovist) are most commonly given by intervascular injection depending on the diagnostic procedure of interest.
Dosage: Levovist at 2.5 g/dose (300 mg/ml).
Implementation: Evaluation of the capability of contrast-enhanced WHI to detect liver metastases compared to fundamental B-mode US and postcontrast CT. Conventional B-mode sonography can be applied to characterize hepatic metastatic lesions. Wideband harmonic imaging is performed 3 minutes after injection of Levovist contrast agent and postcontrast helical CT (HCT). The number and location of the lesions detected and the smallest lesion for individual cases are then recorded for comparison analysis.

Human Model: Cases suffering from hepatic metastases originating from different types of primary malignant lesions (e.g., n = 27).
Analysis and Interpretation: Comparisons reveal an increase in the number of lesions in harmonic mode compared with conventional B-mode images in cases with hepatic metastasis (e.g., n = 27/27) with a mean increase from 9.3 lesions with B-mode to 18.8 lesions with WHI. The smallest lesions are detected with WHI when compared with conventional US and helical CT (HCT) (2 mm with WHI, 5 mm with B-mode, and 5 mm with CT). Wideband harmonic imaging detects more lesions than conventional ultrasound or contrast HCT. Contrast-enhanced WHI appears to be superior to conventional US and HCT for the detection of hepatic metastases, especially for those nodules under 1 cm of diameter.

Improved detection of liver metastases with contrast-enhanced wideband harmonic imaging: Comparison with CT findings. Esteban JM, Molla MA, Tomas C, Maldonado L. Eur J Ultrasound 2002 Oct; 15 (3), pp. 119–26.

Neoplasia: Metastatic Carcinoma/Ring Enhancement Pattern (Early Phase)/Metastatic Carcinoma: Clear Contrast Defect (Delayed Phase)/ Gray-Scale Conventional vs Harmonic Imaging/ Lesion Neovascularization
Sonazoid

Cellular/Molecular Mechanism of Action: Sonazoid possesses a different level of acoustical impedance compared to tissues, organ systems, and "homogenous" biological fluids.
Application: Detection and characterization of hepatic neoplastic lesions (rabbit tumor model).
Route of Administration: Sonazoid echo-enhancing agent (intravenous).
Implementation: Examination of normal livers with Sonazoid echo-enhancing contrast imaging agent utilized in concert with the ultrasonographic imaging modes (i) gray-scale conventional; and (ii) harmonic performed as a time-related analysis. Data is evaluated quantitatively and visually with tumor-model rabbits in order to estimate the diagnostic potential of each modality.

Animal Model: Rabbit liver (*in vivo* normal vs tumor model).
Interpretation and Analysis: Peak enhancement of vessels and parenchyma is observed 1 minute after injection of Sonazid echo-enhancing contrast agent when evaluated with both modes. Signal enhancement in the parenchyma lasts for 120 minutes compared with rapid decay (5–10 minutes) within vessels. When Sonazoid is intravenously injected into metastatic carcinoma-model (VX-2) rabbits, all hepatic tumors show ring enhancement in the early phase, followed by clear contrast defects in the delayed phase because signal enhancement remains only in normal parenchyma. Visual analysis scores for the diagnosis of tumors are improved by Sonazoid injection, and the videodensitometric differences between tumor and normal tissues are significantly greater after injection. Although the harmonic mode tends to show better contrast effects, the conventional mode provides significant contrast enhancement in this hepatic tumor model. Sonazoid might be useful for the detection of undifferentiated tumors in the liver by making it possible to visualize neovascularity in the early phase and clear contrast defects in the delayed phase, not only in the harmonic but also in the conventional mode.

Gray-scale liver enhancement with Sonazoid (NC100100), a novel ultrasound contrast agent: Detection of hepatic tumors in a rabbit model. Watanabe R, Matsumura M, Chen CJ, Kaneda Y, Ishihara M, Fujimaki M. Biol Pharm Bull 2003 Sep; 26 (9), pp. 1272–7.

Neoplasia: Metastatic and Primary/Hepatocellular Carcinoma (HCC)/Hemangioma/Nodular Hyperplasia/Metastases
Microbubble Contrast Agent Prototype (SHU 508 A)

Application: Detection and characterization of physiological conditions and pathological anomalies affecting tissues, organ systems, and vascular structures when used in combination with ultrasound-based imaging modalities.
Route of Administration: Prototype microbubble contrast agent (SHU 508 A) injected intravenously.
Implementation: Evaluate the degree that the microbubble contrast agent SHU 508 A enhances lesion characterization capabilities (imaging profiles) of various focal hepatic lesions utilizing contrast-enhanced gray-scale harmonic ultrasound (US) in combination with coded harmonic angio (CHA) techniques to enhance lesion characterization capabilities. Procedures are performed with a combination of continuous scanning to assess the intratumoral vasculature (vascular imaging) and interval-delay scanning to determine the sequential enhancement pattern (acoustic emission imaging).

Human Model: Hepatic lesions (e.g., n = 95 cases; n = 105 focal lesions; n = 51/105 hepatocellular carcinoma, n = 22/105 metastases, n = 22/105 hemangiomas, n = 4/105 nodular hyperplasia, n = 6/105 non-tumerous nodules).
Analysis and Interpretation: Of the total number of vascular images acquired, approximately 69% of hepatocellular carcinomas show irregular branching vessels (e.g., n = 35/51 HCCs), while 91%

of metastases (e.g., n = 20/22) display a peripherally stippled pattern. Intratumoral vessels are absent in about 95% of hemangiomas (e.g., n = 21/22) and all non-tumorous lesions (e.g., n = 6/6), while approximately 75% of focal nodular hyperplasias display a spoke-wheel pattern (e.g., n = 3/4). In acoustic emission imaging, 71% of HCCs (e.g., n = 36/51) show heterogeneous enhancement and 86% (e.g., n = 19/22) of metastases showed rim- or flamelike peripheral enhancement during the early phase, with washout occurring in essentially all hepatocellular carcinomas and metastases during the late phase (e.g., n = 73/73 or 100%). In hemangiomas, enhancement is either peripheral and nodular (e.g., n = 19/22 or 86%) or persistent and homogeneous (e.g., n = 3/22 or 14%), and 75% of focal nodular hyperplasias (e.g., n = 3/4) become isoechoic during the late phase. Utilizing contrast-enhanced gray-scale US and the CHA technique, a period of continuous scanning reveals the intratumoral vasculature pattern, and interval-delay scanning demonstrates the sequential enhancement pattern. The characteristic findings of various focal hepatic lesions can then be determined.

Focal hepatic lesions: Evaluation with contrast-enhanced gray-scale harmonic US. Jang HJ, Lim HK, Lee WJ, Kim SH, Kim MJ, Choi D, Lee SJ, Lim JH. Korean J Radiol 2003 Apr–Jun; 4 (2), pp. 91–100.

Neoplasia: Metastatic and Primary/Hemangioma/Hepatocellular Carcinoma/Cholangiocellular Carcinoma/Hepatic Metastases/Sensitivity and Specificity

Sonocontrast Agent/Contrast-Enhanced Power Doppler Sonography

Application: Detection and characterization of liver hemangiomas and various forms of hepatic neoplastic disease applying contrast-enhanced power Doppler sonography.
Route of Administration: Sonocontrast agent (intravascular bolus).
Implementation: Classification of the distribution (peripheral, central, mosaic) and extent (none, minimal, moderate, and strong) of intratumoral flow pattern in sonographic images acquired in conditions of hepatic neoplasia.

Human Model: Cases with hepatic neoplasia (e.g., n = 45 cases; n = 57 tumors; n = 22 hemangiomas; n = 24 metastases; n = 10 hepatocellular carcinoma (HCC); n = 1 cholandiocellular carcinoma).
Analysis and Interpretation: The administration of the sonocontrast agent by bolus injection causes enhancement to gradually increase up to 2 minutes and lasts for 4 to 5 minutes. After injection of contrast agent, flow signals appear or increase in 59% of tumors (e.g., n = 34/57). No signal enhancement is observed in most hemangiomas (e.g., n = 18/22), 15% of metastases (e.g., n = 4/22), and 10% of hepatocellular carcinoma (e.g., n = 1/10). The sensitivity and specificity of intratumoral vascularity for the detection of malignant liver tumors is 37.1% and 90.9% for unenhanced power Doppler sonography, and 85.7% and 81.8% for contrast-enhanced power Doppler sonography, respectively. Contrast-enhanced power Doppler sonography is superior to unenhanced power Doppler sonography in the demonstration of malignant tumor vascularity, and is helpful in differentiating between hemangiomas and malignant liver tumors. A specific flow pattern within the tumor is not established in primary and metastatic malignant tumors with contrast-enhanced power Doppler sonography.

Contrast media-enhanced power Doppler sonography for evaluation of hemangiomas and malignant tumors in the liver. Karabacakoglu A, Karakose S, Cil AS, Kaya A. J Gastroenterol Hepatol 2003 Jan; 18 (1), pp. 92–8.

Neoplasia: Vascularity Patterns (Hepatic)/Differential Diagnoses

Levovist Microbubbles

Cellular/Molecular Mechanism of Action: Microbubble preparations possess a different level of acoustic impedance compared to homogenous biological fluids.
Application: Enhance the detection and characterization of physiological processes and anomalies of tissues (e.g., hepatic neoplasias) and vascular structures visualized with the aid of color Doppler imaging modalities.
Route of Administration: Levovist microbubbles (intravenous).
Implementation: Determine the efficacy of using an ultrasound contrast agent (Levovist) to enhance the color Doppler ultrasound imaging of liver neoplasms. One aspect of such analyses can involve delineating the profiles of vascular structures within normal compared to neoplastic hepatic lesions.

Human Model: Cases with hepatic neoplasia (e.g., n = 39).
Analysis and Interpretation: Contrast image-enhanced color Doppler is capable of detecting various hepatic tumors that possess different patterns of lesion vascularity.

In conditions of hepatocarcinoma, a rather unique image signal can be observed in the central region of tumors (e.g., n = 11/16). Conversely, metastatic liver lesions generate enhanced color Doppler signals that appear only at the tumor periphery (e.g., n = 3/16). A rimlike color enhancement can be seen in many of these lesions (e.g., n = 2/3). In cases with hepatic hemangiomas, contrast-enhanced color Doppler imaging demonstrates blood vessels at the margin of neoplasms (e.g., n = 6). In this context, contrast-enhanced color Doppler imaging improves the visualization of hepatic neoplasm vascularity. Such techniques can potentially detect small liver tumors and serve as an approach for differentiating various types of hepatic neoplasms.

Feasibility study of an ultrasound contrast agent (Levovist) in color Doppler imaging of liver neoplasms. Jiang Y, Dai Q, Liu J, Zhang J, Chang X, Cai S, Tan L. Chin Med Sci J 1999 Sep; 14 (3), pp. 167–9.

Neoplasia: Vascularity and Architecture (Hepatic)

Optison/Contrast-Enhanced Power Doppler Sonography (CEPD)/Phase Inversion Harmonic Imaging (PIHI)

Application: Optison is an echo-enhancing agent that can be utilized for the detection and characterization of alterations in vascular structures associated with liver pathology, including neoplastic disease.
Route of Administration: Optison (intravascular).
Implementation: Assessment of liver lesion vascularity and characterization of focal liver lesions applying CEPD and PIHI in combination with Optison as an echo-enhancing agent. Extent and architecture of lesion vascularity, in addition to the kinetics of contrast enhancement within lesions, can also be evaluated.

Human Model: Focal liver lesions (e.g., n = 101).
Analysis and Interpretation: Analysis of tumor vascularity may not be possible in approximately 30% of cases (e.g., n = 30/101) due to motion or blooming artifacts produced by CEPD. Vascularity can be detected in 61% of liver lesions by CEPD and in 95% by PIHI. Phase inversion harmonic imaging identifies significantly more tumor vascularity pattern (93%) than CEPD (57%). Specific lesion diagnosis based on PIHI can result in correct results in 92% compared to 59% of cases utilizing CEPD. Phase inversion harmonic imaging is highly efficient in detecting tumor vascularity and is superior to CEPD in characterizing focal liver lesions.

Phase inversion harmonic imaging vs contrast-enhanced power Doppler sonography for the characterization of focal liver lesions. Strobel D, Raeker S, Martus P, Hahn EG, Becker D. Int J Colorectal Dis 2003 Jan; 18 (1), pp. 63–72. Epub 2002 May 04.

IMMUNE SYSTEM

Lymph Nodes: Regional
Poly(Ethylene Glycol) (PEG)-Coated Magnetite Nanospheres

Semi-Synthetic Methods: Magnetite nanospheres can be prepared with a grafted PEG layer using various PEG lengths from 350 to 1,000 Da. Thermogravimetric analysis is utilized to measure the adsorbed amount of PEG. Colloid stability is confirmed by measurement of particle size and electrophoretic mobility.
Implementation: Evaluation of injection site drainage kinetics and lymph node retention 2 hours after subcutaneous administration of nanospheres coated with PEG lengths of 350, 550, 750, and 1,000 Da. For 750 PEG-coated nanospheres, the kinetics of distribution can be determined over a 48-hour time course.
Interpretation and Analysis: The distribution of the nanospheres is modified and the lymph node localization is enhanced by altering the surface coverage of PEG on the magnetic surface. PEG-coated magnetite nanospheres with different surface characteristics can be utilized to target a diagnostic agent for regional lymph nodes.

Development of systems for targeting the regional lymph nodes for diagnostic imaging: *In vivo* behavior of colloidal PEG-coated magnetite nanospheres in the rat following interstitial administration. Illum L, Church AE, Butterworth MD, Arien A, Whetstone J, Davis SS. Pharm Res 2001 May; 18 (5), pp. 640–5.

Lymph Nodes: Sentinel Nodes for Neoplasia/ Normal vs Metastatic
Carbon Dioxide Microbubbles

Background Information: Although endoscopic ultrasonography is considered the most useful diagnostic modality for regional staging, the capability of diagnosing lymph node metastasis based on endoscopic ultrasonography images alone is not sufficient. To improve the effectiveness of differential diagnosis of lymph node enlargement, contrast-enhanced echolymphography can be performed using endoscopic ultrasonography-guided puncture.
Implementation: Evaluation of the ability of contrast-enhanced echolymphography to differentiate between normal and metastatic lymph nodes. Lymph nodes are punctured under real-time endoscopic ultrasonography guidance, and carbon dioxide microbubbles can be injected to evaluate echo profiles and features before and after microbubbles injection.

***Ex Vivo* Model:** Metastatic lymph nodes (n = 8) surgically resected from cases with gastrointestinal cancers (*in vitro* study).

Human Model: Cases with abdominal lymph node swelling detected by endoscopic ultrasonography (n = 55).
Interpretation and Analysis: Contrast-enhanced echolymphography of freshly resected metastatic lymph nodes show nonhomogeneous echo patterns. In regions demonstrating filling defects detected by contrast-enhanced echolymphography, neoplastic infiltration pathology can be observed. In almost all of the malignant lymph nodes studied *in vivo*, filling defects and heterogeneous enhancements can be observed by contrast-enhanced echolymphography. However, contrast-enhanced echolymphography demonstrates uniform patterns in most of the benign group. Sensitivity, specificity, positive and negative predictive value, and accuracy of differential diagnosis by contrast-enhanced echolymphography are 95.8%, 90.3%, 88.5%, 96.6%, and 92.7%, respectively. Contrast-enhanced echolymphography is a useful method that aids in differentiating between reactive responses and malignant alterations affecting lymph nodes.

Differentiation of benign and malignant lymph nodes with contrast-enhanced echolymphography using endoscopic ultrasound-guided puncture. Kojima S, Goto H, Hirooka Y, Itoh A, Ishiguro Y, Hashimoto S, Hirai T, Hayakawa T. Hepatogastroenterology 2003 Sep–Oct; 50 (53), pp. 1285–91.

MUSCULOSKELETAL SYSTEM

Articular Cartilage/Cartilage Volume and Thickness Estimation/Ultrasonography Compared to Computed Tomography (CT)
Ultrasound Contrast Image-Enhancing Agent

Background Information: A non-invasive imaging technique that can quantify articular cartilage is needed for diagnosis, monitoring, and therapeutic control of osteoarthritis.
Route of Administration: Ultrasound contrast image-enhancing agent (intra-articular).
Implementation: Evaluate the accuracy of 3-dimensional cartilage volume and thickness measurements in the knee with magnetic resonance imaging (MRI) analysis. Such investigations can involve the use of of cadaveric specimens evaluated by sagittal imaging with a fat-suppressed gradient echo sequence. Following contrast agent injection, 2 sagittal computed tomography data sets are obtained, with knee joints repositioned between the examinations. Cartilage thickness is determined, after 3-dimensional reconstruction, using a minimal distance algorithm.

Human Model: Cadaveric specimens (e.g., n = 8).
Analysis and Interpretation: The mean absolute volume deviation between MRI and CT arthrography is 3.3% and that between the 2 computed tomography data sets is 3.6%. The absolute error in determining the maximal cartilage thickness with MRI is on average 0.6 intervals (of 0.5-mm thickness) and that between the CT examinations is 0.5 intervals. In some cases with anterior knee pain, a focal cartilage defect can be seen with MRI, and this can be verified by arthroscopic examination. Using 3-dimensional image processing, MRI can provide accurate data on cartilage volume and thickness in the human knee joint surfaces. This imaging technique potentially may be valuable in the treatment of patients with joint disease.

Accuracy of cartilage volume and thickness measurements with magnetic resonance imaging. Eckstein F, Schnier M, Haubner M, Priebsch J, Glaser C, Englmeier KH, Reiser M. Clin Orthop 1998 Jul (352), pp. 137–48.

Rheumatoid Arthritis/Intra-Articular Vascularization Patterns
Levovist Microbubbles

Application: Microbubbles (Levovist) can be applied to detect and characterize various forms of joint pathology. In cases of rheumatoid arthritis, this contrast agent can improve the detection of increased patterns of intra-articular vascularization between individual joints.
Route of Administration: Levovist microbubbles (intravenous).
Implementation: Assess the usefulness of contrast-enhanced color Doppler ultrasound (CDUS) in the evaluation of intra-articular vascularization pathology of finger joints in patients with rheumatoid arthritis (RA). Prior to image analysis of individual joints, varying levels of inflammation can be classified as active, moderately

active, or inactive. Contrast-enhanced CDUS is performed with a high-frequency multi-D linear array transducer. A microbubble-based US contrast agent (Levovist) is intravenously infused for image enhancement. Doppler findings are rated on the basis of both unenhanced and CDUS images.

Human Model: Rheumatoid arthritis (e.g., n = 198 fingers; n = 46 patients; n = 10 controls; n = 80 control fingers).

Analysis and Interpretation: Healthy joints show no intra-articular vascularization on either unenhanced or contrast-enhanced CDUS. Unenhanced CDUS detects intra-articular vascularization in approximately 8% of inactive joints (e.g., n = 7/83); in 52% of moderately active joints (e.g., n = 31/60); and in 58% of active joints (e.g., n = 32/55). Contrast-enhanced CDUS can detect intra-articular vascularization in 49% of inactive rheumatoid arthritis joints (e.g., n = 41/83); 98% of moderately active rheumatoid arthritis joints (e.g., n = 59/60); and essentially all active rheumatoid arthritis joints (e.g., n = 55/55). Detection of intra-articular vascularization is improved by the administration of a microbubble-based US contrast agent ($p < 0.001$). Contrast-enhanced CDUS can detect differences in intra-articular vascularization between joints with inactive rheumatoid arthritis and those with active rheumatoid arthritis ($p < 0.001$), between joints with inactive rheumatoid arthritis and those with moderately active rheumatoid arthritis ($p < 0.001$), and between joints with moderately active rheumatoid arthritis and those with active rheumatoid arthritis ($p < 0.001$).

The use of a microbubble-based US contrast agent significantly improves the detection of intra-articular vascularization in rheumatoid arthritis–affected finger joints. Such imaging techniques seem to be a useful adjunct in the assessment of disease activity.

Instrumentation: Color Doppler ultrasound equipped with a high-frequency multi-D linear array transducer.

The value of contrast-enhanced color Doppler ultrasound in the detection of vascularization of finger joints in patients with rheumatoid arthritis. Klauser A, Frauscher F, Schirmer M, Halpern E, Pallwein L, Herold M, Helweg G, ZurNedden D. Arthritis Rheum 2002 Mar; 46 (3), pp. 647–53.

Rheumatoid Arthritis/Knee: Increased Intra-Articular Vascular Perfusion/Inflammatory vs Non-Inflammatory Pannus
Levovist Microbubbles

Application: Detection and characterization of physiological alterations and pathological anomalies affecting tissues, organ systems, and vascular structures using ultrasound diagnostic modalities.

Route of Administration: Levovist ultrasound contrast image-enhancing agent (intravenous).

Implementation: Evaluation of the ability for Levovist microbubble preparations to detect, characterize, and distinguish between conditions of rheumatoid arthritis (inflammatory pannus) and non-inflammatory pannus affecting the knee joint. In this context, knee joints can be examined utilizing conventional ultrasonography and power Doppler ultrasonography before and after injection of intravenous ultrasound contrast agent (Levovist). The quantitative estimation of the vascularization of the synovial membrane is performed with time-intensity curves and calculation of the area-under-the-curve (AUC).

Human Model: Cases of rheumatoid arthritis of the knee (e.g., n = 42; n = 31 women) with the index of synovitis activity classified as active, moderately active, or inactive). Clinical and functional assessment (number of swollen joints, intensity of pain, general health-visual analogue scale, disability index-Health Assessment Questionnaire, Ritchie articular index) and laboratory evaluations are performed in addition to establishing the level of disease activity according to the calculation of a disease activity score (DAS) and the chronic arthritis systemic index (CASI) for each individual case.

Analysis and Interpretation: The mean (SD) value of the area underlying time-intensity curves is 216.2 (33.4) in conditions of active synovitis, 186.8 (25.8) with moderately active synovitis, and 169.6 (20.6) in conditions of inactive synovitis. The mean value of the areas differs significantly between cases with active compared to inactive synovitis ($p < 0.01$). The mean value of the AUC of the entire group is weakly correlated with the number of swollen joints ($p = 0.038$), but a strong correlation is found with composite indexes of disease activity such as the DAS ($p = 0.006$) and CASI ($p = 0.01$). No correlation can be appreciated with age, disease duration, and other laboratory and clinical variables.

Power Doppler ultrasonography may be a valuable tool to detect fractional vascular volume and to assist clinicians in distinguishing between inflammatory and non-inflammatory pannus. The transit of microbubbles of ultrasound contrast across a tissue can be used to estimate hemodynamic alterations and may have a role in assessing synovial activity and the therapeutic response to treatment of synovitis of the knee joint.

Power Doppler sonography in the assessment of synovial tissue of the knee joint in rheumatoid arthritis: A preliminary experience. Carotti M, Salaffi F, Manganelli P, Salera D, Simonetti B, Grassi W. Ann Rheum Dis 2002 Oct; 61 (10), pp. 877–82.

Rheumatoid Arthritis/Shoulder Joint: Poor Synovitis Detection and Differentiation of Synovial Inflammation
Levovist Microbubble Contrast Agent

Application: Using magnetic resonance imaging (MRI) as the "gold standard," power Doppler ultrasonography with and without echo-enhancing contrast agent cannot reliably identify synovitis or distinguish synovial inflammation from effusion in the shoulder joint.

Dosage: Levovist microbubble echo-enhancing contrast agent (2.5 g, 300 mg/ml).

Implementation: Evaluation of 1 symptomatic shoulder affected by rheumatoid arthritis utilizing conventional gray-scale sonography and power Doppler ultrasonography before and after intravenous administration of Levovist microbubble echo-enhancing contrast agent.

The degree and extent of altered echo patterns in the subacromial bursa, axillary recess, and glenohumeral joint seen by conventional gray-scale sonography and the intensity of vascular signals of power Doppler ultrasonography are compared with findings from MRI results obtained with T_2-weighted turbo spin-echo sequences and contrast-enhanced T_1-weighted fat-saturated spin-echo sequences. To increase the objectivity of the analysis, MRI findings can be evaluated by 2 readers without knowledge of the sonographic findings.

Human Model: Cases of rheumatoid arthritis affecting the shoulder (e.g., n = 24; mean age = 64).

Analysis and Interpretation: Reference standard MRI examinations can detect joint effusion in 71% (e.g., n = 17/24) and synovitis in 92% (e.g., n = 22/24) of affected cases. Conventional sonography reveals an abnormal articular echo pattern in 96% (e.g., n = 23/24) of cases, particularly in the axillary recess and subacromial bursa. Unfortunately, conventional sonography fails to attribute altered echo patterns to either fluid or specific synovitis. Power Doppler ultrasonography can facilitate establishing a specific diagnosis of synovitis in 33% of affected cases (e.g., n = 8/24), but the simultaneous administration of echo-enchaning contrast agent

increases this parameter to 50% (e.g., n = 12/24). In 42% of affected cases (e.g., n = 10/24), the findings of synovitis demonstrated by MRI correspond to an altered echo pattern by conventional sonography, but vascular signals are absent with power Doppler ultrasonography either with or without echo-enhancing contrast agent. Using MRI as the "gold standard," power Doppler sonography with and without echo-enhancing contrast agent cannot reliably identify synovitis or distinguish synovial inflammation from effusion in the shoulder joint.

Instrumentation: power Doppler ultrasonography and MRI instrumentation with T_2-weighted turbo spin-echo and contrast-enhanced T_1-weighted fat-saturated spin-echo capabilities.

Power Doppler sonography with and without echo-enhancing contrast agent and contrast-enhanced MRI for the evaluation of rheumatoid arthritis of the shoulder joint: Differentiation between synovitis and joint effusion. Wamser G, Bohndorf K, Vollert K, Bücklein W, Schalm J. Skeletal Radiol 2003 Jun; 32 (6), pp. 351–9.

NEOPLASIA

Arteriography of Neoplastic Lesions/Hepatocellular Carcinoma: Response to Percutaneous Radio Frequency Ablation/Relative Effectiveness: 3-Phase Dynamic Computed Tomography (CT) vs Coded Harmonic Angiography
Levovist Microbubbles

Cellular/Molecular Mechanism of Action: Microbubbles variably impede, absorb, and reflect ultrasound energy in a manner different from surrounding tissues, organ systems, or biological fluids.

Application: Microbubbles can be utilized in concert with contrast-enhanced coded phase-inversion harmonic sonography to assess the therapeutic response of hepatocellular carcinoma to percutaneous radio frequency ablation.

Route of Administration: Microbubbles (Levovist) can be infused into the intravascular compartment and into certain other body compartments.

Implementation: Evaluation of hepatocellular carcinoma nodules applying coded harmonic angiography (e.g., coded phase-inversion harmonic sonography) facilitated by the application of microbubble contrast image-enhancing agents before and after percutaneous radio frequency ablation. Intratumoral blood vessels and tumor parenchymal stain can be detected in the early arterial phase and late vascular phase, respectively. The results of contrast-enhanced imaging with coded harmonic angiography can subsequently be compared with those of 3-phase dynamic CT.

Human Model: Cases of hepatocellular carcinoma nodules (e.g., n = 67 cases, n = 107 exams; n = 91 nodular lesions).

Analysis and Interpretation: The vast majority of hepatocellular carcinoma nodules display hypervascular patterns on contrast-enhanced imaging with coded harmonic angiography (e.g., n = 107/107). Following radio frequency ablation, contrast-enhanced coded harmonic angiography detects a persistent signal enhancement of nodules (e.g., n = 41/107 or 38.3%), but the methodology shows no intratumoral enhancement in more than half of examined nodules (e.g., n = 66/107 or 61.7%). Compared with dynamic CT, the sensitivity, specificity, and diagnostic accuracy of contrast-enhanced coded harmonic angiography is approximately 95.3%, 100%, and 98.1%, respectively. With contrast-enhanced coded harmonic angiography, it is difficult to identify the safety margin that can be detected on dynamic CT. Contrast-enhanced imaging with coded harmonic angiography may provide an alternative approach that provides high diagnostic agreement with dynamic CT in assessing the therapeutic effect of radio frequency ablation in hypervascular hepatocellular carcinomas. However, it also has limitations in identifying safety margin parameters.

Radio frequency ablation of hepatocellular carcinoma: Therapeutic response using contrast-enhanced coded phase-inversion harmonic sonography. Wen YL, Kudo M, Zheng RQ, Minami Y, Chung H, Suetomi Y, Onda H, Kitano M, Kawasaki T, Maekawa K. AJR Am J Roentgenol 2003 Jul; 181 (1), pp. 57–63.

Assimilation Enhancement of Neoplasia/Enhanced Selective Systemic/Local-Regional Uptake/Slowing of Local-Regional Blood Flow
Starch Microspheres/Small Unilamellar Vesicles (SUV)-Polyethylene Glycol (PEG) Liposomes

Physiological Mechanism of Action: Starch microspheres can be used to slow local-regional blood flow in a manner that can maximize assimilation of encapsulated liposomes into neoplastic lesions.

Background Information: Systemic adjuvant chemotherapy achieves unsatisfactory results for inoperable liver tumors and metastases. Various clinical studies have shown that loco-regional chemotherapy increases survival rate by several months.

Application: Enhancement of systemic and local-regional uptake of diagnostic and therapeutic pharmaceutical agents.

Route of Administration: Systemic and direct local-regional injection.

Implementation: Evaluate the capacity of liposome encapsulation to selectively facilitate local-regional/systemic targeting of neoplastic cell populations with cytostatic 5-fluouracil (5-FU).

Interpretation and Analysis: Tumor concentrations of 5-FU encapsulated in SUV-PEG liposomes increases by a factor of 27 in systemic therapy and a factor of 90 in loco-regional therapy. The tumor concentration of 5-FU increases by a factor of 8,000 if the blood flow is additionally slowed by starch microspheres (Spherex) during loco-regional therapy with 5-FU encapsulated within liposome preparations.

Liposome encapsulation of cystostatic drugs and starch microspheres improve tumor targeting in loco-regional therapy. An animal experiment study of CC 531 liver tumor. Berger G, Reszka R, Pohlen U, Jung M, Lucas S, Buhr HJ. Langenbecks Arch Chir Suppl Kongressbd 1998; 115 (Suppl I), pp. 693–7.

Blood Flow and Vascularity Patterns of Neoplasia/Mammary Carcinoma/Transplated Tumor Model
Definity Contrast Media

Background Information: Angiogenesis, the development of new blood vessels, is necessary for tumor growth. Antiangiogenic therapies have recently received attention as a possible cancer treatment.

Application: Sonographic imaging and definity contrast agent can be utilized to monitor the vascularity of induced tumors and detect their response to antiangiogenic therapy.

Route of Administration: Definity (intravenous).

Implementation: Evaluation of blood flow patterns to mammary carcinoma transplants applying sonographic imaging (i) prior to drug administration, (ii) during the 1st 51 hours following initial drug administration, and (iii) on days 8 and 15 after initiation of therapy. Tumor volumes can be estimated at each time point using a prolate ellipsoid method from linear dimensions measured on the B-mode ultrasound image in the 3 major axes. A destruction-replenishment technique is used for tumor blood flow evaluation using a con-

stant rate infusion of intravenously delivered ultrasound contrast media (Definity). A destructive pulse is fired 1st, followed by a chain of non-destructive pulses that allow for visualization of vascular contrast agent replenishment. Parametric maps of the time required for contrast agent replenishment and the time-integrated intensity are generated for both the tumor and kidney. Following ultrasound examination, contrast-enhanced computed tomography (CT) of each tumor is performed in the same imaging plane as data used to acquire ultrasound images. Fifteen days after the start of treatment, tumors are excised, preserved in 10% formalin, and sectioned in a plane approximating the ultrasound and CT imaging planes. Sections are prepared for light microscopy with H & E, CD31, and factor VIII immunostain to evaluate overall morphology and vessel distribution.

Animal Model: Rats subcutaneously implanted with R3230 murine mammary adenocarcinomas (e.g., n = 6). Animals are treated orally with an antiangiogenic agent (SU11657) beginning 28 days after tumor implantation (20 mg/kg BW once daily). Additional tumor-bearing control rats can be treated with an equivalent volume of vehicle alone (e.g., n = 3).

Analysis and Interpretation: Ultrasound measurements of tumor volume, the spatial extent of contrast enhancement, and the time required for contrast replenishment within control tumors are significantly different from those of treated tumors. The time-integrated ultrasound contrast enhancement decreases and the time required for replenishment of the contrast agent within the tumor volume increases over the course of antiangiogenic therapy. Parametric maps of integrated intensity correlate with the regions of viable tumor demonstrated on H & E and regions of elevated contrast intensity found on CT images. Contrast-enhanced ultrasound imaging of implanted tumors provides a tool to assess differences in the microcirculation of treated and control tumors in studies of antiangiogenic agents.

Instrumentation: Siemens Sonoline Elegra equipped with a 5.0-MHz linear transducer.

Contrast-assisted destruction-replenishment ultrasound for the assessment of tumor microvasculature in a rat model. Pollard RE, Sadlowski AR, Bloch SH, Murray L, Wisner ER, Griffey S, Ferrara KW. Technol Cancer Res Treat 2002 Dec; 1 (6), pp. 459–70.

Detection Limits and Resolution/Contrast Helical Computed Tomography (CT) and B-Mode Ultrasound (US)
Levovist/Wideband Harmonic Imaging (WHI)

Application: Microbubbles (e.g., Levovist) can be utilized in concert with contrast-enhanced WHI to detect and characterize various types of hepatic metastases (nodules < 1 cm diameter).

Route of Administration: Microbubbles (e.g., Levovist) can be given intravascularly.

Dosage: Levovist at 2.5 g/dose (300 mg/ml).

Implementation: Evaluate the relative capacity for contrast-enhanced WHI to detect liver metastases compared to conventional B-mode US and postcontrast CT. Wideband harmonic imaging can be performed 3 minutes after injection of Levovist contrast agent and postcontrast helical CT (HCT). The number and location of the lesions and the smallest lesion detectable for each case image are recorded.

Human Model: Cases suffering from hepatic metastases originating from different types of primary malignant lesions (e.g., n = 27).

Analysis and Interpretation: Comparisons reveal an increase in the number of lesions in harmonic mode compared with conventional B-mode images in cases with hepatic metastasis (e.g., n = 27/27) with a mean increase from 9.3 lesions with B-mode to 18.8 lesions with WHI. The smallest lesions can be detected with WHI (2 mm), compared with conventional US and HCT (B-mode = 5 mm, CT = 5 mm). Wideband harmonic imaging detects more lesions than conventional ultrasound or contrast HCT. Contrast-enhanced WHI appears to be superior to conventional US and HCT for the detection of hepatic metastases, especially for those nodules under 1 cm of diameter.

Improved detection of liver metastases with contrast-enhanced wideband harmonic imaging: Comparison with CT findings. Esteban JM, Molla MA, Tomas C, Maldonado L. Eur J Ultrasound 2002 Oct; 15 (3), pp. 119–26.

Gene Delivery/Selective Tumor DNA Delivery via Vasculature
Plasmid-Microspheres/Plasmid-Complexed Liposomes

Application: Selective targeting of plasmid-incorporated genetic DNA sequences for neoplastic cell types.

Route of Administration: Arterial catheterization.

Implementation: Evaluation of plasmid DNA delivery into to a renal solid tumor involving the utilization of plasmid bound to microspheres and plasmids complexed with liposomes to evaluate their potential to function as a selective delivery modality to tumors. Selective delivery is in part facilitated by selective catheterization of the major arterial network supplying individual neoplastic tissue masses.

***Ex Vivo* Model:** Rat (established renal solid tumor model).

Interpretation and Analysis: Forty-eight hours postdelivery, tumor-to-normal kidney tissue chloramphenicol acetyltransferase expression ratios are as follows: free (1.8:1), microspherical (3.9:1), and liposomal (1.2:1). Microspheres are able to selectively deliver plasmids to tumors, whereas cationic liposomes distribute plasmids to the parenchymal of both kidneys and tumor cells. The tumor model has the potential of screening delivery vehicles as well as therapeutic agents for the capacity of selective delivery to tumors via vasculature structures.

A model for evaluating selective delivery of plasmid DNA to tumors via the vasculature. Dass CR, Burton MA. Cancer Biother Radiopharm 2002 Oct; 17 (5), pp. 501–5.

Glioma: Malignant/$\alpha_V\beta_3$ Complexes
Echistatin Microbubbles

Background Information: Angiogenesis is a critical determinant that influences tumor growth and metastasis. It has been hypothesized that contrast-enhanced ultrasound (CEU) with microbubbles targeted to α_V-integrins expressed on the neovascular endothelium could be used to image angiogenesis phenomenon.

Implementation: Evaluation of malignant glioma CEU utilizing contrast-enhanced ultrasound in combination with microbubbles targeted to $\alpha_V\beta_3$ by surface conjugation with echistatin. Contrast-enhanced ultrasound perfusion imaging with non-targeted microbubbles can be used to derive tumor microvascular blood volume and blood velocity. Vascular α_V-integrin expression can be assessed by immunohistochemistry, and microbubble adhesion characterized by confocal microscopy.

Animal Model: Rat (athymic; n = 14). Malignant gliomas are produced by intracerebral implantation of U87MG human glioma cell populations. On day 14 or day 28 after implantation, CEU is performed.

Interpretation and Analysis: Mean tumor size increases markedly from 14 to 28 days (2 ± 1 vs 35 ± 14 mm^2, $p < 0.001$).

Tumor blood volume increases by approximately 35% from day 14 to day 28, whereas microvascular blood velocity decreases, especially at the central portions of the tumors. On confocal microscopy, $\alpha_V\beta_3$-targeted but not control microbubbles are retained preferentially within tumor microcirculation structures. Contrast-enhanced ultrasound signals produced by $\alpha_V\beta_3$-targeted microbubbles in tumors increase significantly from 14 to 28 days (1.7 ± 0.4 vs 3.3 ± 1.0 relative units, $p < 0.05$). Contrast-enhanced ultrasound signals from $\alpha_V\beta_3$-targeted microbubbles is greatest at the periphery of tumors, where α_V-integrin expression is the most prominent, and correlates well with tumor microvascular blood volume ($r = 0.86$). Contrast-enhanced ultrasound with $\alpha_V\beta_3$-targeted microbubbles can non-invasively detect early tumor angiogenesis. Such a technique, when coupled with changes in blood volume and velocity, may provide insights into the biology of tumor angiogenesis and be used for various diagnostic applications.

Imaging tumor angiogenesis with contrast ultrasound and microbubbles targeted to $\alpha_V\beta_3$. Ellegala DB, Leong-Poi H, Carpenter JE, Klibanov AL, Kaul S, Shaffrey ME, Sklenar J, Lindner JR. Circulation 2003 Jul 22; 108 (3), pp. 336–41.

Mammary Carcinoma
Levovist

Application: Detection and characterization of vascular anomalies, including microcirculation features of breast lesions, utilizing contrast-enhanced ultrasound (US).
Route of Administration: Microbubbles (e.g., Levovist) bolus injection via a 20-gauge catheter probe.
Dosage: Microbubbles (Levovist) at a rate of 2 ml/s.
Implementation: Evaluation of breast lesions using contrast-enhanced US; these lesions have previously been identified on mammography examination. Ultrasound examinations are performed before and after administration of US contrast medium (e.g., Levovist microbubbles) delivered as a bolus injection (2 ml/s) via a 20-gauge catheter probe. The mechanical index is set to high to obtain instant rupture of the microbubbles under insonation. Intensity/time curves of the transient scattering in the region-of-interest (ROI) after contrast administration is extrapolated. The areas under the ROI curves can also be evaluated to quantitatively assess scattering phenomenon.

Human Model: Cases of female breast cancer ($n = 36$; age = 42–63 years; mean age 55 years) with a single breast lesion previously detected by standard mammography procedures.
Interpretation and Analysis: Ultrasound and color Doppler US imaging can identify benign lesions ($n = 19$; $n = 15$ histologically proven) and malignant lesions ($n = 17$; $n = 16$ histologically proven). Administration of contrast medium does not improve the specificity of the examination. Only by plotting the intensity/time curves of the ROIs and evaluation of the areas under the ROI curves can a significant correlation be detected between US and histopathologic diagnosis. Although further evaluation of a larger case population is indicated, the analysis of breast lesions by contrast-enhanced perfusion US seems to be a promising technique. Perfusion US can effectively complement high-frequency US, especially when mammography procedures are inconclusive.
Instrumentation: ATL HDI 5000 ultrasound instrument (a 5- to 10-MHz linear-array transducer).

Breast lesion characterization with contrast-enhanced US. Work in progress. Caruso G, Ienzi R, Cirino A, Salvaggio G, Campione M, Lagalla R, Cardinale AE. Radiol Med (Torino) 2002 Nov–Dec; 104 (5–6), pp. 443–5.

Mammary Solid Masses/Benign vs Malignant Image Patterns
Microbubbles/Ultrasound Image-Enhancing Contrast Agent

Cellular/Molecular Mechanism of Action: Microbubbles variably impede, absorb, and reflect ultrasound energy in a manner that differs from surrounding tissue, organ systems, vascular structures, and body fluids.
Application: Detection and characterization of physiological alterations and pathological anomalies affecting vascular structures.
Implementation: Comparative evaluation of solid mammary mass lesions utilizing (i) gray-scale sonographic imaging following initial identification by (ii) diagnostic sonography or screening mammography and subsequent (iii) image analysis with contrast-enhanced power Doppler sonography before and after the injection of a microbubble echo-enhancing contrast agent. Such imaging modalities can be employed to determine their relative capacity to differentiate between malignant and benign mass lesions of the breast that are of relatively small size (measuring < 2 cm). Sonographic findings for all 3 techniques, as well as the morphologic features of the Doppler signals for each case before and after injection of the contrast agent on contrast-enhanced power Doppler sonography, are then collectively evaluated. Each lesion is classified as "benign" or "malignant" on the basis of specific criteria for sonographic interpretation. A hemodynamic study is then performed in which time-transit profiles of the Doppler signals on contrast-enhanced power Doppler sonography are generated using a computer-assisted program, and the results for each case compared with the findings from the histopathologic examination of surgical specimens.

Human Model: Females with mammary solid masses (e.g., $n = 36$; $n = 35/36$ women; mean age = 43.5 years; range = 18–69). The tumors ranged from 4 to 19 mm in the largest dimension.
Analysis and Interpretation: Histopathologic examination reveals that approximately 53% of mammary solid masses are benign (e.g., $n = 19/36$), while about 47% (e.g., $n = 17/36$) are malignant. For the morphologic diagnosis of malignant lesions, the sensitivity of gray-scale sonography is 100%, compared with 29% for power Doppler sonography without contrast enhancement. The specificity of gray-scale sonography is 47%, compared with 74% power Doppler sonography without contrast enhancement. Contrast-enhanced power Doppler sonography has a sensitivity of 71% and a specificity of 58%. The diagnostic accuracy is 72% for gray-scale sonography, 53% for power Doppler sonography without contrast enhancement, and 64% for contrast-enhanced power Doppler sonography. The time-transit profiles of the hemodynamic study do not reveal a statistically significant difference in the accuracy rates of contrast-enhanced power Doppler sonography between benign and malignant breast lesions. Compared with power Doppler sonography without contrast enhancement, contrast-enhanced power Doppler sonography provides better visualization of the morphology of vascular Doppler signals that are characteristic of malignancy, and therefore has a higher sensitivity and diagnostic accuracy, albeit a lower specificity. In differentiating between benign and malignant small breast lesions, contrast-enhanced power Doppler sonography can be helpful when used with gray-scale sonography and power Doppler sonography without contrast enhancement.

Value of contrast-enhanced power Doppler sonography using a microbubble echo-enhancing agent in evaluation of small breast lesions. Kook SH, Kwag HJ. J Clin Ultrasound 2003 Jun; 31 (5), pp. 227–38.

Mammary Tumors/Benign vs Malignant Features/ Tumor Vascularization
Ultrasound Contrast Agent: SHU 508

Background Information: An ultrasound contrast agent that survives transit through the pulmonary circulation after injection into a peripheral vein can also be used for the demonstration of flow characteristics within peripheral organs.
Implementation: Examination of breast tumors applying enhancing color-coded Doppler ultrasonography in combination with a prototype ultrasound contrast image-enhancing agent (SHU 508). Observations and interpretations made are then compared with histopathology findings (e.g., confirmed diagnoses).

Human Model: Cases with evidence of mammary tumors (e.g., n = 10).
Analysis and Interpretation: The very distinct enhancement of color-coded Doppler signals by use of the contrast agent allows reliable demonstration of the vascularization characteristics, not only for malignant lesions but also of essentially all benign solid tumors. Color signals are even recorded from normal mammary tissue, which indicates that the demonstration of perfusion no longer has to be used on its own as a diagnostic criterion. Alternatively, the observation of blood supply characteristics for a given tumor can be advantageous, not only with respect to tumor typing but also as it pertains to tumor prognosis. Given this perception, the registration of the arrival, retention, and washout phases specific to a contrast agent appears to furnish particularly interesting information about tumor growth dynamics.

Echo-contrast agent-enhanced color flow imaging of the breast. Duda VF, Rode G, Schlief R. Ultrasound Obstet Gynecol 1993 May; 3 (3), pp. 191–4.

Ovarian Tumors: Malignant vs Benign Lesions/ Relative Degree/Onset/Duration of Doppler Ultrasound Enhancement
Microbubbles

Application: Differentiation of malignant from benign ovarian lesions based on degree, onset, and duration of Doppler ultrasound enhancement facilitated by the infusion of microbubble ultrasound image-enhancing agents.
Route of Administration: Microbubbles (intravascular).
Implementation: Preoperative examination of suspected cases of ovarian neoplasia applying contrast agent-enhanced ultrasound. Images obtained during a 5-minute examination are stored digitally, and the behavior of the contrast agent evaluated objectively with measurements of the time-dependent image intensity within the region of interest acquired with a computer-integrated software program. A time-intensity curve is derived and analyzed for each individual image. The Mann-Whitney U test can then used to compare intensity changes and tumor parameters in benign and malignant adnexal tumors.

Human Model: Suspected cases of ovarian carcinoma.
Analysis and Interpretation: Both the baseline and maximum power Doppler intensities, as well as the absolute and relative (percent) rise in intensity, are significantly higher ($p < 0.001$) in malignant compared to benign tumors. The arrival time is shorter (17.5 vs 22.5 seconds; $p = 0.005$) and the duration of contrast agent effect longer (190.4 vs 103.6 seconds; $p < 0.001$) in malignant tumors in contrast to benign tumors. The area under the time-intensity curve is significantly greater in malignant tumors compared with that in benign tumors ($p < 0.001$). In summary, following microbubble contrast agent injection, malignant and benign adnexal lesions behave differently in degree, onset, and duration with contrast-enhanced Doppler ultrasound image analysis.

Kinetics of a US contrast agent in benign and malignant adnexal tumors. Orden MR, Jurvelin JS, Kirkinen PP. Radiology 2003 Feb; 226 (2), pp. 405–10.

Vascularity of Tumors/Mammary Carcinoma Transplants
Gadolinium: [Gd]-Diethylenetriamine Pentaacetic Acid (DTPA) for MRI/Galactose-Based Ultrasound (US) Contrast Agent

Cellular/Molecular Mechanism of Action: Gadolinium is classified as a paramagnetic metallic ion and its spacial orientation becomes altered when placed within a magnetic field.
Background Information: Angiogenesis is essential for spread and growth of malignant tumors. Because non-invasive methods for observing tumor vascularization are limited, most previous forms of diagnostic analysis have been based on histologic findings alone.
Application: Detection and characterization of physiological alterations and pathological anomalies affecting tissues, organ systems, and vascular structures.
Route of Administration: [Gd]-DTPA (intravenous for MRI); galactose-based contrast image-enhancing agent (intravenous for Doppler US).
Implementation: Evaluation of microvessel density within neoplastic lesions utilizing dynamic parameters obtained using intermittent contrast-enhanced Doppler sonography for comparison with results observed with dynamic magnetic resonance imaging (MRI) modalities. In this context, transplanted tumors are examined with dynamic T_1-weighted sequences using [Gd]-DTPA and images obtained by magnetic resonance (MR) for comparison with images obtained with intermittent power Doppler sonography after a single bolus of galactose-based contrast agent. Following examination, tumors are harvested for examination applying immunofluorescence microscopy (e.g., n = 6 CD31 stained lesions). Using a 2-compartment model, the MR parameters amplitude (reflecting plasma volume) and k_{ep} (influenced by the vessel permeability) are calculated and compared with maximal enhancement (max) and perfusion measured by ultrasound.

Animal Model: Tumor-bearing nude mice (e.g., n = 11).
Analysis and Interpretation: The MR amplitude correlates with the ultrasound parameter max significantly ($r = 0.61$; $p = 0.01$). Max ($r = 0.67$; $p = 0.01$), amplitude ($r = 0.72$; $p = 0.01$), and perfusion ($r = 0.62$; $p = 0.05$) correlate with the microvessel density. Values for k_{ep} moderately correlate with max, but not with perfusion and microvessel density. Dynamic MRI and contrast-enhanced ultrasound are complementary methods for examining perfusion and vascularity of experimental tumors.
Instrumentation: Magnetic resonance scanner (1.5 tesla).

Comparing dynamic parameters of tumor vascularization in nude mice revealed by magnetic resonance imaging and contrast-enhanced intermittent power Doppler sonography. Kiessling F, Krix M, Heilmann M, Vosseler S, Lichy M, Fink C, Farhan N, Kleinschmidt K, Schad L, Fusenig NE, Delorme S. Invest Radiol 2003 Aug; 38 (8), pp. 516–24.

Vascularity of Tumors/Mammary Carcinoma Microcirculation
Levovist

Application: Detection and characterization of vascular anomalies, including microcirculation features of breast lesions, utilizing contrast-enhanced ultrasound (US).

Route of Administration: Microbubbles (e.g., Levovist) bolus injection via a 20-gauge catheter probe.
Dosage: Microbubbles (Levovist) at a rate of 2 ml/s.
Implementation: Evaluation of breast lesions using contrast-enhanced US that have previously been identified on mammography examination. Ultrasound examinations are performed before and after administration of US contrast medium (e.g., Levovist microbubbles) delivered as a bolus injection (2 ml/s) via a 20-gauge catheter probe. The mechanical index is set to high to obtain instant rupture of the microbubbles under insonation. Intensity/time curves of the transient scattering in the region-of-interest (ROI) after contrast administration is extrapolated. The areas under the ROI curves can also be evaluated to quantitatively assess scattering phenomenon.

Human Model: Cases of female breast cancer (n = 36; age = 42–63 years; mean age 55 years) with a single breast lesion previously detected by standard mammography procedures.
Interpretation and Analysis: Ultrasound and color Doppler US imaging can identify benign lesions (n = 19; n = 15 histologically proven) and malignant lesions (n = 17; n = 16 histologically proven). Administration of contrast medium does not improve the specificity of the examination. Only by plotting the intensity/time curves of the ROIs and evaluation of the areas under the ROI curves can a significant correlation be detected between US and histopathologic diagnosis. Although further evaluation of a larger case population is indicated, the analysis of breast lesions by contrast-enhanced perfusion US seems to be a promising technique. Perfusion US can effectively complement high-frequency US, especially when mammography procedures are inconclusive.
Instrumentation: ATL HDI 5000 ultrasound instrument (a 5- to 10-MHz linear-array transducer).

Breast lesion characterization with contrast-enhanced US. Work in progress. Caruso G, Ienzi R, Cirino A, Salvaggio G, Campione M, Lagalla R, Cardinale AE. Radiol Med (Torino) 2002 Nov–Dec; 104 (5–6), pp. 443–5.

PANCREAS

Pancreatic Masses: Characterization
Microbubble Enhancement Media

Cellular/Molecular Mechanism of Action: Microbubbles variably impede, absorb, and reflect ultrasound energy in a manner that differs from surrounding tissues, organ systems, vascular structures, and body fluids.
Application: Characterize and detect alterations in physiological processes and pathological anomalies affecting tissues, organ systems, and vascular structures.
Implementation: Evaluation of the capacity for microbubble contrast-enhanced ultrasonograpy to characterize the vascularity of pancreatic ductal carcinomas. In this context, possible pathological conditions affecting the pancreas include pancreatic masses (e.g., n = 106) consisting of ductal carcinomas (e.g., n = 83/106); endocrine carcinomas (e.g., n = 7/106); intraductal papillary mucinous tumors (e.g., n = 5/106); autoimmune-related pancreatitis (e.g., n = 3/106); solid pseudopapillary tumors (e.g., n = 3/106); chronic pancreatitis (e.g., n = 2/106); serous cystadenoma (e.g., n = 1/106); osteoclastoid giant cell tumor (e.g., n = 1/106); and follicular lymphoma (e.g., n = 1/106). Such pancreatic lesions can be evaluated utilizing contrast-enhanced sonography with coded harmonic imaging utilizing a phase inversion harmonic technique. Contrast enhancement can be achieved through the application of microbubble enhancement media.
Analysis and Interpretation: Internal tumoral vascularity can be detected in a little over half of all ductal carcinomas (e.g., n = 47/83 or 56.6%). Vascular image spreading and homogeneous staining throughout the tumors can be observed in essentially all endocrine carcinomas. Enhancement effects may be appreciated in some cases of intraductal papillary mucinous tumors (e.g., n = 2/5) and in most cases of autoimmune-related pancreatitis (e.g., n = 3/3), but the degree varies. A significant correlation exists between the intensity of enhancement effects and the ratio of patent vessels within tumors ($p < 0.05$). Vascularity can be detected by contrast-enhanced sonography in only about half of all ductal carcinomas, confirming the difficulty in distinguishing those tumors from other pancreatic tumors. A degree of correlation exists between the patency of the vessels in the tumors and their vascularity.

Evaluation of contrast enhancement patterns in pancreatic tumors by coded harmonic sonographic imaging with a microbubble contrast agent. Nagase M, Furuse J, Ishii H, Yoshino M. J Ultrasound Med 2003 Aug; 22 (8), pp. 789–95.

Pancreatic Neoplasia
Contrast-Enhanced Power Doppler Sonography

Background Information: Echo-enhanced power Doppler sonography (power Doppler sonography after injection of a contrast agent) is a non-invasive and increasingly used procedure for differentiating between pancreatic tumors. However, the diagnostic accuracy of this method compared to conventional ultrasound or unenhanced power Doppler sonography has never been investigated in a large prospective controlled study.
Application: Echo-enhanced power Doppler sonography has a high sensitivity and specificity in the differential diagnosis of pancreatic tumors. However, histology serves as a valuable standard reference control to establish diagnostic accuracy (e.g., diagnostic confirmation).
Implementation: Sonography evaluation of suspected conditions of pancreatic cancer. The exact diagnosis is ultimately based on histological evidence from biopsy examination (surgical and fine needle biopsy) or on follow-up exams performed at least 18 months later.

Human Model: Cases suspected of pancreatic neoplasia (e.g., n = 137; mean age = 60 years; range 16–85).
Analysis and Interpretation: Sonographic imaging can detect pancreatic cancer in approximately 35% of case populations suspected of having pancreatic cancer (e.g., n = 47/137). In the residual cases, 30% may have pancreatitis (e.g., n = 41/137); 12% suffer from neuroendocrine tumors (e.g., n = 17/137); 9% have cystic lesions (e.g., n = 12/137); and 7% have other forms of pancreatic disease (e.g., n = 10/137). A normal pancreas can be appreciated in a relatively small percentage of suspected cases (e.g., n = 10/137). The sensitivity of echo-enhanced power Doppler sonography with respect to diagnosing pancreatic carcinoma is approximately 87% and its specificity 94%. The corresponding values for chronic pancreatitis are approximately 85% and 99%, respectively.

Differentiation of pancreatic tumors by conventional ultrasound, unenhanced and echo-enhanced power Doppler sonography. Rickes S, Unkrodt K, Neye H, Ocran KW, Wermke W. Scand J Gastroenterol 2002 Nov; 37 (11), pp. 1313–20.

PROSTATE

Prostatic Carcinoma/Malignant vs. Benign
Galactose-Based Air Microbubbles

Implementation: Evaluate and compare gray-scale and color Doppler before and during intravenous injection of ultrasound contrast agent made of galactose-based air microbubbles. Biopsy sam-

ples can be harvested during contrast injection or directed cores can be collected based on contrast-enhanced imaging (e.g., n = 18). Diagnostic efficiency with and without contrast medium injection for detecting prostate neoplasia is then compared and validated based on biopsy results.

Human Model: Cases evaluated by biopsy of the prostate (n = 85 suspects).

Implications and Analysis: Cancer can be identified in a large number of suspected cases (e.g., n = 58 biopsies/54 cases). Gray-scale imaging can detect a large number of abnormal hypoechoic nodules or irregular zones inside the outer gland (e.g., n = 96/54 cases), of which approximately 50% are found to be malignant on pathological evaluation (e.g., n = 48/96). Contrast-enhanced color Doppler has a higher sensitivity (93%) than unenhanced color Doppler (54%), while specificity increases only 79% to 87% for enhanced imaging. Approximately 90% (e.g., n = 9/10) of isoechoic suspicious zones can be depicted with enhancement, while unenhanced Doppler detects approximately 70% (e.g., n = 7/10). There is no significant difference between the intensity of enhancement and tumor Gleason scores. Contrast-enhanced color Doppler endorectal sonography increases the detection of prostate cancer. Improvement in sensitivity is high, while the difference in specificity is not as pertinent. It is accurate when using a common and routine application ultrasound unit. Such a technique is easy to perform and not time-consuming. Obtaining additional biopsy cores of suspicious enhancing foci significantly improves the detection rate of cancer.

Contrast-enhanced color Doppler endorectal sonography of prostate: Efficiency for detecting peripheral zone tumors and role for biopsy procedure. Roy C, Buy X, Lang H, Saussine C, Jacqmin D. J Urol 2003 Jul; 170 (1), pp. 69–72.

Prostatic Neoplastic Disease/Accuracy of Detection: Left-Right vs Dorsal-Ventral/Time-to-Start Detection/Maximum Enhancement Detection/Rise Time of Enhancement Detection
Ultrasound Contrast-Enhancing Agent

Application: Detect and characterize physiological alterations and pathological anomalies of tissues, organ systems, vascular structures, and body fluids.

Route of Administration: Contrast agent (intravenous bolus).

Implementation: Define enhancement characteristics that correlate to the presence of prostate cancer and to evaluate the value of these characteristics in the localization of prostate cancer applying trans-rectal contrast-enhanced power Doppler ultrasonography.

The biodistribution of contrast-enhanced blood to the prostate is monitored using trans-rectal contrast-enhanced power Doppler ultrasonography. The percentage of a selected area that shows enhancement is then observed over time. The resulting enhancement curves are described using the parameters (i) time to start; (ii) time to maximum point of enhancement; (iii) maximum value of enhancement; and (iv) rise time of the enhancement. Three evaluation protocols divide the prostate into a number of areas of interest, including (i) 2 areas using the left-right and dorsal-ventral protocols; and into (ii) 4 areas using the quadrant-protocol. The enhancement parameters of the areas of interest are compared to identify the most affected area. The results are compared to the histopathological findings.

Human Model: Confirmed cases of intact primary malignant neoplasia of the prostate scheduled for radical prostatectomy (e.g., n = 29).

Analysis and Interpretation: For the left-right protocol, the minimal time to peak can prove to be the most predictive parameter for selecting the major regions of malignancy. Accuracy of establishing a correct diagnosis is approximately 78% (e.g., n = 23/29). Accurate localization of the major malignancy in either the ventral or dorsal side of the prostate, however, is not feasible utilizing the methodology employed. Malignancies can be accurately localized in either the left or the right side of the prostate based on the time to the maximum moment of enhancement. An accurate discrimination between malignancies in either the dorsal or ventral side of the prostate cannot be performed. This is most likely due to anatomical differences between the dorsal and ventral area.

The value of dynamic contrast-enhanced power Doppler ultrasound imaging in the localization of prostate cancer. Goossen TE, de la Rosette JJ, Hulsbergen-van de Kaa CA, van Leenders GJ, Wijkstra H. Eur Urol 2003 Feb; 43 (2), pp. 124–31.

Prostatic Carcinoma (PC-3m)/Vascular Structures and Perfusion Density
Contrast Agent/[Protamine]

Cellular/Molecular Mechanism of Action: Contrast media is utilized to enhance Doppler ultrasound image quality and sensitivity based on the interaction of ultrasound energy with the physical properties of media preparation (echogenic properties/acoustic impedance).

Application: Detection of alterations in tumor vascularity patterns.

Route of Administration: Intravenous.

Implementation: Evaluation of neoplastic lesion vascular structures and tissue density applying color flow signal-pixel rate (SPR) analysis of images aided by calculations established using the number of pixels showing color Doppler signals as a ratio of total pixel number residing within the region-of-interest (ROI) for the suspected lesion of interest.

Animal Model: Mice (BALB/c nude mice; n = 48) with subcutaneous transplants of human prostate carcinoma PC-3m tumor followed by protamine injections (SQ) as an angiogenesis inhibitor. Animals are randomly divided into 3 groups according to protamine dose.

Analysis and Interpretation: The SPR of the high- and low-dose groups is significantly lower than that of control groups ($p < 0.01$). Mean SPR $\pm$ standard deviation is 0.09 ± 0.05, 0.11 ± 0.05, and 0.22 ± 0.10 for different treatment groups, respectively. The SPR parameters correlate significantly with the density of microvessel structures ($r = 0.86$ to 0.94, $p < 0.01$). Contrast agent-enhanced Doppler ultrasound imaging can effectively reveal change in vascularity within neoplastic lesions (e.g., $\pm$ protamine). In addition to microvessel density, contrast agent-enhanced Doppler ultrasound imaging may become 1 of several independent prognostic indexes for initiating angiogenesis inhibitor therapy.

Evaluation of the effect of protamine on human prostate carcinoma PC-3m using contrast-enhanced Doppler ultrasound.Tang J, Li S, Li J, Zhang Y, Li X, Dong B, Shi H, Zhang G. J Urol 2003 Aug; 170 (2 Pt 1), pp. 611–4.

Prostatic Neoplastic Disease/Accuracy of Detection: Left-Right vs Dorsal-Ventral/Time-to-Start Detection/Maximum Enhancement Detection/Rise Time of Enhancement Detection
Ultrasound Contrast-Enhancing Agent

Application: Detect and characterize physiological alterations and pathological anomalies of tissues, organ systems, vascular structures, and body fluids.

Route of Administration: Contrast agent (intravenous bolus).

Implementation: Define enhancement characteristics that correlate to the presence of prostate cancer and to evaluate the value of these characteristics in the localization of prostate cancer applying trans-rectal contrast-enhanced power Doppler ultrasonography.

The biodistribution of contrast-enhanced blood to the prostate is monitored using trans-rectal contrast-enhanced power Doppler ultrasonography. The percentage of a selected area that shows enhancement is then observed over time. The resulting enhancement curves are described using the parameters (i) time to start; (ii) time to maximum point of enhancement; (iii) maximum value of enhancement; and (iv) rise time of the enhancement. Three evaluation protocols divide the prostate into a number of areas of interest, including (i) 2 areas using the left-right and dorsal-ventral protocols; and into (ii) 4 areas using the quadrant-protocol. The enhancement parameters of the areas of interest are compared to identify the most affected area. The results are compared to histopathological findings.

Human Model: Confirmed cases of intact primary malignant neoplasia of the prostate scheduled for radical prostatectomy (e.g., n = 29).

Analysis and Interpretation: For the left-right protocol, the minimal time to peak can prove to be the most predictive parameter for selecting the major regions of malignancy. Accuracy of establishing a correct diagnosis is approximately 78% (e.g., n = 23/29). Accurate localization of the major malignancy in either the ventral or dorsal side of the prostate, however, is not feasible utilizing the methodology employed. Malignancies can be accurately localized in either the left or the right side of the prostate based on the time to the maximum moment of enhancement. An accurate discrimination between malignancies in either the dorsal or ventral side of the prostate cannot be performed. This is most likely due to anatomical differences between the dorsal and ventral area.

RENAL SYSTEM

Perfusion and Contrast Distribution/Spatial Temporal Resolution
Levovist

Background Information: Knowledge of the relative tissue perfusion and distribution of tissue perfusion patterns is a valuable parameter that can be beneficial in the diagnosis of numerous disease states.

Application: Detection and characterization of physiological alterations and pathological anomalies within tissues, organ systems, and vascular structures. Microbubbles (e.g., Levovist) are a type of contrast agent that can be applied for the calculation of functional images with high spatial resolution applying ultrasound (UA) techniques.

Route of Administration: Levovist (IA).

Implementation: Evaluation of techniques for assessing the relative vascular perfusion and distribution of tissue perfusion patterns based on images generated utilizing US contrast agents. In this context, functional imaging can be performed to characterize the transit of contrast agent bolus for delineation of distribution, peak time, peak value, transit time, peak area, wash-in rate, and washout decay constant.

Animal Model: Canine preparations performed under optimized conditions where motion artifacts can be minimized.

Analysis and Interpretation: Processing of radio frequency signals obtained with a 3.5-MHz echo system can provide functional images with a high spatial resolution of 2 mm in axial resolution and 2–5 mm in lateral resolution and a slice thickness of 2 mm. The functional images expose several known aspects of kidney perfusion, like perfusion heterogeneity of the kidney cortex and a different peripheral cortical perfusion compared to the inner cortex. Results suggest that it is likely that the functional images reflect the relative perfusion distribution of the kidney.

Contrast-enhanced ultrasonography provides several advantages compared to established nuclear techniques. Examples include, among others, a better spatial and temporal resolution, the lack of exposure of the patient to ionizing radiation, and the relatively low cost.

High-resolution functional imaging with ultrasound contrast agents based on RF processing in an *in vivo* kidney experiment. Verbeek XA, Willigers JM, Prinzen FW, Peschar M, Ledoux LA, Hoeks AP. Ultrasound Med Biol 2001 Feb; 27 (2), pp. 223–33.

Urinary/Vesicoureteral Reflux Grading (VUR)
Levovist

Background Information: The sonographic diagnosis of VUR with contrast-enhanced voiding urosonography (VUS) is gradually increasing in application. Introduction of VUS as part of the routine diagnostic imaging strategy for detecting reflux significantly reduces the number of voiding cystourethrographies (VCUG) that need to be performed. Like in VCUG grading of reflux, VUS is becoming more and more relevant.

Implementation: Evaluation of any sonomorphologic and sonomorphometric parameters that can correlate with reflux grading in VCUG. In this context, a reflux grading system for VUS can be applied for correlation with VCUG.

The VUS is conducted with intravesical administration of ultrasound (US) contrast medium (Levovist). Ureteral and pelvicalyceal dilatations before administration of US contrast medium and during reflux are then documented and the renal pelvic diameter measured. The density of microbubbles in the renal pelves is scored on a scale of 1 to 3 (low to high). A grading system for reflux in VUS is set up similar to the international reflux grading system for VCUG with the addition of 1 more differentiation parameter, namely whether the reflux is primarily in a dilated or non-dilated urinary tract. Reflux grades in VUS are compared with those in VCUG.

Human Model: C186 children (cases undergoing both VUS and VCUG; n = 186 children; n = 89/186 with VUR in at least 1 and the same kidney-ureter-unit [KUU] in both diagnostic imagings).

Interpretation and Analysis: None of the sonomorphologic and sonomorphometric parameters demonstrate any clear-cut finding that would simplify reflux grading in VUS. In approximately 63% (e.g., n = 59/95) KUUs the reflux grades are the same in both examinations. In approximately 11% (e.g., n = 10/95) and 27% (e.g., n = 26/95) KUUs, the reflux is graded lower or higher, respectively, in VUS than in VCUG. Approximately 57% are in a primarily dilated system and the remaining 43% in a non-dilated one. Approximately 70% of KUUs diagnosed as having grade 1 reflux in VCUG appear as grade 2 on VUS. A reflux grading system similar to the 1 used in VCUG can be applied in VUS. Adding the parameter of reflux into a primarily dilated or non-dilated ureter and/or pelvicalyceal system may function as a valuable dimension to reflux grading in VUS. Most of the refluxes labeled as grade 1 in VCUG are actually grade 2 or higher.

Vesicoureteral reflux grading in contrast-enhanced voiding urosonography. Darge K, Troeger J. Eur J Radiol 2002 Aug; 43 (2), pp. 122–8.

Urinary Bladder Rupture: Ultrasonography
Microbubbles

Background Information: Because urinary bladder rupture can be life threatening, a simple, safe technique for evaluating patients is desirable. Current diagnostic protocols involve radiographic imaging, but ultrasound-based contrast techniques have not been methodically evaluated in veterinary patients with urologic trauma.
Application: Detection of anatomical defects affecting the urinary bladder.
Route of Administration: Urinary catheter.
Implementation: Ultrasound contrast cystography (contrast cystosonography) involves infusion of microbubbled saline solution through a urinary catheter.

Animal (Practice) Model: Canine (naturally occurring urinary bladder rupture).
Interpretation and Analysis: A positive result consists of visualizing microbubbles sonographically in fluid surrounding the bladder immediately after infusion of contrast into the urinary catheter. A positive result can be easily appreciated in both an *in vitro* and *in vivo* (n = 2 dogs) model. Confirmation can be established with radiographic and surgical confirmation of naturally occurring intraperitoneal urinary bladder rupture. Based on results from such studies, ultrasound contrast cystography appears to be more sensitive than 2-dimensional abdominal sonography for detecting naturally occurring urinary bladder rupture in dogs.

Diagnosis of urinary bladder rupture using ultrasound contrast cystography: *In vitro* model and 2 case-history reports. Ccoté E, Carroll MC, Beck KA, Good L, Gannon K. Vet Radiol Ultrasound 2002 May–Jun; 43 (3), pp. 281–6.

Vesiculoureteral Reflux (VUR): Neonatal/Renal Ultrasonography: Contrast-Enhanced/Fluoroscopic Micturating Cystourethrography (MCU)
Stabilized Microbubbles

Background Information: Fluoroscopic MCU can be used for screening and grading conditions of VUR but involves the application of ionizing radiation. The role of sonography is somewhat limited in practice as a screening examination for neonatal populations.
Application: Contrast-enhanced sonography can be applied in predicting the presence or absence of VUR. Its ability to detect cases of high-grade reflux may make it an attractive alternative in case follow-ups of known conditions of VUR, and may help to reduce neonatal radiation exposure.
Implementation: Evaluation of renal ultrasonography imaging to determine the feasibility of grading conditions of VUR. Echo-enhanced sonography in concert with stabilized microbubbles can be utilized to evaluate function. Validation of findings can subsequently be achieved by performing fluoroscopic MCU. Criteria for the diagnosis of VUR is based upon the detection of transient hyperechogenicity appearing within the pelvicalyceal system or ureter.

Applying such a diagnostic strategy, it is possible to compare ultrasound contrast agents for the detection of VUR in at-risk infants and to compare these findings with fluoroscopic MCU with the aim of determining the relative effectiveness and ability to substitute echo-enhanced sonography for fluoroscopic MCU in order to identify neonates who do not have VUR, thus avoiding the use of radiation in this group.

Human Model: Neonates (n = 97/100; n = 69 males, n = 31 females; age = 28–90 days; mean micturations = 2.7 [1–6 range]).
Analysis and Interpretation: Reflux can be detected in 14% of suspect neonatal cases (e.g., n = 14/95 babies, n = 19 kidneys/14 babies) by 1 or the other diagnostic technique. The findings are concordant in approximately 93.2% of kidneys (e.g., n = 181/194 kidneys). Echo-enhanced sonography has a sensitivity of 64% (95% confidence interval 35–87%), a specificity of 100% (95–100%), a positive predictive value of 100% (66–100%), and a negative predictive value of 94% (87–98%).

Comparison of echo-enhanced ultrasound with fluoroscopic MCU for the detection of vesicoureteral reflux in neonates. McEwing RL, Anderson NG, Hellewell S, Mitchell J. Pediatr Radiol 2002 Dec; 32 (12), pp. 853–8. Epub 2002 Sep 25.

REPRODUCTIVE SYSTEM

Infertility (Female): Hysterosalpingography (Tubal Patency)
Levovist

Background Information: Previous experimental and clinical data suggest that insonation of echo-enhancing contrast agents with high acoustic power produces disintegration of microbubbles, resulting in a phenomenon called simulated acoustic emission (SAE).
Implementation: Evaluation of female infertility using x-ray hysterosalpingography (HSG) and SAE-HyCoSy. The order of the 2 procedures can be established randomly for each case after placement of a trans-cervical balloon catheter. For SAE-HyCoSy, the ultrasound contrast medium Levovist is injected, with the acoustic power set at the maximum level permitted on ultrasound machines employing dedicated algorithms. Conventional HSG is performed for comparison.

Human Model: Cases of female infertility (n = 41 and n = 77 fallopian tubes). X-ray HSG for infertility evaluation also receiving SAE-HyCoSy.
Interpretation and Analysis: In the majority of the cases examined, it is possible to detect the creation of SAE phenomenon. In 13% of tubes (e.g., n = 10), proximal filling may not be observed by either SAE-HyCoSy or HSG. In the remaining 87% of tubes (e.g., n = 67), free spill from the distal end of the lumen can be demonstrated in 96% of cases (e.g., n = 64/67) with SAE-HyCoSy and in 97% of cases (e.g., n = 65/67) with HSG. Disagreement between the 2 techniques may be observed in only a few instances (e.g., n = 5/77) with a Cohen's kappa coefficient of 0.76 (95% confidence interval, 0.56–0.96). Therefore, SAE techniques can be successfully applied to HyCoSy and allow visualization of the free spill of contrast agent into the peritoneal cavity in a majority of cases examined. In previous investigations, SAE-HyCoSy has shown good agreement with HSG diagnostic methods.

The sonographic evaluation of tubal patency with stimulated acoustic emission imaging. Prefumo F, Serafini G, Martinoli C, Gandolfo N, Gandolfo NG, Derchi LE. Ultrasound Obstet Gynecol 2002 Oct; 20 (4), pp. 386–9.

Mammary Gland Disease Differentiation/Optical Imaging
Gadolinium/Indocyanine Green (ICG)/Near-Infrared Diffuse Optical Tomography (DOT)

Cellular/Molecular Mechanism of Action: Indocyanine green is an absorbing dye that is bound to albumin within the intravascular compartment.
Application: Indocyanine green is an absorbing dye commonly used as a marker system within the plasma compartment. Under certain conditions, ICG possesses the potential to differentiate disease based on the quantified enhancement of suspicious lesions using magnetic resonance imaging (MRI) concurrently with DOT (contrast enhancement properties).

Route of Administration: Intravascular.

Implementation: Near-infrared diffuse optical tomography analysis of the mammary gland applied in combination/concurrently with MRI. Results are then correlated with histopathological evaluation of suspicious lesions.

Human Model: Cases scheduled for excisional biopsy or surgery.

Interpretation and Analysis: The ICG-enhanced optical images co-register accurately with gadolinium-enhanced magnetic resonance images, thereby validating the ability of DOT to image breast tissue. In contrast to simple transillumination, DOT appears to provide for localization and quantification of exogenous tissue chromophore concentrations. Additionally, ICG has demonstrated a potential to differentiate disease based on the quantified enhancement of suspicious lesions.

Concurrent MRI and diffuse optical tomography of breast after indocyanine green enhancement. Ntziachristos V, Yodh AG, Schnall M, Chance B. Proc Natl Acad Sci U S A 2000 Mar 14; 97 (6), pp. 2767–72.

4 DELIVERY MODALITIES

22 Biological and Synthetic Delivery Modalities

MACRO-BIOLOGICAL PLATFORMS

CELLULAR-BASED DELIVERY SYSTEMS

Lymphocytes/Selective Peripheral Lymphocyte-Mediated Delivery/Hunter's Syndrome: Mucopolysaccharidosis Type II
Iduronate-2-Sulfatase (IDS)/L2sN and L2/Avian β-Actin Promoter in LB2/CMV Early Promoter in LNC2

Cellular/Molecular Mechanism of Action: Utilization of the natural (native) homing properties of peripheral blood lymphocytes (PBL) to selectively deliver diagnostic agents.
Route of Adminstration: Intravenous.
Considerations: Measurement of trans-gene lysosomal enzyme soon after exposure of target cells to vector supernatant may yield a gross overestimate of long-term trans-gene expression by transduced cells.
Implementation: Characterization of IDS expression from 3 different promoters in 4 retroviral vectors performed in peripheral blood lymphocytes (PBL) from cases with Hunter's syndrome (PBL[MPS]). Relevant vectors for LTR include L2SN and L2, avian β-actin promoter in LB2, and the CMV early promoter in LNC2. The production of PBL(MPS) in this manner involves their exposure to packaging cell supernatant.
Interpretation and Analysis: Surprisingly, IDS activities are equally high in all transduced lymphocyte populations: 515 U/mg/h in PBL(MPS)-L2SN, 734 in PBL(MPS)-LB2, 352 in PBL(MPS)-L2, and 389 in PBL(MPS)-LNC2 compared to controls (< 10 in PBL[MPS]-LXSN or PBL[MPS]). The half-life of endocytosed IDS in PBL(MPS) is approximately 1.9 days. However, the level of lymphocyte IDS activity from proviral expression is only a fraction of the total, a large portion being derived from reuptake to enzyme from murine packaging cells, that is, a "2nd source" of enzyme.

Cells can be charged with a lysosomal enzyme to levels much higher than those found in nature. By "supercharging" cells with a lysosomal protein (or other molecule bearing the mannose-6-phosphate ligand), such cells may be exploited as vehicles for systemic delivery of therapeutic or diagnostic agents.

"Supercharged cells" for delivery of recombinant human iduronate-2-sulfatase. Pan D, Jonsson JJ, Braun SE, McIvor RS, Whitley CB. Mol Genet Metab 2000 Jul: 70 (3), pp. 170–8.

Lymphocytes/Selective Peripheral Lymphocyte-Mediated Delivery/Hunter's Syndrome: Mucopolysaccharidosis Type II
Retroviral Vectors (L2SN) /Iduronate-2-Sulfatase (IDS) /Neomycin Resistance Genes

Cellular/Molecular Mechanism of Action: Delivery of genetic sequences.
Background Information: The process of growing and transducing large quantities of human primary peripheral blood lymphocytes (PBLs) with high gene transfer efficiency continues to be one of the major challenges for clinical and experimental therapy.
Implementation: Development of a clinical trial of lymphocyte gene therapy for mucopolysaccharidosis type II (i.e., Hunter's syndrome). One approach to such an objective can entail investigating methods that exploited the innate capability of a hollow-fiber bioreactor system to filter large quantities of vector supernatant and facilitate transduction.
Interpretation and Analysis: The total number of PBLs could be expanded up to 187-fold, ielding up to 10^{10} cells at the end of a 7-day culture period. The multiplicity of infection can be increased (up to 20-fold) by ultrafiltrating a large volume of vector supernatant through a semipermeable membrane of this system. A high level of transduction efficiency (up to 57%) can be achieved, resulting in IDS enzyme activity as high as 1250 U/mg/h in transduced PBL(MPS) 15 days after transduction. This level is markedly increased from that of non-transduced cells (< 3 U/mg/h) and is even greater than that of normal PBLs (mean, 809; n = 10). After 12 days of G418 selection, PBL(MPS) transductants exhibits a proviral IDS enzyme level approximately 3-fold higher than that in normal PBLs. These results indicated t hat a hollow-fiber bioreactor could be used to culture and transduce human primary PBLs in clinically useful quantities with relatively high gene transfer efficiency and transgene expression.

Combined ultrafiltration-transduction in a hollow-fiber bioreactor facilitates retrovirus-mediated gene transfer into peripheral blood lymphocytes from patients with mucopolysaccharidosis type II. Pan D, Shankar R, Stroncek DF, Whitley CB, Hum Gene Ther 1999 Nov 20; 10 (17), pp.2799–810.

Lymphocytes: Natural Killer Cells: Interleukin-2 (IL-2)-Activated Natural Killer Cells/Pulmonary Metastases/Zyn-205 Linker/Doxorubicin
Melanoma

Cellular/Molecular Mechanism of Action: Natural killer cells have an innate ability to localize within and resolve neoplastic lesions perceived as foreign. Exposure of NK cells to IL-2 enhances their cytotoxic potential. Zyn-Linkers are membrane-binding lipophilic dyes.
Application: Adoptively transferred IL-2-activated NK (A-NK) cells selectively accumulate within tumor metastases and can therefore be applied as a biological vehicle for loco-regional drug delivery. Previous investigations have demonstrated that A-NK cells labeled with PKH26 are able to accumulate within established B16 melanoma pulmonary metastases by 16 hours at a concentration of over 600 cells/mm^2 of tumor tissue. Zyn-Linkers are membrane-binding lipophilic dyes that can be coupled by a variety of conjugation chemistries to various pharmaceutical agents.
Route of Administration: Intravascular.

Semi-Synthetic Methods: Zyn-205 is a prodrug in which doxorubicin is attached to a similar Zyn-Linker through an acid-sensitive bond.
Implementation: Optimization of *ex vivo* labeling conditions applying a 10-minute incubation period with 25 μM Zyn-205.
Interpretation and Analysis: Zyn-205 results in uptake of over 10^8 drug molecules per cell and creates no effect on either cell viability or cytolytic activity up to 24 hours postlabeling. Given these parameters, the amount of drug that may be carried to and locally concentrated within metastatic lesions can approach approximately 15 μM. In addition, A-NK cells carrying Zyn-linked doxorubicin at an equivalent dose of 25 μg/kg is therapeutically comparable to a systemic dose of 8 mg/kg (320x more) in the 3LL model of experimental metastasis. These data indicate that A-NK cells bearing Zyn-linked chemotherapeutic agents represent a unique and feasible method to target diagnostic and therapeutic pharmaceutical agents to cancer metastases and that therapeutic doses can be attained without unwanted systemic exposure.

A novel drug delivery system using IL-2 activated NK cells and Zyn-linked doxorubicin. Goldfarb RH, Koelemij R, Muirhead KA, Ohlsson-Wilhelm BM, Gray BD, Kuppen PJ, Basse PH, al-Atrash G, Kitson RP. In Vivo 2000 Jan–Feb; 14 (1), pp. 101–4.

Macrophages: Hepatic Kupffer Cell (KC) Selective Delivery/Antigen Processing Inhibition: Enhanced Adenoviral Vector Delivery
Clodronate Liposomes

Background Information: Tissue macrophages, in particular hepatic KCs, contribute to early inflammatory responses following adenoviral vector administration.
Application: Characterization of hepatic KCs and enhancement of adenoviral vector delivery.
Route of Administration: Intravascular.
Implementation: Evaluate the effect of selective and transient (3 days) depletion of hepatic KCs by a single injection of clodronate liposomes on the *in vivo* activity of high-capacity adenoviral (HC-Ad) vectors that express the human alpha-1 anti-trypsin (hAAT) gene.
Animal Model: Murine (C57BL/6 and C3H strain mice).
Interpretation and Analysis: In mice, KC depletion increases and stabilizes hAAT production levels following intravenous injection of HC-Ad vectors expressing hAAT either from the hAAT promoter or from the human cytomegalovirus promoter. Comparable increases in hAAT levels can be obtained by preinjection with a transcriptionally silent HC-Ad vector. Interestingly, in most instances, depletion of KCs is sufficient to prevent the generation of anti-hAAT antibodies, resulting in prolonged trans-genic expression. Thus, short-term and selective depletion of hepatic macrophages at the same time significantly increases hepatic trans-gene expression and reduces humoral immune response to trans-genic proteins.

Selective depletion or blockade of Kupffer cells leads to enhanced and prolonged hepatic trans-genic expression using high-capacity adenoviral vectors. Schiedner G, Hertel S, Johnston M, Dries V, van Rooijen N, Kochanek S. Mol Ther 2003 Jan; 7 (1), pp. 35–43.

Neoplasia/Cardiovascular Endothelium Adhesion of Neoplastic Cells/Intravital Observation of Cancer Cell/Microcirculation Interactions
CalceinAM Labeled Neoplastic Cells

Background Information: Organ-specific tumor cell adhesion within the microcirculation of host organs is an important step in the metastatic cascade. Circulating tumor cells adhere to the luminal surface of microcirculatory vessels, then quickly stabilize these adhesion interactions. Ultimately, they leave the circulation to avoid the toxic effects of hydrodynamic shear forces exerted by circulating blood.
Application: Intravital observation of colon carcinoma cell adhesion within the hepatic microcirculation.
Route of Administration: Intravascular.
Implementation: CalceinAM can be used to label colon carcinoma cell populations (e.g., HT-29 [human] and CC531 [rat]) in order to track their biodistribution following intra-arterial injection as a single-cell suspension. Intravital fluorescence microscopy can then be applied to detect the development of adhesive interactions between circulating tumor cells and vascular endothelial surfaces within the hepatic microcirculation. These interactions are then analyzed regarding their time course and site localization within the vascular tree.
Animal Model: Rats (Sprague-Dawley).
Interpretation and Analysis: Autofluorescence of liver parenchyma is sufficient to distinguish hepatic sinusoids. Intravital microscopy is capable of differentiating early events in adhesion formation within hepatic sinosoids, adhesion stabilization, and extravasation of tumor cells into the liver parenchyma. Tumor cell adhesion occurs almost exclusively within sinusoidal capillaries; however, the diameter of these vessels is usually larger than that of tumor cells leaving remaining perfused lumen of the capillaries. Colon carcinoma cells rapidly migrate into the liver parenchyma after development of adhesion interactions within the sinusoids. In contrast to common end point assays of the metastatic cascade, this particular *in vivo* model allows investigations of metastatic colon carcinoma cell adhesion phenomenon within the liver microcirculation at specific steps during the formation of hematogenous metastasis and its underlying mechanisms.
Instrumentation: Intravital fluorescence microscopy.

An intravital model to monitor steps of metastatic tumor cell adhesion within the hepatic microcirculation. Haier J, Korb T, Hotz B, Spiegel HU, Senninger N. J Gastrointest Surg 2003 May–Jun; 7 (4), pp. 507–14; discussion 514–5.

Neutrophils and Macrophages/*In Vivo* Labeling of Tuftsin Complexes/Inflammation: Septic and Non-Septic/Central Nervous System (CNS): Multiple Sclerosis/Glucocorticoid Efficacy Evaluation/ Selective Delivery to Leukocytes or Sites of Inflammation/Experimental Allergic Encephalomyelitis
[^{99m}Technetium] ([^{99m}Tc])-RP128

Cellular/Molecular Mechanism of Action: The agent RP128 functions as a chelation agent for [^{99m}Tc], in addition to recognizing and binding to tuftsin receptors expressed by neutrophils and monocyte-macrophages.
Application: The agent [^{99m}Tc]-RP128 can be applied for the *in vivo* labeling of neutrophil and macrophage tuftsin receptor complexes for the purpose of detecting and characterizing focal sites of septic inflammation. Preparations can also potentially be applied for the detection and characterization of human multiple sclerosis conditions. Potentially could be applied to selectively deliver agents to macrophage and neutrophil populations.
Route of Administration: Intravascular.
Implementation: Administration of [^{99m}Tc]-RP128 for the *in vivo* detection of CNS inflammation (e.g., experimental allergic encephalomyelitis [EAE]).
Animal Model: Murine (EAE as a model for human multiple sclerosis).

Interpretation and Analysis: The radiopharmaceutical [^{99m}Tc]-RP128 can be detected at significantly increased levels within CNS tissues in conditions of EAE at 0.5, 1.0, and 3.0 hours postinjection using a dual radioisotope technique to correct for non-extravasated tracer ($p < 0.05$). Moreover, extravascular accumulation of [^{99m}Tc]-RP128 can be clearly demonstrated in inflammatory tissues with minimal loss of sensitivity when the secondary isotopic correction for blood volume is omitted. In addition, [^{99m}Tc]-RP128 can successfully monitor glucocorticoid suppression of inflammation ($p < 0.05$), detected as a typical dose-response to increasing steroid concentration. Clearly, [^{99m}Tc]-RP128 can quantitatively detect CNS inflammation and assess responses to therapy, indicating potential value as an imaging agent both clinically and as a research aid. Furthermore, the rapid *in vivo* labeling by [^{99m}Tc]-RP128 of specific inflammatory cells combined with the ability to monitor the progress of anti-inflammatory therapeutics may validate the use of this cellular radiolabeling agent for detecting a variety of inflammatory conditions.

The detection and quantitation of inflammation in the central nervous system during experimental allergic encephalomyelitis using the radiopharmaceutical [^{99m}Tc]-RP128. Paul C, Peers SH, Woodhouse LE, Thornback JR, Goodbody AE, Bolton C. J Neurosci Methods 2000 May 15; 98 (1), pp. 83–90.

Neutrophils and Monocytes/Consumption vs Production Abnormalities
[^{111}I]-Oxine Neutrophils/[^{111}I]-Merc Neutrophils Doxorubin (Chemotherapeutic "Loaded") Neutrophils

Physiological Mechanism of Action: Neutrophils and macrophages migrate into specific locations (tissues/organs) within the body in response to endogenous (certain cytokines) and exogenous (bacterial origin) agents perceived as chemotactic agents. In this manner, cells move toward an increasing concentration gradient.

Application: Facilitate differentiation between alterations in bone marrow leukocyte production compared to changes in consumption as a cause for neutropenia/monocytopenia or neutrophilia/monocytophia. Additionally, they can be used as an imaging carrier cell preparation for detecting regions of inflammation and sepsis or the selected delivery of diagnostic and therapeutic pharmaceuticals pretargeted with chemotactic agents conjugated with pH or enzyme-sensitive linking groups to site-specific monoclonal antibody fragments.

Route of Administration: Intravascular.

Considerations: Must be prepared fresh.

Semi-Synthetic Methods: Radioisotope markers or chemotherapeutic agents can be passively "loaded" into neutrophil populations at relatively high concentrations without affecting their response to chemotactic stimuli.

Implementation: Highly enriched leukocyte populations purified from fresh whole blood can be radiolabeled with a variety of agents including [^{51}Cr], [^{111}In]-merc, [^{111}In]-oxime, [^{111}In]-tropolone (detergent-free), and [^{99m}Tc]-HMPAO. In a similar manner, leukocytes can be "loaded" with a variety of antibiotic and chemotherapeutic agents, including doxorubicin, which passively penetrate across intact cell membranes and actually accumulate with the nucleus. Usually it is preferable to use neutrophil populations for the production of pharmaceutical-loaded cells, especially pertaining to chemotherapeutic agents, because this cell type does not undergo mitosis so it is unlikely to perpetuate any genetic defect that might possibly develop during the loading process.

Interpretation and Analysis: Declines in intravascular $T_{1/2}$ values for labeled neutrophils imply accelerated consumption or removal from the central compartment. In scenarios where neutrophil numbers are low but $T_{1/2}$ values are normal, this suggests the presence of abnormalities in hematopoeitic (bone marrow) production. Accumulations of radiolabeled cells at specific foci implies the presence of septic or non-septic inflammatory responses.

Antineoplastic activity of chemotherapeutic "loaded" neutrophils against human mammary carcinoma. Coyne CP, Fenwick BW, Ainsworth J. Biotherapy 1997; 10, pp. 145–59.

Neutrophil Leukotriene LTB_4 Receptors/ Induced Myocardial Ischemia
[^{99m}Technetium] ([^{99m}Tc])-RP517/[F]-RP517

Cellular/Molecular Mechanism of Action: In whole blood, [F]-RP517 (500 nmol/L) preferentially labels neutrophil LTB_4 receptor complexes.

Application: [^{99m}Tc]-RP517 is an LTB_4 receptor antagonist that has been developed for imaging acute inflammation or infection. A unique property of [^{99m}Tc]-RP517 is its ability to label white blood cells *in vivo* after intravenous injection.

Route of Administration: [^{99m}Tc]-RP517 (intravenous).

Implementation: Evaluate the relative [^{99m}Tc]-RP517 binding to human leukocyte subtypes and the [^{99m}Tc]-RP517 uptake pattern in myocardium with induced inflammatory lesions. One approach to assessing such conditions can involve delineation of RP517 binding to neutrophil populations *in vitro* within whole blood, and *in vivo* within the intravascular compartment. This can be achieved through the use of fluorescence-activated cell sorter analysis performed on whole human blood samples ($n = 2$) and isolated neutrophils ($n = 4$) with a fluorescent analogue of [^{99m}Tc]-RP517 referred to as [F]-RP517. Approaches *in vivo* can entail administration of [^{99m}Tc]-RP517 to determine its biodistribution within the myocardium before and after coronary occlusion. To facilitate *ex vivo* imaging of the myocardium, the left ventricle can be divided into 72 segments for flow and [^{99m}Tc]-RP517 uptake analyses.

Animal Model: Canine ($n = 9$ dogs; anesthetized, open-chest surgical exposure before coronary occlusion [90 minutes] and reperfusion [120 minutes]; or $n = 3$ dogs before intramyocardial tumor necrosis factor-alpha (TNF-α) administration). In this context, myocardium inflammation can be induced by either coronary occlusion and reperfusion or administration by injection of TNF-α preparations.

Interpretation and Analysis: In whole blood, [F]-RP517 (500 nmol/L) preferentially labels neutrophils. In isolated neutrophil populations, [F]-RP517 (10 nmol/L) binding is inhibited by 44% in the presence of LTB_4 (400 nmol/L). In the analysis of *ex vivo* cardiac samples, an inverse exponential relationship can be detected between [^{99m}Tc]-RP517 uptake and occlusion flow ($r = 0.73$). In the same 15 segments, [^{99m}Tc]-RP517 uptake is highly correlated with neutrophil myeloperoxidase enzyme levels ($r = 0.91$). *Ex vivo* images reveal tracer uptake in the reperfused area (ischemic to normal count ratio $= 2.7 \pm 0.2$). Therefore, it can be concluded that RP517 binds to the neutrophil LTB_4 receptor complex after intravenous injection. After reperfusion, [^{99m}Tc]-RP517 uptake correlates with myeloperoxidase levels and can be observed on *ex vivo* images, indicating that this tracer may have potential as an imaging agent for detecting inflammatory conditions.

Assessment of myocardial inflammation produced by experimental coronary occlusion and reperfusion with [^{99m}Tc]-RP517, a new leukotriene B_4 receptor antagonist that preferentially labels neutrophils *in vivo*. Riou LM, Ruiz M, Sullivan GW, Linden J, Leong-Poi H, Lindner JR, Harris TD, Beller GA, Glover DK. Circulation 2002 Jul 30; 106 (5), pp. 592–8.

Neutrophils/Gastrointestinal Inflammation: Colitis (Acute Chemically Induced) *[^{99m}Technetium] ([^{99m}Tc])-HYNIC-IL-8/ [^{99m}Tc]-Neutrophils*

Cellular/Molecular Mechanism of Action: Interleukin-8 (IL-8) binds to its corresponding membrane-associated receptor complex expressed at relatively high densities by neutrophil and monocyte cell types. Granulocytes are chemotactically attracted to sites of septic and non-septic inflammation.

Physiological Mechanism of Action: Interleukin-8 can function as a chemotactic agent for granulocyte populations.

Implementation: Evaluation of acute colitis conditions facilitated by scintigraphic image analysis with [^{99m}Tc]-HYNIC-IL-8 and [^{99m}Tc]-granulocytes (purified cell populations). Gamma camera images are acquired at 2 minutes and at 1, 2, and 4 hours postinjection. At 4 hours after injection, the uptake of the radiolabel within specific tissues and organs can be determined (postmortem analysis). The dissected colon can be imaged and the inflammatory lesions scored macroscopically. For each affected colon segment, the colitis index (affected colon-to-normal-colon uptake ratio, CI) is calculated and correlated with the macroscopically scored severity of inflammation.

Animal Model: Rabbit (chemically induced acute colitis).

Interpretation and Analysis: Both agents can facilitate visualization of colitis conditions within 1 hour after injection. [^{99m}Tc]-HYNIC-IL-8 images of colonic abnormalities are more accurate and the intensity of uptake in regions of affected colon continuously increase up to 4 hours after injection, whereas no further increase 1 hour after injection is noticed scintigraphically with [^{99m}Tc]-HMPAO-granulocytes. Absolute uptake within affected colon is much higher for IL-8 than for radiolabeled granulocytes with the percentage of injected dose per gram (%ID/g) equal to 0.41 $\pm$ 0.04 %ID/g and 0.09 $\pm$ 0.054 %ID/g hour after injection, respectively. With increasing severity, the CI at 4 hours after injection for [^{99m}Tc]-HYNIC-IL-8 is approximately 4.4 $\pm$ 0.6, 13.5 $\pm$ 0.5, and 25.8 $\pm$ 1.0; for granulocytes, the CI 4 hours after injection is 1.5 $\pm$ 0.1, 3.4 $\pm$ 0.2, and 6.4 $\pm$ 0.5, respectively. Values for CI correlate with the severity of tissue inflammation ($r = 0.95$, $p < 0.0001$ for IL-8; $r = 0.95$, $p < 0.0001$ for granulocytes). Therefore, within 1 hour after injection, visualization of the extent of colonic inflammation *in vivo* is possible with [^{99m}Tc]-HYNIC-IL-8 and [^{99m}Tc]-HMPAO-granulocytes. Within 2 hours after injection, [^{99m}Tc]-IL-8 allows a good evaluation, and within 4 hours after injection, a meticulous evaluation of the severity of inflammatory bowel disease (IBD) is possible. Although [^{99m}Tc]-HMPAO-granulocytes are able to delineate the extent of IBD within 2 hours after injection, an accurate estimation of the severity of inflammation is not possible. [^{99m}Tc]-HYNIC-IL-8 is an inflammation-imaging agent that has demonstrated promising results. [^{99m}Tc]-IL-8 can be prepared off-the-shelf and yields excellent imaging with high target-to-background ratios.

Instrumentation: Gamma camera imaging capabilities.

Rapid imaging of experimental colitis with [^{99m}Tc]-interleukin-8 in rabbits. Gratz S, Rennen HJ, Boerman OC, Oyen WJ, Corstens FH. J Nucl Med 2001 Jun; 42 (6), pp. 917–23.

Platelets/Thrombocytes/Cardiovascular: Arterial Thromboses/Pharmaceutical Efficacy Evaluation: Antiplatelet Therapy *[^{111}Indium] ([^{111}In])-Platelets/ 4-Cyano-5,5-Bis(Methoxyphenyl)-4-Pentenoic Acid*

Cellular/Molecular Mechanism of Action: The radioisotope [^{111}In] emits photons that can be detected as a tracer in a manner that allows it to be used to detect the biodistribution of labeled synthetic diagnostic pharmaceuticals, biological proteins, and purified cell populations. Platelets can accumulate at anatomical (e.g., intravascular) sites of platelet aggregation including vascular injury and arterial clot formation.

Application: Preparations of [^{111}In]-platelets can be utilized for the detection of intravascular thrombosis and evaluation of the efficacy of antithrombotic pharmaceutical agents. Aorta thromboses are composed of a higher percentage of platelets compared to venous thromboses, which contain predominantly polymerized ($\pm$ cross-linked) fibrin monomer.

Route of Administration: Intravascular.

Implementation: Combined application of [^{111}In]-platelet scintigraphy (PSG) and B-mode ultrasonography (US) to determine the short-term effects of antiplatelet agents [e.g., 4-cyano-5,5-bis (methoxyphenyl)-4-pentenoic acid (E5510)]. After 8 weeks, [^{111}In]-PSG and US are repeated. Platelet deposition is then assessed visually and semi-quantitatively using a platelet accumulation index.

Human Model: Cases with platelet deposition at either the carotid bifurcation or abdominal aorta (e.g., $n = 15$) detected by [^{111}In]-PSG. Half of affected cases are administered antiplatelet therapy (e.g., E5510 at 4 mg/day).

Interpretation and Analysis: Visual analysis reveals that a high percentage of cases become negative for platelet deposition after certain antithrombotic therapies (e.g., $n = 7/8$), while essentially no change occurs without the benefit of antithrombotic intervention. The platelet accumulation index in vessels with platelet deposition is significantly reduced after delayed antithrombotic treatment (6.0 $\pm$ 7.1% vs 12.4 $\pm$ 3.9%, $p < 0.01$), while there is no significant change in vessels without platelet deposition (2.9 $\pm$ 3.0% vs 2.9 $\pm$ 4.1%). In cases with early-phase antithrombotic therapy, vessels rarely demonstrate any changes (8.1 $\pm$ 6.4% vs 8.9 $\pm$ 7.3%). However, there is no significant reduction of carotid plaque size in either group. Short-term E5510 therapy inhibits platelet deposition in active atherothrombotic lesions, and the *in vivo* combination of PSG and US can be useful for evaluating the effectiveness of antithrombotic pharmaceuticals.

Effect of E5510, a novel antiplatelet agent, on platelet deposition in atherothrombotic lesions: Evaluation by [^{111}In] platelet scintigraphy. Moriwaki H, Matsumoto M, Handa N, Hashikawa K, Hori M, Nishimura T. Nucl Med Commun 2000 Nov; 21 (11), pp. 1051–8.

Platelets *Thrombogenic Lesions, Stimuli, or Devices/[^{111}Indium] ([^{111}In])-Platelets/[^{99m}Technetium] ([^{99m}Tc])-Platelets*

Physiological Mechanism of Action: The function of normal platelets includes maintenance of vascular endothelial integrity and active participation in thrombogenic responses. Thrombi formed within arterial structures have a higher platelet content than do thrombi found within the venous vasculature.

Application: Detection and characterization of vascular thromboses, the plasma half-life of platelets, and the thrombogenic properties of foreign materials.

Semi-Synthetic Methods: Radiolabeling of highly enriched populations of platelets with [^{111}In]-tropolone (detergent-free) and [^{99m}Tc]-HMPAO following their isolation from fresh whole blood.

Implementation: Evaluation of the platelet thrombogenicity of a hemodialyzer device quantified through the application of [^{99m}Tc]-platelets and [^{111}In]-platelets. Hemodialysis is performed with a hollow-fiber dialyzer (HFD) in a flow-loop, the temperature of which is maintained at 37°C, with flow-rates of 7, 150, and 270 mL/min. Following dialysis, the HFD radioactivity is measured with an ionization chamber and imaged with a gamma camera. The radioactivity of

samples of hollow fibers taken from the top, middle, and bottom of the dialyzer is quantitatively measured with a gamma counter.

Animal Model: Normal beagle dogs and Yorkshire pigs.

Human Model: Human volunteers.

Interpretation and Analysis: The canine platelets are more thrombogenic than porcine and human platelets. The adhesivity of porcine platelets to the biomaterial (cellulose-acetate) of the dialyzer approximates that of human platelets. The [^{99m}Tc] label underestimates thrombus formation ($p < 0.01$). The dynamic processes of thrombosis and embolization from the hemodialyzer device results in large standard deviations around the mean for values associated with the characteristics of adherent thrombi. In spite of this limitation of the dynamic pathology, quantitation of the comparative thrombogenicity utilizing [^{111}In]- and [^{99m}Tc]-labeled platelets suggests that both radionuclides may be used for detecting and quantifying device-induced thrombogenicity and may provide an estimation (extrapolation) of prosthesis-induced thrombogenicity of human platelets from animal studies.

Quantitation of thrombogenicity of hemodialyzer with technetium-99m and indium-111 labeled platelets. Dewanjee MK, Kapadvanjwala M, Ruzius K, Serafini AN, Zilleruelo GE, Sfakianakis GN. Nucl Med Biol 1993 Jul; 20 (5), pp. 579–87.

Platelet Consumption/Intravascular Kinetics/ Disseminated Intravascular Coagulation/ Autoimmune Thrombocytopenia
Platelets/[^{111}Indium] ([^{111}In])-Merc Platelets/ [^{111}In]-Oxine Platelets

Cellular/Molecular Mechanism of Action: Platelets, when exposed to activating agents like adenosine diphosphate and collagen monomer, become activated, undergo degranulation (phase I and II), and aggregate (reversible and irreversible phases).

Physiological Mechanism of Action: Function as active cellular participants in normal and abnormal coagulation events. Platelets, unrelated to their participation in coagulation events, also repair defects in the vascular endothelium.

Background Information: Labeled platelets can be utilized to characterize intravascular platelet kinetics or for diagnostic imaging purposes.

Application: Detection of alterations in platelet intravascular kinetics in conditions of increased consumption (e.g., disseminated intravascular coagulation, autoimmune thrombocytopenia) or decreased bone marrow production (radiation toxicity, chemotherapy sequela). Labeled platelets can also be utilized for diagnostic imaging for the detection of arterial and venous intravascular thromboses. In this context, intravascular arterial thrombi have a relatively higher platelet content than do thrombi formed within the venous vascular network. Lastly, platelets can be "loaded" with pharmaceutical agents for the therapeutic management of various disease states. One of the best examples of this strategy is the loading of platelets with vincristine for managing conditions of autoimmune thrombocytopenia, whereby phagocytized vincristine-loaded platelets by macrophage populations reduce accelerated consumption of immunoglobulin-coated platelets.

Route of Administration: Intravascular.

Semi-Synthetic Methods: Highly enriched platelet populations are isolated from fresh whole blood collected into citrate anticoagulant. Usually, chelating agents are used to label cell populations like platelets because agents like [^{111}In] have a cationic or anionic charge that substantially decreases their ability to penetrate intact cell membrane structures. Other radioisotope preparations that have been applied to label platelets include [^{51}Cr], [^{111}In]-merc, [^{111}In]-oxime, [^{111}In]-tropolone (detergent-free), and [^{99m}Tc]-HMPAO.

Interpretation and Analysis: Decreases in the intravascular kinetic profile for labeled platelet preparations suggest accelerated/elevated platelet consumption. In the event thrombocytopenia is present but platelet intravascular $T_{1/2}$ is normal, then a decrease in bone marrow platelet production should be considered. Regional intravascular accumulation of radiolabeled platelets suggests the presence of clot formation.

Instrumentation: Scintillation counter (intravascular kinetics), gamma camera (imaging).

Radiolabeling of equine platelets in plasma with [^{111}In]-(2-mercaptopyridine-N-oxide) and their *in vivo* survival in the horse. Coyne CP, Kelly AB, Hornof WJ, O'Brien TR, Phelps MS, Lamb JF. Am J Vet Res 1987; 48, pp. 385–91.

Stem Cells/Central Nervous System/ [Parkinson's Disease]

Background Information: The ability to track the patterns of stem cell migration within the brain by *in vivo* neuroimaging will improve current understanding about how these cell types mediate functional recovery after neural transplantation. One major challenge for the development and refinement of stem cell transplantation is to map the spatial distribution and rate of *in situ* migration.

Application: Tracking transplanted stem cells in the ischemia-damaged hippocampus utilizing magnetic resonance imaging (MRI) analysis.

Implementation: Assessment of stem cell migration applying *in vitro* labeling of populations with the novel bifunctional contrast agent gadolinium rhodamine dextran (GRID) prior to transplantation. Detection can be assessed applying either magnetic resonance imaging (MRI) and fluorescence microscopy or with PKH26 (visible exclusively under fluorescence microscopy). At different time points following engraftment, brain tissues can be evaluated applying *ex vivo* MRI techniques and histopathology analysis.

Animal Model: Rat (ischemia-damaged hippocampus).

Interpretation and Analysis: Transplanted stem cells can be identified by MRI only if prelabeled with GRID, whereas fluorescence microscopy can detect transplanted cells using either labeling reagent. Distribution images of GRID-labeled stem cells produced applying MRI closely correlate with results obtained using fluorescence microscopy analysis. Stem cells and their migration can therefore be reliably identified applying GRID-enhanced MRI methodologies.

Tracking transplanted stem cell migration using bifunctional, contrast agent-enhanced, magnetic resonance imaging. Modo M, Cash D, Mellodew K, Williams SC, Fraser SE, Meade TJ, Price J, Hodges H. Neuroimage 2002 Oct; 17 (2), pp. 803–11.

Stem Cells: Embryonic/Monitoring Stem Cell Traffic/Migration
Magnetic Resonance Imaging (MRI) Agent Cell Labeling/Lipofection Cell-Labeling Methodology

Background Information: *In vivo* monitoring of stem cells after grafting is essential for establishing an improved understanding about migration dynamics, cellular differentiation processes, and regeneration potential. Migration of endogenous or grafted stem cells and neurons has been described for vertebrate brain, both under normal conditions (involving the subventricular zone along the rostral migratory stream) and during pathophysiological events (e.g., conditions of degeneration and focal cerebral ischemia). However, previous investigations heavily relied upon invasive forms of analysis (e.g., brain sectioning) in combination with selective staining techniques.

Application: Embryonic stem cells could theoretically function as a selective delivery modality for diagnostic and therapeutic pharmaceutical agents. The concept of labeling stem-cell-like populations could also be utilized as a methodology for monitoring "therapeutic" cellular infiltration into specific regions of pathology (e.g., central nervous system [CNS] foci affected by ischemic insult or Parkinson's disease).

Route of Administration: Variable, including non-selective, selective, and highly selective delivery platforms (e.g., intravascular injection, vs specific catheterization of certain cerebral artery branches, vs direct implantation into tissue foci).

Implementation: External mapping of the *in vivo* dynamics of cell migration over a prolonged period of time. Embryonic stem (ES) cells can be modified to constitutively express green fluorescent protein (GFP) using a lipofection procedure employed in concert with a tracer MRI contrast agent. Contrast agent-labeled ES cells are then directly implanted into tissues, including the brain. To convincingly illustrate the capacity of ES cells to migrate into regions of pathology, they can be implanted into the healthy contralateral cerebral hemisphere.

Animal Model: Rat (e.g., focal lesions of cerebral ischemia induced 2 weeks before implantation of ES cells).

Analysis and Interpretation: Magnetic resonance imaging permits the observation of implanted cells with high contrast against normal tissue background. Confirmation can in part be established by analysis of GFP biodistribution patterns. During a 3-week period, cells migrate along the corpus callosum into the ventricular walls and massively populate the border-zone of damaged brain tissue within the hemisphere opposite to the original site of implantation. Embryonic stem cells can display highly desirable migration dynamics and are attracted to regions of induced cerebral ischemia in a relatively selective manner. Techniques employing labeled embryonic stem cells are ideally suited for the non-invasive imaging of cell migration events, engraftment, and morphological differentiation at high spatial and temporal resolution.

Instrumentation: Magnetic resonance imaging (MRI) at 78-microm isotropic spatial resolution.

Monitoring of implanted stem cell migration *in vivo*: A highly resolved *in vivo* magnetic resonance imaging investigation of experimental stroke in rat. Hoehn M, Kustermann E, Blunk J, Wiedermann D, Trapp T, Wecker S, Focking M, Arnold H, Hescheler J, Fleischmann BK, Schwindt W, Buhrle C. Proc Natl Acad Sci U S A. 2002 Dec 10; 99 (25), pp. 16267–72. Epub 2002 Nov 20.

Stem Cells: Hematopoietic Progenitor Cells
Magnetic Polysaccharide Nanoparticle-Transferrin/ Gadopentetate Dimeglumine Liposomes/P7228 Liposomes/Ferumoxides/Ferumoxtran

Application: Detection and characterization of the biodistribution of labeled human hematopoietic progenitor cells.

Route of Administration: Intravascular or direct implantation by injection (e.g., non-selective, selective, and highly selective delivery).

Semi-Synthetic Methods: Labeling of hematopoietic progenitor cells with ferumoxides, ferumoxtran, magnetic polysaccharide nanoparticles-transferrin, P7228 liposomes, and gadopentetate dimeglumine liposomes to facilitate detection by magnetic resonance imaging (MRI) analyses.

Implementation: Evaluation of the organ/tissue distribution of labeled hematopoietic progenitor cells using MRI (1.5 T). Data can be analyzed by measuring magnetic resonance signal intensities and R1 and R2* relaxation rates of labeled cells and non-labeled control cells. Mean quantitative data for the various contrast agents is then assessed for significant differences between experimental and reference controls utilizing the Scheffe statistical analysis test. As a reference standard, MRI data can be compared with electron microscopic and spectrometric analyses.

Interpretation and Analysis: For all contrast agents, intracellular cytoplasm uptake can be demonstrated by electron microscopy and quantified utilizing spectrometry. Compared to non-labeled control cells, progenitor cells labeled with iron oxides show significant increases in R2* ($p < 0.05$). Cells labeled with gadopentetate dimeglumine liposomes show significantly increased R1. Detection thresholds are approximately 5×10^5 cells for gadopentetate dimeglumine liposomes and ferumoxtran; 2.5×10^5 cells for ferumoxides and P7228 liposomes; and 1×10^5 cells for magnetic polysaccharide nanoparticles-transferrin. Hematopoietic progenitor cells therefore can be labeled with MR contrast agents and detected with a standard 1.5 T magnetic resonance imager.

Instrumentation: Magnetic resonance imaging with T_1- and T_2-weighted spin-echo and fast field-echo sequences (1.5 T).

Targeting of hematopoietic progenitor cells with MR contrast agents. Daldrup-Link HE, Rudelius M, Oostendorp RA, Settles M, Piontek G, Metz S, Rosenbrock H, Keller U, Heinzmann U, Rummeny EJ, Schlegel J, Link TM. Radiology 2003 Sep; 228 (3), pp. 760–7.

Stem Cells/Migration: Mesenchymal/Lymphocytes/ Oligodendrocyte Progenitor CG-4 Cells/Cervical Carcinoma/[Iron Load: *Ex Vivo*]
Mesenchymal Stem Cells/Transfection Agents/ Ferumoxides/MION-46L/[Prussian Blue]

Application: Labeling of mammalian and stem cells by combining commercially available transfection agents with superparamagnetic iron oxide (SPIO) magnetic resonance (MR) imaging enhancing contrast agents.

Route of Administration: Intended primarily for intravascular applications.

Semi-Synthetic Methods: Transfection agents can be incubated with ferumoxides and MION-46L in cell culture medium at various concentrations. Different viable cell types are subsequently incubated 2–48 hours with 25 μg of iron per milliliter of combined transfection agent/superparamagnetic iron oxide (TA/SPIO). Cellular labeling effectiveness can be assessed with T_2 relaxometry, MR imaging of labeled cell suspensions, and Prussian blue staining for detection of iron deposits.

Cellular Model: Human mesenchymal stem cells, mouse lymphocytes, rat oligodendrocyte progenitor CG-4 cells, and human cervical carcinoma cells.

Implementation: Evaluation of the proliferation and viability of mesenchymal stem cells and human cervical carcinoma cells labeled with a combination of transfection agents and ferumoxides.

Interpretation and Analysis: When ferumoxides-TA or MION-46L-TA are used, intracytoplasmic particles stained with Prussian blue stain can be detected in all cell line types with a labeling efficiency of nearly 100%. Limited or no uptake can be observed for cells incubated with ferumoxides or MION-46L alone. For TA-SPIO-labeled cells, MR images and relaxometry findings reveal a 50–90% decrease in signal intensity and a more than 40-fold increase in T_2s. Cell viability varies from 103.7% ± 9 to 123.0% ± 9 compared to corresponding values for reference control cells at 9 days, while cell proliferation is not affected by endosomal incorporation of SPIO nanoparticles. Iron concentrations vary with ferumoxides-TA combinations and cells with a maximum of 30.1 pg ± 3.7 of iron per cell for labeled mesenchymal stem cells. Therefore, in sum-

mary, magnetic labeling of mammalian cells aided by the use of ferumoxides and transfection agents is possible and may enable cellular MR imaging and tracking in experimental and clinical settings.

Clinically applicable labeling of mammalian and stem cells by combining superparamagnetic iron oxides and transfection agents. Frank JA, Miller BR, Arbab AS, Zywicke HA, Jordan EK, Lewis BK, Bryant LH Jr, Bulte JW. Radiology 2003 Aug; 228 (2), pp. 480–7.

Stem Cells: Myogenic Precursor Cells (MPC) (Iron Oxide-Loaded)
Myocardium Infarction/Detailed Segmental Left Ventricle (LV) Function

Cellular/Molecular Mechanism of Action: Myogenic precursor cells detect and accumulate within lesions of myocardial generation.
Application: Evaluation of myocardial implants of MPC loaded with iron oxide to determine how reliably they can be detected by *in vivo* cardiac magnetic resonance imaging (MRI).
Route of Administration: Direct catheterization.
Implementation: Electromechanical mapping of the LV and guided microinjections into normal and infarcted myocardium utilizing injected autologous MPC delivered through a percutaneous catheter. Cardiac MRI can be used to detect implanted MPC previously loaded with iron oxide nanoparticles.
Animal Model: Swine (n = 7 farm pigs; n = 4/7 with anterior myocardial infarction). Magnetic resonance imaging data are compared to LV electromechanical mapping findings and cross-registered pathology.
Interpretation and Analysis: The vast majority of injections into normal (e.g., n = 9/9) and locally damaged (e.g., n = 12/12) myocardium can be detected on T_2-weighted spin echo and inversion-recovery true-FISP MRI (low signal areas) with good anatomical concordance with sites of implantation on electromechanical maps. All sites of injection can be confirmed on pathology that can reveal in all infarct animals iron-loaded MPC at the center and periphery of the infarct, as expected from MRI. In summary, targeted catheter-based implantation of iron-loaded MPC into locally infarcted LV myocardium is accurate and can be reliably demonstrated by *in vivo* cardiac MRI. The ability to non-invasively identify intramyocardial cell implantation may be a determinant for future experimental studies designed to analyze subsequent effects of such therapy on detailed segmental LV function.

Magnetic resonance imaging of targeted catheter-based implantation of myogenic precursor cells into infarcted left ventricular myocardium. Garot J, Unterseeh T, Teiger E, Champagne S, Chazaud B, Gherardi R, Hittinger L, Guéret P, Rahmouni A. J Am Coll Cardiol 2003 May 21; 41 (10), pp. 1841–6.

Stem Cells/Oligodendrocyte Progenitor Cells/ Transferrin Magnetic Nanoparticles
Central Nervous System: Demyelinated Axons/ Transferrin Receptors

Cellular/Molecular Mechanism of Action: Oligodendrocyte progenitor cells naturally migrate to specific foci within the CNS, including demyelinated axons.
Background Information: Demyelination is a common pathological finding in human neurological diseases and frequently persists as a result of failure of endogenous repair. Transplanted oligodendrocytes and their precursor cells can (re)myelinate axons, raising the possibility of therapeutic intervention. The migratory capacity of transplanted cells is of key importance in determining the extent of (re)myelination and can, at present, be evaluated only by the use of invasive and irreversible procedures.
Application: Potential delivery modality that recognizes demyelinated axons.
Route of Administration: Presumably intravascular.
Implementation: Delineation of the capacity for transferrin receptors to function as an effective "target" that can facilitate the intracellular delivery of magnetic nanoparticles and guide the migration of transplanted tagged oligodendrocyte progenitor cells into the spinal cord with myelin-deficient neurons.
Animal Model: Rat (myelin-deficient neurons).
Interpretation and Analysis: Cell migration can be easily detected by using 3-dimensional magnetic resonance microscopy, which demonstrates a close correlation between the areas of contrast enhancement and degree of "new" myelination in an *in vivo* myelin-deficient model. In this context, investigations have demonstrated the feasibility of successfully using magnetic resonance to track transplanted oligodendrocyte progenitor cells. The technique has the potential of being easily extended into other neurotransplantation research investigations involving different precursor cell types.

Neurotransplantation of magnetically labeled oligodendrocyte progenitors: Magnetic resonance tracking of cell migration and myelination. Bulte JW, Zhang S, van Gelderen P, Herynek V, Jordan EK, Duncan ID, Frank JA. Proc Natl Acad Sci U S A 1999 Dec 21; 96 (26), pp. 15256–61.

VECTOR-MEDIATED GENE (OLIGONUCLEOTIDE) DELIVERY SYSTEMS

Cell Transfection: HEK293 and COS-7 Cell Lines/ Gene Expression: Facilitation of Phage Delivery
Plasmids (pBUDLacZ)/Pullulan (Hydrogel) Nanoparticles/Lipofectamine 2000

Application: Enhanced delivery of nucleic acid molecules to cells by encapsulation within hydrogel pullulan nanoparticles.
Route of Administration: Intravascular
Semi-Synthesis Method: Pullulan nanoparticles encapsulating pBUDLacZ plasmid can be prepared inside aqueous droplets of w/o microemulsions.
Implementation: Evalation of cellular viability/vitality (cytotoxicity response) using 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay.
Interpretation and Analysis: Transmission electron microscopy (TEM) imaging reveals that particles are spherical in shape with a size of 45 ($\pm$0.80) nm diameter. Cell cytotoxicity studies reveal that cells incubated with nanoparticles remain more than 100% viable at nanoparticle concentration as high as 1000 μg/ml. From scanning electron microscope images, nanoparticles can be observed to be internalized and cells tend to exhibit vacuoles in the cell body due to nanoparticle internalisation. Endocytosis of nanoparticles results in disruption of F-actin and beta-tubulin cytoskeleton of human fibroblasts. The efficacy of transfection *in-vitro* on HEK293 and COS-7 cells is cell-type dependent, with COS cells demonstrating a higher level of gene expression. The beta-gal expression in COS-7 cells facilitated by pullulan nanoparticle is comparable to commercially available Lipofectamine 2000. The results of this study are encouraging for the development of pullulan nanoparticles as an intracellular delivery system for drugs and genes.

Hydrogel pullulan nanoparticles encapsulating pBUDLacZ plasmid as an efficient gene delivery carrier. Gupta M; Gupta AK J Control Release 2004 Sep 14; 99 (1), pp. 157–66.

Central Nervous System Capillary Endothelium Gene Transfer Model/Beta Galactosidase/ MBEC4 Cell Transfection
Hemagglutination Virus of Japan Liposomes [Liposome-Encapsulated Beta-Galactosidase Plasmid]

Background Information: Bioactive proteins or peptides cannot be effectively delivered into brain capillary endothelial cells (BCECs) or brain parenchyma.
Route of Administration: Super-selective internal carotid artery catheterization.
Implementation: Evaluation of the electiveness of transferring the *Escherichia coli* beta-galactosidase gene (beta-gal) as a model gene into brain capillary endothelial cells (BCEC) utilizing the hemagglutination virus of Japan (HVJ)-liposomes. HVJ-liposomes encapsulating a beta-gal plasmid can be used *in-vitro* to transfect MBEC4 cells, and also *in-vivo* by selective administration.
Animal Model: Rat via the internal carotid artery.
Interpretation and Analysis: Success of the procedure is confirmed by the detection of 116 kDa beta-gal protein in transfected MBEC4 cells and in brain capillaries isolated from transfected rats, by Western blot analysis and histological staining. The enzymatic activities of beta-galactosidase are 5- to 10-fold and 20-fold higher than when beta-gal-containing liposomes without fusogenic activity (uncoated liposomes) or plasmid alone are employed *in-vitro* and *in-vivo*, respectively. Thus, HVJ-liposomes have demonstrated applicability as a vector for the transfer of foreign genes into brain capillary endothelium *in-vivo* (transluminal route).

Transluminal gene transfer into brain capillary endothelial cells *in vivo* with HVJ-*liposomes*. Jiang C; Matsuo H; Koyabu N; Ohtani H; Fujimoto H; Yonemitsu Y; Kaneda Y; Narro M; Tsuruo T; Sawada Y Journal of drug targeting [J Drug Target] 2002 Jun; 10 (4), pp. 345–52.

Central Nervous System/Capillary Endothelium Cells/Brain Parenchyma Cells/Neurotrophic Factor (mGDNF Gene)
Hemagglutination Virus of Japan-Liposomes

Application: Gene delivery into the central nervous system (evaluation of the protective effect for dopamine neurons against a retrograde 6-hydroxydopamine (6-OHDA))
Route of Administration: HVJ-liposomes (internal carotid artery).
Semi-Synthesis Method: The gene encoding mouse glial cell-derived neurotrophic factor (mGDNF gene) can be transfected into brain capillary endothelial cells (BCECs) with the aim of delivering the gene product extensively into the brain parenchyma by making use of BCEC secretory function. First, the mGDNF gene is transfected *in-vitro* into cultured BCECs (MBEC4; mouse brain capillary endothelial cells). The amount of mGDNF protein secreted from the transfected cells into the medium is about 1500 to 3200 pg/mg of cell protein/day, or about sevenfold higher than that accumulated intracellularly. Furthermore, the basolateral-directed secretion of mGDNF protein from the transfected MBEC4 cells is fivefold higher than the apical-directed secretion.
Implementation: Evaluation of the capacity of the hemagglutination virus of Japan (HVJ)-liposomes to deliver the encapsulated mGDNF gene into the central nervous system.
Animal Model: Rat
Interpretation and Analysis: Transfected rats show a marked increase in the brain level of GDNF as assessed by means of enzyme-linked immunosorbent assay (ELISA) and Western blotting on day 3 after the administration, and the level remains significantly elevated for at least 12 days. Furthermore, immunohistochemical staining reveals an increase in GDNF immunoreactivity throughout the transfected forebrain. Such profiles indicate that the gene can be successfully transferred *in-vivo* from HVJ-liposomes into BCECs, where it is expressed, and the gene product is secreted into the brain. Using this delivery method, the protective effect provided to dopamine neurons against a retrograde 6-hydroxydopamine (6-OHDA) lesion can be evaluated (e.g. assessed as a function behavioral and neurochemical indices).

In-vivo delivery of glial cell-derived neurotrophic factor across the blood-brain barrier by gene transfer into brain capillary endothelial cells. Jiang C, Koyabu N, Yonemitsu Y, Shimazoe T, Watanabe S, Naito M, Tsuruo T, Ohtani H, Sawada Y. Hum Gene Ther. 2003 Aug 10;14(12):1181–91.

Central Nervous System Gene Delivery/Cerebral Ishchemia Lesions
Anti-Apototic Transgenes/Human bcl-2 Protein Plasmid DNA Complexes: Liposome Facilitated [Lipoplexes]

Background Information: Acute cerebral ischemia causes hypoxic neuronal cell death by necrosis and apoptosis. Expression of anti-apoptotic transgenes in ischemic brain may provide a useful therapeutic strategy for alleviation of postischemic damage.
Route of Administration: Lipoplexes (intrathecal)
Implementation: Evaluate the potential of liposomes to mediate transfer of human bcl-2 protein into the CNS during conditions of focal transient cerebral ischemia. Two different types of plasmid vectors can be used for bcl-2 expression; [i] one driven by the constitutive cytomegalovirus promoter (pCMV) and [ii] a second based on the hypoxia-inducible human vascular endothelial growth factor promoter (pHRE). Cationic liposome/plasmid DNA complexes (lipoplexes) are injected directly into the cerebrospinal fluid (CSF) of rats immediately after MCA occlusion. The brains of treated and control animals are analyzed 48 hours later. Infarct volumes and numbers of apoptotic cells are then quantified.
Animal Model: Rat (focal transient ischemia created by middle cerebral artery (MCA) occlusion).
Interpretation and Analysis: Occlusion of the MCA results in ipsilateral cerebral infarcts. Transfer of the bcl-2 gene results in high level widespread protein expression in the case of the pCMV-bcl2 plasmid, while animals treated with the pHRE-bcl2 vector show lower expression levels of bcl2 that are limited to the ischemic area. Treatment with pCMV-bcl2, but not with pHRE-bcl2, is able to significantly reduce infarct volumes [109 ± 8 mm^3 for pCMV-bcl2; 152 ± 29 mm^3 for pHRE-bcl2; and 155 ± 18 mm^3 for control animals]. Animals transfected with either of the two vectors have significant reductions in apoptotic cell numbers within infarcts and penumbra area compared to controls. There is no short-term neurological side-effects from CSF lipoplex injection or of bcl-2 expression. Hypoxia-inducible bcl-2 expression mediated by intrathecal lipoplexes may represent a novel, biologically safe and lesion-selective therapeutic approach for neuroprotection after acute cerebral ischemia.

Liposome-mediated transfer of the bcl-2 gene results in neuroprotection after in vivo transient focal cerebral ischemia in an animal model. Cao YJ; Shibata T; Rainov NG Gene therapy [Gene Ther] 2002 Mar; 9 (6), pp. 415–9.

Green Fluorescent Protein (GFP)/Stem Cell: Embryonic/Monitoring Stem Cell Traffic/Migration
Lipofection Cell Labeling Methodology/Magnetic Resonance Imaging Agent Cell

Background Information: *In vivo* monitoring of stem cells after grafting is essential for a better understanding of their migra-

tional dynamics, differentiation characteristics, and their potential for regeneration. Migration of endogenous or grafted stem cells and neurons has been described in the vertebrate brain, both under normal conditions from the subventricular zone along the rostral migratory stream, and under pathophysiological conditions, such as neuronal degeneration or focal cerebral ischemia. However, many studies conducted for such purposes have relied upon the invasive analysis of brain sections in combination with appropriate staining techniques.

Application: Embryonic stem cells could theoretically function as a selective delivery modality for diagnostic and therapeutic pharmaceutical agents. In concept, the labeling of stem-cell like populations could also function as a methodology for monitoring the "therapeutic" infiltration of desirable cell types into specific lesion sites (e.g., CNS focal cerebral ischemia, Parkinson's disease, epilepsy).

Route of Administration: Variable but usually involving intravascular or possibly direct injection delivery into pathologic lesions.

Implementation: Mapping the *in vivo* dynamics of cell migration (e.g. CNS biodistribution) over a prolonged period of time. Embryonic stem (ES) cells, constitutively expressing GFP are labeled with a lipofection procedure employing a MRI contrast agent. Contrast agent-labeled cells are then directly implanted into brains.

Animal Model: Rat. (focal cerebral ischemia induced 2 weeks before implantation of ES cells into the healthy, contralateral cerebral hemispheres).

Interpretation and Analysis: Magnetic resonance imaging (MRI) at 78-μm isotropic spatial resolution permits the observation of implanted cells with high contrast against host tissue background that can be confirmed by GFP detection patterns. During a 3-week period, cells migrate along the corpus callosum into the ventricular walls, and massively populate the borderzone of damaged brain tissue on the hemisphere opposite to the implantation sites. Embryonic stem cells (ES) have high migrational dynamics and are attracted to regions of created cerebral lesions in a relatively selective manner. Techniques employing labeled embryonic stem cells are ideally suited for the non-invasive imaging of cell migration, engraftment, and morphological differentiation at high spatial and temporal resolution.

Monitoring of implanted stem cell migration in vivo: A highly resolved *in vivo* magnetic resonance imaging investigation of experimental stroke in rat. Hoehn M, Kustermann E, Blunk J, Wiedermann D, Trapp T, Wecker S, Focking M, Arnold H, Hescheler J, Fleischmann BK, Schwindt W, Buhrle C. Proc Natl Acad Sci U S A 2002 Dec 10; 99 (25), pp. 16267–72. Epub 2002 Nov 20.

Hunter Syndrome: Mucopolysaccharidosis Type II/ Iduronate-2-Sulfatase/Lymphocyte-Mediated Selective Delivery

L2SN and L2/Avian β-Actin Promoter in LB2/CMV early Promoter in LNC2

Cellular /Molecular Mechanism of Action: Utilization of the natural (native) homing properties of peripheral blood lymphocytes (PBL) to selectively deliver diagnostic agents.

Route of Administration: Intravenous.

Considerations: Measurement of trans-gene lysosomal enzyme soon after exposure of target cells to vector supernatant may yield a gross overestimate of long-term trans-gene expression by transduced cells. Nevertheless, fibroblasts from clinical cases cocultured with transduced PBL(MPS) have reduced [$^{35}SO^{4}$]-GAG accumulation, levels similar to those of normal fibroblasts.

Implementation: Characterization of IDS expression from 3 different promoters in 4 retroviral vectors performed in peripheral blood lymphocytes (PBL) from cases with Hunter's syndrome (PBL[MPS]). Relevant vectors for LTR include L2SN and L2, avian β-actin promoter in LB2, and the CMV early promoter in LNC2. The production of PBL(MPS) in this manner involves their exposure to packaging cell supernatant.

Interpretation and Analysis: Surprisingly, IDS activities are equally high in all transduced lymphocyte populations: 515 U/mg/h in PBL(MPS)-L2SN, 734 in PBL(MPS)-LB2, 352 in PBL(MPS)-L2, and 389 in PBL(MPS)-LNC2 compared to controls ($<$ 10 in PBL[MPS]-LXSN or PBL[MPS]). The half-life of endocytosed IDS in PBL(MPS) is approximately 1.9 days. However, the level of lymphocyte IDS activity from proviral expression is only a fraction of the total, a large portion being derived from reuptake to enzyme from murine packaging cells, that is, a "2nd source" of enzyme.

Cells can be charged with a lysosomal enzyme to levels much higher than those found in nature. By "supercharging" cells with a lysosomal protein (or other molecule bearing the mannose-6-phosphate ligand), such cells may be exploited as vehicles for systemic delivery of therapeutic or diagnostic agents.

"Supercharged cells" for delivery of recombinant human iduronate-2-sulfatase. Pan D, Jonsson JJ, Braun SE, McIvor RS, Whitley CB. Mol Genet Metab 2000 Jul: 70 (3), pp. 170–8.

Hunter's Syndrome: Mucopolysaccharidosis Type II/ Lymphocyte-Mediated Selective Delivery

Retroviral Vectors (L2SN) /Iduronate-2-Sulfatase (IDS)/ Neomycin Resistance Genes

Cellular/Molecular Mechanism of Action: Vectors "transfect" host cells in a manner that leads to the transfer of genetic material (nucleotides) thereby facilitating subsequent gene expression by the host cell population.

Background Information: The process of growing and transducing large quantities of human primary peripheral blood lymphocytes (PBLs) with high gene transfer efficiency continues to be one of the major challenges for clinical and experimental therapy.

Implementation: Development of a clinical trial of lymphocyte gene therapy for mucopolysaccharidosis type II (i.e., Hunter's syndrome). One approach to such an objective can entail investigating methods that exploited the innate capability of a hollow-fiber bioreactor system to filter large quantities of vector supernatant and facilitate transduction. An aliquot (5×10^7) of PBL apheresis product can be precultured in a gas-permeable culture bag or bioreactor, and then transduced with a retroviral vector L2SN containing the iduronate-2-sulfatase (IDS) and neomycin resistance genes.

Interpretation and Analysis: The total number of PBLs could be expanded up to 187-fold, ielding up to 10^{10} cells at the end of a 7-day culture period. The multiplicity of infection can be increased (up to 20-fold) by ultrafiltrating a large volume of vector supernatant through a semipermeable membrane of this system. A high level of transduction efficiency (up to 57%) can be achieved, resulting in IDS enzyme activity as high as 1250 U/mg/h in transduced PBL(MPS) 15 days after transduction. This level is markedly increased from that of non-transduced cells ($<$ 3 U/mg/h) and is even greater than that of normal PBLs (mean, 809; n = 10). After 12 days of G418 selection, PBL(MPS) transductants exhibits a proviral IDS enzyme level approximately 3-fold higher than that in normal PBLs. These results indicated t hat a hollow-fiber bioreactor could be used to culture and transduce human primary PBLs in clinically useful quantities with relatively high gene transfer efficiency and transgene expression.

Combined ultrafiltration-transduction in a hollow-figer bioreactor facilitates retrovirus-mediated gene transfer into peripheral blood lymphocytes from patients with mucopolysaccharidosis type II. Pan D, Shankar R, Stroncek DF, Whitley CB, Hum Gene Ther 1999 Nov 20; 10 (17), pp.2799–810.

Macrophages: Kupffer Cell Selective Delivery/ Antigen Processing Inhibition
Adenoviral Vector Medicated Delivery (Enhanced High Capacity)/Clodronate Liposomes

Background Information: Tissue macrophages, in particular hepatic Kupffer cells (KCs), contribute to early inflammatory responses following adenoviral vector administration.
Application: Characterization of hepatic Kupffer cells and enhancement of adenoviral vector delivery.
Route of Administration: Intravascular.
Implementation: Evaluate the effect of selective and transient (3 days) depletion of hepatic Kupffer Cells (KC) by a single injection of clodronate liposomes on the *in vivo* performance of high-capacity adenoviral (HC-Ad) vectors.
Interpretation and Analysis: Interestingly, in the majority of animals of both strains, the depletion of KCs is sufficient to prevent the generation of anti-hAAT antibodies, resulting in prolonged transgene expression. Thus, short-term and selective depletion of hepatic macrophages at the same time significantly increases hepatic transgene expression and reduces the humoral immune response to the transgenic protein.

Selective depletion or blockade of Kupffer cells leads to enhanced and prolonged hepatic transgene expression using high-capacity adenoviral vectors. Schiedner G, Hertel S, Johnston M, Dries V, van Rooijen N, Kochanek S. Mol Ther 2003 Jan; 7 (1), pp. 35–43.

Neoplastic Disease: Renal Solid Tumors
Plasmid-Microspheres/Plasmids Complexed Liposomes/Selective Tumor DNA Delivery Via Vasculature

Application: Selective targeting of genetic DNA incorporated into plasmid for neoplastic lesions (selective delivery is in part facilitated by selective catheterization of the major arterial network supplying a neoplastic tissue mass.
Route of Administration: Arterial catheterisation
Implementation: Evaluation of plasmid DNA delivery into to an established rat renal solid tumor model involving the utilization of plasmid bound to microspheres, and plasmids complexed with liposomes to evaluate their potential to function as a selective delivery modality for tumors (via arterial catheterization).
Ex-Vivo: Rat renal solid tumor.
Interpretation and Analysis: Forty-eight hours post-delivery, tumor to normal kidney tissue chloramphenicol acetyltransferase expression ratios are as follows: free (1.8:1), microspherical (3.9:1), and liposomal (1.2:1). Microspheres are able to selectively deliver plasmids to tumours, whereas cationic liposomes distribute plasmids to both kidney parenchymal and tumor cells. The tumor model has the potential of screening delivery vehicles as well as therapeutic agents for the capacity of selective delivery to tumors via the vasculature.

A model for evaluating *selective* delivery of plasmid DNA to tumours via the vasculature. Dass CR; Burton MA Cancer biotherapy & radiopharmaceuticals [Cancer Biother Radiopharm] 2002 Oct; 17 (5), pp. 501–5.

Stem Cell Populations: Hematopoietic ($CD34^+$)/ Gene Delivery: EGFP and LNGFR Coding Sequence: Reporter Sequences
Retroviral Vectors (MFG Retroviral Backbone)

Background Information: Retroviral vectors are widely used to deliver foreign genes to hematopoietic stem cells (HSC). Improvement of marking protocols requires reporter genes to facilitate rapid detection and efficient selection of transduced cells. Both EGFP and LNGFR hold great potential as reporter systems and can be used simultaneously to compare their properties using the same retroviral backbone and the same gene transfer procedures. Note: [i] EGFP = enhanced green fluorescent protein; [ii] LNGFR = low-affinity nerve growth factor receptor; [iii] MFG = milk fat globulin; and [iv] ATG = antithymocyte globulin.
Application: Delivery of genetic sequences for their expression in mammalian cell systems. Such strategies could theoretically be utilized to deliver sense or antisense nucleotide strands for various diagnostic purposes.
Implementation: The EGFP and LNGFR coding sequences are separately cloned into the MFG retroviral backbone. A cloning strategy that assures that both genes utilize the same ATG as the start codon can be applied. Marker gene expression, viral titers, transduction efficiency, and vector stability can be evaluated in expanded amphotropic packaging clones and human hematopoietic cell lines by flow cytometry and PCR analysis. Vectors can also be tested for their ability to transduce different cell populations (e.g. CD34+ peripheral blood cells).
Interpretation and Analysis: A significantly larger number of MFG- LNGFR packaging clones can be obtained that produced high viral titers. A direct correlation between viral titer and marker gene expression in packaging clones can be demonstrated for both constructs. Similar expression kinetics and absence of *in vitro* toxicity in transduced cells are also observed for both constructs. Successful infection of CD34+ cells can be achieved even after a short time of exposure to recombinant viruses.

The marker genes, EGFP and LNGFR have been demonstrated to be equally useful for a rapid, specific and non-toxic detection of transduced cells. The MFG-EGFP construct appears useful to optimize gene transfer protocols *in vitro*. Alternatively, the MFG-LNGFR construct, for making possible a more efficient selection of high titer producer clones, as well as for safety and adaptability for *in vivo* use, is more suitable for clinical applications.

A comparative evaluation of gene transfer into blood cells using the same retroviral backbone for independent expression of the EGFP and deltaL-NGFR marker genes. Giaretta I, Madeo D, Bonaguro R, Cappellari A, Rodeghiero F, Giorgio P. Haematologica 2000 Jul; 85 (7), pp. 680–9.

MACRO-SYNTHETIC PLATFORMS

LIPOSOMES

Concepts and Perspectives: Liposomes
Synthetic Liposomes

Cellular/Molecular Mechanism of Action: Liposomes function as a nano-scale reservoirs and mobile *in vivo* delivery platforms for diagnostic agents.
Application: Delivery of *in vivo* diagnostic agents to the lymphatic system.
Route of Administration: Subcutaneous (s.c.) injection resulting in the assimilation of liposomes into the lymphatic system.
Dosage: Designed to establish a correlation between the specific biological activity (efficacy) of aptamer preparations and the corresponding pathological condition. Factors that influence lymphatic absorption and lymph node uptake of liposome administered subcutaneously include mean size and the anatomical site of injection (e.g., regional perfusion variable). Generally, other factors such as lipid composition, charge, and the presence of a hydrophilic poly (ethylene glycol) (PEG)-coating on the liposome surface do not sub-

stantially affect lymphatic absorption and lymph node uptake of s.c. administered liposomes.

Considerations: Subcutaneous injection is the route of delivery that is most effective for characterizing lymph node drainage basins with liposome preparations.

Interpretation and Analysis: Studies on the intranodal fate of liposomes demonstrate that phagocytosis by macrophages is the most important mechanism for lymph node uptake of liposomes. The observation of relatively high uptake of liposomes in regional lymph nodes after s.c. administration has stimulated research on lymphatic targeting of liposomes for diagnostic and therapeutic applications.

Role of macrophages in the localization of liposomes in lymph nodes after subcutaneous administration. Oussoren C, Storm G. Int J Pharm 1999 Jun 10; 183 (1), pp. 37–41.

Concepts and Perspectives: Liposomes/ Clearance Properties

Cellular/Molecular Mechanism of Action: Encapsulation can protect pharmaceutical agents from biochemical degradation and serve as a format for delivering high concentrations to specific organ/tissue targets or as a means for achieving slow-release pharmacokinetic patterns.

Application: Encapsulation can protect pharmaceutical agents from biochemical degradation and serve as a format for delivering high concentrations to specific organ/tissue targets or a platform for achieving slow-release pharmacokinetic patterns.

Route of Administration: Variable but most frequently intravascular.

Considerations: The clearance rate of liposomal drugs from the circulation is determined by the rate and extent of both drug release and uptake of liposomes by cells within the mononuclear phagocyte system (MPS). Intravenously injected liposomes initially come into contact with serum proteins. The interaction of liposomes with serum proteins is thought to play a critical role in the liposome clearance. In contrast to conventional (non-surface modification) liposomes, accelerated clearance of poly(ethylene glycol) (PEG)ylated-liposomes (sterically stabilized long-circulating liposomes) on repeated injection is a phenomenon that has been observed in previous investigations.

Implementation: Evaluation of the role of opsonin-independent and so-called opsonin-dependent mechanisms in promoting enhanced clearance of liposomes.

Interpretation and Analysis: Certain serum proteins can function as so-called opsonins in a manner that enhances the clearance of liposomes, when bound to their exterior surface membrane. In addition to opsonin-dependent liposome clearance, opsonin-independent liposome clearance is also an important consideration.

Liposome clearance. Ishida T, Harashima H, Kiwada H. Biosci Rep 2002 Apr; 22 (2), pp. 197–224.

Concepts and Perspectives/Diagnostic Pharmaceuticals Delivery
Liposomes

Cellular/Molecular Mechanism of Action: Encapsulation of relatively large volumes of diagnostic pharmaceutical agents to reduce biological degradation and diffusion and enhance selective delivery to specific cell types or tissues/organs.

Application: Variable and flexible.

Considerations: Major components of liposomes can include lipids, water, drugs, electrolytes, antioxidants, preservatives, and viscosity-inducing agents. Various methods and techniques have been developed for preparing different types of liposomes, including unilamellar, multilamellar, and immunoliposomes.

Interpretation and Analysis: The effectiveness and extent of liposomal drug delivery systems is directly influenced by vesicle size distribution; concentration of residual organic phase in the phospholipid bilayer system; surface characteristics and properties; efficiency and extent of drug encapsulation; chronological stability; and selective homing properties.

Entrapment of small molecules and nucleic acid-based drugs in liposomes. Fenske DB, Cullis PR. Methods Enzymol 2005; 391, pp. 7–40.

Recent trends in drug delivery systems: Liposomal drug delivery system—preparation and characterization. Chandran S, Roy A, Mishra B. Indian J Exp Biol 1997 Aug; 35 (8), pp. 801–9.

Concepts and Perspectives: Liposomes/ Membrane Fluidity
Diphenylhexatriene (DPH) Fluorescence Anisotropy

Background Information: Some reports have suggested that selective uptake of photosensitizers is due to significantly lower pH levels in interstitial fluid of tumors in contrast to normal tissue.

Application: Diphenylhexatriene can be applied to measure membrane fluidity by fluorescence anisotropy.

Implementation: Evaluation of the cellular uptake of merocyanine 540 (MC 540) examined at two pH levels: 6.8 ± 0.1 and 7.4 ± 0.1. There is no difference in spectral properties (absorption and fluorescence maxima positions, fluorescence intensity) of the drug in the presence of increasing amounts of either human blood plasma or fetal calf serum (FCS) (0–2%) at the 2 pH values evaluated.

Interpretation and Analysis: Nevertheless, significantly higher amounts of the drug are taken up by WiDr cells at pH 6.8 ± 0.1, both in the presence and absence of 10% FCS formulations. The absorption spectra of MC 540 in the presence of egg phosphatidylcholine (PC) liposomes are NaCl concentration-dependent (0.00–0.30 mol/L). Membrane fluidity, as measured by fluorescence anisotropy of DPH, is unchanged within the experimental error for NaCl concentration ranges between 0.01 and 0.30 mol l/L. Spectral changes indicate an enhancement of the incorporation of MC 540 into lipid membranes with increasing ionic strength. Such a concentration-dependent phenomenon for salt suggests a possible involvement of the surface potential in the interaction of MC 540 with lipid membranes. The results might provide an explanation of the pH dependency of the cellular uptake observed for MC 540 preparations.

pH, serum proteins, and ionic strength influence the uptake of merocyanine 540 by WiDr cells and its interaction with membrane structures. Cunderlíková B, Sikurová L, Moan J. Bioelectrochemistry 2003 Apr; 59 (1–2), pp. 1–10.

Concepts and Perspectives: Liposomes/ Protein-Lipid Membrane Interactions
N-[10-(1-Pyrenyl)Decanoyl]Sphingomyelin

Cellular/Molecular Mechanism of Action: The agent N-[10-(1-pyrenyl)decanoyl]sphingomyelin is a fluorescent sphingomyelin derivative.

Background Information: Selective enzymatic hydrolysis, lipid compositional analyses, and fluorescence studies have been performed on acetylcholine receptor (AChR)-rich membranes from Torpedinidae to investigate the topology of sphingomyelin (SM) in the native membrane and its relationship with the AChR protein.

Controlled sphingomyelinase hydrolysis of native membranes shows that SM is predominantly (approximately 60%) localized in the outer half of the lipid bilayer. Differences can also observed in the distribution of SM fatty acid molecular species in the 2 bilayer leaflets.

Application: Characterization of membrane protein-lipid interactions.

Implementation: A fluorescent SM derivative (N-[10-(1-pyrenyl)decanoyl]sphingomyelin; Py-SM) can be used to study protein-lipid interactions in AChR-rich membrane preparations and in affinity-purified Torpedo AChR reconstituted in liposomes made from Torpedo electrocyte lipid extracts. The efficiency of Förster resonance energy transfer (FRET) from the protein to the pyrenyl-labeled lipid as a function of acceptor surface density can be used to estimate distances and topography of the SM derivative relative to the protein. The dynamics of the lipid acyl chains can be explored by measuring the thermal dependence of Py-SM excimer formation, sensitive to the fluidity of the membrane.

Interpretation and Analysis: Differences can be observed in the concentration dependence of excimer/monomer pyrenyl fluorescence when measured by direct excitation of the probe under FRET conditions, indicating differences in the intermolecular collisional frequency of the fluorophores between bulk and protein-vicinal lipid environments, respectively. Py-SM exhibits a moderate selectivity for the protein-vicinal lipid domain, with a calculated relative affinity K_r of approximately 0.55. Upon sphingomyelinase digestion of the membrane, FRET efficiency increases by about 50%, indicating that the resulting pyrenyl-ceramide species have higher affinity for the protein than the parental SM derivative.

Sphingomyelin composition and physical asymmetries in native acetylcholine receptor-rich membranes. Bonini IC, Antollini SS, Gutiérrez-Merino C, Barrantes FJ. Eur Biophys J 2002 Oct; 31 (6), pp. 417–27.

Liposomes: Cardiovascular/Atherosclerosis (Ultrasonography)/Atheroma: Regions of Fibrous Content/Atheroma: Regions of Early Phase Deposition

Antifibrinogen-Liposomes/Anti-ICAM-Liposomes

Background Information: Acoustically reflective liposomes that can be conjugated for site-specific acoustic enhancement.

Application: Selective targeting of acoustically reflective liposomes for atherosclerotic plaques *in vivo* in order to achieve ultrasound image enhancement.

Semi-Synthetic Methods: Liposomes were prepared with phospholipids and cholesterol using a dehydration/rehydration method. Antibodies can be thiolated for liposome conjugation with *N*-succinimidyl 3-(2-pyridyldithio) propionate, resulting in the creation of a thioether linkage between the protein and phospholipid group. Liposomes can also be conjugated to antifibrinogen or anti-intercellular adhesion molecule-1 (anti-ICAM-1).

Implementation: Evaluation of the ability of liposomes coupled to antibodies specific for different components of atherosclerotic plaques and thrombi to target and enhance ultrasonic images *in vivo*. Imaging of arterial plaques can be performed utilizing a 20-MHz intravascular ultrasound catheter and 7.5-MHz trans-vascular linear probe following injection of saline (reference control), unconjugated liposomes (reference control), and antibody-conjugated liposomes.

Animal Model: Swine (Yucatan miniswine model for atherosclerosis developed by crush injury of 1 carotid artery and 1 femoral artery in concert with the ingestion of a hypercholesterolemic diet).

Interpretation and Analysis: Conjugated liposomes retain their acoustically reflective properties and provide ultrasonic image enhancement of their targeted structures. Liposomes conjugated to antifibrinogen attach to thrombi and fibrous portions of atheromas, whereas liposomes conjugated to anti-ICAM-1 attach to early atheromas. Such findings demonstrate that these novel acoustic agent can provide targeting flexibility facilitated with the application of different antibodies with preparations retaining intravascular and trans-vascular acoustic properties.

Instrumentation: 20-MHz intravascular ultrasound catheter and 7.5-MHz trans-vascular linear probe.

In vivo targeting of acoustically reflective liposomes for intravascular and trans-vascular ultrasonic enhancement. Demos SM, Alkan-Onyuksel H, Kane BJ, Ramani K, Nagaraj A, Greene R, Klegerman M, McPherson DD. J Am Coll Cardiol 1999 Mar; 33 (3), pp. 867–75.

Liposomes: Cardiovascular/Blood-Pool Imaging Agent

Iohexol Liposomes

Background Information: Although soluble non-ionic iodine compounds with low systemic toxic effects have been developed for use in computed tomography (CT), they have short residence times of a few minutes or mere seconds, which is insufficient time for blood-pool imaging, even with high-speed multidetector row spiral CT. Moreover, potential renal toxic effects preclude repeated administration of these contrast agents during imaging, as well as their use in cases with compromised renal function.

Implementation: Development and evaluation of a CT contrast agent for blood-pool imaging that remains in the blood for more than 3 hours and that is relatively non-toxic to the kidneys. One candidate agent includes liposomal iohexol formulations and determination of encapsulation efficiency parameters in terms of milligrams of iodine per milliliter of lipid formulation, stability in phosphate buffer solution, and stability in human plasma *in vitro*. Complementary investigations can be devoted to assessing *in vivo* stability, residence time, and enhancement of contrast on images of various organ systems.

Animal Model: Rabbit.

Interpretation and Analysis: Formulations containing 34.8 mg of iodine per milliliter of liposomal iohexol solution retain stability in blood plasma both *in vitro* and *in vivo* postinjection into the central vascular compartment. An intravenous dose of 475 mg of iodine per kilogram of body weight produces contrast enhancement of approximately 130 Hounsfield units (HU) in the aorta and liver cortex and approximately 100 HU in the kidney cortex. Contrast enhancement can be maintained for 3 hours postinjection, and minimal clearance of the contrast agent via the kidneys can be observed. The liposomal iohexol formulation has a sufficient residence time for blood-pool imaging in a rabbit model. Future experiments with long-residence-time iohexol formulations may lead eventually to applications in cardiac imaging and in early tumor detection.

Long-residence-time nano-scale liposomal iohexol for x-ray-based blood-pool imaging. Kao CY, Hoffman EA, Beck KC, Bellamkonda RV, Annapragada AV. Acad Radiol 2003 May; 10 (5), pp. 475–83.

Liposomes: Cardiovascular Endothelial Cells

Liposomes: E-Selectin Directed/[Immunoliposomes]

Cellular/Molecular Mechanism of Action: E-selectin is expressed on the exterior surface membrane of endothelial cell populations.

Background Information: Previous *in vitro* experiments demonstrated that the targeting of immunoliposomes for vascular selectins represents a potential avenue for selective drug delivery sites of inflammation.

Route of Administration: Intravenous.
Implementation: Evaluation of the cellular uptake of targeted immunoliposomes by interleukin-1-activated human endothelial cells detected by spectroscopy and microscopic fluorescence techniques. In this manner it is possible to follow the fate of liposomes after target binding and the route and degree of liposome internalization. Analytical focus is directed at delineating the state of cell activation facilitated by modifying various liposomal parameters (e.g., sterical stabilization, type of antibody or antibody coupling strategy).
Interpretation and Analysis: In attempts to further adapt the targeting experiments to physiological conditions, it has been established that E-selectin-directed immunoliposomes can cumulatively bind to target cells under the simulated shear force conditions of capillary blood flow for up to 18 hours. The use of liposomes labeled with NBD (7-nitrobenz-2-oxa-1,3-diazole or 7-nitro-2-1,3-benzoxadiazol-4-yl) and subsequent fluorescence quenching outside cells with dithionite shows that circa 25% of the targeted immunoliposomes become internalized. According to inhibition experiments with agents that interfere with the endocytotic pathway, it has been determined that the major mechanism of liposome entry is endocytic. The entry of liposomes into cells involves, at least in part, receptor-mediated endocytosis facilitated by E-selectin, followed by liposome accumulation within endosomes and their subsequent acidification, which can be characterized through the use of pyranine spectroscopy techniques. Furthermore, microscopy has revealed that a fusion of liposomes with the cell membrane occurs, followed by a release of entrapped calcein into the cytoplasm. Such observations have provided greater insight into the behavior of E-selectin-targeted immunoliposomes and indicate that this type of immunoliposomes have great potential for use as drug carriers for intracellular drug delivery at inflammatory sites (diagnostic/therapeutic).

Investigation of the cellular uptake of E-selectin-targeted immunoliposomes by activated human endothelial cells. Kessner S, Krause A, Rothe U, Bendas G. Biochim Biophys Acta 2001 Oct 1; 1514 (2), pp. 177–90.

Liposomes: Central Nervous System (CNS) Inflammation/Macrophages/Microglial Cells/ Astrocytes
Poly(Ethylene Glycol) (PEG)-Long-Circulating Liposomes/[^{3}H]-Labeled Prednisolone Liposomes (PL)

Cellular/Molecular Mechanism of Action: Selective delivery into the CNS.
Background Information: High-dose glucocorticosteroid hormones are a mainstay of treatment during episodes of relapse in conditions of multiple sclerosis.
Application: [^{3}H]-labeled PL display selective targeting of the inflamed CNS.
Implementation: Evaluation of liposome as an ultra-high-dose delivery modality for glucocorticosteroids to the CNS using a formulation of PEG-coated long-circulating liposomes encapsulating prednisolone (PL).
Animal Model: Rat (experimental autoimmune encephalomyelitis [EAE]).
Interpretation and Analysis: [^{3}H]-labeled PL possess an ability to selectively target inflamed CNS tissues, where up to 4.5-fold higher radioactivity can be achieved compared to healthy control animals. Analysis by HPLC reveals much higher and more persistent levels of prednisolone within the spinal cord after PL, compared with an equal dose of free prednisolone.

Gold-labeled liposomes can be detected in the target tissue, mostly taken up by macrophages (Mphi), microglial cells, and astrocytes. Blood-brain barrier disruption is greatly reduced by 10 mg/kg PL, which is superior to a 5-fold higher dose of free methylprednisolone (MP). Prednisolone liposomes are also superior to MP in diminishing T cell infiltration by induction of T cell apoptosis within spinal cord. Macrophage infiltration is clearly decreased only by prednisolone liposomes. The percentage of tumor necrosis factor-alpha (TNF-α)-positive T cells or Mphi is greatly reduced by PL and by MP. No adverse effects on glial cells can be detected. A single injection of prednisolone liposomes clearly ameliorates the course of adoptive transfer EAE and EAE induced by immunization. Therefore, PL is a highly effective drug in treatment of EAE and is superior to a 5-fold higher dose of free MP, possibly by means of drug targeting. These findings may have implications for future diagnosis and therapy of autoimmune disorders such as multiple sclerosis.

Drug targeting by long-circulating liposomal glucocorticosteroids increases therapeutic efficacy in a model of multiple sclerosis. Schmidt J, Metselaar JM, Wauben MH, Toyka KV, Storm G, Gold R. Brain 2003 Aug; 126 (Pt 8), pp. 1895–904.

Liposomes: Central Nervous System (CNS)/ Macrophage Selective Depletion/Meningeal and Perivascular/Microglial Cells (Spared)
Clodronate Liposomes

Background Information: Perivascular (PVM) and meningeal (MM) macrophages form a distinct population that is resident within the CNS that selectively expresses the ED2 mature macrophage marker (rat).
Route of Administration: Clodronate liposomes (intraventricular injection).
Implementation: Elucidate the role of PVM and MM during normal functioning of the brain and pathology conditions by employing a single intraventricular injection of clodronate liposomes.
Animal Model: Rat.
Interpretation and Analysis: Intraventricular injection of clodronate liposomes completely depletes PVM and MM. Clodronate liposomes do not deplete the microglial cells. In other parts of the body, a temporal and mild depletion effect can be appreciated, which is restored within 1 week. Detailed analysis of the elimination and repopulation kinetics of the PVM and MM reveals a slow repopulation of the CNS, starting at 14 days postdepletion. Such selective depletion methods for PVM and MM can facilitate increasing the level of knowledge about their functions during normal and pathologic conditions of the CNS.

A method for the selective depletion of perivascular and meningeal macrophages in the central nervous system. Polfliet MM, Goede PH, van Kesteren-Hendrikx EM, van Rooijen N, Dijkstra CD, van den Berg TK. J Neuroimmunol 2001 Jun 1; 116 (2), pp. 188–95.

Liposomes: Central Nervous System (CNS)/ Macrophage Selective Depletion/Meningeal and Perivascular Macrophages
Mannosylated Clodronate Liposomes

Background Information: Meningeal (MM) and perivascular (PVM) macrophages constitute major populations of resident macrophages in the CNS that can be distinguished from microglial cells. So far, there is no direct evidence that demonstrates a possible role of MM and PVM in the CNS during normal or pathologic conditions.
Route of Administration: Mannosylated clodronate liposomes (intraventricular injection).
Implementation: Elucidation of the role of the MM and PVM during CNS inflammation through the application of a single intraventricular injection of mannosylated clodronate liposomes.

Interpretation and Analysis: Mannosylated clodronate liposome injection results in a complete and selective depletion of the PVM and MM from the CNS. Depletion of MM and PVM during experimental pneumococcal meningitis results in increased illness, which correlates with higher bacterial counts within the cerebrospinal fluid and blood. This is associated with a decreased in the influx of leukocytes into the cerebrospinal fluid, which occurs despite elevated production of relevant chemokines (e.g., macrophage-inflammatory protein-2) and higher expression of vascular adhesion molecules (e.g., VCAM-1). Alternatively, higher bacterial counts correlates with elevated production of local and systemic inflammatory mediators (e.g., IL-6) indicating enhanced local leukocyte and systemic immune activation, and this may explain worsening of clinical signs. Such findings show that PVM and MM play a protective role during bacterial meningitis and suggests that 1 of the primary functions of these macrophages is to facilitate the influx of leukocytes at the blood-brain barrier.

Meningeal and perivascular macrophages of the central nervous system play a protective role during bacterial meningitis. Polfliet MM, Zwijnenburg PJ, van Furth AM, van der Poll T, Döpp EA, Renardel de Lavalette C, van Kesteren-Hendrikx EM, van Rooijen N, Dijkstra CD, van den Berg TK. J Immunol 2001 Oct 15; 167 (8), pp. 4644–50.

Liposomes: Central Nervous System (CNS)/ Macrophage Selective Depletion/Meningeal and Perivascular/Microglial Cells (Spared): Encephalitis Research Model
Clodronate Liposomes

Background Information: The perivascular (PVM) and meningeal (MM) macrophages constitute a major population of resident macrophages in the CNS.

Implementation: Evaluation of the possible role of PVM and MM during CNS inflammation in conditions of experimental allergic encephalomyelitis (EAE). Investigations can be facilitated by the selective depletion of CNS PVM and MM utilizing clodronate liposomes.

Animal Model: Rat (EAE).

Interpretation and Analysis: There is a remarkable increase in the expression of the ED2 antigen on PVM and MM (already present at day 9 post-EAE induction), which precedes the onset of clinical symptoms and infiltration of leukocytes into the CNS (occurs at day 13). Therefore, the onset of EAE is accompanied by alterations of PVM and MM, and the ED2 antigen provides an early indicator/marker of pathology during episodes of CNS inflammation. Moreover, selective depletion of the ED2-positive macrophages in the CNS using clodronate liposomes results in a suppression of clinical symptoms. These observations indicate that PVM and MM play a role during the early stages of EAE development.

The role of perivascular and meningeal macrophages in experimental allergic encephalomyelitis. Polfliet MM, van de Veerdonk F, Döpp EA, van Kesteren-Hendrikx EM, van Rooijen N, Dijkstra CD, van den Berg TK. J Neuroimmunol 2002 Jan; 122 (1–2), pp. 1–8.

Liposomes/Central Nervous System (CNS)/ Monocytes and Neutrophils Delivery/CNS Inflammation/Cerebrovascular Disease
Anionic Magnetic Liposomes/Soya Lecithin/Cholesterol/Phosphatidyl Serine/[Arginine-Glycine-Aspartic Acid (RGD)] Anionic PC/Cholesterol/PS/Phopsphatidyl Ethanolamine

Cellular/Molecular Mechanism of Action: Preferential uptake by neutrophils and macrophages.

Application: Selective delivery of diagnostic and therapeutic agents into the CNS facilitated by neutrophil/macrophage-mediated delivery.

Semi-Synthetic Methods: Negatively charged magnetic liposomes can be prepared using soya lecithin (Soya PC), cholesterol, and phosphatidyl serine (PS) in a manner that can preferentially enhance phagocytosis by monocytes and neutrophils within the intravascular compartment. The PS ratio can be optimized in terms of drug and magnetite loading, *in vitro* magnetic responsiveness, and *ex vivo* monocytes/neutrophils uptake. RGD peptide can be covalently coupled to negatively charged liposomes composed of PC, cholesterol, PS, and phosphatidyl ethanolamine (PE) via carbodiimide-mediated coupling.

Implementation: *In vivo* cellular sorting studies performed under magnetic guard indicate an increase in relative count of neutrophils and monocytes. Results suggest that selective uptake of RGD-anchored magnetic liposomes by these cells imparts magnetic properties.

In the brain, high levels of diclofenac sodium can be detected. Negatively charged uncoated magnetic liposome brain levels of diclofenac are 5.95-fold compared to free drug and 7.58-fold when compared to non-magnetic formulations, while for RGD-coated magnetic liposomes this ratio is 9.1-fold compared to free drug solution, 6.62-fold compared to non-magnetic RGD-coated liposomes, and 1.5-fold when compared to uncoated magnetic liposomes. Liver uptake can be significantly enhanced (37.2% and 48.3% for uncoated and RGD-coated magnetic liposomes, respectively). Therefore, negatively charged and RGD-coated magnetic liposomes can serve as a strategy for monocytes/neutrophils-mediated delivery of pharmaceuticals to relatively inaccessible sites of inflammation (e.g., brain). Liposomes prepared in such a fashion represent a strategy for the active delivery of drugs in a manner possibly suitable for the diagnosis and selective treatment of cerebrovascular disease.

RGD-anchored magnetic liposomes for monocytes/neutrophils-mediated brain targeting. Jain S, Mishra V, Singh P, Dubey PK, Saraf DK, Vyas SP. Int J Pharm 2003 Aug 11; 261 (1–2), pp. 43–55.

Liposomes/Central Nervous System (CNS): Vascular Capillary Endothelium/Gene Transfer Model
Hemagglutination Virus of Japan (HVJ)-Liposomes/ Liposome-Encapsulated Beta-Gal Plasmid

Background Information: Bioactive proteins or peptides cannot be effectively delivered into brain capillary endothelial cells (BCECs) or brain parenchyma. Alternatively, cells referred to as MBEC are BCEC cells can be transfected with the mGDNF gene (glial cell-derived neurotrophic factor).

Route of Administration: Superselective internal carotid artery catheterization.

Implementation: Evaluation of the effectiveness of transferring the *Escherichia coli* beta-galactosidase gene (beta-gal) as a model gene into BCEC utilizing the HVJ-liposomes. HVJ-liposomes encapsulating a beta-gal plasmid can be used both *in vitro* to transfect MBEC4 cells and *in vivo* by selective administration/delivery.

Animal Model: Rat (internal carotid artery catheterization).

Interpretation and Analysis: Success of the procedure is confirmed by the (i) detection of 116 kDa beta-gal protein in transfected MBEC4 cells and in brain capillaries isolated from transfected rats; and (ii) Western blot analysis and histological staining. The enzymatic activities of beta-gal are 5- to 10-fold and 20-fold higher when beta-gal-containing liposomes without fusogenic activity (uncoated liposomes) or plasmid alone are employed *in vitro* and *in vivo*, respectively. Thus, HVJ-liposomes have demonstrated applicability

as a vector for the transfer of foreign genes into brain capillary endothelium *in vivo* (trans-luminal route).

Trans-luminal gene transfer into brain capillary endothelial cells *in vivo* with HVJ-liposomes. Jiang C, Matsuo H, Koyabu N, Ohtani H, Fujimoto H, Yonemitsu Y, Kaneda Y, Narro M, Tsuruo T, Sawada Y. J Drug Target 2002 Jun; 10 (4), pp. 345–52.

Liposomes/Central Nervous System (CNS): Vasculature of the Choriocapillaris/Choroidal Angiogram Imaging
Liposomes: Heat Sensitive/Carboxyfluorescein (Encapsulated)/[Laser Targeted Angiography]

Background Information: Preparations can be applied to obtain high-quality angiograms of the rat choriocapillaris with continuous laser-targeted angiography (LTA), for the *in vivo* assessment of choroidal vascular structures.
Application: Characterization of choroidal circulation by angiogram imaging.
Route of Administration: Heat-sensitive liposomes (intravascular).
Implementation: Evaluation of a carboxyfluorescein compound encapsulated into heat-sensitive liposomes and injected intravenously. Local release of encapsulated carboxyfluorescein is induced by applying a continuous heat beam utilizing a diode laser (810 nm) of variable power. Video angiograms are generated with excitation illumination provided by argon laser (488 and 514 nm) to observe highly selective images of the choriocapillaris.
Animal Model: Rat.
Interpretation and Analysis: Three distinct phases (filling, plateau, and draining) can be observed in fluorescent images of choriocapillaris by applying a continuous diode laser. In the plateau phase, a lobe-shaped area of choriocapillaris peripheral to the laser site can be illuminated, and this finite area does not change in size with continuous laser application to the same spot. When laser power is increased, a larger area of choriocapillaris can be illuminated in the plateau phase. The filling and draining phases demonstrate the flow patterns within choriocapillaris lobules, which fill from a central spot and drain along a peripheral ring. Choriocapillaris (rat) is divided into independent functional units and the choroidal circulation is segmentally organized under normal conditions. In LTA, the diode laser warms up a choroidal artery, and released fluorescein flows downstream to an area of choriocapillaris fed by the same artery. Laser-targeted angiography (LTA) appears to be a powerful method for analyzing *in vivo* choroidal circulation.
Instrumentation: Modified slit lamp that incorporates 2 kinds of lasers (argon and diode).

In vivo analysis of choroidal circulation by continuous laser-targeted angiography in the rat. Hirata Y, Nishiwaki H, Miura S, Ieki Y, Kiryu J, Honda Y. Invest Ophthalmol Vis Sci 2003 Jul; 44 (7), pp. 3103–9.

Liposomes/Dermal: Trans-Cutaneous Delivery Modality
Hydrogels: Cross-Linked Chitosan/(Lauric, Myristic, Palmitic, or Stearic Acids)

Application: Protected, selective delivery of diagnostic and therapeutic pharmaceutical agents.
Route of Administration: Topical delivery.
Semi-Synthetic Methods: Chitosan hydrogels can be physically cross-linked with lauric, myristic, palmitic, or stearic acid. Preservation can be achieved by freeze-drying. Propranolol hydrochloride functions as a suitable hydrophilic model drug to facilitate the design of trans-dermal delivery systems and the evaluation of such preparations. In this manner, the nature of the effect of cross-linker on drug permeation through porcine skin and the main permeation parameters (diffusion coefficient, flux, and lag time) can be established.
Interpretation and Analysis: All chitosan hydrogels can provide more trans-cutaneous permeation of propranolol hydrochloride than the corresponding solution of the commercial drug. Among the different chitosan vehicles, chitosan-laurate and chitosan-myristate hydrogels enhance lyophilized drug diffusion through the skin with respect to chitosan-palmitate and chitosan-stearate hydrogels. This can be explained by the interaction of the hydrogels with the stratum corneum, increasing the solubility of the drug within the skin.

Physically cross-linked chitosan hydrogels as topical vehicles for hydrophilic drugs. Cerchiara T, Luppi B, Bigucci F, Orienti I, Zecchi V. J Pharm Pharmacol 2002 Nov; 54 (11), pp. 1453–9.

Liposomes/Endothelial Intercellular Adhesion Molecule (ICAM)/Microvascular (Endothelial) Leukocyte Receptor Complex Expression
[Anti-ICAM]-Paramagnetic Liposomes

Application: The *in vivo* targeting of molecules expressed by vascular endothelium, while providing sufficient signal enhancement at these sites for detection by magnetic resonance imaging (MRI).
Implementation: [Anti-ICAM]-paramagnetic liposomes (ACPL) targeted to ICAM-1 administered *in vivo* for delineating endothelial leukocyte receptor upregulation in the cerebral microvasculature during conditions of autoimmune encephalitis.
Animal Model: Mouse (autoimmune encephalitis).
Interpretation and Analysis: Fluorescence microscopy analysis reveals that fluorescently-tagged ACPLs are localized within the central nervous system (CNS) microvasculature in a pattern consistent with ICAM-1 upregulation. Such findings closely correlate with immunohistochemical analyses. High resolution MRI of mouse brains *ex vivo* demonstrate that ACPL binding patterns confer significant enhancement of signal intensity (SI) as compared to control images. Preparations of ACPLs therefore appear to be a useful MRI contrast agent for visualization of specific molecules expressed on the exterior surface membrane of vascular endothelium during various disease states.
Instrumentation: Magnetic resonance imaging instrumentation.

ICAM-1 expression in autoimmune encephalitis visualized using magnetic resonance imaging. Sipkins DA, Gijbels K, Tropper FD, Bednarski M, Li KC, Steinman L. J Neuroimmunol 2000 Apr 3; 104 (1), pp. 1–9.

Liposomes/Gastrointestinal: Colitis
[^{99m}Technetium] ([^{99m}Tc])-Liposomes

Cellular/Molecular Mechanism of Action: Liposomes can protect encapsulated pharmaceutical agents from biological degradation and facilitate variable levels of selective delivery.
Application: Selective accumulation of diagnostic agents or therapeutic pharmaceuticals within inflamed regions of the colon.
Considerations: Therapeutic intervention in inflammatory bowel diseases (IBDs) is often associated with severe toxicity related to non-specific and ubiquitous interaction of drugs with organs and tissues. In order to prevent side effects from aggressive and prolonged treatment with glucocorticoids and immunosuppressive agents, preferential accumulation of these potent drugs in diseased tissue is desired.
Implementation: Evaluation of the disposition of [^{99m}Tc]-liposomes monitored by gamma camera imaging, and determination of the biodistribution of radioactivity within various organs.

Animal Model: Rat.
Interpretation and Analysis: Images reveal distinct accumulation of radioactivity in the colon within regions of colitis, while the abdomen of normal rats is conspicuously free of any visible radioactivity. Although images acquired 4 hours after [^{99m}Tc]-liposome injection are clear enough for diagnostic purposes, the real potential of liposomes for drug delivery is evident in 24-hour images, where it is evident that the major organs of liposome accumulation are dwarfed by intense colon activity in animals with colitis. On necropsy, 13.5% ± 5.48 of the activity is within the inflamed colon compared to only 0.1% in the normal colon, giving a target-to-nontarget ratio of 135. Blood-borne radioactivity is 9% ± 2.12 (colitis) and 25.7% ± 4.27 (normal), indicating that the decrease in circulating liposomes is associated with an increase in liposome accumulation in the inflammatory site. The other 2 major organs that accumulate liposomes are the spleen (10.7% normal vs 11% colitis) and liver (8% normal vs 10.1% colitis). Liposomes therefore have an innate propensity to accumulate in the sites of inflammation, which demonstrates the potential of liposomes loaded with therapeutic drugs or diagnostic agents to selectively target colitis conditions.

Accumulation of PEG-liposomes in the inflamed colon of rats: Potential for therapeutic and diagnostic targeting of inflammatory bowel diseases. Awasthi VD, Goins B, Klipper R, Phillips WT. J Drug Target 2002 Aug; 10 (5), pp. 419–27.

Liposomes/Gene Delivery/Nucleic Acid Sequences
Glycosylated Cationic Liposomes

Cationic liposomes have been considered as a potential non-viral vector for gene delivery because, unlike viral vectors, they possess a low level of immunogenicity. The gene transfer efficiency of cationic liposomes is lower than that of viral vectors, but recent advances have shown that it is possible to enhance the gene expression levels facilitated by cationic liposomes. The main problem with cationic liposomes seems to be the lack of organ or cell selectivity, because the lung has the highest level of gene expression after non-selective intravenous injection. Applying cell-specific targeting technology to liposomes would improve *in vivo* gene delivery and reduce any unexpected side effects. Both liver parenchymal and non-parenchymal cells exclusively express large numbers of high-affinity asialoglycoprotein and mannose receptors, respectively. Receptor-mediated gene delivery systems *in vivo* are able to introduce foreign DNA into specific cell types. Not only the nature of the ligands grafted to carriers but also the overall physicochemical properties of the complexes need to be optimized for effective cell-selective targeting of plasmid DNA (e.g., plasmid DNA/glycosylated cationic complexes).

Glycosylated cationic liposomes for cell-selective gene delivery. Kawakami S, Yamashita F, Nishida K, Nakamura J, Hashida M. Crit Rev Ther Drug Carrier Syst 2002; 19 (2), pp. 171–90.

Liposomes/Gene Delivery/Nucleic Acid Sequences
Cationic Liposome-Mediated Gene Delivery/Mechanisms of Intracellular Incorporation

Cellular/Molecular Mechanism of Action: Liposomes diminish biological degradation and elimination of encapsulated pharmaceuticals and biopharmaceutical agents. Cationic properties of liposomes can be used as an approach for selectively targeting liposome preparations for predetermined anatomical sites (e.g., anionic tumor microvascular structures).
Application: Cationic liposome-mediated gene delivery as an alternative approach for promoting internalization of large lipoplex particles.
Interpretation and Analysis: Significant changes in particle size and zeta potential of liposomes and their physical structures (assessed by atomic force microscopy) are created with addition of DNA sequences. These alterations appear to be dependent on the relative (±) charge ratio created. Atomic force microscopy images reveal that lipoplexes are formed from extensively fused and apparently homogeneous lipid particles encapsulating DNA sequences. Lipoplexes are internalized within cells through the endocytosis pathways. Lipoplex-cell fusion mainly occurs at the plasma membrane level; however, this lipoplex-cell membrane fusion is essential for the uptake of large particles.
Instrumentation: Atomic force microscopy.

Cationic liposome-mediated gene delivery: Biophysical study and mechanism of internalization. Almofti MR, Harashima H, Shinohara Y, Almofti A, Baba Y, Kiwada H. Arch Biochem Biophys 2003 Feb 15; 410 (2), pp. 246–53.

Liposomes/Gene Delivery Model: Nucleic Acid Sequences/Brain Capillary Endothelium
Hemagglutination Virus of Japan (HVJ) Liposomes/ Liposome-Encapsulated (Escherichia Coli Beta-Galactosidase [Beta-Gal]) Plasmid

Background Information: Bioactive proteins or peptides cannot be effectively delivered into brain capillary endothelial cells (BCECs) or brain parenchyma.
Route of Administration: Superselective internal carotid artery catheterization.
Implementation: Evaluation of the selectiveness of the *E. coli* beta-gal plasmid as a model for gene transfer into BCECs utilizing the HVJ-liposomes as a vector modality. Such preparations of HVJ-liposomes encapsulating a beta-gal plasmid can subsequently be tested *in vitro* to transfect MBEC4 cells, and also evaluated *in vivo* utilizing selective catheter administration techniques.
Animal Model: Rat (internal carotid artery selective delivery).
Interpretation and Analysis: Success of the procedure has been confirmed by the detection of 116 kDa beta-gal protein in transfected MBEC4 cells and in brain capillaries isolated from transfected rats, using Western blot analysis and histological staining. The enzymatic activities of beta-gal are 5- to 10-fold and 20-fold higher than when beta-gal-containing liposomes without fusogenic activity (uncoated liposomes) or plasmid alone are employed *in vitro* or *in vivo*, respectively. Thus, HVJ-liposomes have demonstrated applicability as a vector platform for the *in vivo* transfer of foreign genes into brain capillary endothelium (trans-luminal route).

Trans-luminal gene transfer into brain capillary endothelial cells *in vivo* with HVJ-liposomes. Jiang C, Matsuo H, Koyabu N, Ohtani H, Fujimoto H, Yonemitsu Y, Kaneda Y, Narro M, Tsuruo T, Sawada Y. J Drug Target 2002 Jun; 10 (4), pp. 345–52.

Liposomes/Gene Delivery/Nucleic Acid Sequences/ Central Nervous System (CNS)/Capillary Endothelium Cells/Brain Parenchyma Cells
Hemagglutination Virus of Japan (HVJ) Liposomes

Application: Facilitated gene delivery into the CNS in a manner that enhances expression.
Route of Administration: HVJ-liposomes (internal carotid artery).
Semi-Synthetic Methods: Evaluation of the protective effect for dopamine neurons against a retrograde 6-hydroxydopamine [6-OHDA]). The gene encoding mouse glial cell-derived neurotrophic

factor (mGDNF gene) can be transfected into brain capillary endothelial cells (BCECs) with the aim of delivering the gene product extensively into brain parenchyma by making use of BCEC secretory function. First, the mGDNF gene is transfected *in vitro* into cultured BCECs (MBEC4; mouse brain capillary endothelial cells). The amount of mGDNF protein secreted by transfected cells into the medium is about 1,500 to 3,200 pg/mg of cell protein/day, or about 7-fold higher than that accumulated intracellularly. Furthermore, the basolateral-directed secretion of mGDNF protein from the transfected MBEC4 cells is 5-fold higher than the apical-directed secretion.

Implementation: Evaluation of the capacity of the HVJ-liposomes to deliver the encapsulated mGDNF gene into CNS tissues.

Animal Model: Rat.

Interpretation and Analysis: Transfected rats show a marked increase in brain levels of GDNF as assessed by means of enzyme-linked immunosorbent assay (ELISA) and Western blotting analysis on day 3 after administration, and the level remains significantly elevated for at least 12 days. Furthermore, immunohistochemical staining reveals an increase in GDNF immunoreactivity throughout the transfected forebrain. Such profiles indicate that the gene can be successfully transferred into BCECs *in vivo* utilizing HVJ-liposomes, where it is expressed, and the gene product is secreted into the brain. Using this delivery method, the protective effect for dopamine neuron against a retrograde 6-OHDA lesion can be evaluated (assessed as a function of observed behavioral and neurochemical indices).

In vivo delivery of glial cell-derived neurotrophic factor across the blood-brain barrier by gene transfer into brain capillary endothelial cells. Jiang C, Koyabu N, Yonemitsu Y, Shimazoe T, Watanabe S, Naito M, Tsuruo T, Ohtani H, Sawada Y. Hum Gene Ther 2003 Aug 10; 14 (12), pp. 1181–91.

Liposomes/Gene Delivery/Nucleic Acid Sequences/ Central Nervous System (CNS) Tumor/Gliosarcoma

Liposomes: Cationic/Triethyl Aminopropane Carbamoyl Cholesterol (TEAPC-Chol)-Dioleoyl Phosphatidyl Ethanolamine (DOPE) Cationic Liposomes/ Poly-L-Lysine Plasma DNA Preconditioning/ Poly(Ethylene Glycol) (PEG)

Application: Delivery and transfection of genetic DNA sequences into cells within the CNS.

Semi-Synthetic Methods: Cationic liposome can be prepared from TEAPC-Chol and a helper lipid in the form of DOPE.

Implementation: Evaluation of a strategy for transfecting genes into gliosarcoma cell lines (9L) using an original cholesterol-based cationic liposome as a carrier platform.

Animal Model: Murine (nude mice with subcutaneous neoplastic lesions).

Interpretation and Analysis: Liposomes at specific concentrations are not cytotoxic based on MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) cytoxic staining analysis. TEAPC-Chol/DOPE liposomes allow plasmids encoding reporter genes to enter the nucleus as validated both by electron microscopy and functionality tests using fluorescence detection of green fluorescent protein (GFP) and luminometric measurements of luciferase activity. By changing the cationic lipid/DNA molar charge ratio, optimal properties can be determined. Further, improvement of the transfection level can be obtained by either precondensing plasmid DNA with poly-L-lysine or by adding PEG in the transfection medium. The optimal conditions determined are different depending on whether transfection can be achieved within cells in culture or with tumors induced by subcutaneous injection of cells into *in vivo* animal models. For *in vivo* assays, a simple method to overcome the interference of hemoglobin with the chemiluminescence intensity of luciferase has been used. These results would be useful for gaining knowledge about the potential for the cationic liposome TEAPC-Chol/DOPE to transfect brain tumors efficiently.

Evaluation and optimization of DNA delivery into gliosarcoma 9L cells by a cholesterol-based cationic liposome. Lesage D, Cao A, Briane D, Lievre N, Coudert R, Raphael M, Salzmann J, Taillandier E. Biochim Biophys Acta 2002 Aug 31; 1564 (2), pp. 393–402.

Liposomes/Gene Delivery/Nucleic Acid Sequences/ Central Nervous System (CNS)/Hippocamus Neurons/Neuronal Nucleoli Entry

Anionic Liposomes/Liposome-Encapsulated Cy3-Labeled Oligonucleotides

Background Information: Anionic liposomes can efficiently introduce foreign DNA into postmitotic neurons and other cell types.

Application: Liposome-encapsulated Cy3-labeled oligonucleotides can be applied to deliver DNA sequences into the nucleus of CNS neurons.

Implementation: Evaluation of the mechanism of liposome uptake established through characterization of internalization processes for anionic liposome-encapsulated Cy3-labeled oligonucleotides (AL-Cy3ONs) in hippocampal neuron populations.

Interpretation and Analysis: Uptake of AL-Cy3ONs is widespread and occurs as a function of time and temperature(e.g., dependent variables), which is indicative of receptor-mediated endocytosis. The low-density lipoprotein receptor-related protein (LRP) is crucial for anionic liposome endocytosis because the receptor-associated protein or an anti-LRP antibody inhibits internalization, and fibroblasts lacking LRP do not internalize AL-Cy3ONs. Using selective endocytosis inhibitors, it can be determined that liposome endocytosis and intracellular transport require clathrin, dynamin, an intact cytoskeletal network, and phosphatidylinositol 3-kinase activity. Cy3ONs does not significantly co-localize with recycling endosomal/lysosomal markers and enter neuronal nuclei within 1 to 3 hours of incubation. Approximately 50% of the internalized liposomal phospholipids are recycled back to the cell surface, in keeping with the fluidity of their acyl chains. Liposome endocytosis does not require heparan sulfate proteoglycans or cause calcium influx into neurons. Thus, constitutive endocytosis of anionic liposomes by LRP utilizes only 1 component, in contrast to the more involved heparan sulfate proteoglycan-LRP pathway implicated in the pathogenesis of Alzheimer's disease.

Instrumentation: Confocal microscopy.

Low-density lipoprotein receptor-related protein mediates the endocytosis of anionic liposomes in neurons. Lakkaraju A, Rahman YE, Dubinsky JM. J Biol Chem 2002 Apr 26; 277 (17), pp. 15085–92.

Neurons are protected from excitotoxic death by p53 antisense oligonucleotides delivered in anionic liposomes. Lakkaraju A, Dubinsky JM, Low WC, Rahman YE. J Biol Chem 2001; 276, pp. 32000–7.

Liposomes/Gene Delivery/Nucleic Acid Sequences/ Central Nervous System (CNS)/Ischemia: Cerebral (Focal)

Liposome/Plasmid DNA Complexes/[Lipoplexes]

Background Information: Acute cerebral ischemia causes hypoxic neuronal cell death by necrosis and apoptosis. Expression of antiapoptotic transgenes in ischemic brain may provide a useful therapeutic strategy for alleviation of postischemic damage.

Route of Administration: Lipoplexes (intrathecal).

Implementation: Evaluation of the potential of liposomes to mediate transfer of human bcl-2 protein into the CNS during conditions of focal transient cerebral ischemia. Two different types of

plasmid vectors can be used for bcl-2 expression, including (i) constitutive cytomegalovirus promoter (pCMV) and the (ii) hypoxia-inducible human vascular endothelial growth factor promoter (pHRE). Cationic liposome/plasmid DNA complexes (lipoplexes) can be injected directly into the cerebrospinal fluid (e.g., rat CSF) immediately after middle cerebral artery (MCA) occlusion. The brains of treated and control *in vivo* models are then analyzed 48 hours later. Infarct volumes and numbers of apoptotic cells can then be quantified.

Animal Model: Rat (focal transient ischemia created by MCA occlusion).

Interpretation and Analysis: Occlusion of the MCA results in ipsilateral cerebral infarcts. Transfer of the bcl-2 gene results in high-level widespread protein expression in the case of the pCMV-bcl2 plasmid, while animals treated with the pHRE-bcl2 vector show lower expression levels of bcl2 that are limited to ischemic regions. Treatment with pCMV-bcl2, but not with pHRE-bcl2, is able to significantly reduce infarct volumes (109 ± 8 mm^3 for pCMV-bcl2; 152 ± 29 mm^3 for pHRE-bcl2; and 155 ± 18 mm^3 for controls). The transfection with either of the 2 vectors results in significant reductions in apoptotic cell numbers within infarcts and penumbra areas compared to controls. There are no short-term neurological side effects from CSF lipoplex injection or bcl-2 expression. Hypoxia-inducible bcl-2 expression mediated by intrathecal lipoplexes may represent a novel, biologically safe, and lesion-selective therapeutic approach for neuroprotection after acute cerebral ischemia.

Liposome-mediated transfer of the bcl-2 gene results in neuroprotection after *in vivo* transient focal cerebral ischemia in an animal model. Cao YJ, Shibata T, Rainov NG. Gene Ther 2002 Mar; 9 (6), pp. 415–9.

Liposomes/Gene Delivery/Nucleic Acid Sequences/Hepatic Sinusoidal Gene Delivery/Antisense Oligonucleotide/[*In Vivo* Genetic Messenger RNA (mRNA) Expression]

Albumin-Coated Cationic Lipoplexes (CCLs)/Anti-ICAM-1/Antisense Oligonucleotides (ODN)/Cationic Lipid (DOTAP)/Poly(Ethylene Glycol) (PEG)/Aconitylated Albumin (AcoHSA)/Anti-ICAM-1-ODN-[DOTAP]-PEG-Neutral Lipid (Aco-HAS)

Application: Massive uptake of liposomes that have been surface modified with negatively charged AcoHSA by liver sinusoidal endothelial cells (EC) *in vivo* has previously been reported for targeting various cell types.

Route of Administration: Albumin-CCLs (intravascular).

Semi-Synthetic Methods: Anti ICAM-1 ODN can be complexed with the cationic lipid DOTAP and the complex coated with an excess of neutral lipids including a lipid-anchored PEG. Aco-HSA is coupled to the CCLs.

Implementation: Plasma disappearance and organ and intrahepatic distribution of Aco-HSA modified CCLs can be determined using [^{3}H]-cholesteryl oleyl ether and [^{32}P]-labeled ODN as markers.

Animal Model: Rat.

Interpretation and Analysis: Aco-HSA coupled CCLs are $<$ 160 nm in size and contain 1.03 ± 0.35 nmol ODN and 54 ± 18 μg Aco-HSA per micromol total lipid. Such CCLs are rapidly eliminated from plasma with about 60% the injected dose of [^{3}H]- or [^{32}P]-label entering the liver after 30 minutes. Within the liver, the EC account for two-thirds of total liver uptake. Control non-targeted CCLs are eliminated very slowly because after 30 minutes, $>$ 90% of the particles are still present in the blood. Laboratory findings have demonstrated efficient targeting of antisense ODN to EC *in vivo*, employing plasma-stable CCLs, surface modified with negatively charged albumin. Over a period of 30 minutes, approximately 40% of injected ODN is delivered to predetermined "target cell" populations.

Massive and selective delivery of lipid-coated cationic lipoplexes of oligonucleotides targeted *in vivo* to hepatic endothelial cells. Bartsch M, Weeke-Klimp AH, Meijer DK, Scherphof GL, Kamps JA. Pharm Res 2002 May; 19 (5), pp. 676–80.

Liposomes/Gene Delivery and Expression/Neoplastic Disease/Lewis Lung Carcinoma Model/Fibroblasts (NIH-3T3)/Cardiomyocytes (H9C2)/Nucleic Acid Sequences/*Ex Vivo* and *In Vivo* Cell Transfection/Gene Transfer and Detection/pEGFP-N1 Plasmid Encoding Green Fluorescent Protein (GFP)

Liposomes (TAT-Modified) Complexed with DNA Sequences

Application: Preparations of TATp-liposome-DNA complexes can be utilized in protocols for *in vitro* and *in vivo* transfection techniques. Such procedures have utility as a form of *in vitro* or *ex vivo* cell treatment schemes as well as for facilitating localized *in vivo* gene therapy.

Laboratory Methodologies: Mouse NIH/3T3 fibroblasts and rat H9C2 cardiomyocytes can be transfected *in vitro* with TATp-liposome-DNA complexes. Both *in vitro* and *in vivo* transfection with TATp-liposome-DNA complexes is possible.

Interpretation and Analysis: Liposomes modified with TAT peptide (TATp-liposomes) show fast and efficient translocation into the cell cytoplasm with subsequent migration into the perinuclear zone. TATp-liposomes containing a small quantity ($\leq$ 10 mol %) of a cationic lipid form "firm" non-covalent complexes with DNA.

Transfection with the TATp-liposome-associated pEGFP-N1 plasmid encoding for GFP is high, whereas the cytotoxicity is lower than that of commonly used cationic lipid-based gene-delivery systems. Intratumoral injection of TATp-liposome-DNA complexes into the Lewis lung carcinoma tumor of mice also results in the expression of GFP within tumor cells.

Cell transfection *in vitro* and *in vivo* with non-toxic TAT peptide-liposome-DNA complexes. Torchilin VP, Levchenko TS, Rammohan R, Volodina N, Papahadjopoulos-Sternberg B, D'Souza GG. Proc Natl Acad Sci U S A 2003 Feb 18; 100 (4), pp. 1972–7. Epub 2003 Feb 05.

Liposomes/Gene Delivery/Nucleic Acid Sequences/Neoplastic Disease/Melanoma/Vascular Endothelium of Tumors/Melanocyte-Specific Tyrosinase Promoter/$\alpha_V\beta_3$-Integrins

Liposomes: Artificial Retroviral Envelope Structure Mimics

Semi-Synthetic Methods: A semi-synthetic liposome can be designed to function in a vectorlike fashion, in part due to formulation of its composition so that it mimics the properties of retroviral envelope structures (serum-resistant, non-toxic, $\leq$ 200 nm in size). The DNA is condensed using low molecular weight branched polyethylenimine (PEI).

Interpretation and Analysis: Addition of a cyclic arginine-glycine-aspartic acid (RGD) peptide ligand to these particles as a targeting device (i) renders them selective for tumor endothelial and melanoma cells that express high levels of $\alpha_V\beta_3$-integrins; and (ii) allows for an efficient delivery of the enclosed genetic material. The

specificity of the vector system for melanoma cells theoretically can be further improved by using a melanocyte-specific tyrosinase promoter to drive trans-gene expression.

A new colloidal lipidic system for gene therapy. Fahr A, Muller K, Nahde T, Muller R, Brusselbach S. J Liposome Res 2002 Feb–May; 12 (1–2), pp. 37–44.

Liposomes/Gene Delivery/Nucleic Acid Sequences/ Neoplastic Disease/Ovarian Carcinoma Plasmid Transfection of a (Mammalian Cell Type)/Non-Viral Vector Platform/Green Phosphorous Protein/DDC/ DNA Complex

Cationic DOTAP:DOPE:Cholin Liposomes

Application: Various strategies have been attempted to design efficient protocols for ovarian cancer gene therapy, but there has been little progress toward their clinical application.

Semi-Synthetic Methods: Preparations of DDC liposome are produced by mixing DOTAP:DOPE:Cholin at a 1:0.7:0.3 molar ratio using the extrusion method.

Implementation: Evaluation of cationic liposomes prepared with dioleoyltrimethylaminopropane (DOTAP), 1,2-dioleoyl-3-phosphophatidylethanolamine (DOPE), and cholesterol (Chol) DDC for plasmid DNA transfer into ovarian cancer cells. Plasmid DNA (pEGFP-C1) and DDC are complexed at various weight ratios to find the optimum conditions followed by determining the percentage of transfected cells created. Detection can be appreciated through the application of a green fluorescence protein (GFP) expressing cell line in combination with flow cytometry analysis. The transfection efficiency of the DDC liposome is compared with 3[*N*-(*N*,*N*-dimethylaminoethylene) carbamoyl] cholesterol (DC-Chol)/DOPE liposome and commercially available lifopectin.

Interpretation and Analysis: The optimal transfection of plasmid DNA can be achieved at a 1:4 (w/w) ratio of DDC to DNA. The DDC/DNA complex exhibits higher transfection efficiency in human ovarian cancer cells (OVCAR-3 and SK-OV-3 cells) compared to that observed in other types of cell lines (NCI-NIH:522 and HepG2 cells). Flow cytometric analysis reveals that the DDC/DNA complex exhibits an over 4-fold increase in GFP expression compared with DC-Chol/DOPE or lipofectin in OVCAR-3 cells. Such findings can be further confirmed by confocal microscopy and reverse transcriptase-polymerase chain reaction (RT-PCR) analysis. In summary, cationic liposome (DDC) appears to be a promising non-viral vector for treating ovarian adenocarcinoma because of its high level of selective gene transfer capabilities in ovarian cancer cells.

Instrumentation: Flow cytometry.

Non-viral vector for efficient gene transfer to human ovarian adenocarcinoma cells. Kim CK, Haider KhH, Choi SH, Choi EJ, Ahn WS, Kim YB. Gynecol Oncol 2002 Jan; 84 (1), pp. 85–93.

Liposomes/Gene Delivery/Nucleic Acid Sequences/ Neoplastic Disease/Solid Tumor Masses

Liposome: Cationic (100–200 nm)/Porphyrin Derivatives (< 1 nm)/Branched Chain Dendrimers (10 nm)/ Polyethylenimine Polymers (10 nm)/Nanoparticles (20–1,000 nm)/Microspheres (> 1 μm)/ Cyclodextrins (CyDs 1.5 nm)

Background Information: The vascular network of a tumor provides the most effective route by which neoplastic cells may be reached and eradicated with drugs. The fact that a tumor's vasculature is relatively more permeable than healthy host tissue should enable selective delivery of drugs to tumor tissue. Such delivery is relevant to carrier-mediated delivery of gene therapy to tumors. Cationic liposomes have been used for the introduction of nucleic acids into mammalian cells.

Application: Nucleic acid delivery into cells (*in vitro* and *in vivo*).

Semi-Synthetic Methods: Cationic liposomes are generally 100–200 nm in diameter, whereas CyDs typically span 1.5 nm across.

Implementation: Evaluate the potential for delivering therapeutic oligonucleotides (ONs) to tumors using cationic liposomes and CyDs, in addition to assessing the major hindrances posed by the tumor itself on such forms of delivery.

Interpretation and Analysis: CyD molecules are routinely used as agents that engender cholesterol efflux from lipid-laden cells, thus having an efficacious potential in the management of atherosclerosis. A recent trend is to employ these oligosaccharide molecules for both *in vitro* and *in vivo* delivery of nucleic acids to cell populations. Comparisons have been made with other oligonucleotide delivery agents, such as porphyrin derivatives (< 1 nm), branched chain dendrimers (approximately 10 nm), polyethylenimine polymers (approximately 10 nm), nanoparticles (20–1,000 nm), and microspheres (> 1 μm), in the context of delivery to solid tumors. The chemical and physical properties of these carriers and how they may affect the uptake of oligonucleotides into cells, particularly *in vivo,* have been described.

Vehicles for oligonucleotide delivery to tumors. Dass CR. J Pharm Pharmacol 2002 Jan; 54 (1), pp. 3–27.

Liposomes/Gene Delivery/Nucleic Acid Sequences/ Neoplastic Disease/Transferrin Receptors

Transferrin-Poly(Ethylene Glycol) (PEG)-Polyethylenimine/TNF-cDNA

Application: Selective delivery of specific cDNA sequences to "target" cell populations.

Route of Administration: Intravenous.

Considerations: Tumor-targeting DNA complexes that can readily be generated by mixing stable, freeze-thawed preparations would be advantageous for diagnostic/therapeutic applications.

Semi-Synthetic Methods: Complexes can be formulated by mixing plasmid DNA, linear polyethylenimine (PEI22, 22 kDa as the main DNA condensing agent), PEG-PEI (PEG-conjugated PEI for surface shielding), and Tf-PEG-PEI (transferrin-PEG-PEI) to provide a ligand for receptor-mediated cell uptake.

Within the shielding conjugates, PEG chains of varying size (5, 20, or 40 kDa) are conjugated with either linear PEI22 (22 kDa) or branched PEI25 (25 kDa). The 3 polymer components are mixed together at various ratios with DNA; particle size, surface charge, and then the *in vitro* transfection activity, and systemic gene delivery to tumors is delineated.

Interpretation and Analysis: The particle size or surface charge of the complexes containing the PEG-PEI conjugate does not significantly change after freeze-thawing, while complexes without the shielding conjugate aggregate.

In general, increasing the proportion of shielding conjugate in the complex reduces surface charge, particle size, and *in vitro* transfection efficiency in transferrin receptor-rich K562 cells. Complexes containing PEG-PEI conjugate efficiently transfect K562 cells after freeze-thawing. Furthermore, the systemic application of freeze-thawed complexes exhibits *in vivo* tumor targeted expression. For complexes containing the luciferase reporter gene the highest expression is found in tumor tissue of mice. An optimum formulation for

in vivo application, PEI22/Tf-PEG-PEI/PEI22-PEG5, containing plasmid DNA encoding for the tumor necrosis factor-alpha (TNF-α), can inhibit tumor growth in 3 different murine tumor models. These new DNA complexes offer simplicity and convenience, with tumor targeting activity *in vivo* after freeze-thawing.

Novel shielded transferrin-polyethylene glycol-polyethylenimine/DNA complexes for systemic tumor-targeted gene transfer. Kursa M, Walker GF, Roessler V, Ogris M, Roedl W, Kircheis R, Wagner E. Bioconjug Chem 2003 Jan–Feb; 14 (1), pp. 222–31.

Liposomes/Gene Delivery/Nucleic Acid Sequences/ Pulmonary/Cystic Fibrosis (CF) Trans-Membrane Conductance Regulator (CFTR) Gene *(CFTR-DNA)-DC-Chol/DOPE Cationic Liposomes/ Genetic DNA Sequences*

Background Information: The major cause of mortality in patients with CF is lung disease. Expression of the CFTR gene product in the airways is a potential avenue for treatment. Clinical studies in which the CFTR cDNA is delivered to the respiratory epithelia of CF patients have resulted in modest, transient gene expression. It seems likely that repeated administration of the gene transfer vector is required in order to achieve long-term gene expression.
Application: Delivery of genetic DNA sequences (*in vitro* and *in vivo*) into cell populations to induce gene expression.
Route of Administration: DNA/liposome formulation (variable but primarily intravascular for clinical purposes).
Implementation: Evaluation of multiple doses of a DNA/liposome formulation to determine its ability to serve as a delivery platform into nasal epithelium (double blinded study). Complementary *in vivo* investigations can employ the administration of plasmid DNA expressing the CFTR cDNA complexed with DC-Chol/DOPE cationic liposomes (e.g., n = 10; n = 2 placebo controls). Each case receives 3 doses, administered 4 weeks apart.

Nasal epithelial cells can be collected 4 days after each dose for a series of efficacy assays, including quantitation of vector-specific DNA and mRNA, immunohistochemistry of CFTR protein, bacterial adherence, and detection of halide efflux *ex vivo*. Airway ion transport can also be assessed *in vivo* by repeated nasal potential difference (PD) measurements.

***Ex Vivo* Model:** Nasal epithelium harvested from cases of CF.
Human Model: Cases of CF.
Interpretation and Analysis: There is no evidence of inflammation, toxicity, or an immune response toward the DNA/liposomes or the expressed CFTR gene. On average, over half of treated subjects are positive for CFTR gene transfer after each dose (e.g., n = 6/10). All subjects positive for CFTR function are also positive for plasmid DNA, plasmid-derived mRNA, and CFTR protein.

Repeat administration of DNA/liposomes to the nasal epithelium of patients with cystic fibrosis. Hyde SC, Southern KW, Gileadi U, Fitzjohn EM, Mofford KA, Waddell BE, Gooi HC, Goddard CA, Hannavy K, Smyth SE, Egan JJ, Sorgi FL, Huang L, Cuthbert AW, Evans MJ, Colledge WH, Higgins CF, Webb AK, Gill DR. Gene Ther 2000 Jul; 7 (13), pp. 1156–65.

Liposomes/Gene Transfer/Nucleic Acid Sequences/ Neoplastic Disease/Ovarian Cancer *O-Chol:DNA Lipoplex (Catioinic)/3-β-[l-Ornithinamide-Carbamoyl] Cholesterol/Luciferase and β-Galactosidase Reporter Genes*

Background Information: Synthesis of cationic liposomes that displays high efficiency and low toxicity in the form of 3 β[l-ornithinamide-carbamoyl] cholesterol (O-Chol) using solid-phase synthesis techniques has been described previously.
Application: The preparation O-Chol can function as a highly effective trans-fection reagent. Nucleotide sequences encoding for luciferase and β-galactosidase are effective reporter genes.
Implementation: Evaluation of O-Chol to facilitate gene delivery applying *in vitro* and *in vivo* models for ovarian cancer. Intraperitoneal gene delivery into peritoneal disseminated ovarian cancer populations can be assessed using a stable chloramphenicol acetyl transferase (CAT)-expressing ovarian cancer cell line (OV-CA-2774/CAT), which allows quantification of the exact tumor burden of organs.

***Ex Vivo* Model:** Stable ovarian carcinoma cell type expressing CAT in cell line OV-CA-2774/CAT.

Animal Model: Murine (nude mice). An intraperitoneal route of administration can be applied *in vivo* to create disseminated populations of ovarian carcinoma within the peritoneal cavity.
Interpretation and Analysis: Applying luciferase and β-galactosidase genes as reporter genes, O-Chol shows better efficiency than other commercial transfection reagents such as lipofectin, lipofect AMINE, DC-Chol, and FuGENE 6, in both *in vitro* and *in vivo* models. Moreover, the transfection efficiency of the cationic lipid reagent remains high in serum-containing medium and under serum-free conditions. Furthermore, *in vivo* transfection with O-Chol shows high levels of gene expression specific for peritoneal tumor cells. Consequently, O-Chol:DNA lipoplexes appear to offer several potential advantages over other commercial transfection reagents because of its (i) higher level of gene expression *in vitro* and *in vivo*; (ii) reduced susceptibility to serum inhibition; and (iii) highly selective transfection into tumor cells. Therefore, O-Chol:DNA lipoplex is a promising tool in gene therapy for conditions of peritoneal disseminated ovarian cancer.

Intraperitoneal gene delivery mediated by a novel cationic liposome in a peritoneal disseminated ovarian cancer model. Lee MJ, Cho SS, You JR, Lee Y, Kang BD, Choi JS, Park JW, Suh YL, Kim JA, Kim DK, Park JS. Gene Ther 2002 Jul; 9 (13), pp. 859–66.

Liposomes/Glucose Binding Avidity *Di-Branched Amino Acid Derivative Liposome/ Dihexadecyl-Glutamate-Glutamine/ Dihexadecyl-Glutamate-Asparagine/Dihexadecyl-Glutamate-Glutamate*

Cellular/Molecular Mechanism of Action: Di-branched amino acids possess binding avidity for glucose moieties.
Application: Detection and physical binding to glucose moieties, including glycosylated moieties of cell receptor complexes.
Semi-Synthetic Methods: Di-branched amino acid derivatives, such as dihexadecyl-glutamate-glutamine (DHD-glu-gln), dihexadecyl-glutamate-asparagine (DHD-glu-asn), and dihexadecyl-glutamate-glutamic acid (DHD-glu-glu), can be synthesized and then incorporated into lipid vesicles (liposomes) using dipalmitoylphosphatidylcholine (DPPC). To form binding sites for glucose, the liposomes containing amino acid derivatives are mixed with glucose above the phase transition temperature (PTT) of DPPC, and subsequently the temperature is lowered below the PTT.
Implementation: Evaluation of liposomes with amino acid derivatives possessing glucose-binding affinity (± glucose imprinting properties) incorporated into their membrane layer utilizing surface plasmon resonance (SPR) and equilibrium dialysis techniques.
Interpretation and Analysis: Surface plasmon resonance of liposomes containing individual amino acid derivative or a combination of all 3 amino acid derivatives reveals that only liposomes con-

taining all 3 amino acid derivatives have glucose-binding affinity. The glucose-imprinting process is essential to fix the amino acid derivatives into a glucose binding site on liposomes. Equilibrium dialysis studies of glucose-imprinted liposomes produces curvilinear Scatchard plots, indicating that the amino acid derivatives play a direct role in glucose binding. Therefore, synthesized di-branched amino acid derivatives are promising agents for the development of biocompatible synthetic glucose binding materials.

Preparation of liposomes with glucose binding sites: Liposomes containing di-branched amino acid derivatives. Seong H, Choi WM, Kim JC, Thompson DH, Park K. Biomaterials 2003 Nov; 24 (24), pp. 4487–93.

Liposomes/Hematology: Platelets (Activated)/ Platelet GPIIb-IIIa Receptor Complexes *[Arginine-Glycine-Aspartate]-Oligodextran-Liposome*

Background Information: Cardiovascular disease processes such as atherosclerosis, restenosis, and inflammation are typically localized within discrete regions of the vasculature, which affords a great opportunity for developing targeted diagnostic and therapeutic pharmaceutical agents. Liposomes are potentially advantageous targeted drug carriers for such intravascular applications
Route of Administration: [Arginine-glycine-aspartate]-oligodextran-liposome (intravascular).
Implementation: Evaluation of 3 potential components of liposome design that can function as delivery vehicles, including (i) candidate cell surface receptors for targeting; (ii) ligands that maintain binding specificity and affinity; and (iii) prevention of rapid nonspecific clearance of liposomes by the reticuloendothelial organs.
Interpretation and Analysis: Surface modifications can simultaneously influence both the clearance/longevity and targeting specificity of liposome preparations. In this context, peptides can be applied to guide liposomes to desired receptor complexes and influence *in vivo* liposome stability. One example is the use of arginine-glycine-aspartic acid (RGD) containing peptides as a model ligand for targeting liposomes to integrin GPIIb-IIIa complexes expressed on the exterior surface membrane of activated platelets. Additionally, oligodextran surfactants incorporated into liposomes can provide insight into the effect of vesicle perturbations on liposome clearance and the importance of molecular geometry in designing oligosaccharide surface modifications.

Surface modification of liposomes for selective cell targeting in cardiovascular drug delivery. Lestini BJ, Sagnella SM, Xu Z, Shive MS, Richter NJ, Jayaseharan J, Case AJ, Kottke-Marchant K, Anderson JM, Marchant RE. J Control Release 2002 Jan 17; 78 (1–3), pp. 235–47.

Liposomes/Hepatic Kupffer Cells (Macrophages): Selective Delivery/Hepatic Trans-Gene Expression/ Antigen Processing Inhibition: Enhanced Adenoviral Vector Delivery *Clodronate Liposomes/High-Capacity Adenoviral (HC-Ad) Vectors*

Background Information: Tissue macrophages, in particular hepatic Kupffer cells (KCs), contribute to early inflammatory responses following adenoviral vector administration.
Implementation: Evaluate the effect of selective and transient (3 days) depletion of hepatic KCs by a single injection of clodronate liposomes on the *in vivo* activity of HC-Ad vectors.
Interpretation and Analysis: Interestingly, in the majority of animals of both strains, the depletion of KCs is sufficient to prevent the generation of anti-hAAT antibodies, resulting in prolonged transgene expression. Thus, short-term and selective depletion of hepatic macrophages at the same time significantly increases hepatic transgene expression and reduces the humoral immune response to transgenic protein.

Selective depletion or blockade of Kupffer cells leads to enhanced and prolonged hepatic transgene expression using high-capacity adenoviral vectors. Schiedner G, Hertel S, Johnston M, Dries V, van Rooijen N, Kochanek S. Mol Ther 2003 Jan; 7 (1), pp. 35–43.

Liposomes/Hepatic Parenchymal Cells/ Non-Parenchymal Hepatic Cell Assimilation/ Manipulation of Hepatic Targeting Strategies *Liposomes: Distearoyl-L-Phosphatidylcholine/DSPC/ Chol/Gal-C4-Chol (60:35:5) (Gal)/DSPC/Chol/ Gal-C4-Chol/Tween 20/DSPC/Chol/Gal-C4-Chol/ PEG_{2000}-DSPE (59:35:5:1) (PEG_{2000}-Gal)/DSPC/Chol/ Gal-C4-Chol/PEG_{350}-DSPE (59:35:5:1)/(PEG_{350}-Gal)*

Application: Control the delivery rate of liposome-encapsulated diagnostic and therapeutic pharmaceutical agents to hepatic parenchyma.
Route of Administration: Modified liposomes (intravascular).
Semi-Synthetic Methods: Modification of DSPC/Chol (60:40) liposomes with a galactosylated cholesterol derivative (Gal-C4-Chol) and polysorbate (Tween-20 or 1,2-distearoyl-sn-glycero-3-phosphoethanolamine-N-polyethylene glycol (PEG(x)-DSPE).
Implementation: Evaluate the capacity of PEG_{350}-DSPE to control the targeted and sustained delivery rate of Gal-liposomes to liver parenchymal cells without losing targeting capabilities.
Interpretation and Analysis: Following intravenous injection, DSPC/Chol/Gal-C4-Chol (60:35:5) (Gal) liposomes are rapidly eliminated from the blood circulation and are mostly recovered from the liver. The blood elimination of DSPC/Chol/Gal-C4-Chol/Tween 20 (55:35:5:5) (Tween 20-Gal) liposomes is slightly reduced compared to Gal-liposomes. Alternatively, a significant reduction in the blood elimination can be observed with DSPC/Chol/Gal-C4-Chol/ PEG_{2000}-DSPE (59:35:5:1) (PEG_{2000}-Gal) liposomes. Hepatic uptake of DSPC/Chol/Gal-C4-Chol/PEG_{350}-DSPE (59:35:5:1) (PEG_{350}-Gal) liposomes is intermediate between PEG_{2000}-Gal-liposomes and Tween 20-Gal-liposomes. The uptake of PEG_{350}-Gal-liposomes by liver parenchymal cells is 7.7-fold higher than that by non-parenchymal cells. Such findings imply that PEG_{350}-DSPE can control the delivery rate of Gal-liposomes to liver parenchymal cells without losing their targeting capabilities.

Targeted and sustained drug delivery using PEGylated galactosylated liposomes. Managit C, Kawakami S, Nishikawa M, Yamashita F, Hashida M. Int J Pharm 2003 Nov 6; 266 (1–2), pp. 77–84.

Liposomes/Immunity: Antigen Delivery/(IgE Selective Unresponsiveness) *OVA-Liposome Conjugate Pretreatment*

Background Information: Previous investigations have reported the capacity of intraperitoneal injections of OVA-liposome conjugates to induce OVA-specific and IgE-selective unresponsiveness in mice.
Application: Antigen-liposome conjugates can potentially be administered orally to control antigen-specific IgE antibody production, without affecting IgG antibody production.
Implementation: Evaluate the effects of oral pretreatment with OVA-liposome conjugates compared to plain OVA solution on anti-OVA IgE antibody production.

Animal Model: Murine (mice immunized with alum-adsorbed OVA; control mice receive only the immunization).
Interpretation and Analysis: Serum levels of anti-OVA IgG antibody following oral administration of OVA-liposome are comparable to those observed in reference controls. However, with the oral administration of the same dose of plain OVA, levels of serum anti-OVA IgE antibody are significantly lower than those in control mice. Surprisingly, anti-OVA IgE antibody production is completely inhibited with the oral administration of OVA-liposome conjugates. Splenic $CD4^+$ T cells of mice receiving orally administered OVA-liposome and those of reference controls result in the production of comparable levels of cytokines, while those of mice receiving oral plain OVA solution produce significantly lower levels of cytokines than those in the other 2 groups. Orally administered OVA-liposomes do not affect anti-OVA IgG production but do not inhibit anti-OVA IgE antibody production, while orally administered OVA solution inhibits production of both IgG and IgE antibodies.

Selective inhibition of systemic anti-OVA IgE production in response to oral pretreatment with OVA-liposome conjugates. Naito S, Taneichi M, Kato H, Tanaka Y, Ami Y, Suzaki Y, Mori M, Nakano Y, Yamamura H, Morokuma K, Ohkuma K, Miyake H, Kiniwa M, Komuro K, Uchida T. Int Arch Allergy Immunol 2002 Dec; 129 (4), pp. 314–9.

Liposomes/Immunity: Antigen Delivery to Dendritic Cells/Balanced $CD8^+$ and $CD4^+$ T Cell Responses
Sterically Stabilized Liposomes

Cellular/Molecular Mechanism of Action: Liposomes function as a modality that can delay the metabolism and elimination of pharmaceuticals, in addition to protecting innocent organ systems from unwanted exposure and promoting or facilitating selective delivery.
Background Information: Liposomes have been proposed as a potential vehicle for delivering proteins to antigen-presenting cells (APC) including dendritic cells (DC) in a manner that can stimulate strong T cell–mediated immune responses. Unfortunately, because of their *in vivo* instability and their rapid uptake by cells of the mononuclear phagocyte system on intravenous administration, most types of conventional liposomes lack clinical applicability.
Application: Selective delivery to APC types, including DC.
Route of Administration: Intravascular.
Animal Model: Murine
Interpretation and Analysis: Sterically stabilized liposomes (SL) have increased *in vivo* stability. Both immature and mature dendritic cells take up sterically stabilized liposomes into neutral or mildly acidic compartments distinct from endocytic vacuoles. These DC present SL-encapsulated protein to both $CD4^+$ and $CD8^+$ T cells (*in vitro*). Although $CD4^+$ T cell responses were comparable to those induced by soluble protein, $CD8^+$ T cell proliferation is up to 300-fold stronger when dendritic cells are pulsed with SL containing encapsulated ovalbumin. Dendritic cells process SL with encapsulated antigen through a TAP-dependent mechanism. Immunization with SL with encapsulated ovalbumin facilitates antigen presentation by DC *in vivo* and stimulates greater $CD8^+$ T cell responses than immunization with soluble protein or with conventional or positively charged liposomes carrying ovalbumin. Application of SL with encapsulated antigens offers a novel, effective, safe vaccination approach if a combination of $CD8^+$ and $CD4^+$ T cell responses is desired (i.e., in antiviral or antitumor immunity).

Presentation of proteins encapsulated in sterically stabilized liposomes by dendritic cells initiates $CD8^+$ T cell responses *in vivo*. Ignatius R, Mahnke K, Rivera M, Hong K, Isdell F, Steinman RM, Pope M, Stamatatos L. Blood 2000 Nov 15; 96 (10), pp. 3505–13.

Liposomes/Immunity: Antigen Delivery to Dendritic Cells/Lymph Node Antigen Processing
[Fluorescein Isothiocyanate (FITC)]-H-2K_b CTL Epitope (SIINFEKL)/pH-Sensitive Liposomes

Cellular/Molecular Mechanism of Action: Fluorescein isothiocyanate emits fluorescent light when excited by certain wavelengths of light energy. Liposomes that are pH sensitive provide a modality for protecting their internal contents from metabolic degradation or accelerated elimination but also have the property of degrading upon exposure to environments within a specific hydrogen ion concentration.
Background Information: Cytotoxic lymphocytes (CTL)
Application: Fluorescein isothiocyanate can be applied as a fluorescent tracer molecule in biological systems. Fluorescein isothiocyanate-conjugated H-$2K_b$ CTL epitope (SIINFEKL) liposomes that have pH-sensitive properties have been designed so that they release their internal contents through mechanisms of lysis when exposed to environments within a specific pH range.
Interpretation and Analysis: Fluorescence can initially be detected in lymph nodes 3 hours after immunization, and its intensity reaches a peak level in superficial inguinal lymph nodes at 9 hours. No trace amounts can be detected in the spleen, even with prolonged monitoring for up to 24 hours. These results strongly suggest that the presentation of CTL-peptide antigen delivered by pH-sensitive liposomes exclusively occurs in lymph nodes. In mice immunized with the H-$2K_b$ CTL epitope–encapsulated pH-sensitive liposomes, peptide-specific CTL response can be detected at day 3. The response is strongly augmented by a 2nd immunization and persists up to at least 45 days. Therefore, liposomes formulated to be pH-sensitive can function as potential adjuvants of peptide antigens and are useful for the *in vivo* induction of antigen-specific CTLsv.

Investigation of antigen delivery route *in vivo* and immune-boosting effects mediated by pH-sensitive liposomes encapsulated with K_b-restricted CTL epitope. Lee KY, Chun E, Seong BL. Biochem Biophys Res Commun 2002 Apr 5; 292 (3), pp. 682–8.

Liposomes: Immunity/Macrophages: Mannosyl-Fucosyl Receptors
Mannosylated Liposomes

Background Information: Despite the rapid development in medicinal and pharmaceutical technology, the targeting of drugs to phagocytic cells in macrophage-related disease states still remains a major unsolved problem.
Application: Selective liposome-mediated delivery to macrophage populations.
Route of Administration: Mannosylated liposomes (intravascular).
Implementation: Evaluation of liposome modalities for their ability to selectively target mannosyl-fucosyl receptors on macrophages as a potential model for targeting antileishmanial pharmaceuticals encapsulated within mannosylated or fucosylated liposomes to treat leishmaniasis.

One approach for achieving such an objective can involve loading liposomes with an indigenous drug, andrographolide, a labdane diterpenoid isolated from the Indian medicinal plant *Andrographis paniculata*, which can be prepared and tested against experimental leishmaniasis.

Animal Model: Hamster (experimental leishmaniasis model).
Interpretation and Analysis: Mannosylated liposomes are relatively efficient in delivering antileishmanial drugs to phagocytic cells. Mannosylated liposomes loaded with the drug are found to be

most potent in reducing the parasitic burden within the spleen as well as in reducing the hepatic and renal toxicity. In addition, mannosylated drug-loaded liposome-treated *in vivo* models show a normal blood picture and splenic tissue histoarchitecture when compared with those treated with free drug or regular liposomal drug preparations. Such a drug-vehicle formulation may have considerable applicability for clinical environments.

Targeting of liposomal andrographolide to L. donovani-infected macrophages *in vivo*. Sinha J, Mukhopadhyay S, Das N, Basu MK. Drug Deliv 2000 Oct–Dec; 7 (4), pp. 209–13.

Liposomes: Immunity/Macrophages: Phagocytic Clearance Capacity and Enhancement/ [Altered Phagocytic Activity in Neoplasia] *[^{99m}Technetium] ([^{99m}Tc])-Liposomes/ Methoxypoly(Ethylene Glycol)2000/Poloxamine-908*

Background Information: Intravenous injection of an endotoxin-free solution of poloxamine-908 can enhance the phagocytic clearance capacity of tissue macrophages, particularly those of the liver and the spleen.
Semi-Synthetic Methods: Methoxypoly(ethylene glycol)2000 liposomes (mean size of 87 nm) can be labeled with [^{99m}Tc] utilizing the *N*-hydroxysuccinimidyl hydrazine nicotinate hydrochloride derivative of distearoyl phosphatidylethanolamine.
Animal Model: Rat.
Interpretation and Analysis: Poloxamine-908 stimulated macrophages cells are able to clear a significant portion of intravenously injected methoxypoly(ethylene glycol)2000 liposomes (labeled with [^{99m}Tc] via the N-hydroxysuccinimidyl hydrazine nicotinate hydrochloride derivative of distearoyl phosphatidylethanolamine) within 4 hours postadministration. Liposomes prepared in this fashion otherwise exhibit long circulatory behavior in control *in vivo* models, with poor localization within the liver and spleen. Such [^{99m}Tc]-labeled engineered vesicles may be of aid for detection of the liver and spleen macrophages with enhanced phagocytic clearance capacity by gamma scintigraphy. Alterations in the phagocytic activity of liver and spleen macrophages is known to occur during cancer. Therefore, such diagnostic procedures may prove useful for case selection or for monitoring the progress of treatment with long circulating nanoparticles carrying anticancer agents, thus minimizing damage to this important line of the body's defense mechanism.

Recognition and clearance of methoxypoly(ethylene glycol) 2000-grafted liposomes by macrophages with enhanced phagocytic capacity. Implications in experimental and clinical oncology. Laverman P, Carstens MG, Storm G, Moghimi SM. Biochim Biophys Acta 2001 Jun 15; 1526 (3), pp. 227–9.

Liposomes: Immunity/Macrophages: Selective Depletion/Alveolar Macrophages (Pulmonary) *Liposomal Dichloromethylene Diphosphonate*

Application: Relatively selective depletion of macrophage populations.
Implementation: Evaluation of the alveolar macrophages participation in host defense mechanisms directed against *Pneumocystis carinii*, their role in organism degradation, and their clearance from the lung utilizing liposomal dichloromethylene diphosphonate (L-Cl2MDP) as a modality for depleting macrophage populations.
Animal Model: Rats.
Interpretation and Analysis: Over a period of 72 hours, L-Cl2MDP exposure creates a loss of $>$ 85% of alveolar macrophages. Alternatively, L-PBS-treated *in vivo* models have cellular differentials identical to negative reference controls (e.g., phosphate buffered saline [PBS] administration).

The role of alveolar macrophages in *Pneumocystis carinii* degradation and clearance from the lung. Limper AH, Hoyte JS, Standing JE. J Clin Invest 1997 May 1; 99 (9), pp. 2110–7.

Liposomes/Immunity: Macrophage Selective Depletion/Hepatic and Spleen Populations/Alveolar Macrophage Sparing/Platelet Kinetics/ Biodistribution *Cl2MBP-Liposomes/5-Hydroxytryptamine (5HT or Serotonin)*

Background Information: Liposomes encapsulating dichloromethylene bisphosphonate (Cl2MBP-liposomes) have been shown to cause selective depletion of phagocytic macrophages.
Route of Administration: Cl2MBP-liposomes (intravascular/intravenous).
Implementation: Evaluate the capacity of Cl2MBP-liposomes to induce an almost complete depletion of F4/80-positive cells (mature macrophages) within the liver and in the splenic red pulp, but not in the lung.

Platelets contain a large amount of 5HT and so, by measuring 5HT, it is possible to assess the translocation of platelets to tissues.

Animal Model: Murine
Interpretation and Analysis: Injection of Cl2MBP-liposomes induces a prolonged and marked increase in 5HT that occurs selectively within the spleen. Alternatively, 5HT in the blood decreases by as much as 50%. These changes in 5HT correspond well with each other in terms of both time course and dose-response relationship. To judge from measurements made at the peak of the response, the 5HT increase within the spleen corresponds with about 80% of the 5HT lost from the blood. Electron microscopic analysis reveals a great accumulation of platelets in splenic cords. It has been shown that aggregation and degranulation of platelets in the lung is involved in rapid anaphylactoid shock within 10 minutes of intravenous injection into mice of a lipopolysaccharide fraction. Biphasic, organ-specific, and strain-specific accumulation of platelets can be induced by *Escherichia coli* lipopolysaccharide and in part respresents a component of shock responses. Contrasting effects have been observed for lipopolysaccharides (endotoxins) from oral black-pigmented bacteria and *Enterobacteriaceae* on platelets (major source of serotonin) and on histamine-forming enzyme. Such shock is almost completely prevented in those mice in which platelets are displaced from the blood by Cl2MBP-liposomes. These results suggest that in the spleen the depletion of phagocytic macrophages may impair the function or structure of this organ. This may lead to the entry of platelets into the spleen in such large numbers as to reduce their level within the blood and result in their prolonged accumulation in the spleen. The Cl2MBP-liposome may be an excellent tool for the *in vivo* investigation of the role of platelets, as well as that of macrophages.

Biphasic, organ-specific, and strain-specific accumulation of platelets induced in mice by a lipopolysaccharide from *Escherichia coli* and its possible involvement in shock. Shibazaki M, Nakamura M, Endo Y. Infect Immun 1996 Dec; 64 (12), pp. 5290–4.

Displacement of platelets from blood to spleen following intravenous injection of liposomes encapsulating dichloromethylene bisphosphonate. Shibazaki M, Nakamura M, Nitta Y, Endo Y. Immunopharmacology 1998 Mar; 39 (1), pp. 1–7.

Liposomes/Neoplastic Disease: Assimilation Enhancement/Enhanced Selective Systemic/Local-Regional Uptake/Slowing of Local-Regional Blood Flow

Small Unilamellar Vesicles (SUV)-Poly(Ethylene Glycol) (PEG) Liposomes/Starch Microspheres

Physiological Mechanism of Action: Starch microspheres can be used to slow local-regional blood flow in a manner that can maximize assimilation of encapsulated liposomes within neoplastic lesions.

Background Information: Systemic adjuvant chemotherapy achieves unsatisfactory results for inoperable liver tumors and metastases. Various clinical studies have shown that loco-regional chemotherapy increases survival rate by a few months.

Application: Enhancement of systemic and local-regional uptake of diagnostic and therapeutic pharmaceutical agents.

Route of Administration: Systemic and local-regional.

Implementation: Evaluate the capacity of liposome encapsulation to selectively facilitate local-regional/systemic targeting of neoplastic cell populations with cytostatic 5-fluouracil (5-FU).

Interpretation and Analysis: Tumor concentrations of 5-FU encapsulated within SUV-PEG liposomes increases by a factor of 27 with systemic injection, and by a factor of 90 with loco-regional delivery. The tumor concentration of 5-FU increases by a factor of 8,000, if vascular blood flow is additionally slowed by starch microspheres (Spherex) during loco-regional therapy with 5-FU encapsulated liposomes.

Liposome encapsulation of cystostatic drugs and starch microspheres improve tumor targeting in loco-regional therapy. An animal experiment study of CC 531 liver tumor. Berger G, Reszka R, Pohlen U, Jung M, Lucas S, Buhr HJ. Langenbecks Arch Chir Suppl Kongressbd 1998; 115 (Suppl I), pp. 693–7.

Liposomes/Neoplastic Disease: Carbohydrate Binding Proteins/Stability of Radiolabeling Techniques

[^{125}I]-Glycoprotein Liposome Conjugate (GCL)

Cellular/Molecular Mechanism of Action: Specific glycoproteins can be designed that selectively bind to complexes uniquely expressed by neoplastic cell types.

Application: Selective delivery of diagnostic and therapeutic pharmaceuticals/radiopharmaceuticals to neoplastic cell populations.

Route of Administration: [^{125}I]-GCL (intravascular).

Semi-Synthetic Methods: In order to obtain radiolabeled GCL at a high labeling efficiency, *p*-hydroxyphenylpropyl groups can be introduced into liposome membranes through the amine moiety of a constitutive phospholipid, dipalmitoylphosphatidylethanolamine (DPPE), by using the Bolton-Hunter reagent (BHR). Radioiodination of the introduced tyrosyl groups can be performed using the Chloramine-T method.

Implementation: Evaluate the suitability of a radiolabeling method for GCL, in order to investigate its potential utility as a drug carrier modality that can target functional cellular carbohydrate-binding proteins.

Interpretation and Analysis: The labeling efficiency of BHR-treated liposome conjugate is high compared to that of the BHR-untreated liposome conjugate. Inhibition studies (*in vitro*) show that the binding affinity of [^{125}I]-labeled BHR-treated GCL ([^{125}I]-F3S-BH) with lectin is twice as high as that of untreated conjugate ([^{125}I]-F3S). The biodistribution of [^{125}I]-F3S-BH in mice is considerably different from that of [^{125}I]-F3S. [^{125}I]-F3S-BH is more rapidly taken up by the liver and is more rapidly excreted from the liver than [^{125}I]-F3S. Moreover, [^{125}I]-F3S-BH accumulates more rapidly within the kidney, resulting in lower radioactivity in the blood circulation at an earlier time point than is observed with [^{125}I]-F3S preparations. The characteristics of tumor [^{125}I]-F3S-BH and [^{125}I]-F3S accumulation are similar to those in blood. If F3S is to be employed as an *in vivo* targeting ligand in biodistribution studies, BHR would be a suitable tool for radiolabeling because it allows GCL to retain the biological activity and characteristics of the unmodified conjugate.

Radioiodination of glycoprotein-conjugated liposomes by using the Bolton-Hunter reagent and biodistribution in tumor-bearing mice. Shimura N, Sogawa Y, Kawakita Y, Ikekita M, Yamazaki N, Kojima S. Nucl Med Biol 2002 May; 29 (4), pp. 491–6.

Liposomes/Neoplastic Disease: Carcinoma of the Colon/Selective Delivery/5-Fluoro-2′-Deoxyuridine (FUdR)

Immunoliposomes

Background Information: Immunoliposomes, liposomes with monoclonal antibodies attached, have been developed for targeting the anticancer drug FUdR to colon cancer cells.

Application: Selective delivery of pharmaceuticals to neoplastic cell populations.

Semi-Synthetic Methods: A monoclonal antibody directed against colon carcinoma can be covalently coupled to liposomes containing a dipalmitoylated derivative of the anticancer drug FUdR (FUdR-dP) as a prodrug in their bilayers.

Implementation: Evaluation of different types of immunoliposomes that have antibody incorporated into their exterior surface at various positions and orientations, and delineate how these features affect their interaction with neoplastic cell types. Complementary investigations can assess the *in vitro* antitumor activity of liposome preparations and the mechanism by which the active drug FUdR is delivered intracellularly.

Cell Type: Rat colon carcinoma (CC531 cell type).

Interpretation and Analysis: Specific binding of the immunoliposomes to tumor cells can be observed. Immunoliposomes containing FUdR-dP cause a much stronger inhibition of CC531 cell growth *in vitro* than FUdR-dP in non-targeted liposomes. After binding to the cell surface, only a limited number of immunoliposomes become internalized. Alternatively, immunoliposome-incorporated FUdR-dP is intracellularly hydrolyzed virtually completely to the parent drug within 24 hours. The mechanism of intracellular delivery of the drug most likely involves a selective transfer of lipophilic prodrug from the liposomes to the cell membrane and subsequent intracellular processing. In conclusion, it is entirely possible to formulate targeted liposomal preparations that can deliver chemotherapeutics (e.g., FUdR) to colon carcinoma cells intracellularly at a high level of efficiency, without the need for cells to internalize liposomes as such. Such an approach may be attractive for lipophilic diagnostic pharmaceuticals or other lipophilic anticancer (pro)drugs. In this sense the system described may also serve as a model for the development of new lipid-based drug delivery systems for anticancer therapy.

Efficient intracellular delivery of 5-fluorodeoxyuridine into colon cancer cells by targeted immunoliposomes. Koning GA, Kamps JA, Scherphof GL. Cancer Detect Prev 2002; 26 (4), pp. 299–307.

Liposomes/Neoplastic Disease: Carcinoma Preferential Uptake/Mammary Carcinoma/ Ovarian Carcinoma/Prostatic Carcinoma
PEGylated Liposomes

PEGylated liposomal doxorubicin (doxorubicin HCl liposome injection; Doxil or Caelyx) is a liposomal formulation of doxorubicin that has a lower level of uptake by the reticuloendothelial system due to the attachment of poly(ethylene glycol) polymers to a lipid anchor. The chemotherapeutic is stable and retained to a relatively high degree as a result of liposomal entrapment via an ammonium sulfate chemical gradient. These features result in a pharmacokinetic profile characterized by an extended circulation time and a reduced volume of distribution, thereby enhancing tumor uptake. Preclinical studies have demonstrated the presence of a 1- or 2-phase plasma concentration-time profile. Most of the drug is cleared with an elimination half-life of 20 to 30 hours. The volume of distribution is close to the blood volume, and the area-under-the-concentration-time-curve (AUC) is increased at least 60-fold compared with free doxorubicin. Studies of tissue distribution indicate preferential accumulation into various implanted tumors and human tumor xenografts, with an enhancement of drug concentrations in tumors compared with free drug. PEGylated liposomal doxorubicin has been employed in several human disease states, including AIDS-related Kaposi's sarcoma (ARKS) and a variety of solid tumors, including ovarian, breast, and prostate carcinomas. The pharmacokinetic profile in humans at doses between 10 and 80 mg/m^2 is similar to that in animal models, with 1 or 2 distribution phases: an initial phase with a half-life of 1 to 3 hours, and a 2nd phase with a half-life of 30 to 90 hours. The AUC after a dose of 50 mg/m^2 is approximately 300-fold greater than that with free drug. Clearance and volume of distribution are drastically reduced (at least 250-fold and 60-fold, respectively). Preliminary observations indicate that utilizing the distinct pharmacokinetic parameters of PEGylated liposomal doxorubicin in dose scheduling is an attractive option. In agreement with the preclinical findings, the ability of PEGylated liposomes to extravasate through the leaky vasculature structures of tumors, as well as their extended circulation time, results in enhanced delivery of liposomal drugs and/or radiotracers to the tumor sites in cancer patients. There is evidence of selective tumor uptake in malignant effusions, ARKS skin lesions, and a variety of solid tumors. The toxicity profile of PEGylated liposomal doxorubicin is characterized by dose-limiting mucosal and cutaneous toxicities, mild myelosuppression, decreased cardiotoxicity compared with free doxorubicin, and minimal alopecia. The mucocutaneous toxicities are dose limiting per injection; however, the reduced cardiotoxicity allows a larger cumulative dose than that acceptable for "free" doxorubicin administration. Thus, PEGylated liposomal doxorubicin represents a new class of chemotherapy delivery system that may significantly improve the therapeutic index of doxorubicin.

Pharmacokinetics of PEGylated liposomal doxorubicin: Review of animal and human studies. Gabizon A, Shmeeda H, Barenholz Y. Clin Pharmacokinet 2003; 42 (5), pp. 419–36.

Liposomes/Neoplastic Disease/Carcinoma: Mammary/Vasoactive Intestinal Peptide (VIP) Receptor Complexes
[^{99m}Technetium] ([^{99m}Tc])-HMPAO-[SSL-VIP] Liposomes

Cellular/Molecular Mechanism of Action: Vasoactive intestinal peptide recognizes and physically binds to its respective receptor complex.

Background Information: Targeted delivery of radionuclides and therapeutic agents to specific biomarkers of breast cancer has important implications for the diagnosis and therapy of breast cancer. Vasoactive intestinal peptide receptors (VIP-R) are expressed at levels that are approximately 5-fold higher in human breast cancer lesions, compared to normal breast tissue.

Semi-Synthetic Methods: Incorporation of VIP (28 amino acid mammalian neuropeptide), as a breast cancer targeting moiety for selective imaging of breast cancer. VIP can be covalently attached to the surface of sterically stabilized liposomes (SSL) encapsulating [^{99m}Tc]-HMPAO radionuclide.

Implementation: Evaluation of liposome preparations as a potential delivery platform for imaging agents to facilitate detection and characterization of mammary carcinoma. Complementary investigations can delineate the pharmacokinetics and biodistribution of [^{99m}Tc]-HMPAO encapsulating SSL with and without VIP.

Animal Model: Rats with *n*-methyl nitrosourea (MNU)-induced *in situ* breast cancers.

Interpretation and Analysis: The presence of VIP does not alter the size and [^{99m}Tc]-HMPAO encapsulation ability of SSL. It also does not alter the pharmacokinetic profile of SSL. Long-circulating liposomes with and without VIP on their surface accumulate at significantly higher concentrations in breast cancer compared to normal breast, indicating passive targeting of these constructs for neoplastic lesions. Importantly, in breast cancer, [^{99m}Tc]-HMPAO encapsulating SSL with VIP show significantly more accumulation than SSL without VIP. The tumor to non-tumor ratio is also significantly higher for [^{99m}Tc]-HMPAO encapsulating VIP-SSL than [^{99m}Tc]-HMPAO encapsulating SSL without VIP, suggesting active targeting of VIP-SSL for mammary carcinoma lesions. Collectively, these data show that [^{99m}Tc]-HMPAO encapsulating VIP-SSL can be successfully used for targeted imaging of breast cancer.

VIP grafted sterically stabilized liposomes for targeted imaging of breast cancer: *In vivo* studies. Dagar S, Krishnadas A, Rubinstein I, Blend MJ, Onyuksel H. J Control Release 2003 Aug 28; 91 (1–2), pp. 123–33.

Liposomes/Neoplastic Disease/Carcinoma: Ovarian
Virosomes/Immunoliposomes/425 MoAb-PEG-PE/ Fusogenic Di-Peptide/Diphtheria Toxin Chain A

Application: Facilitated delivery of therapeutically active macromolecules into the cytosol of target cell populations.

Semi-Synthetic Methods: Detergent solubilized influenza virus envelopes can be reconstituted to form virosomes. Cell specificity can be created by incorporating poly(ethylene glycol (PEG)-derivatized lipids with mAB 323/A3 (Fab′ fragments) connected to their distal PEG end. These cell-specific, modified virosomes maintain their fusogenic activity at lower pH levels. Most importantly, antibody-mediated binding is a prerequisite for low pH-induced membrane fusion. Basic problems that can be encountered include (i) extensive virosome leakage; and (ii) usually immunogenic/antigenic properties of virosome preparations. A solution to correct leakage and potential immunogenicity of site-specific liposomal structures is to use immuno-PEG-liposomes with a pH-dependent fusogen inside the liposome. One approach to achieving this objective includes the use or incorporation of (i) a fusogenic di-peptide dINF-7; (ii) the monoclonal antibody 425 connected to the distal end of PEG-PE (for site-specific binding and endosomal uptake); (iii) diphtheria toxin chain A (DTA, as carrier-dependent active compound); and (iv) phosphatidylcholine/cholesterol as "bilayer backbone."

Implementation: Evaluate the degree of selective binding and pH-dependent destabilization of (endosomal) membranes. To test the

cytotoxic activity of DTA-loaded liposomes, OVCAR-3 cells can be used as an *ex vivo* testing model. OVCAR-3 cells express the epidermal growth factor receptor, which is the ligand for antibody 425.

Interpretation and Analysis: *In vitro*, these site-specific and fusogenic liposomes show a remarkable, cell-specific cytotoxic effect.

Targeted liposomes for delivery of protein-based drugs into the cytoplasm of tumor cells. Mastrobattista E, Crommelin DJ, Wilschut J, Storm G. J Liposome Res 2002 Feb–May; 12 (1–2), pp. 57–65.

Liposomes/Neoplastic Disease/Carcinoma: Prostatic/Prostate-Specific Membrane Antigen (PSMA)/Glutamyl Carboxypeptidase/ Endothelial Tumor Antigen

Prostate-Specific Membrane Antigens/Soluble Extracellular Tissue Factor (PSMA Catalytic Site)

Cellular/Molecular Mechanism of Action: Prostate-specific membrane antigen is a glutamyl-preferring carboxypeptidase.

Background Information: Prostate-specific membrane antigen is present in prostate and other carcinomas where it is expressed on both tumor cells and endothelial cells of associated microvascular structures. It has been shown that the channel structures delineated by PSMA-expressing cells in human and rat prostate tumors are in functional continuity with the vasculature and thus form part of the tumor microvasculature. The PSMA-positive cell-outlined channels are CD31 negative and mutually exclusive of CD31-positive cell-lined channels elsewhere in the tumor consistent with tumor cells adapted to a pseudoendothelial phenotype in vasculogenic mimicry.

Application: Molecular strategy for selectively targeting the microvasculature network of neoplastic lesions.

Implementation: Evaluation of the functional aspects of (i) PSMA-lined microvasculature to selectively direct infarctive tumor therapy combined with the application of (ii) soluble extracellular domain of tissue factor to a PSMA catalytic site inhibitor to create a PSMA-directed selective tumor vascular thrombogen (STVT).

Interpretation and Analysis: The semi-synthetic protein induces selective local *in vivo* infarctive necrosis of the rat Mat Lu prostate tumor when administered intravenously. The combined administration of this STVT with low-dose doxorubicin produces a profound tumoricidal effect, resulting in complete eradication of some tumors. This is consistent with the therapeutic potential for a PSMA-directed STVT and expands the potential for selective infarctive ablation of tumors.

Prostate-specific membrane antigen directed selective thrombotic infarction of tumors. Liu C, Huang H, Doñate F, Dickinson C, Santucci R, El-Sheikh A, Vessella R, Edgington TS. Cancer Res 2002 Oct 1; 62 (19), pp. 5470–5.

Liposomes/Neoplastic Disease: Chondroitin Sulfate (CS) Expression/Solid Tumors

Cationic Poly(Ethylene Glycol) (PEG)-TRX-20 Liposomes/ Cationic 3,5-Dipentadecycloxybenzamidine

Cellular/Molecular Mechanism of Action: The cationic lipid 3,5-dipentadecycloxybenzamidine hydrochloride (TRX-20) binds to CS complexes expressed on the exterior surface membrane of neoplastic cell types.

Background Information: An increased level of CS expression on the cell surface is often associated with malignant transformation and the pathological progression of tumor cells.

***Ex Vivo* Model:** Neoplastic cells (LM8G5 and ACHN cell lines).

Implementation: Evaluation of the capacity for CS expressed on highly metastatic tumor cells to function as a unique "target" to facilitate selective delivery of anticancer drugs by PEG-coated liposomes that contain a cationic lipid (e.g. 3,5-dipentadecycloxybenzamidine hydrochloride or TRX-20).

Animal Model: Murine (mice bearing solid subcutaneous LM8G5 tumors).

Interpretation and Analysis: PEG-coated TRX-20 liposomes (TRX-20 liposomes) bind preferentially to certain CS, including CS B, CS D, and CS E, whereas PEG-coated liposomes lacking TRX-20 show no significant binding to any of the glycosaminoglycans tested. *In vitro*, TRX-20 liposomes, but not plain PEG-liposomes, avidly bind to and are readily internalized by highly metastatic tumor cells such as LM8G5 and ACHN cells, which express large amounts of CS on their exterior surface membrane. When TRX-20 liposomes are loaded with cisplatin, they effectively kill CS-expressing tumor cells *in vitro*, whereas cisplatin-PEG liposomes lacking TRX-20 are totally ineffective. When injected systemically, TRX-20 liposomes preferentially accumulate in the liver and in solid LM8G5 tumors. Therapeutic experiments in mice bearing M8G5 tumors reveal that cisplatin-loaded TRX-20 liposomes are significantly more effective in reducing local tumor growth than cisplatin-loaded plain PEG-liposomes or free cisplatin. Furthermore, cisplatin-loaded TRX-20 liposomes markedly suppress metastatic spreading of LM8G5 tumor cells to the liver, and significantly increase overall survival time (e.g., tumor-bearing mice). Therefore, CS-targeted delivery of anticancer drugs by novel cationic liposomes represents a potentially useful strategy for preventing local growth and metastasis, particularly to the liver, relevant to tumor cells that display enhanced CS expression.

Novel chondroitin sulfate-binding cationic liposomes loaded with cisplatin efficiently suppress the local growth and liver metastasis of tumor cells *in vivo*. Lee CM, Tanaka T, Murai T, Kondo M, Kimura J, Su W, Kitagawa T, Ito T, Matsuda H, Miyasaka M. Cancer Res 2002 Aug 1; 62 (15), pp. 4282–8.

Liposomes/Neoplastic Disease: Delivery and Extravasation Potential

Poly(Ethylene Glycol) (PEG)-Liposomes (100–200 nm)/ PEG-Liposomes (400 nm)

Route of Administration: PEG-liposomes (intravascular).

Semi-Synthetic Methods: Liposomes composed of distearoyl phosphatidylcholine, cholesterol, and distearoylphosphatidylethanolamine derivative of PEG can be prepared in various size ranges.

Implementation: Evaluation of the size dependence of extravasation and interstitial localization of PEG-liposomes within solid tumor tissue by means of electron microscopic observation. Of particular interest is the assessement of the degree of tumor accumulation.

Animal Model: Murine.

Interpretation and Analysis: PEG-liposomes with an average diameter of 100 to 200 nm have the most prolonged circulation time and the greatest tumor accumulation in all the solid tumors employed in this experiment. Although large PEG-liposomes with a diameter of 400 nm show a short circulation time in normal mice, the results in splenectomized mice indicate that they do have an intrinsically prolonged *in vivo* circulation profile. However, large PEG-liposomes do not extravasate into solid tumor tissue. These results indicate that the size of liposomes is critical for extravasation. The electron microscopic observations reveal the almost exclusive engulfment of extravasated liposomes by tumor-associated macrophages; very few are taken up by tumor cells.

Size-dependent extravasation and interstitial localization of polyethyleneglycol liposomes in solid tumor-bearing mice. Ishida O, Maruyama K, Sasaki K, Iwatsuru M. Int J Pharm 1999 Nov 10; 190 (1), pp. 49–56.

Liposomes/Neoplastic Disease/Delivery of Chemotherapeutics/Doxorubicin (Example)
Liposomes

Cellular/Molecular Mechanism of Action: Liposomes function as a carrier modality for pharmaceutical agents.
Background Information: The optimization of drug disposition in the body leads to an increase in therapeutic effect and a decrease in adverse effects involving innocent tissues and organ systems. Liposomes can serve as a potential drug carrier system that can be utilized for such purposes. However, the behavior of a drug carrier system under *in vivo* conditions is complex. Therefore, a more complete understanding of the pharmacokinetics of liposomes themselves, as well as that of the encapsulated drug, is a mandatory requirement.
Route of Administration: Intravenous.
Dosage: Dependent upon procedure and the type of pharmaceutical incorporated into liposome preparations.
Implementation: The optimization of the pharmacokinetic profile of liposomes can be performed by linking a pharmacodynamic model of free drugs encapsulated into liposome preparations. Sensitivity analysis based on maximizing the antitumor effects of liposomal doxorubicin can be applied as a guide for optimizing delivery systems. Advanced forms of biotechnology for ligand-mediated selective targeting and intracellular targeting have also been developed to facilitate superior intracellular introduction of antitumor agents and gene delivery systems.

Pharmacokinetics of targeting with liposomes. Harashima H, Ishida T, Kamiya H, Kiwada H. Crit Rev Ther Drug Carrier Syst 2002; 19 (3), pp. 235–75.

Liposomes/Neoplastic Disease/Endothelium of Tumor Microvasculature Structures/ Anionic Targeting of the Endothelial Surface Membrane/Melanoma
Liposomes: Cationic/Rhodamine-Labeled Cationic Liposomes

Cellular/Molecular Mechanism of Action: The microvasculature of neoplastic lesions appears to express anionic characteristics that can be physically recognized by cationic liposomes.
Background Information: Cationic liposomes have been shown to selectively target tumor endothelial cells. Therefore, the encapsulation of diagnostic and antineoplastic pharmaceuticals into cationic liposomes is a promising tool for improving selective drug delivery by targeting tumor vasculature.
Application: Cationic liposomes can be applied to selectively deliver pharmaceutical agents to microvasculature structures of neoplastic cell populations.
Route of Administration: Intravenous infusion over a period of 90 minutes.
Dosage: Lipid dose, 150 mg/kg body weight; paclitaxel dose, 5 mg/kg body weight.
Implementation: Evaluate the capacity for cationic liposomes (LipoPac) to enhance the *in vivo* chemotherapeutic properties of encapsulated paclitaxel (Taxol) by targeting the anionic exterior surface membrane of endothelial cells associated with tumor microvascular structures. Reference controls can include the administration of free drug paclitaxel (Taxol); glucose 5%; and unloaded cationic liposomes in order to accurately determine selectivity for tumor cells and relative ability to modify cancer cell growth, tumor volume, and presence of regional lymph node metastases quantified.
Animal Model: Hamsters (Syrian golden strain bearing hamster melanoma A-Mel-3 in dorsal skinfold preparations). Growth of tumor cells can be observed after subcutaneous inoculation (day 0).
Interpretation and Analysis: Vascular targeting of rhodamine-labeled cationic liposomes is achieved after encapsulation of paclitaxel when evaluated by *in vivo* fluorescence microscopy (ratio of dye concentration, tumor:normal tissue = 3:1). Subcutaneous tumor growth evaluation reveals a remarkable retardation of tumor growth after treatment with LipoPac (1.7 ± 0.3 cm^3). Alternatively, control tumors show exponential tumor growth (tumor volume at the end of the observation period [mean $\pm$ standard error]: 5% glucose, 17.7 ± 1.9 cm^3; unloaded cationic liposomes, 10.0 ± 1.6 cm^3; Taxol, 10.7 ± 1.7 cm^3). In addition, the appearance of regional lymph node metastases is significantly delayed by treatment with paclitaxel encapsulated into cationic liposomes compared to all other test groups. Therefore, cationic liposomes are a powerful tool for selective and efficient drug delivery to tumor microvasculature structures. This may serve as proof of the concept of neovascular tumor targeting diagnostic therapeutic pharmaceuticals by cationic liposomes.

Neovascular targeting therapy: Paclitaxel encapsulated in cationic liposomes improves antitumoral efficacy. Schmitt-Sody M, Strieth S, Krasnici S, Sauer B, Schulze B, Teifel M, Michaelis U, Naujoks K, Dellian M. Clin Cancer Res 2003 Jun; 9 (6), pp. 2335–41.

Liposomes/Neoplastic Disease/Endothelium of Tumor Microvascular/Vascular Marker System
Liposomes: Fluorescent Encapsulation/ Fluorescent-Lectin

Cellular/Molecular Mechanism of Action: Cationic liposomes display binding avidity for unique anionic domains expressed by the vascular endothelium with neoplastic lesions.
Background Information: Cationic liposomes have been shown to preferentially target the angiogenic endothelium of tumors.
Application: Cationic liposomes can be applied for selective delivery to angiogenic tumor vessels. Anionic and neutral liposomes may be used as carriers of drugs to the extravascular compartment of tumors by processes of extravasation. Fluorescently labeled lectin can be utilized as a vascular marker for either validation of other reagents or as a diagnostic tool.
Route of Administration: Liposomes (intravenous).
Implementation: Evaluation of the influence of liposomal surface charge on the uptake and kinetics of liposomes into solid tumors and tumor vasculature. In this context, fluorescently labeled liposomes prepared with different surface charge properties can be evaluated *in vivo* for their ability to localize within amelanotic melanoma lesions. Accumulation of liposomes can be detected utilizing fluorescence microscopy of tumor and surrounding normal healthy tissue. The histological distribution of liposomes can be analyzed by double-fluorescence microscopy 20 minutes after application of fluorescently labeled lectin as a vascular marker.
Animal Model: Syrian Golden Hamster (male animals with amelanotic hamster melanoma A-Mel-3 growing in a dorsal skin fold chamber preparation).
Interpretation and Analysis: Following intravenous application of anionic and neutral liposomes, an almost homogeneous distribution can be appreciated for liposome-induced fluorescence throughout the chamber preparation without specific targeting to tumor tissue. Alternatively, cationic liposomes exhibit a significant level of enhanced accumulation within tumor tissue and tumor

vasculature up to 3-fold higher compared to surrounding tissues ($p < 0.05$). The histological distribution of neutral and anionic liposomes reveals extravasation 20 minutes after intravenous injection, while cationic liposomes display a highly selective accumulation on vascular endothelium. Cationic liposomes exhibit a preferential uptake in angiogenic tumor vessels and they therefore provide an efficient tool for the selective delivery of diagnostic or therapeutic agents to angiogenic blood vessels of solid tumors. Additionally, anionic and neutral liposomes may be used as carriers of drugs to the extravascular compartment of tumors due to their extravasation.

Instrumentation: Quantitative intravital fluorescence microscopy.

Effect of the surface charge of liposomes on their uptake by angiogenic tumor vessels. Krasnici S, Werner A, Eichhorn ME, Schmitt-Sody M, Pahernik SA, Sauer B, Schulze B, Teifel M, Michaelis U, Naujoks K, Dellian M. Int J Cancer 2003 Jul 1; 105 (4), pp. 561–7.

Liposomes/Neoplastic Disease/Folate Receptor Expression
Folate Liposomes

The folate receptor is a cell surface protein that has recently been identified as a tumor marker due to its differential overexpression in several malignancies. Current research indicates that folate can be covalently attached to the surface of liposomes to mediate their selective internalization by tumor cells through the folate receptor-mediated endocytic pathway. Optimized liposome formulations, characterized by improvements in drug loading, extended residence times within the intravascular compartment, and improved drug release, have been developed to improve the biodistribution of therapeutic molecules. Theoretically, folate receptor targeting can be combined with liposome encapsulation to synergistically affect disease outcome by enhancing the delivery of chemotherapeutic agents to neoplastic cells, while reducing systemic toxicities to normal tissues.

Folate receptor-targeted liposomes as vectors for therapeutic agents. Gosselin MA, Lee RJ. Biotechnol Annu Rev 2002; 8, pp. 103–31.

Liposomes/Neoplastic Disease/Folate Receptors/ Ovarian Carcinoma/Acute Myelogenous Leukemia (AML)/Granulocytes/Neutrophils/Donor Bone Marrow
Folate-Coated Liposomes [Fluorescent Cacein Marker]/ All-Trans-Retinoic Acid (ATRA)

Background Information: Upregulation of folate receptor (FR) type-beta in AML by ATRA and its restricted normal tissue distribution makes it a potential target for therapeutic intervention.

Implementation: Evaluation of multicomponent folate liposomes to selectively bind to folate receptor complexes expressed by peripheral blood granulocytes.

***Ex Vivo* Model:** Granulocytes; donor bone marrow cell preparations; folate receptor negative (FR^-) cell lines (e.g., KG-1a murine leukemia cells, L1210, and Chinese hamster ovary [CHO]); and folate receptor positive (FR^+) cell lines (e.g., FR-beta expression KG-1 human AML cells, L1210 JF, and recombinant CHO-FR-beta).

Animal Model: Murine (mouse ascites leukemia) using L1210JF or KG-1 cell lines.

Interpretation and Analysis: The FR-beta in peripheral blood granulocytes is unable to bind folate and appears to have a variant glycosylphosphatidylinositol (GPI) membrane anchor, evident from its insensitivity to phosphatidylinositol-specific phospholipase C but not nitrous acid. Granulocyte FR-beta lack mutations, and neither deglycosylation nor detergent solubilization restores folate binding. The posttranslational modification causing its non-functionality is evidently absent in FR-beta from AML cells from donor marrow that binds folate. From flow cytometric analysis of 78 AML bone marrow specimens of different subtypes, 68% express FR-beta, most of which are also $CD34^+$. In model cell lines that are FR^- (KG-1a, L1210, and CHO) or FR^+ (KG-1, L1210 JF, and recombinant CHO-FR-beta), selective FR^--mediated binding and cytotoxicity can be obtained using folate-coated liposomes encapsulating fluorescent calcein (f-L-calcein) and doxorubicin (f-L-DOX), respectively, which can be blocked by free folic acid (1 mM). In the FR-beta-expressing KG-1 human AML cells, treatment with ATRA further increases this specificity. In mouse ascites leukemia models generated using L1210JF or KG-1 cells, increases in median survival times can be obtained with f-L-DOX treatment compared to non-targeted L-DOX. In the KG-1 model, ATRA treatment increases the cure rate with f-L-DOX from 10% to 60%. Appreciation of these data serves to further support the feasibility and potential usefulness of selective ATRA-facilitated liposomal drug delivery in FR-$beta^+$ AMLs.

Strategy for the treatment of acute myelogenous leukemia based on folate receptor beta-targeted liposomal doxorubicin combined with receptor induction using all-trans-retinoic acid. Pan XQ, Zheng X, Shi G, Wang H, Ratnam M, Lee RJ. Blood 2002 Jul 15; 100 (2), pp. 594–602.

Liposomes/Neoplastic Disease/Melanoma c-myc Oncogene/Neuroblastoma (GD_2 Positive)
Cationic Immunoliposomes/Antidisialoganglioside (GD_2)/Antisense c-myb Olidodeoxynucleotide

Background Information: Melanoma is a highly malignant and increasingly common tumor. Because the cure rate of metastatic melanoma by conventional treatment is very low, new therapeutic approaches are needed. Reports have previously described that coated cationic liposomes (CCL) targeted with a monoclonal antibody against the disialoganglioside (GD_2) and containing c-myb antisense oligodeoxynucleotides (asODNs) result in a selective inhibition of (GD_2)-positive neuroblastoma cells *in vitro* proliferation.

Considerations: Melanoma is a neuroectodermal tumor that, along with neuroblastoma cell types, shares the expression of GD_2 complexes.

Application: Selective delivery to melanoma and neuroblastoma neoplastic cell types.

Route of Administration: Intravascular.

Implementation: Evaluation of the selective *in vivo* delivery capabilities and antineoplastic properties of liposomes encapsulating antisense oligonucleotides for the c-myc oncogene of melanoma and designed to target GD_2-positive cell lines (e.g., melanoma).

Interpretation and Analysis: Preparations of GD_2-targeted liposomes can be produced that entrap in a stable manner 90% of added c-myc asODNs. Such liposomes show a selective binding *in vitro* for GD_2-positive melanoma cells. Melanoma cell proliferation is inhibited to a greater extent by GD_2-targeted liposomes containing c-myc asODNs (aGD_2-CCL-myc-as) than by non-targeted liposomes or free asODNs. The pharmacokinetic results obtained after intravenous injection of [^{3}H]-myc-asODNs, free or encapsulated in non-targeted CCLs or GD_2-targeted CCLs, reveals that free c-myc-asODNs are rapidly cleared, with less than 10% of the injected dose remaining in the blood 30 minutes after injection. Sequences of c-myc-asODNs encapsulated within either CCL or aGD_2-CCL demonstrate a more favorable profile within the vascular compartment, with about 20% of the injected dose of each preparation remaining *in vivo* at 24 hours after injection. In *in vivo* melanoma

experimental metastatic models, aGD_2-CCL-myc-as, at a total dose of only 10 mg of asODN per kilogram, significantly inhibits the development of microscopic metastases into the lung compared with animals treated with myc-asODNs, free or entrapped in non-targeted liposomes, or aGD_2-CCL encapsulating scrambled asODNs ($p < 0.01$). Moreover, mice bearing established subcutaneous human melanoma xenografts treated with aGD_2-CCL-myc-as exhibit significantly lower levels of tumor growth and increased survival ($p < 0.01$ vs control mice). The mechanism for the antitumor effects appears to be downregulation of c-myc protein expression and interruption of c-myc-mediated signaling: induction of p53 and inhibition of Bcl-2 proteins, leading to extensive tumor cell apoptosis. Such observations suggest that inhibition of c-myc proto-oncogene by GD_2-targeted antisense therapy could provide an effective approach for the treatment of melanoma in an adjuvant setting.

Targeted liposomal c-myc antisense oligodeoxynucleotides induce apoptosis and inhibit tumor growth and metastases in human melanoma models. Pastorino F, Brignole C, Marimpietri D, Pagnan G, Morando A, Ribatti D, Semple SC, Gambini C, Allen TM, Ponzoni M. Clin Cancer Res 2003 Oct 1; 9 (12), pp. 4595–605.

Liposomes/Neoplastic Disease/Photoexposure (Ultraviolet [UV]) Induced Selective Delivery
Sterically Stabilized Liposomes/Poly(Ethylene Glycol) (PEG)-Liposomes/Photoperturbed PEG-Liposomes/ Photoexposure-Induced Delivery

The use of liposomes for the delivery of therapeutic agents to tumor sites took a major step forward with the introduction of sterically stabilized liposomes (PEG-liposomes). Several research groups reported the increased localization of PEG-liposomes at tumor sites. Once PEG-liposomes reach these sites, they may demonstrate the desirable feature of releasing encapsulated compound(s) at a relatively rapid rate. The use of radiation for this purpose is an attractive option because it can allow delivery in a spatially and temporally selective manner. An effective strategy for the photoperturbation of PEG-liposomes relies on the photoinitiated polymerization of reactive lipids in the liposomal bilayer. Previous studies have revealed that the inclusion of the photoreactive 1,2-bis[10-(2′,4′-hexadienoyloxy)decanonyl]-sn-glycero-3-phosphocholine (bis-SorbPC(17,17)) among the lipids of PEG-liposomes has little effect on their permeability until the PEG-liposomes are exposed to UV light. Photoexposure increases the permeability of the PEG-liposomes 200-fold. Additional investigations characterizing this phenomena have revealed that PEG-liposomes can be designed that have extremely low permeabilities to water-soluble fluorescent probes at 37°C in the dark, yet the permeability can be increased 28,000-fold upon exposure to UV irradiation. The large increase in the rate of photoinitiated release of the encapsulated contents may be a consequence of increased phase separation between photoreactive and saturated phospholipids used in the PEG-liposomes.

Rapid release of liposomal contents upon photoinitiated destabilization with UV exposure. Spratt T, Bondurant B, O'Brien DF. Biochim Biophys Acta 2003 Apr 1; 1611 (1–2), pp. 35–43.

Liposomes/Neoplastic Disease/Proliferating Populations/Low-Density Lipoprotein (LDL) Receptor Complexes
LDL Lipsomes

Cellular/Molecular Mechanism of Action: Low-density lipoprotein fractions recognize and physically bind to LDL receptor complexes.

Background Information: In photodynamic therapy, 1 of the problems limiting the use of many photosensitizers (PS) is the difficulty in preparing pharmaceutical formulations that enable their parenteral administration. Due to their low water solubility, the hydrophobic PS cannot be simply injected intravenously. Different strategies, including polymer-PS conjugation or encapsulation of the drug in colloidal carriers such as oil-dispersions, liposomes, and polymeric particles, have been investigated. Although these colloidal carriers tend to accumulate selectively in tumor tissues, they are rapidly taken up by the mononuclear phagocytic system. In order to reduce this undesirable uptake by phagocytic cells, long-circulating carriers that consist of surface-modified carriers have been developed. Moreover, considerable effort has been directed toward using other types of carriers to improve tumor targeting and to minimize the side effects.
Application: Selective targeting of proliferating cell populations.
Semi-Synthetic Methods: Lipophilic agents (e.g., photosensitizing therapeutics) can be entrapped within the lipophilic core of LDL without altering their biological properties.
Interpretation and Analysis: The LDL receptor pathway is an important factor in the selective accumulation of lipophilic agents (e.g., photosensitizing therapeutics) within tumor tissues owing to the increased number of LDL receptors on the proliferating cell surface. Specific targeting can also be achieved by binding of monoclonal antibodies or specific tumor-seeking molecules to PS or by the coating of lipophilic agent-loaded carriers.

State of the art in the delivery of photosensitizers for photodynamic therapy. Konan YN, Gurny R, Allémann E. J Photochem Photobiol B 2002 Mar; 66 (2), pp. 89–106.

Liposomes/Neoplastic Disease: Transferrin Receptor Expressing Cancers/(HeLa Cells)
Transferrin Poly(Ethylene Glycol) (PEG) Liposomes

Cellular/Molecular Mechanism of Action: Transferrin recognizes and physically binds to transferrin receptor complexes.
Background Information: Many tumor cells, including HeLa cells, overexpress the transferrin receptor complexes on the exterior surface membranes.
Application: Selective targeting of neoplastic cell populations that overexpress transferrin receptor complexes.
Route of Administration: Transferrin-conjugated PEG-liposomes (intravascular).
Considerations: Photodynamic therapy has attracted increasing interest over the last few years, whereby the activation of photosensitizers by light causes the production of reactive oxygen species (ROS), such as cytotoxin singlet oxygen species.
Semi-Synthetic Methods: Production of transferrin-conjugated PEG-liposomes that contain AlPcS4 photodynamic agent.
Implementation: Evaluation of liposome cellular internalization facilitated by tranferrin receptor-mediated endocytosis. The antiproliferative activity of the targeted liposomes is then evaluated and compared to native AlPcS4 and non-targeted liposome preparations. Laboratory data are then correlated with findings regarding the intracellular concentration of the photoactive compounds. Accumulation together with ROS production after irradiation is then visualized to confirm data found in antiproliferative and accumulation assays.
Interpretation and Analysis: Transferrin liposomes containing ALPcS4 phododynamic agent (Tf-Lip-AlPcS4) are 10 times more photocytotoxic (IC_{50}, 0.63 μM) than free AlPcS4 at a light dose of 45 kJ/m, whereas Lip-AlPcS4 displays no photocytotoxicity at all. The high photocytotoxicity of Tf-Lip-AlPcS4 is the result of a high

intracellular concentration (136.5 μM) in HeLa cells, which can be lowered dramatically by incubating the conjugate with a competing transferrin concentration. The images of intracellular accumulation and ROS production match the accumulation and photocytotoxicity profile of the different photo-active compounds. The photodynamic activity of the Tf-Lip-AlPcS4 conjugate on HeLa cells is much more potent than free AlPcS4 as a result of selective transferrin receptor-mediated uptake.

Instrumentation: Confocal microscopy.

Targeting of the photocytotoxic compound AlPcS4 to HeLa cells by transferrin-conjugated PEG-liposomes. Gijsens A, Derycke A, Missiaen L, De Vos D, Huwyler J, Eberle A, de Witte P. Int J Cancer 2002 Sep 1; 101 (1), pp. 78–85.

Liposomes/Neoplastic Disease: Vasculature Supply/ Selective Tumor DNA Delivery
Plasmid-Microspheres/Plasmid-Complexed Liposomes

Application: Selective targeting of genetic DNA sequences incorporated into plasmid vectors for neoplastic lesions (selective delivery is in part facilitated by selective catheterization of the major arterial network supplying a neoplastic tissue mass).

Route of Administration: Selective catheterization of major arterial branches of neoplastic lesions.

Implementation: Evaluation of the capacity for a plasmid vector bound to liposomes and microsphere to mediate delivery of DNA sequences (chloramphenicol acetyltransferase) into an established rat renal solid tumor model. Preparations are selectively administered via an arterial catheter system.

***Ex Vivo* Model:** Rat renal solid tumor.

Interpretation and Analysis: Forty-eight hours postdelivery, tumor to normal kidney tissue chloramphenicol acetyltransferase expression ratios are as follows: free (1.8:1), microspherical (3.9:1), and liposomal (1.2:1). Microspheres are able to selectively deliver plasmids to tumors, whereas cationic liposomes distribute plasmids to both kidney parenchymal and tumor cells. The tumor model has the potential of screening delivery vehicles as well as therapeutic agents for the capacity of selective delivery to tumors via the vasculature.

A model for evaluating selective delivery of plasmid DNA to tumours via the vasculature. Dass CR, Burton MA. Cancer Biother Radiopharm 2002 Oct; 17 (5), pp. 501–5.

Liposomes/Peptide (Protein) Delivery Modality: Oral Route/Biological Peptides/Vaccine Antigen
Liposomes

Cellular/Molecular Mechanism of Action: Liposomes can protect peptides/proteins from degradation within the gastrointestinal tract and facilitate their absorption across mucosal surfaces and subsequent entry into the intravascular compartment.

Application: Delivery of biological proteins and synthetic peptides across the gastrointestinal mucosa following oral administration.

Route of Administration: Oral.

Semi-Synthetic Methods: The tested mixtures include [EggPC/Chol] 1:1 (formula I), [EggPC/Chol/SM] 1:1:1 (formula II), [EggPC/Chol/SM/GM type III] 1:1:1:0.14 (formula III), [EggPC/Chol/SM/GM1] 1:1:1:0.14 (formula IV), and [DIAPC/DMPC] 1:1 non-polymerized (formula V) and polymerized (formula VI); all mole ratio.

Implementation: Evaluation of the usefulness of liposomes as possible vaccine vehicles (oral and subcutaneous). Stability of liposomes can be assessed in buffer, plasma, and saliva at 25 and 37°C, followed by analysis using fluorescence and enzymatic methodologies. Complementary investigations can delineate blood and feces anti-GM1 responses to antigen-associated liposomes after subcutaneous and oral administration.

Animal Model: Murine.

Interpretation and Analysis: Liposome formulations I and II are more stable in buffer at 25°C. Formulations III and IV are more stable in plasma at 37°C; formula VI is more stable in plasma at 37°C than in buffer or saliva. Formulations IV and V liposomes are both stable in saliva for at least 1 hour. After immunization of formula IV, no detectable antiganglioside GM1 antibody response can be detected. Negative stain transmission electron microscopy shows that liposomes containing SM, GM1, GM type III, and DIAPC: DMPC are twice the size of those made with EggPC/Chol. The hydrophobicity factor expressed as A(570/500) is obtained using the probe merocynine 540 (MC540). The order of fluidity increases from mixture II < mixture I < mixture III < mixture IV < mixture V < mixture VI. Although the high hydrophobicity factor for polymerizable lipids is an important characteristic, there are other factors like stability that must be taken into account according to the desired route of administration. The hydrophilicity of groups protruding from the membrane interphase into the surrounding solution in the case of subcutaneous inoculation is very relevant, and for oral administration, stability is an important property that needs to be characterized due to exposure to different biologically active fluids within the gastrointestinal tract. Liposome preparations containing GM1, GM type III, or DIAPC/DMPC are therefore stable in saliva and plasma at 37°C and can potentially serve effectively as a delivery vehicle for oral and subcutaneously administered non-viral vaccines.

Study of *in vitro* stability of liposomes and *in vivo* antibody response to antigen associated with liposomes containing GM1 after oral and subcutaneous immunization. Fabani MM, Gargini R, Taira MC, Iacono R, Alonso-Romanowski S. J Liposome Res 2002 Feb–May; 12(1–2), pp. 13–27.

Liposomes/Peptide Delivery/Biological Proteins: Anti-Inflammatory Interleukins
Liposome-(Interleukin [IL]-4)/Liposome-(IL-10)

Inflammatory bowel disease (IBD) is comprised of the 2 disorders ulcerative colitis (UC) and Crohn's disease (CD). Although the etiology is still unclear, initiation and aggravation of the inflammatory processes seem to be due to a massive local mucosal immune response. An increased number of greatly activated macrophages seems to contribute to the onset of IBD by expressing upregulated co-stimulatory molecules (e.g., CD80/CD86) and a cytokine profile favoring a type I proinflammatory response. The release of IL-2 and interferon-gamma (IFN-γ) by naive T lymphocytes predominantly stimulates cytotoxic T lymphocytes, macrophages, and natural killer (NK) cells and increases the antigen-presenting potential of all these cell types. Opposite this proinflammatory immune reaction a compensatory Type II anti-inflammatory response has been suggested to occur within inflamed mucosa, involving mainly IL-4 and IL-10. Both cytokines are able to downregulate inflammatory mediators, including tumor necrosis factor-alpha (TNF-α) and IL-1, and favor a humoral immune response. Previous clinical trials have evaluated local liposome-mediated gene transfer of these 2 anti-inflammatory cytokines, IL-4 and IL-10, in patients with severe IBD of the rectum. Local administration of anti-inflammatory cytokines avoids toxic systemic side effects and prevents blocking of the beneficial effects of proinflammatory cytokines (e.g., TNF-α in other tissue compartments and increases the local concentration of IL-4 and IL-10 over a prolonged period of time). The combined effects of IL-4 and IL-10

have been shown to shift the Th1/Th2 cell activation in favor of a Th2 immune response, which seems to be essential for fighting against the inflammation and facilitating healing.

Transfer of interleukin-4 and interleukin-10 in patients with severe inflammatory bowel disease of the rectum. Rogy MA, Beinhauer BG, Reinisch W, Huang L, Pokieser P. Hum Gene Ther 2000 Aug 10; 11 (12), pp. 1731–41.

Liposomes/Peptide Delivery/Biological Proteins
Liposomes/Example: Liposome-Encapsulated Interferon-Alpha-2b (IFN-α-2b)

Cellular/Molecular Mechanism of Action: Liposomes can be applied for the purpose of selective delivery, protection against premature excretion or metabolism, and transport across biological membrane barriers.

Background Information: Systemic administration of IFN-α-2b by injection for treatment of dermal fibrosis is uncomfortable, requires a large quantity of the cytokine, and cannot be easily used in children. IFN-α-2b can potentially be encapsulated within liposomes without compromising its *in vitro* antifibrogenic effects on dermal fibroblasts. In this context, liposomes are a potentially useful vehicle for the topical delivery of various pharmaceuticals and biological agents.

Application: Modality for the delivery of biologically active peptides across cellular membranes and cutanous barriers.

Route of Administration: Topical application of an IFN-α-2b liposome cream preparation.

Dosage: IFN-α-2b-encapsulated liposomes (100 mg/wound containing 3,000 units of liposome-encapsulated IFN-α-2b).

Semi-Synthetic Methods: Empty sonicated liposome vesicles are mixed with various concentrations of IFN-α-2b and then dried and rehydrated. An enzyme-linked immunosorbent assay (ELISA) can be used to determine the efficiency of encapsulation and the stability of the preparation under experimental conditions.

Implementation: Topical application and evaluation of the the ability of liposomes to effectively deliver encapsulated IFN-α-2b as a function of reduced scar tissue formation. Efficacy of peptide delivery can be assessed by applying liposome preparations on wounds (e.g., right side receiving a cream of liposome-encapsulated IFN-α-2b, while wounds on the left side receiving cream containing empty liposomes). Northern analysis can be applied to evaluate the messenger RNA (mRNA) expression for Type I and Type III collagens. Cellularity can be assessed by measurement of cellular vimentin content.

Animal Model: Guinea pig (n = 36 full thickness skin wounds; n = 6/animal, n = 3 on each side that are made with an 8 mm disposable punch).

Interpretation and Analysis: There is a significant reduction in rate of contraction of wounds treated with IFN-α-2b liposomes as early as 5 days after wounding. Reductions remain significant for a period of up to 10 days. Northern analysis reveals that expression of mRNA transcripts for Type I and Type III collagens in response to IFN-α-2b is markedly reduced in abundance for the pro-α1(I) chain of type 1 collagen on days 11 and 14 after wound production. Similarly, the level of mRNA for Type III procollagen is markedly reduced as early as day 7 and remains depressed up to day 14. These findings were consistent with results obtained for the total collagen content in tissue samples. Cellularity of IFN-α-2b-treated wounds, assessed by measurement of vimentin content, is also markedly reduced at day 7 and remains depressed for up 14 days. Liposome-associated IFN-α-2b applied 5 days after completion of epithelialization reduces mRNA for the pro-α1(I) chain of Type 1 collagen, confirming its trans-epidermal penetration and effectiveness. The activity of liposome-associated IFN-α-2b *in vivo* supports the concept of the topical use of antifibrogenic agent of this type for treatment of fibroproliferative disorders.

Liposome-associated interferon-alpha-2b functions as an antifibrogenic factor in dermal wounds in the guinea pig. Ghahary A, Tredget EE, Shen Q, Kilani RT, Scott PG, Takeuchi M. Mol Cell Biochem 2000 May; 208 (1–2), pp. 129–37.

Liposomes/Pharmacokinetic Profile/Prolongation
[^{51}Cr]-D-Mannose Surface-Modified Liposomes/ [^{51}Cr]-6-Amino-6-Deoxy-D-Mannose Surface-Modified Liposomes

Cellular/Molecular Mechanism of Action: The relatively massive size of liposomes compared to simple molecules prevents the elimination of pharmaceutical or biological peptides contained within their interior. The size of liposomes prevents their passage into the glomerular filtrate. Liposomes also prevent biological degradation and can facilitate selective delivery. Modification of the chemical composition of the external surface of liposomes with *D*-mannose and 6-amino-6-deoxy-*D*-mannose can facilitate the selective delivery and site-specific release/deposition of diagnostic radioisotopes (e.g., [^{51}Cr]-).

Application: Selective delivery of diagnostic pharmaceutical agents facilitated by molecular determinant incorporated into the exterior surface of liposome membranes.

Route of Administration: Intravenous.

Synthetic Chemistry and Analysis: Liposomes with synthetic saccharide determinants can be prepared from synthetic cholesterol conjugates of *D*-mannose and 6-amino-6-deoxy-*D*-mannose and labeled with [^{51}Cr]-chromate.

Implementation: The kinetics and tissue distribution of the radiolabel can be determined after footpad and subcutaneous injection (mice). These results show that incorporation of synthetic glycolipids can substantially alter the *in vivo* lifespan and distribution of liposomes outside the bloodstream. Such surface-modified liposomes may be useful for sustained release or selective delivery of therapeutic or diagnostic agents.

Animal Model: Murine.

Interpretation and Analysis: Liposomes bearing either of the saccharides determinants *D*-mannose and 6-amino-6-deoxy-*D*-mannose greatly increase retention of label at the injection sites compared to control liposomes, which contain no glycolipid, and to free [^{51}Cr]-chromate. Draining lymph nodes contain small fractions of the injected radioactivity but in some cases the retention is saccharide dependent and highly concentrated. Incorporation of synthetic glycolipids can substantially alter the *in vivo* lifespan and distribution of liposomes outside the intravascular compartment.

Modified *in vivo* behavior of liposomes containing synthetic glycolipids. Wu MS, Robbins JC, Bugianesi RL, Ponpipom MM, Shen TY. Biochim Biophys Acta 1981 Apr 17; 674 (1), pp. 19–29.

Liposomes/Sepsis and Inflammation: Peptide Delivery/Anti-Inflammatory Interleukins (Ils)
Liposome-(IL-4)/Liposome-(IL-10)

Inflammatory bowel disease (IBD) is comprised of the 2 disorders ulcerative colitis (UC) and Crohn's disease (CD). Although the etiology is still unclear, initiation and aggravation of the inflammatory processes seem to be due to a massive local mucosal immune response. An increased number of greatly activated macrophages seems to contribute to the onset of IBD by expressing upregulated co-stimulatory molecules (e.g., CD80/CD86) and a cytokine profile

favoring a type I proinflammatory response. The release of IL-2 and interferon-gamma (IFN-γ) by naive T lymphocytes predominantly stimulates cytotoxic T lymphocytes, macrophages, and natural killer (NK) cells and increases the antigen-presenting potential of all these cell types. Opposite this proinflammatory immune reaction a compensatory Type II anti-inflammatory response has been suggested to occur within inflamed mucosa, involving mainly IL-4 and IL-10. Both cytokines are able to downregulate inflammatory mediators, including tumor necrosis factor-alpha (TNF-α) and IL-1, and favor a humoral immune response. Previous clinical trials have evaluated local liposome-mediated gene transfer of the two anti-inflammatory cytokines, IL-4 and IL-10, in patients with severe IBD of the rectum. Local administration of anti-inflammatory cytokines avoids toxic systemic side effects and prevents blocking of the beneficial effects of proinflammatory cytokines (e.g., TNF-α in other tissue compartments and increases the local concentration of IL-4 and IL-10 over a prolonged period of time). The combined effects of IL-4 and IL-10 have been shown to shift the Th1/Th2 cell activation in favor of a Th2 immune response, which seems to be essential for fighting against the inflammation and facilitating healing.

Transfer of interleukin-4 and interleukin-10 in patients with severe inflammatory bowel disease of the rectum. Rogy MA, Beinhauer BG, Reinisch W, Huang L, Pokieser P. Hum Gene Ther 2000 Aug 10; 11 (12), pp. 1731–41.

Liposomes/Septic Abscesses: *Staphylococcus Aureus Biotin-Poly(Ethylene Glycol) (PEG)-Distearoylphosphatidylethanolamine/Avidin*

Cellular/Molecular Mechanism of Action: Avidin binds with high affinity to biotin to form a stable complex.
Application: Detection and characterization of localized regions of septic inflammation (e.g., abscess).
Route of Administration: Intravascular.
Semi-Synthetic Methods: Biotinylated liposomes were radiolabeled with [^{99m}technetium] ([^{99m}Tc])-hydrazinonicotinamide.
Implementation: Evaluation of avidin to determine if it can be applied to accelerate the clearance of biotinlyated liposomes from the intravascular compartment after a portion of the dose has accumulated within a septic lesion. Biotin can then be coupled to PEG-distearoylphosphatidylethanolamine (DSPE) and subsequently incorporated into PEG-liposomes followed by radiolabeling with [^{99m}Tc]-hydrazinonicotinamide. Efficacy of preparations can be assessed by performing *in vitro* binding studies to determine the optimal liposome biotin concentration. In biodistribution analyses performed *in vivo* with [^{99m}Tc]-biotin-PEG liposomes, the findings are then compared with the biodistribution profiles corresponding to non-biotinylated [^{99m}Tc]-PEG liposomes. Complementary *in vivo* investigations can be employed to assess both the effect of the biotin content and the optimal avidin dose that allows for the most efficient clearance of liposomes. Other analysis that can be peformed includes the application of liposomes containing 0.5 or 1.0 mol% biotin-PEG-DSPE in order to compare their *in vivo* ability to accumulate within septic foci. Avidin is injected 4 hours after injection of liposomes.
Animal Model: Rat biodistribution studies (septic foci created by injection of *S. aureus* into the left calf musculature). Avidin is then injected 4 hours after liposome injections.
Interpretation and Analysis: Biotinylation of the liposomes does not affect their *in vivo* behavior. All biotin-PEG liposome formulations display good *in vitro* avidin binding with 50% inhibitory concentrations ranging from 36 to 8 μmol/L. With avidin doses higher than 100 μg, both preparations are rapidly cleared from the circulation. As a result, abscess-to-blood ratios increase 5-fold. In an *in vivo* environment, avidin promotes clearance of radiolabeled PEG-liposomes and improves the detection of subcutaneous *S. aureus* abscesses applying [^{99m}Tc]-biotin-PEG liposomes as an imaging agent. The infection can best be visualized only after injection of 100 μg avidin. Therefore, biotin-coated [^{99m}Tc]-PEG liposomes in combination with the injection of avidin can lead to improved imaging of infection or localized inflammation especially in regions with high blood-pool activity.

Improved imaging of infections by avidin-induced clearance of [^{99m}Tc]-biotin-PEG liposomes. Laverman P, Zalipsky S, Oyen WJ, Dams ET, Storm G, Mullah N, Corstens FH, Boerman OC. J Nucl Med 2000 May; 41 (5), pp. 912–8.

Liposomes/Thermosensitive Delivery/Melanoma Plumbagin Delivery
Liposomes: Thermosensitive Preparations/Localized Hyperthermia

Semi-Synthetic Methods: Small-sized, thermosensitive liposomes can be prepared by thin film hydration in combination with sonication. Liposome products are then evaluated for the characteristics of size, phase transition temperature, *in vitro* drug release, and stability. The results of particle size analysis indicate that almost 90% of the vesicles are below 0.19 microm in size. The phase transition temperature of liposomes as determined by differential scanning calorimetry is approximately 41.32°C. The results of *in vitro* release studies in phosphate buffered saline with plasma (e.g., murine) indicate that maximum drug release (51.25%) occurs at 42°C, compared to the less than 9% release at 37°C. Superior stability profiles are observed when plumbagin liposomes are stored at 4°C.
Implementation: Evaluation of the capacity for thermosensitive liposomes and the application of local hyperthermia to facilitate selective *in vivo* delivery of plumbagin to melanoma lesions.
Animal Model: Murine (mice bearing C57B:/6J melanoma)
Interpretation and Analsis: When combined with the application of localized hyperthermia (43°C, 30 minutes or 1 hour), liposomal plumbagin administered intravenously in conditions of melanoma exhibits better anticancer activity compared to in vivo models treated with an equivalent dose of free plumbagin with or without hyperthermia, which is evident by enhanced tumor volume doubling time and growth delay.

Temperature sensitive liposomes of plumbagin: Characterization and *in vivo* evaluation in mice bearing melanoma B16F1. Tiwari SB, Pai RM, Udupa N. J Drug Target 2002 Dec; 10 (8), pp. 585–91.

Liposome Production/Cryoprotection: Hyaluronan/Sustained Release
Liposomes: Lyophilized/Unilamellar

Cellular/Molecular Mechanism of Action: Liposomes function as a form of encapsulation for various diagnostic and therapeutic agents, thereby diminishing the rate of biological degradation and premature elimination and potentially facilitating selective delivery. Hyaluronan incorporation into liposomes can enhance their bioadhesive properties but also serves as a cryoprotectant involving the function of substitute structure-stabilizing H-bonds in a manner similar to cryoprotectant sugars.
Physiological Mechanism of Action: Liposomes protect pharmaceutical agents from certain forms of degradation, enhance high-concentration delivery to specific organ/tissues, and provide time-delayed release in a manner that creates improved pharmacokinetic parameters.
Background Information: Lyophilized unilamellar liposomes (ULV) revert upon reconstitution to larger multilamellar liposomes (MLV). Such confirmational alterations are detrimental to the many carrier-mediated agents that require delivery facilitated by particles

of small size. High doses of sugars such as trehalose, sucrose, and others, included in the original formulations for cryoprotection, have also been shown to prevent conversion to multilamellar liposomes.

Application: Selective, protected delivery of diagnostic and pharmaceutical agents.

Route of Administration: Usually intravenous.

Dosage: Dependent upon intent and nature of encapsulated pharmaceutical agent.

Implementation: Characterization and evaluation of liposomes pertaining to assessement of structural and physicochemical properties in order to identify differences between reconstituted hyaluronan-unilamellar liposomes (HA-ULV) and similar regular ULV (RL-ULV) liposomes (e.g., reference controls). In the evaluation of liposomes, several properties need to be delineated, including particle size, zeta potential, encapsulation efficiency, and half-life of drug release ($tau_{1/2}$) for each individual pharmaceutical agent (e.g., chloramphenicol [CAM], vinblastine [VIN,] and mitomycin C [MMC]].

Interpretation and Analysis: Encapsulation efficiencies are very similar for RV-ULV liposomes and HA-ULV liposomes (range 25–70%). All liposome preparations are capable of acting as sustained-release drug depots with drug-release ($tau_{1/2}$) ranging from 1.3 to 5.3 days. Drug species and lipid composition are the major determinants that influence encapsulation and release properties. Lyophilization of liposomes creates several significant changes in the reconstituted RV-ULV liposome (17-fold increase in diameter; tripling of zeta potential; 25–60% drop in encapsulation efficiencies; 25–30% decrease in drug-release [$tau_{1/2}$]). Alternatively, reconstituted HA-ULV preparations retain the same physical dimensions, zeta potentials, encapsulation efficiencies, and drug-release ($tau_{1/2}$) of the original systems. In this context, hyaluronan appears to function as a cryoprotectant, and these properties are believed to be provided by substitute structure-stabilizing H-bonds in a manner similar to cryoprotectant sugars.

Hyaluronan is a key component in cryoprotection and formulation of targeted unilamellar liposomes. Peer D, Florentin A, Margalit R. Biochim Biophys Acta 2003 May 2; 1612 (1), pp. 76–82.

Liposome Production/Cryoprotection
Liposomes: Sodium Diclofenac/Lactose Cryoprotectant/ Mannitol Cryoprotectant

Semi-Synthetic Methods: Large liposomes (1–10 microm) containing sodium diclofenac can be prepared in lyophilized form using lactose or mannitol (7.5% in respect to the lipid content) as cryoprotectants.

Interpretation and Analysis: Physical studies on liposomes performed during 30 days of storage in a dry or resuspended form reveals that lyophilization of large liposomes and storage in dry form at 5°C increases their physical stability. Lactose is a cryoprotectant that does not create changes in liposome physical properties pertaining to size, encapsulation efficacy, and release rate. Large liposomes lyophilized in the presence of mannitol tend to increase in size and encapsulation efficacy, but the lipid bilayers are stabilized and less permeable to sodium diclofenac.

The effect of cryoprotectants on the physical properties of large liposomes containing sodium diclofenac. Janicki S, Jankowski J, Szulc J, Woyczikowski B, Sznitowska M. Acta Pol Pharm 2002 May–Jun; 59 (3), pp. 187–91.

Liposome Production/Determinants of Structure
Liposomes: Calcein

Semi-Synthetic Methods: Extrusion methods can be used to prepare liposomes composed of egg phosphatidylcholine (EggPC) or dimyristoylphosphatidylcholine (DMPC) and containing poly(ethylene glycol) (PEG)-lipids covering a range of 0 to 30 mol%. Physicochemical properties including size evolution and calcein permeation can be evaluated to determine the effect of PEG-lipids on bilayer structure.

Interpretation and Analysis: The results from quasielasetic light scattering (QELS), freeze-fracture microscopy, and gel exclusion chromatography reveal that low PEG-lipid concentrations results in declines in vesicle size. Increases in PEG-lipid concentrations lead to a transition from the production of lamellar membranes to micelles. The permeability for calcein increases with increases in the concentration of distearoylphosphatidylethanolamine (DSPE)-PEG. Conversely, permeability decreases with low amounts of cholesterol-PEG (below 20% cholesterol-PEG) and increases with high amounts of it. The maximum concentration of PEG-lipid that may be incorporated without alteration of the liposome structure depends on the bilayer composition. The concentration of DSPE-PEG2000 incorporated into vesicles without damaging vesicle structures is < 20 mol% for EggPC and < 10% for DMPC.

Physicochemical properties of PEG-grafted liposomes. Sriwongsitanont S, Ueno M. Chem Pharm Bull (Tokyo) 2002 Sep; 50 (9), pp. 1238–44.

Liposome Production/Dispersion: Delayed Pharmaceutical Release
Dispersions (Concentrated): Vesicular Phospholipid Gels/Chemotherapeutics: 5-Fluorouracil (5-FU)

Applications: Vesicular phospholipid gels (VPG), also known as highly concentrated liposomal dispersions, are suitable for entrapping substances such as anticancer drugs with particular high-encapsulation efficiencies (EE).

Semi-Synthetic Methods: Different formulations of VPG can be prepared with 30% (w/w) lipid containing 5-FU applying high-pressure homogenization. Analysis of preparations involves assessment of EE and drug release capabilities. Using mixtures of hydrogenated soy phosphatidylcholine and cholesterol with molar ratios ranging from 55/45 to 75/25, a decrease in cholesterol content correlates with an increase in EE that is probably due to a reduced amount of smaller vesicles and number of lamellae.

Interpretation and Analysis: Using a 5-FU solution at a pH 8.6 for VPG preparation, an EE of approximately 40% can be achieved after redispersion of the gel to a liposomal dispersion and separation of free drug from liposomal drug by size exclusion chromatography. The reduced encapsulation efficiency for preparations at lower pH levels is attributed to a fast initial drug release due to the increased drug lipophilicity below an 8 pKa value. After redispersion of a VPG of pH 8.0, an initially faster release of about a 3rd of the entrapped drug is detected during the 1st 20 minutes, followed by stable entrapment over many hours. The rapid initial release may be due to the portion of liposomes smaller than 40 nm in diameter, detected by photon correlation spectroscopy. Cryo electron microscopic images reveal that these small liposomes have a lentil-like shape. The membrane defects on the edges are probably the reason for the very high initial drug release rate. The half-life time for the release of 5-FU from intact FU-VPG at both pH 7.4 and 8.0 is in the order of 4 to 5 hours and the kinetics are typical for matrix-controlled drug diffusion. The *in vitro* data of 5-FU loaded VPG suggest their applicability as implants with controlled release properties or, after redispersion, as intravenously injected liposomal formulations.

5-fluorouracil in vesicular phospholipid gels for anticancer treatment: Entrapment and release properties. Kaiser N, Kimpfler A, Massing U, Burger AM, Fiebig HH, Brandl M, Schubert R. Int J Pharm 2003 Apr 30; 256 (1–2), pp. 123–31.

Liposome Production / Lyophilization of Pharmaceuticals/Example: Doxorubicin *Liposomes*

Background Information: Doxorubicin can be loaded into preformed liposome by remote loading. Lyophilization of liposomes results in particle size increase and content leakage. Cryoprotectants have been used to improve the stability of liposomal formulations during lyophilization.
Semi-Synthetic Methods: Liposomes composed of egg phosphatidylcholine/cholesterol and containing either glucose or sucrose as a cryoprotectant can be prepared by polycarbonate membrane extrusion. Doxorubicin can be loaded into liposome preparations by a pH-gradient-based technique performed either before or after lyophilization and reconstitution. The loading efficiency of doxorubicin can be established by gel-filtration chromatography.
Implementation: Evaluation of a formulation kit for liposomal doxorubicin production based on lyophilized liposomes incorporating specific cryoprotectants.
Route of Administration: Intravenous.
Interpretation and Analysis: Cryoprotectants are effective in maintaining liposome size distribution but not drug retention during lyophilization. Doxorubicin loading efficiency of reconstituted liposomes is nearly quantitative and comparable to that of freshly prepared liposomes. In this context, liposomal doxorubicin preparations can be stored as a lyophilized product that can be reconstituted without significant changes to critical formulation properties.

Formulation kit for liposomal doxorubicin composed of lyophilized liposomes. Stevens PJ, Lee RJ. Anticancer Res 2003 Jan–Feb; 23 (1A), pp. 439–42.

Liposome Production/Membrane Characterization/ Optimization of Properties *ANS Fluorescent Probe/Diphenylhexatriene (DPH) Fluorescent Probe/Poly-L-Lysine Backbone*

Cellular/Molecular Mechanism of Action: Fluorescent probes emit detectable light energy when excited by specific wavelengths of radiant energy.
Application: Fluorescent probes can be applied as visible molecular makers for assessing various *in vitro* and *in vivo* properties associated with liposome preparations.
Implementation: Evaluation of the systematic physicochemical characteristics of 2 branched chain polymers (based on a poly-*L*-lysine backbone) with a general formula poly[Lys-(DL-Ala_m-X_i)], where X = Orn (OAK) or *N*-acetyl-Glu (Ac-EAK) and m congruent with 3, using surface pressure and fluorescence polarization methods. Experimental findings are compared with those of the linear poly-*L*-Lys from which OAK and Ac-EAK are derived. Complementary investigations can involve the delineation of interactions between these polymers with phospholipid bilayers (neutral or negatively charged) with vesicles labeled with 2 fluorescent probes: ANS and DPH.
Interpretation and Analysis: The 2 polymers show a moderate surface activity, able to form stable monomolecular layers at the air-water interface. Poly-*L*-Lys, the most hydrophilic, has the lowest surface activity. Results indicate that the polymers are able to accommodate in their internal structure, mainly through electrostatic interactions, a certain amount of ANS marker molecule, but fluorescence increases of the ANS-polypeptide complexes are so low that its influence in further polarization measurements can be discarded. After interaction with liposomes, polymers induce an increase in the polarization of the probes, thus indicating a rigidification of the bilayers. Electrostatic forces seem to be very important in this interaction; cationic polymers are clearly more active, with PG-containing liposomes, than Ac-EAK. Moreover, in assays, poly-*L*-Lys behaves as the more active compound. This fact is probably due to its major ability to form alpha-helical structures that can insert readily into bilayers. Such findings indicate that the polymeric structures studied can be used as carriers for biologically active molecules, because their interactions with bilayers remain soft and have a positive effect on the stability of the membranes.

Physicochemical characterization of branched chain polymeric polypeptide carriers based on a poly-lysine backbone. Nagy IB, Hudecz F, Alsina MA, Reig F. Biopolymers 2003 Nov; 70 (3), pp. 323–35.

Liposome Production/Stability and Biodistribution/ Radiolabeling Reagents *[^{99m}Technetium] ([^{99m}Tc])-BMEDA/[^{99m}Tc]-BMEDA + BT/ [^{99m}Tc]-BMBuA/[^{99m}Tc]-BMBuA + BT*

Background Information: Liposomes are important carriers for controlled drug release, for gene or antisense therapy, and for immunization. Radiolabeled liposomes can be used to evaluate the *in vivo* behavior of different liposome formulations as well as their applicability for diagnostic imaging and radionuclide therapy.
Application: Radiolabeling of liposomes can be performed in order to delineate their *in vivo* stability and biodistrubution for research or clinical purposes.
Route of Administration: Intravenous.
Semi-Synthetic Methods: Methods have been described for radiolabeling liposomes with [^{99m}Tc]-"SNS/S" complexes, in addition to [^{186}Re] and [^{188}Re] (e.g., therapeutic radionuclides). One production strategy involves [^{99m}Tc] labeling of *N*,*N*-bis(2-mercaptoethyl)-*N*′, *N*′-diethyl-ethylenediamine (BMEDA), *N*,*N*-bis(2-mercaptoethyl)-1-butylamine (BMBuA), and benzene thiol (BT), yielding [^{99m}Tc]-BMEDA, [^{99m}Tc]-BMEDA + BT, [^{99m}Tc]-BMBuA, and [^{99m}Tc]-BMBuA + BT, which can ultimately be applied for the labeling of glutathione-encapsulated liposomes.
Implementation: Evaluation of the *in vitro* properties and *in vivo* biodistribution of [^{99m}Tc]-liposomes composed of distearoyl phosphatidylcholine (DSPC) and cholesterol.
Interpretation and Analysis: Labeling efficiencies for [^{99m}Tc]-reduced glutathione (GSH) liposomes is approximately 36.9–69.2%. After incubation in serum, [^{99m}Tc]-GSH liposomes labeled with [^{99m}Tc]-BMEDA or [^{99m}Tc]-BMEDA + BT have the best labeling stability. Distribution studies after intravenous injection of [^{99m}Tc]-liposomes composed of distearoyl phosphatidylcholine (DSPC) and cholesterol have a slow blood clearance and high spleen accumulation, demonstrating the *in vivo* labeling stability of the radiolabeled liposomes. Preparations of [^{99m}Tc]-liposomes have great potential as a radiopharmaceutical agent applicable for evaluating various kinds of liposomes of different lipid compositions, for evaluating in advance a subsequent radionuclide therapy strategy using [^{186}Re]- or [^{188}Re]-labeled liposomes, and for specialized diagnostic imaging procedures.

A novel liposome radiolabeling method using 99mTc-"SNS/S" complexes: *In vitro* and *in vivo* evaluation. Bao A, Goins B, Klipper R, Negrete G, Mahindaratne M, Phillips WT. J Pharm Sci 2003 Sep; 92 (9), pp. 1893–904.

Liposome Production/Aqueous and Oily Phase Preparations

Application: Modification of the rate at which pharmaceuticals are absorbed from the gastrointestinal tract.
Route of Administration: Oral.

Dosage: Not applicable.
Semi-Synthetic Methods: Ampicillin trihydrate can be formulated in different oily and aqueous suspensions.
Implementation: Evaluation of the bioavailability of aqueous and oily phase ampicillin in plasma samples determined by using microbiological-based biological assay techniques.
Interpretation and Analysis: Oily and sucrose-containing aqueous formulations enhance the extent of ampicillin absorption (nearly statistically significant). Ampicillin appears to be absorbed at essentially the same rate from both aqueous and oily formulations. The latter shows plasma-level time curves with biphasic absorption profiles and is likely to produce prolonged plasma concentrations of ampicillin because of the effects of enterohepatic recycling. Viscosity appears to play an insignificant role in the results obtained because the bioavailability parameters correlate poorly with the viscosity, except Cmax. It has been suggested that enhancement in ampicillin bioavailability is due to a decrease in the gut transit rate brought about by the oil, which predominates and masks the other effects of viscosity and osmotic effects of sucrose. Existence of a correlation between the *in vitro* drug-release rate (t50%) and viscosity, in addition to the lack of correlation between *in vivo* and *in vitro* parameters, supports the suggestion and indicates that traditional dissolution rate tests, such as flask-stirrer method, are unsatisfactory as bioavailability indicators when applied in dosage forms that cause marked changes in physiological factors like gastroesophogeal reflux (GER) and biliary excretion.

Effects of oils and pharmaceutical excipients on the bioavailability of ampicillin orally administered, different oily and aqueous suspensions in rabbit. Alhamami OM. Drug Dev Ind Pharm 2003 Jan; 29 (1), pp. 51–60.

Liposome Production/Biopolymers/Microcapsules/Casein
Sustained Release of Pharmaceuticals

Cellular/Molecular Mechanism of Action: Casein microcapsulation acts like a molecular matrix that can incorporate pharmaceuticals in a manner that facilitates delayed/sustained release.
Application: Casein microcapsules can function as a sustained-release system (e.g., acetaminophen drug model).
Semi-Synthetic Methods: Casein microcapsules can be prepared by aqueous coacervation in lactate buffer containing gelatin, hydroxypropyl cellulose (HPC), and lecithin. After preparation, microcapsules (± glutaraldehyde) can be treated with a cross-linking agent. Casein microcapsules are subsequently loaded using 2 distinctly different procedures, either by (i) dissolving 50% of the drug (w/w), relative to casein, in the polymer dispersion; or by (ii) dissolving the drug in a coacervating solution. The drug introduced into casein/microcapsules can be quantified applying high-performance liquid chromatography (HPLC) following an enzymatic degradation assay, complemented by scanning electron microscopy and thermal analysis (differential scanning calorimetry and thermogravimetrical analysis) of casein/microcapsule preparations.
Considerations: The use of biopolymers in sustained-release systems has been studied by many research groups because of the bioavailability and biodegradability of these compounds. Casein is a natural biopolymer whose degradation results in biologically utilizable compounds.
Interpretation and Analysis: Loading of the pharmaceutical agent is approximately 8% (w/w) and is associated with a high resistance to enzymatic degradation. The absence of an acetaminophen melting peak indicates that there is no drug present on the surface of the cross-linked systems. In addition, pharmaceutical loading is accompanied by a reduction of the specific heat capacity of the systems and suggests a decrease in stability. The outer morphology of the encapsulating polymer is affected by the process of microencapsulation. Therefore, the microencapsulation process of aqueous coacervation and cross-linking appears to be appropriate for the preparation of microencapsulated systems for sustained drug delivery.

Physicochemical characterization and enzymatic degradation of casein microcapsules prepared by aqueous coacervation. Santinho AJ, Ueta JM, Freitas O, Pereira NL. J Microencapsul 2002 Sep–Oct;19 (5), pp. 549–58.

Liposome Production/Solubilization of Lipophilic Pharmaceuticals and Biopharmaceuticals/Hydrophilic Compound Coating/Evaporative Precipitation into Aqueous Solution
Dichloromethane/Carbamazepine

Cellular/Molecular Mechanism of Action: Evaporative precipitation into aqueous solution (EPAS) in order to coat poorly water-soluble drugs.
Application: "Coating" poorly water-soluble drugs.
Methodology: A heated organic solution of the drug in dichloromethane is sprayed though a fine nozzle into a heated aqueous solution.
Interpretation and Analysis: The rapid evaporation of the organic solvent produces high supersaturation and rapid precipitation of the drug in the form of a colloidal suspension that is stabilized by a variety of low molecular weight and polymeric surfactants. The stabilizer adsorbs to the drug surface and prevents particle growth and crystallization during the spray process. The suspensions are dehydrated by spray drying or ultra-rapid freezing. The high dissolution rates are a consequence of the following advantages of the EPAS process: a small primary particle size, a hydrophilic coating on the particles that enhances wetting, and low crystallinity.

Enhanced drug dissolution using evaporative precipitation into aqueous solution. Sarkari M, Brown J, Chen X, Swinnea S, Williams RO 3rd, Johnston KP. Int J Pharm 2002 Aug 28; 243 (1–2), pp. 17–31.

MICROBUBBLES AND MICROSPHERES

Acoustic Parameters
Definity/Optison/SonoVue/Sonazoid

Implementation: Evaluation of the acoustic properties of 4 ultrasonic contrast agents (Optison, Definity, SonoVue, and Sonazoid) at 30 MHz. A range of contrast agent concentrations can be studied using either saline or glucose as a diluting media. Mean backscatter power is measured within regions-of-interest (ROIs) at distances of 1, 1.5, 2, 3, 4, and 5 mm from the center of the intravascular probe and normalized to the ultrasound (US) data collected from a standard glass reflector.
Interpretation and Analysis: For all of the agents, the mean backscatter power at 30 MHz varies in a linear manner with concentration between 0.01 million microbubbles/mL and 1 million microbubbles/mL. Furthermore, for 2 of the agents, mean backscatter enhancement is detectable at concentrations as low as 2 microbubbles/sample volume.
Instrumentation: Boston Scientific ClearView Ultra intravascular US scanner modified to allow access to the unprocessed US data.

In vitro acoustic characterization of 4 intravenous ultrasonic contrast agents at 30 MHz. Moran CM, Watson RJ, Fox KA, McDicken WN. Ultrasound Med Biol 2002 Jun; 28 (6), pp. 785–91.

Arthritis/Rheumatoid Arthritis of the Knee/ Inflammatory vs Non-Inflammatory Pannus Vascularity
Levovist

Application: Characterization of vascular structures including the intra-articular vascularity of knee-joint synovial pannus in conditions of rheumatoid arthritis (RA) using power Doppler ultrasonography (PDS) and an echo-contrast-enhancing agent.
Implementation: Evaluation of arthritic knee joints. Disease activity is evaluated using the disease activity score (DAS) and the chronic arthritis systemic index (CASI) for each case. Examinations are performed with conventional ultrasonography and PDS before injection of an intravenous ultrasound contrast agent (Levovist). Quantitative estimation of synovial membrane vascularity is performed utilizing time-intensity curves and calculation of the area-under-the-curves (AUCs) for specific regions-of-interest (ROIs). Parameters calculated from time-intensity curves are then correlated with measures of disease activity, including clinical and functional assessments (e.g., number of swollen joints, intensity of pain, general health-visual analogue scale, disability index-Health Assessment Questionnaire, Ritchie articular index) and clinical pathology analyses. Disease activity is evaluated using the DAS and the CASI for each case.

Human Model: Cases with signs and history of arthritis of the knee ($n = 42$ rheumatoid arthritis; $n = 31$ women, $n = 11$ men) classified according to a modified index of synovitis activity (active, moderately active, and inactive).
Interpretation and Analysis: The mean (standard deviation [SD]) value of the area underlying time-intensity curves is 216.2 (33.4) in cases with active synovitis, 186.8 (25.8) in cases with moderately active synovitis, and 169.6 (20.6) in those with inactive synovitis. The mean value for AUCs differs significantly between cases with active and those with inactive synovitis ($p < 0.01$). The mean value of the AUC of the entire group weakly correlates with the number of swollen joints ($p = 0.038$), but a strong correlation is found with composite indexes of disease activity such as the DAS ($p = 0.006$) and CASI ($p = 0.01$). No correlation can be appreciated for age, disease duration, and other laboratory and clinical variables. Power Doppler ultrasonography may be a valuable tool to detect fractional vascular volume and to assist clinicians in distinguishing between inflammatory and non-inflammatory pannus. The transit of microbubbles of ultrasound contrast across a tissue can be used to estimate hemodynamic alterations and may have a role in assessing synovial activity and the therapeutic response to treatment of synovitis of the knee joint.

Power Doppler sonography in the assessment of synovial tissue of the knee joint in rheumatoid arthritis: A preliminary experience. Carotti M, Salaffi F, Manganelli P, Salera D, Simonetti B, Grassi W. Ann Rheum Dis 2002 Oct; 61 (10), pp. 877–82.

Cardiovascular Endothelium: ICAM-1 Expression/ Optimization of Binding/Antibody-Density/ Wall Shear Rate
Anti-ICAM-1 Microbubbles/Lipid-Based Perfluorobutane-Filled Microbubble

Background Information: The early stages of atherosclerosis are characterized by increased endothelial cell (EC) surface expression of leukocyte adhesion molecules (LAMs). Ultrasound detection of acoustically active LAM-targeted microbubbles might provide a means to non-invasively assess the functional status of vascular endothelium.
Application: Non-invasive ultrasound assessment of the functional status of vascular endothelium.
Route of Administration: Intravascular.
Semi-Synthetic Methods: Production of a lipid-based perfluorobutane-filled microbubbles synthesized with various densities of anti-ICAM-1 monoclonal antibodies conjugated to the bubble shell (1%, 5%, 10%, 50%, 75%, and 100% of maximum coverage) and possessing various wall shear rates (100, 175, 250, 350, and 500 s^{-1}).
Implementation: Evaluation of the hypothesis that modulating the surface antibody density can permit regulation of the endothelial adhesion characteristics of microbubbles, and that microbubble adhesion is dependent on local wall shear rate. Such a hypothesis can be addressed by exposing coronary artery endothelials cells to microbubbles produced with different surface antibody densities and various wall shear rates in a parallel plate perfusion chamber.

***Ex Vivo* Model:** Human coronary artery ECs cultured on coverslips. Endothelial cells are either normal or activated by interleukin-1 beta (IL-1β) in a manner that induces ICAM-1 overexpression.
Interpretation and Analysis: Immunomicrobubble adhesion is greater in the presence of activated vs normal endothelial cell ($p < 0.001$); increases with increasing surface antibody density ($p < 0.01$); and decreases with increasing wall shear rate ($p = 0.02$). In conclusion, shell antibody density and wall shear rate are critical parameters controlling differential microbubble adhesion. This phenomenon might ultimately permit imaging of clinically relevant (*in vivo*) LAM expression.

Modulating targeted adhesion of an ultrasound contrast agent to dysfunctional endothelium. Weller GE, Villanueva FS, Klibanov AL, Wagner WR. Ann Biomed Eng 2002 Sep; 30 (8), pp. 1012–9.

Cardiovascular Endothelium: ICAM-1 Expression/ Endothelial Dysfunction: Coronary Ischemia
Microbubbles

Background Information: Clinical signs and symptoms of coronary artery disease are predated in decades by endothelial dysfunction, an aberration in the vascular lining that permits the development and propagation of atherosclerotic lesions, and vasomotor dysfunction in the arterial circulation. These ultimately lead to acute and chronic coronary ischemic syndromes. Other pathophysiologic scenarios encountered in clinical cardiology practice, such as cardiac transplant rejection and the period following coronary angioplasty or cardiac surgery, also are associated with endothelial dysfunction. Endothelial dysfunction parallels coronary risk factors and is potentially reversible, rendering early identification of the phenomenon a clinically important end point. Current methods for detecting endothelial dysfunction are limited.
Application: Characterization of vascular endothelial integrity based on the detection of alterations in the expression of surface membrane complexes, including intracellular adhesion molecule 1 (ICAM-1) using targeted ultrasound imaging techniques.
Route of Administration: Intravascular.
Considerations: Implications pertain to other disease processes besides coronary ischemia and encompass both diagnostic and therapeutic delivery strategies.
Implementation: Evaluation of endothelial cell viability and biology as a function of unique surface marker expression (e.g., ICAM-1).
Interpretation and Analysis: Myocardial contrast echocardiography using microbubbles targeted to bind to cell surface markers uniquely expressed by dysfunctional endothelial cells may offer an approach for the non-invasive detection of endothelial disease using clinical ultrasound imaging techniques.

Microbubble-endothelial cell interactions as a basis for assessing endothelial function. Villanueva FS, Klibanov A, Wagner WR. Echocardiography 2002 Jul; 19 (5), pp. 427–38.

Cardiovascular Thromboses
[Lys-Gla-Ala-Gly-Asp-Val]-Aerosomes-Entrapped Microbubbles

Cellular/Molecular Mechanism of Action: Microbubbles can function as a means for delaying excretion, suppressing biological degradation, and enhancing site-specific accumulation of diagnostic and therapeutic pharmaceutical agents.
Application: Ultrasound can be used as a primary diagnostic technique for the detection of deep venous thrombosis. Microbubble preparations can potentially enhance the detection and characterization of intravascular thrombi.
Route of Administration: Intravascular.
Semi-Synthetic Methods: In the 1st phase of production, the synthetic linear hexapeptide (lysine-glutamine-alanine-glycine-aspartate-valine) can be coupled to a lipid moiety. The targeted lipid moiety is then incorporated into a lipid blend, followed by entrapment of Aerosomes contrast agent (ImaRx) yielding perfluorobutane-entrapped microbubbles. Prior to administration microbubble preparations are then sized for uniformity.
Implementation: Evaluation of the *in vitro* capacity of sized perfluorobutane-entrapped microbubbles to (i) retain high levels of acoustic stability; (ii) recognize (bind) to blood clots; and (iii) enhance ultrasound image analysis of intravascular thromboses (blood clots).
Interpretation and Analysis: Experimental results reveal that the mean size of the specific ultrasound contrast agent (MRX-408) is about 2.0 microm. Microbubbles appear as smooth spherical structures. Microscopic analysis reveals that targeted bubbles bind to blood clots, whereas control, non-targeted bubbles do not bind to blood clots. *In vitro* acoustic studies reveal similar levels of stability for modified microbubbles compared with control microbubbles. Targeted microbubbles enhance *in vitro* blood clot visualization, whereas non-targeted microbubbles do not increase clot detection. Therefore, this new thrombus-specific ultrasound contrast agent could potentially improve the detection of thrombosis by ultrasound and may be useful for distinguishing between new and old thrombosis. Investigations performed *in vivo* have been initiated to further characterize the applicability of these preparations.

In vitro studies of a new thrombus-specific ultrasound contrast agent. Unger EC, McCreery TP, Sweitzer RH, Shen D, Wu G. Am J Cardiol 1998 Jun 18; 81 (12A), pp. 58G–61G.

Controlled/Delayed/Sustained Release of Diagnostic Agents
Microcapsules: Casein

Cellular/Molecular Mechanism of Action: Casein microencapsulation functions like a molecular matrix that can incorporate pharmaceutical agents in a manner that facilitates delayed/sustained release.
Application: Casein microcapsules can function as a sustained-release system (acetaminophen drug model).
Semi-Synthetic Methods: Casein microcapsules can be prepared by aqueous coacervation in lactate buffer containing gelatin, hydroxypropyl cellulose (HPC), and lecithin. After preparation, microcapsules (± glutarldehyde) can be treated with a cross-linking agent. Casein microcapsules are subsequently loaded using 2 distinct procedures, involving either (i) dissolving 50% of the drug (w/w), relative to casein, in the polymer dispersion; or by (ii) dissolving the drug in the coacervating solution. The drug introduced into casein/microcapsules can be quantified applying high-performance liquid chromatography (HPLC) following an enzymatic degradation assay, in concert with scanning electron microscopy and thermal analysis (differential scanning calorimetry and thermogravimetrical analysis) of casein/microcapsule preparations.
Considerations: The use of biopolymers in sustained release systems has been studied by many research groups because of the bioavailability and biodegradability of these compounds. Casein is a natural biopolymer whose degradation results in biologically relevant compounds.
Interpretation and Analysis: Loading of the drug is approximately 8% (w/w), and preparations have a high resistance to enzymatic degradation. Absence of an acetaminophen melting peak indicates that there was no drug present on the surface of the cross-linked systems. In addition, pharmaceutical loading is accompanied by a reduction of the specific heat capacity of the systems and suggests a decrease in stability. The outer morphology of the encapsulating polymer is affected by the process of microencapsulation. Laboratory data suggests that the microencapsulation processes of aqueous coacervation and cross-linking are appropriate for the preparation of microencapsulated systems for sustained drug delivery.

Physicochemical characterization and enzymatic degradation of casein microcapsules prepared by aqueous coacervation. Santinho AJ, Ueta JM, Freitas O, Pereira NL. J Microencapsul 2002 Sep–Oct; 19 (5), pp. 549–58.

Controlled/Sustained/Delayed Release/Systemic Delivery Post-Intramuscular (IM) Injection
Gelatin Microspheres/Genipin-Cross-Linked Gelatin Microspheres

Cellular/Molecular Mechanism of Action: Gradually, gelatin microspheres are degraded when implanted into tissues, thereby facilitating the release of their contents for systemic absorption from the site of deposition (e.g., IM injection).
Background Information: Gelatin microspheres have been widely evaluated as a drug carrier. Nevertheless, gelatin dissolves rather rapidly in aqueous environments, making the use of the polymer difficult for the production of long-term delivery systems. Such an undesirable feature requires the use of a cross-linking agent to form a non-soluble network within microspheres. However, the use of cross-linking agents such as formaldehyde and glutaraldehyde can lead to toxic side effects due to residual amounts of cross-linkers.
Application: Slow, prolonged release of diagnostic and therapeutic pharmaceutical agents from a site of administration (e.g., IM injection).
Route of Administration: Intramuscular (example) with potential applications for delivery to other organ systems, tissues sites, and body compartments (e.g., gastrointestinal tract, subcutaneous tissues, intrathorax, intraperitoneal, intrathecal, intravascular, and intra-articular).
Considerations: Glutaraldehyde can be used as a reference control.
Semi-Synthetic Methods: In an attempt to overcome the problem of rapid decomposition, a naturally occurring cross-linking agent (genipin) can be used to cross-link gelatin microspheres to produce a biodegradable drug-delivery system for intramuscular administration.
Implementation: Evaluate the (i) *in vitro* morphology, dynamic swelling, and antienzymatic degradation properties of test microspheres; and (ii) biocompatibility and degradability of test microspheres implanted in skeletal muscle following intramuscular injection.
Animal Model: Rat (intramuscular injection).

Interpretation and Analysis: Results obtained under controlled conditions suggest that cross-linking of gelatin microspheres with glutaraldehyde or genipin produces distinct cross-linking structures. The water transport mechanism in both glutaraldehyde- and genipin-cross-linked gelatin microspheres exhibits anomalous behavior ranging from Fickian to case II extremes. Increases in the swelling diameter for the genipin-cross-linked microspheres is significantly less than that observed for the glutaraldehyde-cross-linked microspheres. In an *in vivo* (skeletal muscle) environment, the degree of induced inflammatory reaction for tissues implanted with genipin-cross-linked microspheres is significantly less than muscle implanted with the glutaraldehyde-cross-linked microspheres. Additionally, the degradation rate for genipin-cross-linked microspheres is significantly slower than their glutaraldehyde-cross-linked counterparts. Such findings indicate that the genipin-cross-linked gelatin microspheres may be used as a long-acting drug carrier for intramuscular administration.

Genipin-cross-linked gelatin microspheres as a drug carrier for intramuscular administration: *In vitro* and *in vivo* studies. Liang HC, Chang WH, Lin KJ, Sung HW. J Biomed Mater Res. 2003 May 1; 65A (2), pp. 271–82.

Estradiol
Microspheres: Biodegradable Production

Cellular/Molecular Mechanism of Action: Encapsulation of pharmaceutical agents for protection against degradation and to delay excretion, in addition to promoting selective distribution at high concentrations to specific tissue/organ targets.
Semi-Synthetic Methods: Preparations of poly (D, L-lactic acid) (PLA)/D, L-lactide/glycolide copolymer (PLGA) can be used to produce biodegradable and biocompatible carriers to achieve sustained release of estradiol. Microspheres can be formed by an emulsification-solvent evaporation method. Quality control measures include the measurement of various parameters and properties, including *in vitro* drug release behavior; effects of polyvinyl alcohol (PVA) concentration in the aqueous phase; concentration of PLA in the organic phase; stirring speed; volume O/W ratio; weight ratio of E2/PLA fed; and polymer type and molecular weight.

Preparation and evaluation of poly (D, L-lactic acid) (PLA) or D, L-lactide/glycolide copolymer (PLGA) microspheres with estradiol. Xinteng Z, Weisan P, Ruhua Z, Feng Z. Pharmazie 2002 Oct; 57 (10), pp. 695–7.

Hysterosalpingography (Tubal Patency)/ Infertility (Female)
Levovist

Background Information: Previous experimental and clinical data suggest that insonation of echo-enhancing contrast agents with high acoustic power produces disintegration of microbubbles, resulting in a phenomenon called simulated acoustic emission (SAE).
Implementation: Evaluation of female infertility using x-ray hysterosalpingography (HSG) and SAE-HyCoSy. The order of the 2 procedures is randomly established for each case after placement of a trans-cervical balloon catheter. For SAE-HyCoSy, the ultrasound contrast medium Levovist is injected, with the acoustic power set at the maximum level permitted on ultrasound machines employing dedicated algorithms. Conventional HSG is performed for comparison.

Human Model: Cases of female infertility (n = 41 and n = 77 fallopian tubes). X-ray hysterosalpingography for infertility evaluation also receive SAE-HyCoSy.

Interpretation and Analysis: In the majority of cases, it is possible to appreciate the SAE phenomenon. In 13% of tubes, (e.g., n = 10) proximal filling is not observed by either SAE-HyCoSy or HSG. In the remaining 87% of tubes (e.g., n = 67), free spill from the distal end of the lumen can be demonstrated in 96% of cases (e.g., n = 64/67) with SAE-HyCoSy and in 97% of cases (e.g., n = 65/67) with HSG. Disagreement between the 2 techniques may be observed in only a few instances (e.g., n = 5/77; Cohen's kappa coefficient of 0.76; 95% confidence interval, 0.56–0.96). Therefore, SAE techniques can successfully be applied to HyCoSy, and they allow visualization of the "free spill" of contrast agent into the peritoneal cavity in the majority of cases. SAE-HyCoSy has shown good agreement with HSG in previous preliminary studies.

The sonographic evaluation of tubal patency with stimulated acoustic emission imaging. Prefumo F, Serafini G, Martinoli C, Gandolfo N, Gandolfo NG, Derchi LE. Ultrasound Obstet Gynecol 2002 Oct; 20 (4), pp. 386–9.

Lymph Nodes: Regional
Poly(Ethylene Glycol) (PEG)-Coated Magnetite Nanospheres

Semi-Synthetic Methods: Magnetite nanospheres can be prepared with a grafted PEG layer using various PEG lengths from 350 to 1,000 Da. Thermogravimetric analysis can be utilized to measure adsorbed amounts of PEG. Colloid stability is confirmed by measurement of particle size and electrophoretic mobility.
Implementation: Evaluation of the kinetics of injection site drainage and lymph node retention 2 hours after subcutaneous administration of nanospheres coated with PEG lengths of 350, 550, 750, and 1,000 Da. For 750 PEG-coated nanospheres, the kinetics of distribution can be determined over a 48-hour time course.
Interpretation and Analysis: The distribution of nanospheres is modified and lymph node localization is enhanced by altering the surface coverage of PEG on the magnetic surface. PEG-coated magnetite nanospheres with different surface characteristics can be utilized to target regional lymph nodes with diagnostic agent.

Development of systems for targeting the regional lymph nodes for diagnostic imaging: *In vivo* behavior of colloidal PEG-coated magnetite nanospheres in the rat following interstitial administration. Illum L, Church AE, Butterworth MD, Arien A, Whetstone J, Davis SS. Pharm Res 2001 May; 18 (5), pp. 640–5.

Lymph Nodes (Sentinel)/Normal vs Metastatic
Carbon Dioxide Microbubbles

Background Information: Although endoscopic ultrasonography is considered the most useful diagnostic modality for regional staging, the capability of diagnosing lymph node metastasis based on endoscopic ultrasonography images alone is not sufficient. To improve the capability of establishing a differential diagnosis of lymph node enlargement, contrast-enhanced echolymphography can be performed using endoscopic ultrasonography-guided puncture.
Implementation: Evaluation of the ability of contrast-enhanced echolymphography to differentiate between normal and metastatic lymph nodes. Guided puncture of lymph nodes can be performed under real-time endoscopic ultrasonography, followed by carbon dioxide microbubble injection to evaluate echo features before and after microbubble injection.

***Ex Vivo* Model:** Metastatic lymph nodes (n = 8) surgically removed from cases with gastrointestinal cancer (*in vitro* study).

Human Model: Cases with abdominal lymph node swelling detected by endoscopic ultrasonography (n = 55).

Interpretation and Analysis: Contrast-enhanced echolymphography of freshly resected metastatic lymph nodes display nonhomogeneous echo patterns. In regions demonstrating filling defects detected by contrast-enhanced echolymphography, neoplastic infiltration pathology can be observed. In the vast majority of the malignant lymph nodes studied *in vivo*, filling defects and heterogeneous enhancements can be observed by contrast-enhanced echolymphography. However, contrast-enhanced echolymphography demonstrates uniform patterns for most lesions classified as benign. Sensitivity, specificity, positive and negative predictive value, and accuracy of differential diagnosis by contrast-enhanced echolymphography are 95.8%, 90.3%, 88.5%, 96.6%, and 92.7%, respectively. Contrast-enhanced echolymphography is a useful method for differentiating between reactive and malignant lymph node alterations.

Differentiation of benign and malignant lymph nodes with contrast-enhanced echolymphography using endoscopic ultrasound-guided puncture. Kojima S, Goto H, Hirooka Y, Itoh A, Ishiguro Y, Hashimoto S, Hirai T, Hayakawa T. Hepatogastroenterology 2003 Sep–Oct; 50 (53), pp. 1285–91.

Neoplastic Disease/Gene Delivery/Selective Tumor DNA Delivery via Vasculature
Plasmid-Microspheres/Plasmid-Complexed Liposomes

Application: Selective targeting of plasmid-incorporated genetic DNA sequences for neoplastic cell types.
Route of Administration: Arterial catheterization.
Implementation: Evaluation of plasmid DNA delivery into a renal solid tumor involving the utilization of plasmid bound to microspheres and plasmids complexed with liposomes to evaluate their potential to function as a selective delivery modality to tumors. Selective delivery is in part facilitated by selective catheterization of the major arterial network supplying individual neoplastic tissue masses.

***Ex Vivo* Model:** Rat (established renal solid tumor model).
Interpretation and Analysis: Forty-eight hours postdelivery, tumor-to-normal kidney tissue chloramphenicol acetyltransferase expression ratios are as follows: free (1.8:1), microspherical (3.9:1), and liposomal (1.2:1). Microspheres are able to selectively deliver plasmids to tumors, whereas cationic liposomes distribute plasmids to the parenchyma of both kidneys and tumor cells. The tumor model has the potential of screening delivery vehicles as well as therapeutic agents for the capacity of selective delivery to tumors via vascular structures.

A model for evaluating selective delivery of plasmid DNA to tumors via the vasculature. Dass CR, Burton MA. Cancer Biother Radiopharm 2002 Oct; 17 (5), pp. 501–5.

Neoplastic Disease: Liposome Assimilation Enhancement/Enhanced Selective Systemic/Local-Regional Uptake/Slowing of Local-Regional Blood Flow
Starch Microspheres/Small Unilamellar Vesicles (SUV)-Poly(Ethylene Glycol) (PEG) Liposomes

Physiological Mechanism of Action: Starch microspheres can be used to slow local-regional blood flow in a manner that can maximize assimilation of encapsulated liposomes into neoplastic lesions.
Background Information: Systemic adjuvant chemotherapy achieves unsatisfactory results for inoperable liver tumors and metastases. Various clinical studies have shown that loco-regional chemotherapy increases survival rate by several months.
Application: Enhancement of systemic and local-regional uptake of diagnostic and therapeutic pharmaceutical agents.
Route of Administration: Systemic and direct local-regional injection.
Implementation: Evaluate the capacity of liposome encapsulation to selectively facilitate local-regional/systemic targeting of neoplastic cell populations with cytostatic 5-fluouracil (5-FU).
Interpretation and Analysis: Tumor concentrations of 5-FU encapsulated in SUV-PEG liposomes increases by a factor of 27 in systemic therapy and a factor of 90 in loco-regional therapy. The tumor concentration of 5-FU increases by a factor of 8,000 if the blood flow is additionally slowed by starch microspheres (Spherex) during loco-regional therapy with 5-FU encapsulated within liposome preparations.

Liposome encapsulation of cystostatic drugs and starch microspheres improve tumor targeting in loco-regional therapy. An animal experiment study of CC 531 liver tumor. Berger G, Reszka R, Pohlen U, Jung M, Lucas S, Buhr HJ. Langenbecks Arch Chir Suppl Kongressbd 1998; 115 (Suppl I), pp. 693–7.

Neoplastic Disease/Malignant Glioma ($\alpha_v\beta_3$)
Echistatin Microbubbles

Background Information: Angiogenesis is a critical determinant that influences tumor growth and metastasis. It has been hypothesized that contrast-enhanced ultrasound (CEU) with microbubbles targeted to α_V-integrins expressed on the neovascular endothelium could be used to image angiogenesis phenomenon.
Implementation: Evaluation of malignant glioma CEU utilizing contrast-enhanced ultrasound in combination with microbubbles targeted to $\alpha_V\beta_3$ by surface conjugation with echistatin. Contrast-enhanced ultrasound perfusion imaging with non-targeted microbubbles can be used to derive tumor microvascular blood volume and blood velocity. Vascular α_V-integrin expression can be assessed by immunohistochemistry, and microbubble adhesion characterized by confocal microscopy.

Animal Model: Rat (athymic; $n = 14$). Malignant gliomas are produced by intracerebral implantation of U87MG human glioma cell populations. On day 14 or day 28 after implantation, CEU is performed.
Interpretation and Analysis: Mean tumor size increases markedly from 14 to 28 days (2 ± 1 vs 35 ± 14 mm^2, $p < 0.001$). Tumor blood volume increases by approximately 35% from day 14 to day 28, whereas microvascular blood velocity decreases, especially at the central portions of the tumors. On confocal microscopy, $\alpha_V\beta_3$-targeted but not control microbubbles are retained preferentially within tumor microcirculation structures. Contrast-enhanced ultrasound signals produced by $\alpha_V\beta_3$-targeted microbubbles in tumors increase significantly from 14 to 28 days (1.7 ± 0.4 vs 3.3 ± 1.0 relative units, $p < 0.05$). Contrast-enhanced ultrasound signals from $\alpha_V\beta_3$-targeted microbubbles is greatest at the periphery of tumors, where α_V-integrin expression is the most prominent, and correlates well with tumor microvascular blood volume ($r = 0.86$). Contrast-enhanced ultrasound with $\alpha_V\beta_3$-targeted microbubbles can non-invasively detect early tumor angiogenesis. Such a technique, when coupled with changes in blood volume and velocity, may provide insights into the biology of tumor angiogenesis and be used for various diagnostic applications.

Imaging tumor angiogenesis with contrast ultrasound and microbubbles targeted to $\alpha_V\beta_3$. Ellegala DB, Leong-Poi H, Carpenter JE, Klibanov AL, Kaul S, Shaffrey ME, Sklenar J, Lindner JR. Circulation 2003 Jul 22; 108 (3), pp. 336–41.

Neoplastic Disease/Prostatic Carcinoma
Galactose-Based Air Microbubbles

Implementation: Evaluate and compare gray-scale and color Doppler before and during intravenous injection of ultrasound contrast agent made of galactose-based air microbubbles. Biopsy samples can be harvested during contrast injection or directed cores can be collected based on contrast-enhanced imaging (e.g., n = 18). Diagnostic efficiency with and without contrast medium injection for detecting prostate neoplasia are then compared and validated based on biopsy results.

Human Model: Cases evaluated by biopsy of the prostate (n = 85 suspects).

Implications and Analysis: Cancer can be identified in a large number of suspected cases (e.g., n = 58 biopsies/54 cases). Gray-scale imaging can detect a large number of abnormal hypoechoic nodules or irregular zones inside the outer gland (e.g., n = 96/54 cases), of which approximately 50% are found to be malignant on pathological evaluation (e.g., n = 48/96). Contrast-enhanced color Doppler has a higher sensitivity (93%) than unenhanced color Doppler (54%), while specificity increases only 79% to 87% for enhanced imaging. Approximately 90% (e.g., n = 9/10) of isoechoic suspicious zones can be depicted with enhancement, while unenhanced Doppler detects approximately 70% (e.g., n = 7/10). There is no significant difference between the intensity of enhancement and tumor Gleason scores. Contrast-enhanced color Doppler endorectal sonography increases the detection of prostate cancer. Improvement in sensitivity is high, while the difference in specificity is not as pertinent. It is accurate when using a common and routine application ultrasound unit. Such a technique is easy to perform and not time-consuming. Obtaining additional biopsy cores of suspicious enhancing foci significantly improves the detection rate of cancer.

Contrast-enhanced color Doppler endorectal sonography of prostate: Efficiency for detecting peripheral zone tumors and role for biopsy procedure. Roy C, Buy X, Lang H, Saussine C, Jacqmin D. J Urol 2003 Jul; 170 (1), pp. 69–72.

Nucleic Acid (Gene) Delivery/Epidermal Growth Factor Receptor Messenger RNA (mRNA)/ Antisense cDNA
[5-Fluorouracil (5-FU)] Microspheres/[Antisense Oligodeoxynucleotides] Microspheres

Cellular/Molecular Mechanism of Action: Liposomes, due to their low ionic character, are able to traverse across intact cell membranes, thereby facilitating the intracellular release of encapsulated contents.

Background Information: Antisense oligonucleotides (AODNs) can selectively inhibit oncogene expression by Watson-Crick hybridization to target mRNA sequences. Such strategies are being increasingly considered for use in combination with conventional drugs for potential anticancer therapy.

Application: Selective delivery to neoplastic lesions.

Route of Administration: Intravascular (1° intravenous).

Considerations: Combination therapy of AODNs and cytotoxic agents using biodegradable polymeric delivery systems potentially offers several advantages, including site-specific or organ-directed targeting, protection from digesting enzymes, and improved pharmacokinetics/pharmacodynamics resulting from sustained delivery of the entrapped drugs.

Semi-Synthetic Methods: Production of poly-(lactide-co-glycolide) (P(LA-GA)) microsphere formulations. Antisense oligodeoxynucleotides and 5-FU can be either co-entrapped in a single microsphere formulation or individually entrapped in 2 separate microsphere formulations. Release profiles over time can be determined *in vitro*.

Implementation: Evaluate the effectiveness of P(LA-GA) microsphere formulations to deliver (i) a model AODN for targeting epidermal growth factor receptor mRNA sequences (overexpressed by several cancers including breast and brain neoplasias); in combination with (ii) the cytotoxic chemotherapeutic agent 5-FU.

Interpretation and Analysis: Using a double emulsion method for preparing P(LA-GA) microspheres, suitable entrapment and sustained release can be achieved for both types of formulations over a period of 35 days. Release of AODN and 5-FU from all formulations appears to be biphasic. However, the release rates of the 2 agents are significantly slower when co-entrapped as a single microsphere formulation compared to those obtained with 2 separate formulations. Electrophoretic mobility shift assays suggested that this might be, in part, due to an interaction of 5-FU with the oligodeoxynucleotide (ODN). Such findings suggest that mixing individual formulations of 5-FU and ODNs at different mass ratios allows for greater flexibility in achieving a desired release profile, as well as avoiding potential drug-drug interactions. Thus, co-administration of individual P(LA-GA) microsphere formulations containing AODNs and 5-FU, at appropriate mass ratios, appears worthy of further investigation for the potential *in vivo* co-delivery of these anticancer agents.

Co-delivery of an antisense oligonucleotide and 5-fluorouracil using sustained release poly (lactide-co-glycolide) microsphere formulations for potential combination therapy in cancer. Hussain M, Beale G, Hughes M, Akhtar S. Int J Pharm. 2002 Mar 2; 234(1–2), pp. 129–38.

Nucleic Acid (Gene) Delivery/Leukocyte Depletion of Neoplastic Tissues Prior to Genetic Analysis
Magnetic Microspheres

Application #1: Selective "targeted" delivery and controlled or sustained release of encapsulated diagnostic agents.

Example #1: A method of delivering recombinant adeno-associated virus 2 (rAAV), resulting in increased vector transduction efficiencies using microspheres reversibly conjugated to rAAV vectors. A major hurdle in most current gene-delivery modalities is the ability to transduce target tissues at very high efficiencies sufficient to ultimately lead to therapeutic levels of trans-gene expression.

Example #2: Enhanced Kuppfer cell phagocytosis of superparamagnetic particles. The evolution of the proton transverse magnetization of an organ perfused with increasing doses of starch-coated magnetic microspheres is followed by analysis utilizing the Carr-Purcell-Meiboom-Gill sequence with various echo times for images acquired using contrast media preparations.

Example #3: Magnetic microsphere-methoxtrexate conjugates.

Example #4: Microspheres coated with CD45 for the purpose of depleting tumor-infiltrating T lymphocytes. Due to masking or dilution of infrequent tumor cell events, the presence of normal cell types, such as inflammatory cells and fibroblasts, can interfere with accurate DNA analysis of solid tumor samples. In conditions simulating human breast tumor samples employing mixed cell populations (e.g., MDA-MB-175-VII human breast carcinoma cells, WI-38 human lung fibroblast cells, and peripheral blood leukocytes), preparations of CD45-conjugated magnetic microspheres can be used to selectively deplete tumor-infiltrating leukocytes, thus producing a sample that is highly enriched with neoplastic cells.

Example #5: Purging of bone marrow in children with acute lymphocytic leukemia with monoclonal antibody conjugated magnetic microspheres in concert with high-dose VP-16 60 mg/kg; fractionated total body irradiation (12 Gy: 2 × 2 Gy daily); and autologous bone marrow rescue.

Example #6: Selective recognition of neurblastoma cell populations utilizing monoclonal antibody conjugated to microsphere preparations. Depending on the monoclonal antibody, cell lines can be selected that have specific differences in size, morphology, phenotype, neurite process development, and proliferation rate. Due in part to the specificity of the monoclonal antibody applied, all cell lines express the M_r 145,000 neurofilament, and a few express the M_r 200,000 neurofilament, with very little or no expression of the M_r 68,000 neurofilament. Approximately 80% of all cells lines have near-diploid DNA content. High expression of MDR-1 protein is present in about 27% of isolated cell lines. Great heterogeneity can be observed in the expression of N-myc oncoprotein, with a large percentage overexpressing protein fractions. Such findings are accompanied by the expression of c-myc oncoprotein in all cell lines (4- to 10-fold lower than the N-myc oncoprotein). Localization studies of c-myc and N-myc oncoproteins on the level of light microscopy and electron microscopy reveal exclusive nuclear localization of c-myc, while N-myc is localized within the nucleus and cytoplasm.

Route of Administration: Intravenous but depends on each individual preparation.

Synthetic Chemistry and Analyses: Example methodology: Magnetic microsphere-methotrexate (MM-MTX) can be prepared by the following methods: (i) reaction of MTX with poly(ethylene glycol) 1500 (PEG) to form a PEG-methotrexate conjugate (PEGMTX), which is then added to a ferrous/ferric ion salt solution to give MM-MTX I; (ii) reaction of ferrous/ferric ion salts with PEG to give a ferromagnetic polymer complex, which is then coupled with MTX to give MM-MTX II; (iii) MM-MTX IIIA can be prepared by reacting MTX with amino-terminated magnetic microspheres in the presence of 1-ethyl-3,3-bis(methylamino)propylcarbodiimide (EDCI); (iv) reaction of aminohexanol with di-tert-butyl dicarbonate to form an [N-(tert-butoxycarbonyl)amino]hexanol (t-Boc-AH), which is then coupled with MTX in the presence of 1,3-dicyclohexylcarbodiimide and 4-pyrrolidinopyridine to give a t-Boc-AH-MTX conjugate, which is then saturated with hydrogen chloride to give an aminohexanol-methotrexate (AH-MTX) conjugate. MM-MTX IIIB can then be prepared by reacting AH-MTX with carboxyl-terminated magnetic microspheres in the presence of EDCI and 4-(dimethylamino)pyridine. The identity of MTX conjugates is confirmed using ultraviolet, infrared, and nuclear magnetic resonance spectroscopy. Drug content of the magnetic microsphere-methotrexate conjugates as determined by high-performance liquid chromatography (HPLC) is 0.45% (w/w), 4.0% (w/w), and 6.3% (w/w) MTX for MM-MTX I, MM-MTX II, and MM-MTX IIIB, respectively.

Considerations: A major hurdle in most current diagnostic/therapeutic gene modalities is the ability to transduce target tissues at very high efficiencies. Conjugation of agents to microspheres should result in a higher effective concentration within predetermined tissue or organ targets as it moves through tissue vasculature, as well as providing a relatively longer retention time of diagnostic agents within a given site or lesion of interest. Depending on the objective and agent being applied, *in vitro* investigations have demonstrated that preparations conjugated to microspheres can be 100 times more efficient in reaching a predetermined target site compared to a scenario where the preparation is evaluated without the benefits or attributes associated with microspheres. Application of magnetic microspheres allows the advantage of enhancing regional accumulation. Furthermore, *in vivo* microsphere-mediated strategies can result in higher efficiencies of delivery and induced biological effect compared to agents in "free" form administered either intramuscularly or intravenously. Often, this can be accompanied by prolonged retention of microsphere preparations within capillary bed structures.

Application #2: From the multiexponential fit of the echo train, the amplitudes and the relaxation rates R2 of the liver tissue can be obtained. Results from such studies clearly indicate that shortly after contrast medium administration, internalization takes place, which can be followed by the rapid and biphasic evolution of the transverse relaxation rate of water protons. A very fast decaying component looking like an initial loss of the magnetization can be observed together with an increase in the relaxation rate of the remaining water tissue. Such a regime is strongly dependent on both the echo time and iron concentration (e.g., behavior characteristic of agglomerations of magnetic particles). The examination of liver tissues by electron microscopy shows that this clustering arises within cytoplasmic vacuoles.

Improved method of recombinant AAV2 delivery for systemic targeted gene therapy. Mah C, Fraites TJ Jr, Zolotukhin I, Song S, Flotte TR, Dobson J, Batich C, Byrne BJ. Mol Ther 2002 Jul; 6 (1), pp. 106–12.

Nucleic Acid (Gene) Delivery/Solid Tumors
Microspheres (> 1 μm)/Liposome: Cationic (100–200 nm)/Porphyrin Derivatives (< 1 nm)/Branched-Chain Dendrimers (10 nm)/ Polyethylenimine Polymers (10 nm)/Nanoparticles (20–1,000 nm)/Microspheres (> 1 μm)/ Cyclodextrins (CyDs 1.5 nm)

Background Information: The vasculature of a tumor provides the most effective route by which neoplastic cells may be reached and eradicated by drugs. The fact that a tumor's vasculature is relatively more permeable than healthy host tissue should enable selective delivery of drugs to tumor tissue. Such delivery is relevant to carrier-mediated delivery of genetic medicine to tumors. Cationic liposomes have been used for the introduction of nucleic acids into mammalian cells for more than a decade.

Application: Nucleic acid delivery into cells (*in vitro* and *in vivo*).

Semi-Synthetic Methods: Cationic liposomes are generally 100–200 nm in diameter, whereas CyDs typically span 1.5 nm across.

Implementation: Evaluate the potential of delivering therapeutic oligonucleotides (ONs) to tumors using cationic liposomes and cyclodextrins (CyDs) and the major hindrances posed by the tumor itself on such delivery.

Interpretation and Analysis: CyD molecules are routinely used as agents that engender cholesterol efflux from lipid-laden cells, thus having an efficacious potential in the management of atherosclerosis. A recent trend is to employ these oligosaccharide molecules for delivering nucleic acids in cells both *in vitro* and *in vivo*. Comparisons have been made with other oligonucleotide delivery agents, such as porphyrin derivatives (< 1 nm), branched-chain dendrimers (approximately 10 nm), polyethylenimine polymers (approximately 10 nm), nanoparticles (20–1,000 nm), and microspheres (> 1 μm), in the context of delivery to solid tumor. The chemical and physical properties of these carriers and how they may affect the uptake of oligonucleotides into cells, particularly *in vivo*, have been reviewed.

Vehicles for oligonucleotide delivery to tumours. Dass CR. J Pharm Pharmacol 2002 Jan; 54 (1), pp. 3–27.

Ocular Tissues and Adnexa: Budesonide Delivery/ Retinal Pigment Epithelial Cells/(Ocular Globe Delivery: Subconjunctival Injection)
Microparticles and Nanoparticles

Route of Administration: Topically (*in vitro* tissue culture populations) and subconjunctivally by injection (*in vivo*) into 1 eyelid (Sprague-Dawley rats).
Dosage: Budesonide (100 pM to 10 μM in exposed tissue culture cell populations).
Semi-Synthetic Methods: DL-polylactide (PLA) nanoparticles and microparticles containing budesonide can be prepared using a solvent evaporation technique, and the particles can then be profiled for the characteristics of size, morphology, encapsulation efficiency, and *in vitro* release.
Implementation: Evaluation of the influence that budesonide has on vascular endothelial growth factor (VEGF) secretion, VEGF messenger RNA (mRNA) expression, and cytotoxicity in cell populations assessed by ELISA, real-time polymerase chain reaction (RT-PCR), and cell-viability assays, respectively.
***Ex Vivo* Model:** ARPE-19 cell lines.
Animal Model: Rat (Sprague-Dawley).
Interpretation and Analysis: At concentrations devoid of cytotoxicity, budesonide inhibits VEGF secretion as well as VEGF mRNA expression in ARPE-19 cell lines in a dose-dependent manner. Glucocorticoid receptor antagonists (e.g., RU486) suppress budesonide-mediated inhibition of VEGF secretion and VEGF mRNA expression, thereby implying a role of this receptor type in the observed effects mediated by budesonide.

Budesonide-PLA nanoparticles (345 nm) and microparticles (3.6 μm), with an encapsulation efficiency of 65% and 99%, respectively, possess properties of sustained *in vitro* release of budesonide. In an *in vivo* model, subconjunctival administration of both budesonide-PLA nanoparticles and microparticles produces sustained budesonide levels within the retina and other ocular tissues (measured in the retina, vitreous, lens, and cornea at 1, 7, and 14 days postinjection).

Subconjunctival nano- and microparticles sustain retinal delivery of budesonide, a corticosteroid capable of inhibiting VEGF expression. Kompella UB, Bandi N, Ayalasomayajula SP. Invest Ophthalmol Vis Sci 2003 Mar; 44 (3), pp. 1192–201.

Parkinson's Disease (Bromocryptine Mesylate)
Poly(L-Lactide)/Poly(D,L-Lactide)/Poly(D,L-Lactide-co-Glycolide)/Microspheres (Biodegradable)

Cellular/Molecular Mechanism of Action: Encapsulation of pharmaceutical agents for protection against degradation and premature elimination in a manner that can enhance accumulation of preparations within a specific organ or tissue.
Application: Delivery of pharmaceutical agents in a manner that is protected from degradation and a means of selectively concentrating preparations within a specific organ/tissue lesion.
Semi-Synthetic Methods: Bromocryptine mesylate can be encapsulated into biodegradable polymers using the polymers poly(L-lactide), poly(D,L-lactide), and poly(D,L-lactide-co-glycolide).
Interpretation and Analysis: Photomicrographs (scanning electron microscopy [SEM]) have shown that microsphere morphology depends significantly on the polymer and emulsifying agent. Regardless of the polymer type, increases in emulsifying agent concentration from 0.25 to 0.75% w/v markedly decreases microsphere particle size. Delineation of particle size characteristics reveals that the use of 0.75% w/v of emulsifying agent concentration and a polymer solution concentration of 10% w/v results in the production of particles of optimum proportions and size. In order to prepare biodegradable microspheres with high drug content and small particle size, selection of polymer concentration, as well as emulsifying agent concentration, is critical. Polymer type has a less pronounced effect on the percent encapsulation efficiency and particle size of microspheres than on the (t50%). Microspheres prepared utilizing all 3 polymers, at a polymer concentration of 10% w/v and an emulsifying agent concentration of 0.75% w/v with NaCMC:SO (4:1, w/v), produce a formulation that produces optimum characteristics.

Biodegradable bromocryptine mesylate microspheres prepared by a solvent evaporation technique. I: Evaluation of formulation variables on microspheres characteristics for brain delivery. Arica B, Kas HS, Orman MN, Hincal AA. J Microencapsul 2002 Jul–Aug; 19 (4), pp. 473–84.

Protein Delivery
Microparticles (Solvent-Free)

Preparations: Solvent-free microparticles, loaded with protein fractions, can be produced using a supercritical (SC) fluid-based coating technology.
Semi-Synthetic Methods: Coating material consists of either trimyristin (Dynasan 114) or Gelucire 50-02. Microparticles produced in this manner are categorized according to the characteristics of morphology, protein content, and *in vitro* release profile. A discontinuous coating made of trimyristin micro-needles leads to an initial burst release (approximately 70% within 30 minutes). However, a prolonged release of reference protein fractions (e.g., bovine serum albumin [BSA]) can be achieved in a phosphate buffer solution at 37°C over a 24-hour period from particles coated with Gelucire 50-02. In addition, it has been shown that BSA does not undergo degradation after supercritical CO_2 treatment conditions used during the coating process.

A supercritical fluid-based coating technology. 3: Preparation and characterization of bovine serum albumin particles coated with lipids. Ribeiro Dos Santos I, Richard J, Thies C, Pech B, Benoit JP. J Microencapsul 2003 Jan–Feb; 20 (1), pp. 110–28.

Protein Delivery
Microencapsulation

Application: Delivery of peptide, lipoproteins, and glycoprotein diagnostic biopharmaceuticals.
Semi-Synthetic Methods: Preparations are made using a mixer that consists of an array of microchannels. Advantages of the system are that it is simple to assemble, requires only a very small work space, lacks moving parts, and offers simple control of microsphere size. Scale-up from lab bench to industrial production is easily feasible through parallel installation of a sufficient number of micromixers. Poly(lactic-co-glycolic acid) microspheres can be loaded with a model reference protein (e.g., bovine serum albumin [BSA]) and the influence of various process and formulation parameters on the characteristics of the microspheres can be examined, particularly with respect to the properties of particle size and distribution. Because of its simple setup and its suitability for continuous production, static micromixing is preferred for the automated and aseptic production of protein-loaded microspheres.
Implementation: Evaluate the potential of a static micromixer to be utilized in the production of protein-loaded biodegradable polymeric microspheres by a modified solvent extraction process.

Interpretation and Analysis: Microspheres with monomodal size distributions having mean diameters of 5 to 30 μmeters can be produced with excellent consistency (reproducibility). Particle size distributions are largely unaffected by polymer solution concentration, polymer type, and nominal protein fraction load with BSA, but this characteristic is dependent on the polymer solvent. Moreover, particle mean diameters can be varied over a considerable range by modulating the flow rates of the mixed fluids. Protein fraction encapsulation efficiencies are mostly in the range of 75 to 85% (e.g., BSA) and product yields range from 90 to 100% (e.g., BSA).

Solvent extraction employing a static micromixer: A simple, robust and versatile technology for the microencapsulation of proteins. Freitas S, Walz A, Merkle HP, Gander B. J Microencapsul 2003 Jan–Feb; 20 (1), pp. 67–85.

Pharmaceutical Delivery: Eudragit RS 100/ Eudragit RL 100/Microencapsulation Coatings *Microcapsules: Sulphamethoxazole*

Physiological Mechanism of Action: Facilitates sustained release of compounds from microcapsule formulation.
Application: Eudragit is used as a coating material in microencapsulation techniques.
Analytical Methodology: Evaluation of preparation characteristics for sulphamethoxazole microcapsules coated with Eudragit RS 100 and RL 100 stored at room temperature for 10 years for comparison with freshly formulated microcapsules. Determination of the various storage conditions over a 6-month period can also be used as a strategy for assessing stability and retained integrity. Critical properties of interest include analysis for total drug content, dissolution, surface properties, and physical properties.
Interpretation and Analysis: The parameters of drug content, dissolution, surface properties, and physical properties evaluated for sample preparations stored at room temperature for 10 years compared to fresh preparations, and formulations subjected to various storage conditions for a period of 6 months, reveal that 70% of the core material is still intact in 10-year-old samples. Similarly, dissolution studies of 10-year-old sustained-release microcapsule samples show that drug release ranges from 4% in the 1st hour to 65% at the end of 8 hours. Drug release from the freshly prepared microcapsule (keeping the manufacturing parameters the same as that followed for older sample) ranges from 25% in the 1st hour to 98% at the end of the 8th hour. Infrared spectra of freshly prepared microcapsules and that of the 10-year-old microcapsules are identical and indicate that no interaction occurs between the coating polymer and core substance even after 10 years.

Accelerated stability of sulphamethoxazole microcapsules coated with Eudragit RS 100 and Eudragit RL 100. Basnet S, Ganesan M, Pal TK. Boll Chim Farm 2002 May–Jun; 141 (3), pp. 202–9.

Pharmaceutical Delivery/Example: Eudragit RL *Microencapsulation/Preparation (Solvent Evaporation Technique)*

Cellular/Molecular Mechanism of Action: Functions as a delivery modality that can protect pharmaceutical agents from degradation and premature elimination, in addition to facilitating selective accumulation of preparations within a given target tissue or organ system.
Application: Delivery of pharmaceutical.
Semi-Synthetic Methods: Microcapsules composed of Eudragit RL can be prepared applying a solvent evaporation techniques. In example preparations using Diclofenac sodium as a model reference pharmaceutical for encapsulation, a solution of drug and Eudragit RL is dissolved in acetone-isopropyl alcohol (1:1) and sprayed into liquid paraffin.
Route of Administration: Usually intravenous.
Dosage: Dependent upon encapsulated pharmaceutical and intended application.
Interpretation and Analysis: The microcapsules obtained are uniform and free-flowing particles. The release rate is more sustained if the polymer concentration is increased. As an experimental procedure, this technique has promise as a rapid and convenient method for the preparation of Eudragit RL microcapsules.

A novel method for preparation of Eudragit RL microcapsules. Satturwar PM, Mandaogade PM, Dorle AK. J Microencapsul 2002 Jul–Aug; 19 (4), pp. 407–13.

Pharmaceutical Delivery/Controlled Release *Microspheres: Reacetylated Chitosan*

Cellular/Molecular Mechanism of Action: Functions as a delivery modality that can protect pharmaceutical agents from degradation,and premature elimination, in addition to facilitating selective accumulation of preparations within a given target tissue or organ system.
Considerations: The high aqueous solubility of chitosan restricts the utility of chitosan microspheres for gastric drug delivery.
Semi-Synthetic Methods: Two different microencapsulation techniques can be optimized in order to efficiently encapsulate hydrophilic (e.g., amoxycillin) and hydrophobic (e.g., metronidazole) compounds. Reacetylated chitosan microspheres exhibit a controlled water swelling capacity and gelify at acidic pH levels, resulting in prolonged release of encapsulated antibiotics.
Implementation: Evaluation of reacetylated chitosan microspheres possessing desirable properties to determine their capacity to facilitate controlled release of pharmaceutical agents within the gastrointestinal system (e.g., active antimicrobial agents, including amoxycillin and metronidazole).
Interpretation and Analysis: The reacetylation time is an important variable affecting not only drug release but also encapsulation efficiency and antimicrobial activity of encapsulated compounds. Encapsulation efficiency and biological activity is also dependent on drug solubility within the reacetylating agent. Using short reacetylation time periods, it is possible to efficiently control the release of both hydrophilic and lipophilic antibiotics, while maintaining their biological activity (antimicrobial properties). Based on preliminary findings, reacetylated chitosan microspheres appear to be promising vehicles for the controlled delivery of pharmaceutical agents (e.g., antimicrobial agents) within the gastric lumen for the purpose of achieving a specific outcome (e.g., *Helicobacter pylori* eradication or imaging/treatment of gastric carcinoma).

Reacetylated chitosan microspheres for controlled delivery of antimicrobial agents to the gastric mucosa. Portero A, Remunan-Lopez C, Criado MT, Alonso MJ. J Microencapsul 2002 Nov–Dec; 19 (6), pp. 797–809.

Pharmaceutical Delivery/Ultrasound-Triggered Focal Delivery/Acoustic Power: Optimization/ Signal Intensity Maximization/Bulk Modulus/ Influence of Difference in Shell Characteristics *Microbubbles/Acoustic Lability*

Background Information: Low mechanical index perfusion imaging relies on the detection of signals produced by microbubble oscillation at low acoustic powers that results in minimal microbubble destruction.

Route of Administration: Intravascular.
Consideration: Localized ultrasound-mediated disruption of microbubble preparations containing encapsulated pharmaceutical agents has been employed as a modality for selective delivery.
Implementation: Evaluation of the hypothesis that the optimal acoustic power for real-time imaging differs for microbubbles with different shell characteristics. One approach for pursuing this hypothesis can involve the evaluation of 3 microbubble agents with varying shell elastic properties according to their polymer composition. Differences in the elastic properties of these microbubbles can be demonstrated by (i) measurement of their bulk modulus, and (ii) evaluation of their acoustic lability by microscopic visualization of microbubble destruction during insonification at incremental acoustic powers. The ultrasound signal generated by these microbubbles at various mechanical indexes and the degree of microbubble destruction during continuous imaging is then determined both in an *in vitro* flow system and during *in vivo* open-thorax imaging.

Animal Model: Canine (open-thorax preparations).
Interpretation and Analysis: Optimal power for achieving maximal signal intensity with minimal microbubble destruction is influenced by the shell elastic properties. Acoustic power for maximizing acoustic signal without destroying microbubbles during low mechanical index imaging varies according to specific shell characteristics.

Influence of microbubble shell properties on ultrasound signal: Implications for low-power perfusion imaging. Leong-Poi H, Song J, Rim SJ, Christiansen J, Kaul S, Lindner JR. J Am Soc Echocardiogr 2002 Oct; 15 (10 Pt 2), pp. 1269–76.

Pharmaceutical Delivery/Ultrasound (US)-Triggered Focal Delivery/Cardiovascular Endothelium: Endothelium Injury/Endothelial Cell (EC) Viability: *Ex Vivo*/[Local Delivery]
Microbubbles/Propidium Iodine (PI)

Background Information: Microvascular EC may be subject to the bioeffects induced by contrast US because of their proximity to the circulating microbubbles.
Application: Potential modality for the selective delivery of diagnostic or therapeutic pharmaceutical agents contained with microbubble preparations that can subsequently be liberated by exposure to ultrasound-induced disruption (lysis).
Route of Administration: Intravascular.
Implementation: Evaluation of EC injury produced in mesentery microvessel sections (e.g., arteriole, capillary, or venule) by exposure of ultrasound microbubble contrast agents to ultrasound energy. Assessment of such phenomenon can involve injection of microbubble preparations, followed by US exposure at a 1-Hz or 30-Hz frame rate. Propidium iodide, a fluorescent indicator of cell injury, can then be employed to visualize impaired endothelial cell integrity. Note: PI-positive nuclei should be equally few among the 3 control preparations.

Animal Model: Rat (mesenteric vasculature) in 5 experimental groups, including 3 controls (sham operation, microbubble injection alone, US exposure with saline injection); and 2 contrast US groups (1-Hz or 30-Hz frame rates).
Interpretation and Analysis: Contrast US increases the number of PI-positive cells in capillaries (1-Hz frame rate, 2.4 ± 2.2 cells per 0.1 mm vessel length, $p = 0.09$; 30-Hz frame rate, 4.3 ± 1.8 cells, $p < 0.01$) and in venules (1-Hz frame rate, 4.1 ± 2.5 cells, $p < 0.05$; 30-Hz frame rate, 13.8 ± 3.6 cells, $p < 0.01$) compared with sham preparations (0.10 ± 0.22 cells). Such findings indicate that diagnostic contrast ultrasound potentially causes endothelial injury, particularly within venules and capillaries.

Endothelial cell injury in venule and capillary induced by contrast ultrasonography. Kobayashi N, Yasu T, Yamada S, Kudo N, Kuroki M, Kawakami M, Miyatake K, Saito M. Ultrasound Med Biol 2002 Jul; 28 (7), pp. 949–56.

Pharmaceutical Delivery/Estrogen/Systemic Delivery (Protected)
Estradiol Microspheres: Biodegradable

Cellular/Molecular Mechanism of Action: Encapsulates pharmaceutical agents for protection against degradation and selective distribution at high concentrations to specific tissue/organ targets.
Semi-Synthetic Methods: Preparations of poly (D, L-lactic acid) (PLA)/D, L-lactide/glycolide copolymer (PLGA) can be used to produce biodegradable and biocompatible carriers to achieve sustained release of estradiol. Microspheres can be formed by an emulsification-solvent evaporation method. Quality control measures include the measurement of various parameters and properties, including *in vitro* drug release behavior; effects of polyvinyl alcohol (PVA) concentration in the aqueous phase; concentration of PLA in the organic phase; stirring speed; volume oil/water (O/W) ratio; weight ratio of E2/PLA fed; and polymer type and molecular weight.

Preparation and evaluation of poly (D, L-lactic acid) (PLA) or D, L-lactide/glycolide copolymer (PLGA) microspheres with estradiol. Xinteng Z, Weisan P, Ruhua Z, Feng Z. Pharmazie 2002 Oct; 57 (10), pp. 695–7.

Protein Delivery/Enzymes: Preparation Optimization
Microparticulates Enzyme Prolidase Stability/ Poly[Lactide-Co-Glycolide] (PLGA)/Microparticulate Enzyme Formulations

Semi-Synthetic Methods: Various strategies can be applied to determine the stability of prolidase and its interaction with reagents, in addition to delineating the effectiveness of various condition variables applied during the emulsification of prolidase-loaded PLGA microparticulate systems. Such forms of evaluation are necessary in order to characterize optimal semi-synthetic techniques. Enzyme stability can be tested pertaining to contact with methylene chloride, ethyl acetate, PLGA polymers, and several agents used as emulsifiers such as polyvinyl alcohol (PVA), polyvinyl pyrolidone (PVP), carboxymethyl cellulose (CMC), and sodium oleate (NaOl). Evaluation of enzyme stability to temperature and mechanical stirring of prolidase-loaded PLGA microspheres ideally should be performed in order to detect alterations in protein activity.
Interpretation and Analysis: Prolidase-loaded PLGA microspheres can be prepared only upon enzyme stabilization by addition of both bovine serum albumin (BSA) and $MnCl_2$ into TRIS formulations. Methylene chloride is a suitable organic solvent for use in double emulsion techniques, together with PVA as a dispersing agent in the outer aqueous phase. Low temperatures during the emulsification step and very short process times are recommended, in order to maintain maximum enzyme activity. In these conditions spherical microspheres can be obtained, releasing active prolidase for up to 15 days.

Evaluation of enzyme stability during preparation of polylactide-co-glycolide microspheres. Perugini P, Genta I, Pavanetto F, Modena T, Maculotti K, Conti B. J Microencapsul 2002 Sep–Oct; 19 (5), pp. 591–602.

Protein Delivery/Immunity and Inflammatory Mediators (Endogenous)

Poly(Lactic/Glycolic Acid) Microspheres/Interleukin (IL)-1α

Physiological Mechanism of Action: Interleukin-1α is a pleiotropic cytokine mediator with multiple antitumor activities.

Background Information: Microspheres encapsulating IL-1α have the potential of functioning as an immunotherapy platform for the management of neoplastic disease.

Application: Microspheres can be applied to deliver labile biological protein fractions, including endogenous mediators of immunity and inflammation (e.g., IL-1α).

Semi-Synthetic Methods: Encapsulation of IL-1α within biodegradable poly(lactic/glycolic acid) microspheres, 1–5 μm diameter in size.

Implementation: Enhance IL-1α-mediated activation of macrophages using microspheres as a delivery vehicle.

Animal Model: Murine.

Interpretation and Analysis: Preparations of IL-1α microspheres are efficiently internalized by macrophages in tissue culture and after intraperitoneal injection. In culture, phagocytosis of the microspheres reaches a saturation level within 3 hours and there is no apparent effect of polymer type on the extent of uptake. *In vivo* uptake of human IL-1α microspheres by macrophages leads to cell activation reflected as an enhanced level of murine IL-1α, IL-6, and IL-12 production. Control microspheres, containing bovine serum albumin, induce only background, to low levels of cytokine production. These cytokines, when expressed or secreted from macrophages, may *in situ* stimulate diverse immune and inflammatory responses, including T cell–mediated immune responses such as those involved in the development of Th1 cells and cytotoxic lymphocytes. Thus, directed delivery of IL-1α to macrophage populations via appropriate microsphere preparations may serve as a unique approach for modulating the immunoregulatory properties of this cell type and enhancing their *in situ* participation in antitumor immune responses.

Macrophage activation for the production of immunostimulatory cytokines by delivering interleukin-1 via biodegradable microspheres. Mullerad J, Cohen S, Voronov E, Apte RN. Cytokine 2000 Nov; 12 (11), pp. 1683–90.

Protein Delivery/Sustained Peptide Release (*In Vivo*)/Example: Insulin

Microspheres: Inherently Fluorescent

Cellular/Molecular Mechanism of Action: Microspheres can function as a delivery platform that can prevent degradation, delay the rate of elimination, control systemic release, and/or facilitate selective delivery in a manner that minimizes innocent organ/tissue exposure and enhances concentrations at desired target regions.

Application: Selective or protracted pharmaceutical release.

Route of Administration: Intravenous.

Semi-Synthetic Methods: Inherently fluorescent microspheres composed of a fluorescent polyanhydride (e.g., poly(p-(carboxyethylformamido) benzoic anhydride, or PCEFB, and poly(lactide-co-glycolide) [PLGA]) can be prepared using a water-in-oil-in-water (w/o/w) emulsion solvent evaporation technique. Characterization of microsphere blends can be achieved applying combinations of gel permeation chromatography (GPC), infrared spectrometry (IR), fluorometry, and scanning electron microscopy (SEM) analyses.

Implementation: Evaluation of the effect of the PCEFB/PLGA feed ratio and composition of the oil phase on insulin entrapment and microsphere diameter.

Interpretation and Analysis: Insulin entrapment efficiency increases with PCEFB content and acetone percent in the oil phase. Microsphere diameter decreases as acetone is added into the oil phase. Although slight degradation of PCEFB during the fabrication process can be identified by GPC and IR, PCEFB/PLGA microspheres can still be clearly visualized by either confocal laser scanning microscopy (CLSM) or fluorescent microscopy in a manner that makes it possible to directly detect microspheres *in vivo* by fluorometry without the need for fluorescent dye labeling techniques. The surface of PCEFB/PLGA (1:2) microspheres is smooth, while PCEFB/PLGA (2:1) microspheres have rough and uneven surfaces. Sustained release of insulin from the microspheres can be achieved over a period of approximately 4 days.

Bioadhesive fluorescent microspheres as visible carriers for local delivery of drugs. I: Preparation and characterization of insulin-loaded PCEFB/PLGA microspheres. Jiang HL, Zhu KJ. J Microencapsul 2002 Jul–Aug; 19 (4), pp. 451–61.

Release Evaluation

Brilliant Blue Microspheres/Tumor Necrosis Factor-Alpha (TNF-α) Microspheres/Poly(D,L-Lactic-Co-Glycolic Acid) Multiphase Microspheres

Cellular/Molecular Mechanism of Action: Brilliant blue functions as a dye marker reagent that is compatible with biological systems.

Application: Brilliant blue can be applied to evaluate the rate of release of compounds incorporated into microsphere preparations.

Route of Administration: Intravascularly or within individual body cavities.

Semi-Synthetic Methods: Microspheres can be prepared using an anhydrous multiple-emulsion solvent evaporation method.

Implementation: Evaluation of the *in vivo* rate of release within the peritoneal cavity.

Animal Model: Murine (intraperitoneal).

Interpretation and Analysis: Multiphase microspheres containing brilliant blue exhibit a 3-phase release profile *in vitro* and display a significantly lower level of dye released during the initial phase compared to conventional matrix-type microspheres. Slow release of the dye is observed during the 2nd phase, which is followed by disintegration of the polymer wall during the 3rd phase of the release process. *In vitro* dissolution profiles of TNF-α can be calculated following compensation for the simultaneous degradation of the protein that occurs in the dissolution medium. The initial burst release of TNF-α is significantly reduced with multiphase microspheres. The 3-phase release profile, as seen with the dye, is not observed for microspheres containing TNF-α. The rate of release of protein from microspheres can be determined *in vivo* by analyzing the residual level of TNF-α remaining in the particles following intraperitoneal administration of microspheres. The release of protein from microspheres *in vivo* is significantly faster than predicted from the results observed during *in vitro* studies. The absence of an initial burst release of TNF-α from multiphase microspheres is recognized as a significant reduction in plasma TNF-α levels when compared to matrix-type microspheres and a solution of the biological protein. The controlled release property of multiphase microspheres is expected to overcome adverse reactions due to dose dumping that can occur following local TNF-α administration.

In vitro and *in vivo* release properties of brilliant blue and tumor necrosis factor-alpha (TNF-α) from poly(D,L-lactic-co-glycolic acid) multiphase microspheres. Iwata M, Nakamura Y, McGinity JW. J Microencapsul 1999 Nov–Dec; 16 (6), pp. 777–92.

Respiratory System: Pulmonary Delivery (Passive)
Albumin Microspheres/[Terbutaline]

Background Information: Terbutaline sulfate is widely used as a bronchodilator for the therapeutic management of bronchial asthma, chronic bronchitis, and emphysema. As it has a short biological half-life, a long-acting terbutaline sulfate formulation would considerably improve clinical compliance.
Application: Passive pulmonary delivery. Speculation suggests that preferential uptake of albumin microspheres is due to a combination of several variables, including (i) partial wedging within the lumen of microvascular structures of a specific diameter if preparations are given by jugular vein injection because the pulmonary vasculature is the first capillary bed they would encounter following administration; and/or (ii) if preparations were given by jugular vein injection, the first physical contact microspheres would have with large populations of cells belonging to the mononuclear phagocytic system would be within the lung (e.g., intravascular and alveolar macrophage populations). So in reality, the preferential distribution pattern may instead be a direct result of the route of administration in concert with the anatomical and functional features of the lung instead of a true molecular-based form of selective delivery.
Semi-Synthetic Methods: Preparation of bovine serum albumin (BSA) microspheres by an emulsion polymerization method using glutaraldehyde as a cross-linking agent. All microspheres are spherical and smooth with a mean particle size in the range of 22 to 30 μm.
Interpretation and Analysis: Drug release from BSA microspheres displays a biphasic pattern characterized by an initial fast release, followed by a slower release phase. The amount released decreases with increases in glutaraldehyde concentration. In the absence of trypsin, the time required for complete degradation of microspheres is increased from 144 to 264 hours when the glutaraldehyde concentration increases from 0.1 to 0.7 ml. In the presence of trypsin, a linear relationship can be observed between degradation rate and trypsin concentration, which indicates that saturation of the biological system has not yet been reached. Biodistribution studies indicate that the degree of uptake by the lungs is higher than that for other organ systems. Therefore, terbutaline sulfate–loaded microspheres can be used for passive lung targeting.

Preparation, characterization and *in vivo* distribution of terbutaline sulfate–loaded albumin microspheres. Sahin S, Selek H, Ponchel G, Ercan MT, Sargon M, Hincal AA, Kas HS. J Control Release 2002 Aug 21; 82 (2–3), pp. 345–58.

Semi-Synthetic Technique Optimization
Microparticulates/Enzyme Prolidase Stability

Implementation: Various strategies can be applied to determine the stability of prolidase and its interaction with reagents, in addition to determining the influence of various condition variables applied during the emulsification of prolidase-loaded poly(lactide-co-glycolide) (PLGA) microparticulate systems. Such information is of benefit for characterizing optimal semi-synthetic techniques. Enzyme stability can be tested following contact with methylene chloride, ethyl acetate, PLGA polymers, and several agents used as emulsifiers such as polyvinyl alcohol (PVA), polyvinyl pyrolidone (PVP), carboxymethyl cellulose (CMC), and sodium oleate (NaOl). Evaluation of enzyme stability to temperature and mechanical stirring of prolidase-loaded PLGA microspheres ideally should be performed in order to detect alterations in protein activity.
Interpretation and Analysis: Prolidase-loaded PLGA microspheres can be prepared effectively if the enzyme fraction is stabilized by addition of both bovine serum albumin (BSA) and $MnCl_2$ into TRIS formulations. Methylene chloride is a suitable organic solvent for use in double emulsion techniques, together with PVA as a dispersing agent in the outer aqueous phase. Low temperatures during the emulsification step and very brief processing times are recommended in order to maintain maximum enzyme activity. Under such conditions, spherical microspheres can be generated releasing active prolidase for up to 15 days.

Evaluation of enzyme stability during preparation of polylactide-co-glycolide microspheres. Perugini P, Genta I, Pavanetto F, Modena T, Maculotti K, Conti B. J Microencapsul 2002 Sep–Oct; 19 (5), pp. 591–602.

Stability Evaluation of Microbubble Formulations/Saline in Plastic vs Glass Vials/Saline in Vacuum vs Non-Vacuum Vials/Bladder Contrast Enhanced Voiding Urosonograpy
Microbubbles (Galactose-Based Formulations: Levovist)

Background Information: The sonographic diagnosis of vesicoureteral reflux with intravesical administration of ultrasound contrast media is increasingly more frequent.
Application: Lower urinary tract examination.
Route of Administration: Urethral catheter.
Considerations: Rapid dissolution of microbubbles in the bladder filled with normal saline can occasionally be appreciated during the course of ultrasound examinations.
Implementation: Evaluate the degree of interaction between normal saline and ultrasound contrast media in concert with elucidating any potential causes for such interactions. Such an objective can be addressed applying an *in vitro* experimental model to characterize normal saline solution and a galactose-based ultrasound contrast medium (Levovist) formulated at gradient concentrations and then scanned utilizing predefined parameters. As a point of reference, the oxygen concentration of the solutions are also measured (pO_2 and O_2 mg/l).
Interpretation and Analysis: Ultrasound contrast medium has a significantly longer contrast duration when mixed with normal saline from plastic containers rather than glass containers. The contrast duration difference is even more marked between normal saline from containers sealed under vacuum and those not sealed under vacuum (e.g., 0.7 and 12 minutes, respectively). The oxygen concentration in normal saline from vacuum-sealed containers is one-third or less that from non-vacuum-sealed containers. The high concentration of dissolved oxygen in normal saline seems to prevent the diffusion of air from the microbubbles into the solution and thus their collapse. Desaturated normal saline has a detrimental effect on microbubbles of galactose-based ultrasound contrast agents. For the purpose of filling the bladder during contrast-enhanced voiding urosonography, only normal saline solution from non-vacuum-sealed containers should be used. For practical purposes, normal saline from plastic containers is safest.

Interaction of normal saline solution with ultrasound contrast medium: Significant implication for sonographic diagnosis of vesicoureteral reflux. Darge K, Bruchelt W, Roessling G, Troeger J. Eur Radiol 2003 Jan; 13 (1), pp. 213–8.

Systemic Delivery
Polymer Millrods: Doxorubicin Loaded

Cellular/Molecular Mechanism of Action: Pharmaceutical delivery modality.

Application: Quantify the key parameters governing drug transport processes in radiofrequency (RF) thermoablated and non-ablated liver tissues.
Route of Administration: Variable.
Dosage: Not applicable (delivery modality).
Implementation: Determination of the spatial distribution of doxorubicin by measuring fluorescence imaging from 1 to 96 hours after implantation of doxorubicin-containing polymer millirods. A mathematical model can be applied to quantitatively describe the transport processes in ablated and non-ablated rat livers.

Animal Model: Rat (ablated and non-ablated liver tissue).
Interpretation and Analysis: At all time points, doxorubicin has significantly higher tissue penetration and retention in ablated tissues than in non-ablated tissues. Based on the experimental data and mathematical models, the optimal estimates of apparent drug diffusivities in ablated and non-ablated tissues are 1.1×10^{-7} and 6.7×10^{-7} cm^2/s, respectively, and the apparent drug elimination rate coefficient is $9.6 \times 10^{-4}/s$ in non-ablated tissues. Results from this study contribute to the fundamental understanding of *in vivo* drug transport in liver tissues and provide the quantitative parameters for the rational design of polymer millirods for liver cancer treatment and diagnosis.

Quantification of *in vivo* doxorubicin transport from PLGA millirods in thermoablated rat livers. Qian F, Stowe N, Liu EH, Saidel GM, Gao J. J Control Release 2003 Aug 28; 91 (1–2), pp. 157–66.

Urinary: Vesicoureteral Reflux Grading
Levovist

Background Information: The sonographic diagnosis of vesicoureteral reflux (VUR) with contrast-enhanced voiding urosonography (VUS) is gradually increasing. Introduction of VUS as part of the routine diagnostic imaging modalities for reflux has significantly reduced the number of voiding cystourethrographies (VCUG) necessary in a clinical environment. Similar to VCUG, the grading of reflux in VUS is becoming more and more clinically relevant.
Implementation: Determine if there are any sonomorphologic and sonomorphometric parameters that correlate with reflux grading in VCUG. Complementary investigations involve testing the degree of correlation between the reflux grading system proposed for VUS and the grading system used for VCUG.

The VUS is conducted by the intravesical administration of ultrasound (US) contrast medium (Levovist). Ureteral and pelvicalyceal dilatations before administration of US contrast medium and during reflux are then documented and the renal pelvic diameter measured. The density of microbubbles in the renal pelves is scored on a scale of 1 to 3 (low to high). A grading system for reflux in VUS can be established similar to the international reflux grading system for VCUG with the addition of 1 more differentiation parameter, namely whether the reflux is primarily in a dilated or non-dilated urinary tract. Reflux grades in VUS are then compared with those in VCUG.

Human Model: Children undergoing both VUS and VCUG (n = 186 children, n = 89/186 with VUR in at least 1 and the same kidney-ureter-unit (KUU) in both diagnostic imagings).
Interpretation and Analysis: None of the sonomorphologic and sonomorphometric parameters demonstrate any clear-cut finding that would simplify reflux grading in VUS. In 62% (e.g., n = 59/95) KUUs the reflux grades are the same in both examinations. In 11% (e.g., n = 10/95) and 27% (e.g., n = 26/95) KUUs, the reflux is graded lower or higher, respectively, in VUS than in VCUG. Approximately 57% are in a primarily dilated system and the remaining 43% in a non-dilated one. Approximately 70% of KUUs diagnosed as having grade I reflux in VCUG show as grade 2 VUS procedures. A reflux grading system similar to the 1 used in VCUG can be applied in VUS. Adding the parameter of reflux into a primarily dilated or non-dilated ureter and/or pelvicalyceal system may contribute a further dimension to the reflux grading in VUS. Most of the refluxes labeled as grade 1 in VCUG are actually grade 2 or higher.

Vesicoureteral reflux grading in contrast-enhanced voiding urosonography. Darge K, Troeger J. Eur J Radiol 2002 Aug; 43 (2), pp. 122–8.

Urinary Bladder Rupture: Ultrasonography
Microbubbles

Background Information: Because urinary bladder rupture can become life threatening, a simple, safe technique for detecting such conditions is clinically desirable. Current diagnostic protocols involve radiographic imaging, but ultrasound contrast-based techniques have not been thoroughly evaluated for applicability in conditions of urologic trauma.
Implementation: Ultrasound contrast cystography (contrast cystosonography) can be performed by the infusion of microbubbles suspended in saline solution through a urinary catheter.

Animal Model: Canine (naturally occurring clinical cases of urinary bladder rupture).
Interpretation and Analysis: A positive result consists of visualizing microbubbles sonographically in fluid (urine) contained within the bladder immediately after infusion of contrast into the urinary catheter. A positive result can be easily appreciated in both an *in vitro* model and *in vivo* (n = 2 dogs). Confirmation can be established by radiographic examination and exploratory surgery of the abdomen for conditions of naturally occurring intraperitoneal urinary bladder rupture. Based on previous clinical experience, ultrasound contrast cystography appears to be more sensitive than 2-dimensional abdominal sonography for detecting naturally occurring urinary bladder rupture in dogs.

Diagnosis of urinary bladder rupture using ultrasound contrast cystography: *In vitro* model and 2 case-history reports. Ccoté E, Carroll MC, Beck KA, Good L, Gannon K. Vet Radiol Ultrasound 2002 May–Jun; 43 (3), pp. 281–6.

NANOPARTICLES AND NANOSPHERES

Cardiovascular/Endothelial $\alpha_V\beta_3$ Integrin
Anti-$\alpha_V\beta_3$ Integrin Linked [Gd]-Perfluorocarbon Nanoparticles

Cellular/Molecular Mechanism of Action: Anti-α_V β_3 integrin monoclonal antibody recognizes and physically binds to $\alpha_V\beta_3$ integrin complexes. Gadolinium is an element that has its special orientation modified by magnetic fields. Nanoparticles can serve as a selective delivery modality for a compound and/or diminish elimination and metabolism within the plasma compartment.
Background Information: $\alpha_V\beta_3$ integrin is a molecular marker that is a biological characteristic of angiogenic endothelium.
Application: Site-directed contrast image enhancement of (micro)angiogenic vessels. Gadolinium can be detected by magnetic resonance (MR) imaging capabilities.
Route of Administration: Intravenous.

Animal Model: Rabbit (corneal micropocket with neovascularization induced using basic fibroblast growth factor).
Interpretation and Analysis: Selectively targeted contrast agent *in vivo* displays a 25% increase in the average MR signal intensity 90 minutes postinjection. Control groups in which nanoparticles are either used alone, linked to an isotype-matched antibody, or linked to DM101 and administered following receptor blocking do

not display MR contrast enhancement at similar dose levels. Antibody-targeted agents enhance MR signal intensity of the capillary bed in a corneal micropocket model of angiogenesis and are selectively retained within the angiogenic region via specific interaction with $\alpha_V\beta_3$ epitopes.

Magnetic resonance contrast enhancement of neovasculature with $\alpha_v\beta_3$-targeted nanoparticles. Anderson SA, Rader RK, Westlin WF, Null C, Jackson D, Lanza GM, Wickline SA, Kotyk JJ. Magn Reson Med 2000 Sep; 44 (3), pp. 433–9.

Cardiovascular Endothelium: Angiogenesis/ Atherosclerosis
$\alpha_v\beta_3$-Integrin-Targeted Paramagnetic Nanoparticles

Background Information: Angiogenesis is a critical feature of plaque development in atherosclerosis and might play a key role in both the initiation and subsequent rupture of plaques that lead to myocardial infarction and stroke. The precursory molecular or cellular events that initiate plaque growth and that ultimately contribute to plaque instability, however, cannot be detected directly with any current diagnostic modality.
Application: Detection of alterations in vascular angiogenesis.
Route of Administration: Intravascular.
Implementation: Evaluation of angiogenesis phenomenon using $\alpha_V\beta_3$-integrin-targeted paramagnetic nanoparticles injected intravenously.
Animal Model: New Zealand White rabbits (atherosclerosis model dietarily induced by feeding 1% cholesterol for approximately 80 days).
Interpretation and Analysis: $\alpha_V\beta_3$-integrin-targeted paramagnetic nanoparticles can specifically detect neovasculature structures within 2 hours by routine magnetic resonance imaging (MRI) at a clinically relevant field strength (1.5 T). Increased angiogenesis can be detected as a 47 $\pm$ 5% enhancement in MRI signal averaged throughout the abdominal aortic wall following $\alpha_V\beta_3$-targeted paramagnetic nanoparticle administration. Pretreatment of atherosclerotic rabbits with $\alpha_V\beta_3$-targeted non-paramagnetic nanoparticles competitively blocks specific contrast enhancement of the $\alpha_V\beta_3$-targeted paramagnetic agent. Magnetic resonance imaging analysis can detect patterns of increased $\alpha_V\beta_3$-integrin distribution within the atherosclerotic wall that are spatially heterogeneous along both transverse and longitudinal planes of the abdominal aorta. Histology and immunohistochemistry can detect marked proliferation of angiogenic vessels within the aortic adventitia, coincident with prominent, neointimal proliferation among cholesterol-fed, atherosclerotic *in vivo* models in comparison with a sparse incidence of neovasculature in reference controls. Such approaches for molecular imaging may provide a method for defining the burden and evolution of atherosclerosis in susceptible individuals as well as responsiveness of individual conditions to antiatherosclerotic therapies.

Molecular imaging of angiogenesis in early-stage atherosclerosis with $\alpha_v\beta_3$-integrin-targeted nanoparticles. Winter PM, Morawski AM, Caruthers SD, Fuhrhop RW, Zhang H, Williams TA, Allen JS, Lacy EK, Robertson JD, Lanza GM, Wickline SA. Circulation 2003 Nov 4; 108 (18), pp. 2270–4.

Cardiovascular Endothelium: Selective Targeting/ Inflammation/Ischemia/Neoplastic Disease
Polymerized Nanoparticle

Background Information: Successful formulation of personalizing treatment regimens requires the implementation of protocols for appropriate case selection, discovery of surrogate diagnostic biomarkers for monitoring the effects of treatment, and development of an efficacious targeted form of therapy.
Application: Selective detection and targeting of disease-specific biomarker systems.
Route of Administration: Intravascular.
Implementation: Development of a polymerized nanoparticle platform technology that will allow the application of different targeting moieties on the surface of particle platforms, in addition to loading the particles with different contrast and therapeutic agents.
Interpretation and Analysis: Nanoparticles can be targeted to endothelial receptors for the delivery of different payloads of contrast agents and therapeutic pharmaceuticals in a manner that provides a high target-to-background ratio. Using this combined vascular targeted imaging and therapy approach, it is highly possible that personalized/individualized treatment regimens can be developed for a variety of disease processes such as cancer, inflammation, and ischemia.

Combined vascular targeted imaging and therapy: A paradigm for personalized treatment. Li KC, Guccione S, Bednarski MD. J Cell Biochem Suppl 2002; 39, pp. 65–71.

Central Nervous System (CNS): Blood-Brain Barrier (BBB) Penetration
Nanoparticles (Solid Lipid)/Superparamagnetic Solid Lipid Nanoparticles

Cellular/Molecular Mechanism of Action: Nanoparticles function as a carrier modality that is capable of changing the pharmacokinetic parameters and biodistribution of various pharmaceutical agents.
Application: Solid lipid nanoparticles (SLN) are able to target drugs to lymph after duodenal administration and diffuse across the BBB of the CNS. In addition, SLN have the potential of functioning as an effective carrier/contrast agent modality for CNS magnetic resonance imaging (MRI) analyses.
Semi-Synthetic Methods: Superparamagnetic SLN can be prepared to possess colloidal size characteristics and have *in vitro* relaxometric properties (e.g., similar to Endorem).
Route of Administration: Intravascular.
Interpretation and Analysis: *In vivo* MRI of the CNS with both SLN and Endorem shows that superparamagnetic SLN have slower blood clearance than Endorem. Results from MRI analysis are consistent with the CNS uptake of SLN that lasts up to 135 minutes. Based on these observations, SLN can traverse across the BBB of the CNS.

In vitro and *in vivo* study of solid lipid nanoparticles loaded with superparamagnetic iron oxide. Peira E, Marzola P, Podio V, Aime S, Sbarbati A, Gasco MR. J Drug Target 2003 Jan; 11 (1), pp. 19–24.

Central Nervous System (CNS)/Blood-Brain Barrier (BBB) Penetration
[^{14}C]-PEGylated Polyalkylcyanoacrylate Nanoparticles/ Poloxamine 908-Coated Polyalkylcyanoacrylate Nanoparticles/Non-Long-Circulating Polyalkylcyanoacrylate Nanoparticles

Background Information: Under healthy conditions, the BBB limits the passage of solutes and cells from the blood to the CNS. During neurological diseases, BBB permeability increases dramatically, and it has been hypothesized that drug carrier systems such as polymeric nanoparticles could cross the BBB and penetrate into the CNS.

Application: PEGylated polyalkylcyanoacrylate nanoparticles (long-circulating carrier) can potentially be applied as a carrier modality for the transport of agents across the BBB, as has been demonstrated in preliminary investigations for conditions of experimental allergic encephalomyelitis (murine EAE).
Route of Administration: Intravascular.
Implementation: Evaluation of brain and spinal cord concentrations of [^{14}C]-radiolabeled PEGylated polyalkylcyanoacrylate nanoparticles compared to another blood long-circulating carrier (poloxamine 908-coated polyalkylcyanoacrylate nanoparticles) and conventional non-long-circulating polyalkylcyanoacrylate nanoparticles. To better characterize deposition/localization within neurologic tissues, microscopic examination can be performed to detect fluorescent nanoparticles in order to further understand the mechanism by which they penetrate across the BBB.
Interpretation and Analysis: Concentrations of PEGylated nanoparticles in the CNS, especially within white matter regions, is greatly increased compared to profiles noted for conventional non-PEGylated nanoparticles. In addition, this increase is significantly higher in pathological situations where BBB permeability is augmented and/or macrophage populations have infiltrated. Passive diffusion and macrophage uptake in inflammatory lesions seems to be the mechanism underlying the brain penetration of such particles. Due to their long-circulating properties within blood and on their surface characteristics that promote cell interactions, PEGylated nanoparticles penetrate into the CNS to a greater extent than all other related formulations tested to date. Thus, PEGylated polycyanoacrylate nanoparticles can potentially function as a new brain delivery system during conditions of neuroinflammatory diseases.

Quantification and localization of PEGylated polycyanoacrylate nanoparticles in brain and spinal cord during experimental allergic encephalomyelitis in the rat. Calvo P, Gouritin B, Villarroya H, Eclancher F, Giannavola C, Klein C, Andreux JP, Couvreur P. Eur J Neurosci 2002 Apr; 15 (8), pp. 1317–26.

Central Nervous System (CNS)/Blood-Brain Barrier (BBB)/Transferrin Receptor Complexes/ Demyelinated Axons
Oligodendrocyte Progenitor Cells/ [Transferrin Magnetic Nanoparticles]

Cellular/Molecular Mechanism of Action: Oligodendrocyte progenitor cells naturally migrate to specific foci within the CNS, including demyelinated axons.
Background Information: Demyelination is a common pathological finding in human neurological diseases and frequently persists as a result of failure of endogenous repair. Transplanted oligodendrocytes and their precursor cells can (re)myelinate axons, raising the possibility of therapeutic intervention. The migratory capacity of transplanted cells is of key importance in determining the extent of (re)myelination and can, at present, be evaluated only by the use of invasive and irreversible procedures.
Application: Potential delivery modality that recognizes demyelinated axons.
Route of Administration: Presumably intravascular.
Implementation: Delineation of the capacity for transferrin receptors to function as an effective "target" that can facilitate the intracellular delivery of magnetic nanoparticles and guide the migration of transplanted tagged oligodendrocyte progenitor cells into the spinal cord containing myelin-deficient neurons.
Animal Model: Rat (myelin-deficient neurons).
Interpretation and Analysis: Cell migration can be easily detected by using 3-dimensional magnetic resonance microscopy, which demonstrates a close correlation between the areas of contrast enhancement and degree of "new" myelination in an *in vivo* myelin deficient model. In this context, investigations have demonstrated the feasibility of successfully using magnetic resonance to track transplanted oligodendrocyte progenitor cells. The technique has the potential of being easily extended into other neurotransplantation research investigations involving different precursor cell types.

Neurotransplantation of magnetically labeled oligodendrocyte progenitors: Magnetic resonance tracking of cell migration and myelination. Bulte JW, Zhang S, van Gelderen P, Herynek V, Jordan EK, Duncan ID, Frank JA. Proc Natl Acad Sci U S A 1999 Dec 21; 96 (26), pp. 15256–61.

Central Nervous System (CNS)/Infarction/ Discrimination of Normal vs Infarctive Lesions/ Blood-Brain Barrier (BBB)/Discrimination: Normal vs Infarcted Myocardium
Peptide Delivery/Polysorbate 80-Coated Polybutylcyanoacrylate Nanoparticles

Background Information: The BBB limits the penetration of substances into the brain. Because many drugs, particularly peptides, therefore can't be delivered to the brain, carrier systems need to be developed to overcome this problem. Previous investigations have demonstrated the central analgesic effects of the peptide dalargin (dal) after systemic administration, when this substance is bound to the exterior surface of polybutylcyanoacrylate nanoparticles and coated with polysorbate 80, but not when given alone.
Application: Delivery of polypeptides across the BBB.
Route of Administration: Intended for intravascular administration, but preparations have the potential of facilitating oral routes of administration for biologically active peptides.
Implementation: Determine the body distribution of [^{3}H]-labeled dal bound to nanoparticles compared to unbound dal after intravenous injection. The radioactivity in several tissues, including the brain, is separated into subcellular preparations and measured over time after a single intravenous injection.
Animal Model: Murine.
Interpretation and Analysis: Dal radioactivity levels in brain preparations is 3 times higher when the drug is bound to nanoparticles, whereas the 1st-pass pathway in liver is reduced. Such results support previous reports that nanoparticles can be used to transport peptides across the BBB.

Body distribution of [^{3}H]-labeled dalargin bound to poly(butyl cyanoacrylate) nanoparticles after i.v. injections to mice. Schroeder U, Schroeder H, Sabel BA. Life Sci 2000; 66 (6), pp. 495–502.

Central Nervous System (CNS) Neoplasia/Tumor Proliferation Rate/Tumor-Associated Macrophages/ Tumor-Associated Angiogenesis
Dextran-Coated Iron Oxide Particles (LCDIO)/ Rhodaminated LCDIO Green Fluorescent Protein (GFP)/ Hoechst 33258

Cellular/Molecular Mechanism of Action: Hoechst 33258 dye can be applied as an intravital endothelial stain. Rhodaminated LCDIO particles can preferentially localize intracellularly within certain malignant neoplastic cell types (e.g., gliosarcoma).
Application: Detection and characterization of CNS neoplastic lesions (e.g., gliosarcoma).
Route of Administration: Intravascular.
Implementation: Determination of the distribution of LCDIO preparation in tumors. Accumulation of LCDIO in tissue sections is

evaluated using multichannel fluorescence microscopy in combination with rhodaminated LCDIO, GFP functioning as a tumor marker, and Hoechst 33258 dye serving as an intravital endothelial stain. Uptake into tumor cells is corroborated with results from immunohistochemical and cell culture uptake analyses. The effect of intratumoral LCDIO uptake on magnetic resonance imaging (MRI) signal intensity is evaluated with a 1.5-T superconducting magnet.

Animal Model: Rodent gliosarcoma.

Interpretation and Analysis: Tumoral accumulation of LCDIO is 0.11% ± 0.06 of the injected dose per gram of tissue in brain tumors and is sufficient for detection using MR imaging. In tumor sections, LCDIO preferentially localizes in tumor cells (49.0% ± 4.6) but is also taken up by macrophages within tumors (21.0% ± 3.1) and by endothelial cells in the areas of active angiogenesis (6.5% ± 1.4). In cell culture, LCDIO uptake strongly correlates with growth rate of tumor cell lines. Tumoral LCDIO accumulation is not negligible and helps explain MRI signal intensity changes observed in clinical trials. Microscopically, LCDIO accumulates predominantly in tumor cells and tumor-associated macrophages. Uptake into tumor cells appears to be directly proportional to cellular proliferation rate.

Instrumentation: Magnetic resonance imaging signal intensity evaluated with a 1.5-T superconducting magnet.

Tumoral distribution of long-circulating dextran-coated iron oxide nanoparticles in a rodent model. Moore A, Marecos E, Bogdanov A Jr, Weissleder R. Radiology 2000 Feb; 214 (2), pp. 568–74.

Fluorescent Probe Delivery
Nanospheres: Fluorescent Probe Protected Delivery/ PEBBLEs: Probes Encapsulated by Biologically Localized Embedding

Cellular/Molecular Mechanism of Action: Nanospheres can influence the pharmacodynamics of a compound by delaying elimination, slowing biological degradation, and facilitating selective delivery.

Route of Administration: Intravascular injection.

Semi-Synthetic Methods: Spherical optical nanosensors, or PEBBLEs, can be produced in various sizes, including ranges between 20 nm and 200 nm (diameter). The sensors are fabricated in a microemulsion and consist of fluorescent indicators entrapped in a polyacrylamide matrix. A generalized polymerization method has been developed that permits production of sensors containing any hydrophilic dye or combination of dyes within the matrix.

Interpretation and Analysis: The PEBBLE matrix protects fluorescent dyes from interference by proteins, allowing reliable *in vivo* dye calibration. Sensor response times are less than 1 ms. Cell viability assays indicate that PEBBLEs are biocompatible and exert negligible biological effects compared to reference controls. Several sensor delivery methods have been studied, including liposomal delivery, gene gun bombardment, and *pico*-injection into single living cells.

Optical nanosensors for chemical analysis inside single living cells. 1. Fabrication, characterization, and methods for intracellular delivery of PEBBLE sensors. Clark HA, Hoyer M, Philbert MA, Kopelman R. Anal Chem 1999 Nov 1; 71 (21), pp. 4831–6.

Gastrointestinal: Trans-Mucosal Delivery/ Epithelial Cell Tight Junctions: Induced Opening
Poly[Methacrylic Acid-Grafted-Poly(Ethylene Glycol)]/Nanospheres/[Trypan Blue Exclusion]

Background Information: The challenges of oral delivery for therapeutic agents with unfavorable physicochemical properties, such as proteins, have been the primary motivating factor leading to the design and development of novel oral delivery systems that could circumvent biological barriers.

Application: Facilitate delivery of diagnostic and therapeutic agents across anatomical barriers such as the mucosa of the gastrointestinal tract. Trypan blue is applied as a cell vitality stain reagent (exclusion vitality dye reagent).

Route of Administration: Oral (nanospheres); topical (trypan blue).

Implementation: Examine the influence of complexation-sensitive hydrogel nanospheres composed of poly[methacrylic acid-grafted-poly(ethylene glycol)] (P(MAA-g-EG)) on a model biological environment. An example of how to evaluate such properties can entail determination of the cytotoxic effects of the polymeric carrier and its effects on the cell monolayer integrity. The determination of the cytotoxic effects of the polymer network on the cell monolayer can be performed by a colorimetric assay and by the counting of viable cells using the trypan blue exclusion method. Electrophysiological measurements can also be performed to measure the transepithelial electrical resistance changes in the monolayers in the presence and absence of the nanosphere suspension.

***Ex Vivo* Model:** Intestinal mucosal cells propagated *in vitro* in a tissue culture environment (Caco-2 cell line).

Interpretation and Analysis: The examination of the physicochemical interactions of P(MAA-g-EG) nanosphere system with Caco-2 cell monolayers reveals that these systems possess low cytotoxicity and are capable of opening the tight junctions between epithelial cells, therefore significantly reducing trans-epithelial electrical resistance.

Physicochemical behavior and cytotoxic effects of p(methacrylic acid-g-ethylene glycol) nanospheres for oral delivery of proteins. Torres-Lugo M, García M, Record R, Peppas NA. J Control Release 2002 Apr 23; 80 (1–3), pp. 197–205.

Gene Delivery/Metalloproteases/Influence on Inflammatory Response/Tumor Necrosis Factor-Alpha (TNF-α), Interleukin (IL)-1β, IL-6, and IL-10 and Metalloproteinases (MMP-2 and MMP-9)
Chytosan-DNA Nanoparticles

Physiological Mechanism of Action: Macrophages play an important and active role in inflammatory processes.

Background Information: The use of nanoparticles for gene therapy is gaining more and more interest for medical applications. Chitosan is among the candidate polymers that can potentially be applied as a gene delivery modality.

Application: Chitosan is a candidate compound potentially suitable for facilitating gene (e.g., olidonucleotide) delivery.

Considerations: Before using chitosan-DNA nanoparticles *in vivo*, it is necessary to first thoroughly characterize their interactions with cells and determine how such phenomenon influences their biological properties.

Implementation: Evaluation of the influence of chitosan-DNA nanoparticles on macrophage-mediated inflammatory responses (e.g., human THP-1 cell lines). Profiling over time the production and release of cytokines (TNF-α, IL-1β, IL-6, and IL-10) and metalloproteinase (MMP-2 and MMP-9), as well as their inhibitors (TIMP-1 and TIMP-2) in the presence of different amounts of nanoparticles is 1 approach to determining the biological properties of such preparations. Concentration of these mediators of immunity and inflammation can be quantified by enzyme-linked immunosorbent assay (ELISA). Gelatinolytic activity of MMP-2 and MMP-9 can be determined by zymography in cell supernatants and lysates.

Interpretation and Analysis: Cytokine secretion can usually not be detected even in the presence of high amounts of nanoparti-

cles. Alternatively, the secretion of MMP-9 in cell supernatants increases significantly after 24 hours and 48 hours compared to negative reference control cell populations. MMP-2 secretion is augmented only after 48 hours with the highest concentrations of nanoparticles (10 and 20 μg/ml DNA content). However, zymography studies have shown that secreted MMPs are in the zymogen (proenzyme) forms, while the active form of MMP-9, but not MMP-2, can be detected in cell lysates when 10 and 20 μg/ml DNA containing nanoparticles are used. In conclusion, exposure of THP-1 macrophages to Ch-DNA nanoparticles does not induce the release of proinflammatory cytokines. The presence of active MMP-9 within macrophages may be related to nanoparticle phagocytosis and degradation rather than to inflammatory reactions.

Metalloproteinase and cytokine production by THP-1 macrophages following exposure to chitosan-DNA nanoparticles. Chellat F, Grandjean-Laquerriere A, Naour RL, Fernandes J, Yahia L, Guenounou M, Laurent-Maguin D. Biomaterials 2005 Mar; 26 (9), pp. 961–70.

Gene Delivery: Oligonucleotide (Hybridization)
Magnetic Bead-Linked Oligonucleotide Probes

Cellular/Molecular Mechanism of Action: Oligonucelotides (e.g., antisense strands) incorporated into magnetic bead-linked oligonucleotide probes will hybridize with sense oligonucleotide strands (e.g., form cDNA/cDNA diamers or mRNA/cDNA heteriomers).
Application: Methodology for the detection of gene expression that could potentially be developed or adapted as a technique for the non-invasive detection of *in vivo* gene expression.
Route of Administration: Intravascular most commonly (selective and non-selective delivery).
Implementation: Hybridization of a target oligonucleotide to magnetic bead-linked oligonucleotide probes is followed by binding of the streptavidin-coated metal nanoparticles to the captured DNA, dissolution of the nanometer-sized gold tag, and potentiometric stripping measurements of the dissolved metal tag at single-use thick-film carbon electrodes.

An advanced magnetic processing technique is used to isolate the DNA duplex and to provide low-volume mixing. The influence of relevant experimental variables, including the amounts of gold nanoparticles and the magnetic beads, the duration of the hybridization and gold dissolution steps, and the parameters of the potentiometric stripping operation, on the hybridization signal can be effectively optimized and have been previously described by several laboratories.
Interpretation and Analysis: Transmission electron microscopy micrographs indicate that hybridization leads to the bridging of the gold nanoparticles to the magnetic beads. Further signal amplification, and lowering of the detection limits to the nanomolar and picomolar range, are achieved by precipitating gold or silver, respectively, onto the colloidal gold label. The new electrochemical stripping metallogenomagnetic protocol couples the inherent signal amplification of stripping metal analysis with discrimination against non-hybridized DNA and the use of microliter sample volumes and disposable transducers, and hence offers great promise for decentralized genetic testing.

Metal nanoparticle-based electrochemical stripping potentiometric detection of DNA hybridization. Wang J, Xu D, Kawde AN, Polsky R. Anal Chem 2001 Nov 15; 73 (22), pp. 5576–81.

Gene Expression: Phage Facilitated Delivery
Pullulan (Hydrogel) Nanoparticles/ [Lipofectamine 2000]

Application: Nanoparticles can facilitate the transport of vectors across intact cell membranes. Vectors (e.g., phage) can be utilized to transfect cells with "foreign" DNA sequences in a manner that allows amplified production of the desired gene and the biological protein translated from its corresponding messenger RNA (mRNA) sequence.
Route of Administration: Intravascular.
Semi-Synthetic Methods: Pullulan nanoparticles encapsulating pBUDLacZ plasmid can be prepared inside aqueous droplets with or without the use of microemulsions.
Implementation: Evaluation of cellular viability/vitality (cytotoxicity response) using 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay following cellular transfection.
Interpretation and Analysis: Transmission electron microscopy (TEM) imaging reveals that particles are spherical in shape with a size of 45 (± 0.80) nm diameter. Cell cytotoxicity studies reveal that cells incubated with nanoparticles remain more than 100% viable at nanoparticle concentration as high as 1,000 μg/ml. From scanning electron microscope images, nanoparticles can be observed internalized within cells that tend to exhibit vacuole changes within their cell body. Endocytosis of nanoparticles results in disruption of F-actin and beta-tubulin cytoskeleton of human fibroblasts. The effect of *in vitro* tranfection on HEK293 and COS-7 cells is cell-type dependent, with COS cells demonstrating a higher level of gene expression. The beta-gal expression in COS-7 cells facilitated by pullulan nanoparticle is comparable to commercially available Lipofectamine 2000. Such findings are encouraging for the development of pullulan nanoparticles as an intracellular delivery system for drugs and genes.

Hydrogel pullulan nanoparticles encapsulating pBUDLacZ plasmid as an efficient gene delivery carrier. Gupta M, Gupta AK. J Control Release 2004 Sep 14; 99 (1), pp. 157–66.

Gene Delivery/Solid Tumor Nucleic Acid Delivery
Nanoparticles (20–1,000 nm)/Liposome: Cationic (100–200 nm)/Porphyrin Derivatives (< 1 nm)/ Branched-Chain Dendrimers (10 nm)/ Polyethylenimine Polymers (10 nm)/Nanoparticles (20–1,000 nm)/Microspheres (> 1 μm)/Cyclodextrins (CyDs 1.5 nm)

Background Information: The vasculature of a tumor provides the most effective route by which neoplastic cells may be reached and eradicated by chemotherapeutics and biopharmaceuticals. The fact that a tumor's vasculature is relatively more permeable than healthy host tissue should enable selective delivery of diagnostic and therapeutic agents to neoplastic tissues. Such approaches to delivery are relevant to the carrier-mediated delivery of genetic-based therapies to tumors. Cationic liposomes have been used for the introduction of nucleic acids into mammalian cells for more than a decade.
Application: Nucleic acid delivery into cells (in vitro and in vivo).
Semi-Synthetic Methods: Cationic liposomes are generally 100–200 nm in diameter, whereas CyDs typically have a diameter span of 1.5 nm.
Implementation: Evaluate the potential of delivering therapeutic oligonucleotides (ONs) to tumors using cationic liposomes and CyDs, and determine the major biological properties of tumors that hinder such delivery modalities.
Interpretation and Analysis: CyD molecules are routinely used as agents that engender cholesterol efflux from lipid-laden cells, thus having efficacious potential in the management of atherosclerosis. A recent trend is to employ these oligosaccharide molecules for delivering nucleic acids into the interior of cells in both *in vitro* and *in vivo* environments. Comparisons have been made with other oligonucleotide delivery agents, such as porphyrin derivatives

(< 1 nm), branched-chain dendrimers (approximately 10 nm), polyethylenimine polymers (approximately 10 nm), nanoparticles (20–1,000 nm), and microspheres (> 1 μm), in the context of delivery formats for solid tumors. The chemical and physical properties of these carriers and how they may affect the uptake of oligonucleotides into cells, particularly *in vivo*, have been described in published reports.

Vehicles for oligonucleotide delivery to tumors. Dass CR. J Pharm Pharmacol 2002 Jan; 54 (1), pp. 3–27.

Lymphatic System Delivery
Nanospheres

Synthetic Chemistry and Analysis: Development and production of a sub-100 nm biodegradable colloidal system for the efficient delivery of drugs and diagnostic agents to the lymphatic system. Nanospheres of poly(lactide-co-glycolide) can be prepared by interfacial polymer deposition. Nanospheres are coated with block copolymers in order to modify their surface characteristics. Radiolabeling of the nanospheres for *in vivo* tracing can be achieved by incorporation of the lipophilic complex [^{111}In]-oxine during the preparation of nanospheres. Stability of radiolabeled nanospheres *in vitro* can be determined at 37°C (e.g., rat serum).
Interpretation and Analysis: The lymphatic distribution of nanospheres determined after subcutaneous administration (rat) reveals lymphatic uptake of all coated systems is enhanced compared to non-coated nanospheres. Maximal uptake of 17% of the administered dose in the regional lymph nodes can realistically be achieved and suggests that nanospheres are a suitable modality for diagnostic and therapeutic applications in clinical and experimental medicine.

Lymph node localization of biodegradable nanospheres surface modified with poloxamer and poloxamine block copolymers. Hawley AE, Illum L, Davis SS. FEBS Lett 1997 Jan 6; 400 (3), pp. 319–23.

Lymphatic System Delivery: Selective
Biodegradable Nanoparticulate Systems/ (Nanospheres, Emulsions, Liposomes)

Cellular/Molecular Mechanism of Action: Nanospheres and nanoparticles can influence the pharmacodynamics of a compound by delaying elimination, slowing biological degradation, and facilitating selective delivery.
Application: Selective delivery and accumulation of agents (diagnostic pharmaceuticals/chemotherapeutic agents, antigens) within regional lymph node structures. Localization of diagnostic agents in the regional lymph nodes can be of benefit as an anatomical/pathological guide during surgical procedures. Furthermore, they potentially serve as a modality that can enhance the oral bioavailability of macromolecular drugs, like polypeptides or biological proteins, that are known to selectively localize within the Peyer's patches of the intestine.
Route of Administration: Subcutaneous.
Implementation: Nanocapsules (ultrafine oily droplet-coated polymeric substances) are probably 1 of the most promising candidates of colloidal carriers. Surface engineering by the interfacial deposition method can create a suitable size distribution and the necessary surface characteristics required of nanocapsules.
Diagnostic Interpretation and Implications: Recent *in vivo* studies have demonstrated that polyisobutylcyanoacrylate nanocapsules possess enhanced accumulation of biological compounds and pharmaceuticals within lymph nodes, compared with other carriers such as emulsions and liposomes.

Lymphatic targeting with nanoparticulate system. Nishioka Y, Yoshino H. Adv Drug Deliv Rev 2001 Mar 23; 47 (1), pp. 55–64.

Lymphatic System Delivery: Selective
Nanoparticulate Systems: Biodegradable/ (Nanospheres, Emulsions, Liposomes)

Cellular/Molecular Mechanism of Action: Nanospheres and nanoparticles can influence the pharmacodynamics of a compound by delaying elimination, slowing biological degradation, and facilitating selective delivery.
Application: Selective delivery and accumulation of agents (diagnostic pharmaceuticals/chemotherapeutic agents) within structures of the lymphatic system (regional lymph nodes and lymphatic vessels). Localization of diagnostic agents in the regional lymph nodes can be of benefit as an anatomical/pathological guide during surgical procedures. Additionally, they can potentially serve as a modality for enhancing the oral bioavailability of macromolecular drugs, like polypeptides or proteins that are known to selectively accumulate within the Peyer's patches of the intestine.
Route of Administration: Subcutaneous.
Synthetic Chemistry and Analysis: The surface modification of model polystyrene (PS) and poly(lactide-co-glycolide) (PLGA) nanospheres by poly(lactide)-poly(ethylene glycol) (PLA:PEG) copolymers has been assessed by *in vitro* laboratory analyses and *in vivo* biodistribution studies following subcutaneous administration of the nanospheres (rat). Preparations of PLA:PEG copolymers have been characterized that possess PEG chain lengths of 750, 2,000, and 5,000 Da.

Preparations of PS and PLGA nanospheres can subsequently be "coated" with PLA:PEG copolymers or the latter can be co-precipitated in the formation of PLGA-PLA:PEG nanospheres. Validation of PLA:PEG "coating" of nanospheres can be established by detecting an increase in their overall particle size and a corresponding decrease in surface potential.
Considerations: A substantial amount of research has previously been devoted to delineating strategies capable of selectively "targeting" diagnostic pharmaceutical agents for the lymphatic system using colloidal carrier compounds. Nanocapsules, which are ultrafine oily droplet-coated polymeric substances, are probably one of the most promising candidates of colloidal carriers. Surface engineering utilizing the interfacial deposition method can produce a suitable size distribution and necessary surface characteristics to the nanocapsules. Observations noted in preliminary investigations have demonstrated the feasibility of producing fully biodegradable synthetic nanosphere systems that possess excellent lymph node targeting characteristics.
Interpretation and Analysis: Investigations conducted *in vivo* have demonstrated that polyisobutylcyanoacrylate nanocapsules can enhance the accumulation of pharmaceuticals within lymph nodes to a relatively greater degree compared to other carriers such as emulsions and liposomes. The kinetics of injection site drainage and lymph node retention determined over a 24-hour time period for non-"coated," "coated," and co-precipitated nanosphere systems demonstrate that their distribution is dependent upon the composition of their exterior surface. Significant modification of their characteristics can be achieved through such strategies for the purpose of achieving variable degrees of lymph node accumulation. Such features are extensively enhanced by "coating" their exterior surface with PLA:PEG copolymers or through their production as co-precipitated PLGA or PLA:PEG nanospheres. Dependent on the surface characteristics, the distribution of nanospheres can be significantly modified and the lymph node localization dramatically enhanced by coat-

ing their surfaces with PLA:PEG copolymers or by producing coprecipitate nanospheres of PLGA and PLA:PEG.

Preparation of biodegradable, surface engineered PLGA nanospheres with enhanced lymphatic drainage and lymph node uptake. Hawley AE, Illum L, Davis SS. Pharm Res 1997 May; 14 (5), pp. 657–61.

Lymph Node (Regional)/Selective Delivery
Poly(Ethylene Glycol) (PEG)-Modified Magnetite Nanospheres

Application: Selective diagnostic imaging or selective pharmaceutical delivery to regional lymph nodes.
Route of Administration: Subcutaneous injection (rat).
Synthetic Chemistry and Analysis: Magnetite nanospheres can be prepared with a grafted PEG layer using various PEG lengths ranging from 350 to 1,000 Da. Thermogravimetric analysis can be utilized to measure the adsorbed amount of PEG. Colloid stability can be confirmed by measuring particle size and electrophoretic mobility.
Considerations: Effectiveness of surface modifications of magnetite nanospheres with PEG can be assessed by *in vitro* characterization and *in vivo* biodistribution studies following subcutaneous administration (rat).
Implementation: The kinetics of injection site drainage and lymph node retention can be determined 2 hours after subcutaneous administration for nanospheres coated with PEG lengths of 350, 550, 750, and 1,000 Da, while for 750 PEG-coated nanospheres, the kinetics of distribution can be determined over a 48-hour time period.
Implications and Analyses: The distribution of nanospheres is modified and the lymph node localization enhanced by altering the surface coverage of PEG on the magnetic surface. PEG-coated magnetite nanospheres with different surface characteristics can be utilized to target diagnostic agents to regional lymph nodes.

Development of systems for targeting the regional lymph nodes for diagnostic imaging: *In vivo* behavior of colloidal PEG-coated magnetite nanospheres in the rat following interstitial administration. Illum L, Church AE, Butterworth MD, Arien A, Whetstone J, Davis SS. Pharm Res 2001 May; 18 (5), pp. 640–5.

Macrophage Function/Hepatic Mononuclear Phagocytic Activity
Superparamagnetic Iron Oxide (AMI-25)/ [^{99m}Technetium] ([^{99m}Tc])-Phytate

Cellular/Molecular Mechanism of Action: Superparamagnetic iron oxide (AMI-25) is non-selectively assimilated intracellularly by the hepatic mononuclear phagocytic system.
Application: Assessment of hepatic phagocytic activity with potential applications for also evaluating the pulmonary phagocytic system.
Route of Administration: Intravascular.
Implementation: Evaluation of the potential for measuring hepatic phagocytic activity by dynamic superparamagnetic iron oxide-enhanced magnetic resonance (MR) imaging. One approach that can be utilized for achieving this objective includes the application of dynamic MR imaging analysis in concert with performing a radioisotope study with [^{99m}Tc]-phytate. In a dynamic MR study of this nature, the ratio (Rv) of the distribution volumes of iron oxide (Vm/Ve) can be obtained by applying a 3-compartment model to data obtained simultaneously from the kidney and liver. Changes in Rv caused by silica injection and by dosing superparamagnetic iron oxide, AMI-25, can subsequently be evaluated. In the dynamic MR study using an *in vivo* model, the input function can be calculated from data obtained from the hepatic artery and portal vein.

Animal Model: Rabbits (New Zealand White) randomly allocated to normal and silica-treated groups.

Animal Model: Beagle dog (hepatic artery and portal vein).
Interpretation and Analysis: The ratio of the distribution volumes for iron oxide (Vm/Ve) reaches a maximum value at around 80 minutes after AMI-25 injection. The Rv of the normal controls groups is approximately 5.06 $\pm$ 1.53, whereas the Rv of the silica-treated group is approximately 2.13 $\pm$ 1.20. The results are similar to tissue count data obtained in radioisotope study. The Rv value is not dependent on the injected dose of AMI-25. The rate of transport constants (k1, k2, k3) cannot be estimated with a 3-compartment model regardless of obtaining the input function. It has therefore been concluded that the ratio of the distribution volumes for iron oxide (Vm/Ve) may be a quantitative index reflecting decreases in phagocytic activity within the liver as determined by dynamic superparamagnetic iron oxide-enhanced MR imaging.

Pharmacokinetic modeling of phagocytic activity of the liver using superparamagnetic iron oxide nanoparticles in dynamic MR imaging. Na JB, Suh JS, Huh YM, Kim SJ, Kim SH, Cha SH, Lee SH. Yonsei Med J 2003 Jun 30; 44 (3), pp. 429–37.

Macrophages: Vascular Lesions/Atherosclerotic Plaques
Ultrasmall Superparamagnetic Iron Oxide Particles (USPIOs)/(Sinerem, Guerbet)

Cellular/Molecular Mechanism of Action: Iron oxide particles change their spatial orientation when placed within an intense magnetic field. Macrophages perceive the particles as foreign and internalize them by phagocytic mechanisms.
Application: Detection and characterization of atherosclerotic plaques.
Dosage: Ultrasmall superparamagnetic particles of iron oxide (1 mmol Fe/kg).
Implementation: Evaluation of USPIOs for their ability to be internalized by macrophages and detect atherosclerosis-associated inflammatory changes in vessel walls before progressing to luminal narrowing. One approach to addressing this objective can entail characterization of the thoracic aorta using 3-dimensional magnetic resonance angiography (MRA) with enhancement of images using a paramagnetic contrast agent. One week later, USPIO (Sinerem, Guerbet) are then injected.

***Ex Vivo* Model:** Rabbit aorta.

Animal Model: Rabbit (n = 6 heritable hyperlipemic New Zealand White; and n = 3 New Zealand White control rabbits).
Interpretation and Analysis: Evaluation of 3D MRA data sets collected over a 5-day period following administration reveals an increasing signal within the aortic lumen. No vascular lesions can be detected at the time of initial imaging. The aortic wall of reference controls remains smooth and bright. Marked susceptibility effects become evident on day 4 within the aortic walls of hyperlipidemic rabbits. *Ex vivo* imaging of aortic specimens confirms such *in vivo* findings. Histopathology analysis can detect macrophage Fe uptake for cells embedded in atherosclerotic plaques in scenarios of hyperlipidemia. Electron microscopy analysis reveals multiple cytoplasmic Fe particles within macrophages. No such changes can be appreciated in reference controls or in conditions of hyperlipidemic not receiving Sinerem. In summary, USPIOs are phagocytosed by macrophages in atherosclerotic plaques of the aortic wall in chronic conditions of hyperlipidemia in a quantity sufficient to cause susceptibility effects that are detectable by MRI.

Magnetic resonance imaging of atherosclerotic plaque with ultrasmall superparamagnetic particles of iron oxide in hyperlipidemic rabbits. Ruehm SG, Corot C, Vogt P, Kolb S, Debatin JF. Circulation 2001 Jan 23; 103 (3), pp. 415–22.

Macrophages/Mononuclear/Neutrophil/ Phagocytic Function
Fluorescent Polymethacrylic Nanoparticles

Cellular/Molecular Mechanism of Action: Fluorescent polymethacrylic nanoparticles are recognized by and intracellularly assimilated by mononuclear cells and, to a lesser extent, neutrophils.
Application: Quantitative evaluation of phagocytosis by human mononuclear and polymorphonuclear cells. One possible application of fluorescent-labeled nanoparticles is the simultaneous characterization of cell surface antigens and cell phagocytic activity.
Route of Administration: Intravascular.
Semi-Synthetic Methods: Preparation of nanoparticles involves emulsion copolymerization of methacrylic monomers combined with delineation of their physicochemical properties.
Implementation: Evaluation of fluorescent polymethacrylic nanoparticles (0.3 micron) as a flow cytometric reagent in the quantitative evaluation of phagocytosis by human mononuclear and polymorphonuclear cells. In this context, nanoparticles coupled with a fluorescent agent (ethidium bromide) can be used in flow cytometric assays to study opsonin-independent phagocytosis by human neutrophils (PMNs) and human monocytes. Phagocytosis of nanospheres by monocytes is determined by flow cytometry based on their patterns of fluorescence distribution, while ingestion is visualized utilizing scanning and transmission electron microscopy.
Instrumentation: Flow cytometry and scanning and transmission electron microscopy.

Flow cytometric quantitative evaluation of phagocytosis by human mononuclear and polymorphonuclear cells using fluorescent nanoparticles. Rolland A, Merdrignac G, Gouranton J, Bourel D, Le Verge R, Genetet B. J Immunol Methods 1987 Feb 11; 96 (2), pp. 185–93.

Macrophage Function/Mononuclear Phagocytic System/Reticuloendothelial System
Nanoparticles: Copolymer Non-Ionic Surfactants/ Polyoxypropylene and Polyoxyethylene

Background Information: A frequently observed but ignored phenomenon following intravenous injection of polymer-modified long-circulating colloidal systems is their eventual recognition and clearance by macrophages (reticuloendothelial system, mononuclear phagocytic system).
Application: Nanoparticles composed of polyoxypropylene and polyoxyethylene copolymer non-ionic surfactants can be applied to detect and characterize the function of macrophage populations.
Route of Administration: Intravascular.
Implementation: Evaluation of the design, handling, and biological assessment of long-circulating nanoparticles composed of polyoxypropylene and polyoxyethylene copolymer non-ionic surfactants. Nanoparticles produced in this fashion are phagocytized by macrophage populations.
Interpretation and Analysis: The pharmacokinetics as well as the tissue distribution of such so-called "stealth" nanoparticles becomes altered after repeated intravenous injection in a time-dependent manner. An understanding of immunological and pathological factors that control the pharmacokinetic and biological behavior of long-circulating particles after single or repeated administration is therefore crucial for the design of a system possessing an optimal degree of diagnostic and/or therapeutic efficacy.

Capture of stealth nanoparticles by the body's defenses. Moghimi SM, Hunter AC. Crit Rev Ther Drug Carrier Syst 2001; 18 (6), pp. 527–50.

Neoplasia: Biomarker Detection/Cervical Cancer
[Probe Molecules]-Gold Nanoparticles

Cellular/Molecular Mechanism of Action: Physically bind to biomarker systems that are unique to specific neoplastic cell types.
Background Information: Recent developments in photonic technology have made it feasible to non-invasively image cells *in vivo,* and these diagnostic strategies therefore have the potential of dramatically improving the prevention, detection, and therapy of epithelial cancers. Endoscope-compatible microscopy, such as optical coherence tomography and reflectance confocal microscopy, image reflected light in a manner that can generate 3-dimensional pictures of tissue microanatomy with excellent spatial resolution (1–10 microm). However, their ability to image molecular biomarkers associated with cancer is limited.
Application: Vital *in vivo* imaging of precancerous conditions.
Route of Administration: Intravascular.
Semi-Synthetic Methods: Development of a class of molecule-specific contrast agents suitable for vital reflectance imaging that is based on attachment of gold nanoparticles to probe molecules with high affinity for specific (unique) cellular biomarkers.
Implementation: Evaluation of the effectiveness of vital reflectance imaging of precancerous conditions using gold bioconjugated nanoparticles containing probe molecules with high affinity for specific cellular biomarkers.
***Ex Vivo* Model:** Three-dimensional cancer cell suspensions in addition to normal and neoplastic fresh cervical biopsies.
Interpretation and Analysis: Gold conjugates can be delivered topically for imaging throughout the whole epithelial surface. Such contrast agents have the potential to extend the ability of vital reflectance microscopy for *in vivo* molecular imaging. In addition, they can potentially enable combined screening, detection, and therapy of diseases using inexpensive imaging systems. Such tools could allow mass screening of diseases such as cancer in resource-poor settings.

Real-time vital optical imaging of precancer using anti-epidermal growth factor receptor antibodies conjugated to gold nanoparticles. Sokolov K, Follen M, Aaron J, Pavlova I, Malpica A, Lotan R, Richards-Kortum R. Cancer Res 2003 May 1; 63 (9), pp. 1999–2004.

Neoplasia: Carcinoma (Mammary)/Tyrosine Kinase Her-2/neu Receptors
Streptavidin-Conjugated Iron Oxide Nanoparticles/ Biotinylated Monoclonal IgG (Anti Her-2/neu Receptor).

Cellular/Molecular Mechanism of Action: Monoclonal antibody fractions designed to selectively bind to Her-2/neu receptor complexes.
Background Information: One of the clinically relevant targets is the tyrosine kinase Her-2/neu receptor, which has importance in the staging and treatment of breast cancer.
Application: Creation of adjunct information directly relevant to the staging and treatment of breast cancer.
Route of Administration: Intravascular.
Implementation: Detection and characterization of Her-2/neu receptor expression in breast cancer cell populations that express the receptors on their exterior surface membranes at variable densities. Cell populations of interest are pretargeted with anti-Her-2/neu monoclonal antibody followed by exposure to streptavidin-conjugated superparamagnetic nanoparticles as a strategy for selective magnetic resonance (MR) imaging of HER-2/new receptor expression.

Interpretation and Analysis: Streptavidin-conjugated superparamagnetic nanoparticles, when used in combination with pretargeting strategies with biotinylated anti-Her-2/neu monoclonal IgG, can function as an effective strategy for detecting and characterizing the expression of these receptor complexes by magnetic resonance imaging analysis in conditions of mammary carcinoma. In this fashion, strong T_2 MR signals can be generated by Her-2/neu-expressing cells. Furthermore, the contrast observed in MR images is proportional to the expression level of Her-2/neu receptors determined independently by fluorescence-activated cell sorting (FACS) analysis. In this context, iron oxide nanoparticles are attached to the membrane surface of mammary carcinoma cell types, and they are not internalized into the cytosol, which is a major advantage for the *in vivo* applications of such diagnostic strategies.

MR molecular imaging of the Her-2/neu receptor in breast cancer cells using targeted iron oxide nanoparticles. Artemov D, Mori N, Okollie B, Bhujwalla ZM. Magn Reson Med 2003 Mar; 49 (3), pp. 403–8.

Neoplasia: Carcinoma (Pulmonary)/ Lewis Pulmonary Carcinoma *[Monoclonal IgG]-Bovine Serum Albumin Nanospheres (BSA-NS)*

Cellular/Molecular Mechanism of Action: Immunoglobulins (antibodies) can be either naturally or artificially designed to recognize and physically bind to specific molecules (e.g., biological proteins).
Application: Potentially can function as a selective delivery modality for neoplastic lesions, including Lewis lung carcinoma. Brief secondary (non-specific) accumulations also occur within the liver, lungs, and kidney.
Route of Administration: Intravascular.
Semi-Synthetic Methods: Bovine serum albumin nanospheres can be prepared using glutaraldehyde cross-linking and ultrasonication, followed by coating with antibodies utilizing covalent cross-linking techniques (Schiff's base formation) that involve cross-linking the aldehyde groups at the surface of the nanospheres with antibody (IgG) amino groups. Existence of the coating layer can be confirmed using fluorescein isothiocyanate-conjugated antibodies and also by assessment of antigen-antibody interactions using Sepharose beads. Rapid *in vitro* degradation of BSA-NS can initially be confirmed by incubating a radioactive nanosphere suspension at 37°C in sucrose solution (0.25 M) with liver or lung extracts (1%).
Implementation: The radioactive compound conjugated BSA-NS suspension can be evaluated to discover its *in vivo* biodistribution following intravenous injection. Organ/tissue distribution profiles for BSA-NS can be examined using whole body autoradiography.
Animal Model: Murine (mice bearing Lewis lung carcinoma).
Interpretation and Analysis: Preparations of BSA-NS localize mainly in the liver, the lungs, and the kidneys and by 4 hours and 24 hours after injection, almost all radioactivity has disappeared except for that in the kidneys. The *in vitro* binding ratio of monoclonal antibodies to tumor cells is 2–2.5 times greater than that of control antibodies (mouse IgG) based on gamma ray counter measurements. Binding tests performed have revealed that monoclonal antibodies might preferentially recognize the target organ (Lewis lung carcinoma). Based on the nature of these findings, BSA-NS coated with monoclonal antibodies have been found to be trapped in tumor masses of Lewis lung carcinoma-bearing mice more than in reference controls (BSA-NS coated with mouse IgG) at 24 hours after injection. Thus, BSA-NS preparations offer potential as useful drug carriers enabling the concentration (accumulation) of drugs at specific target sites. Furthermore, their rapid elimination from the body and their degradability suggest that side effects due to long-lasting accumulation in several organs may be avoided.

Preparation and evaluation of bovine serum albumin nanospheres coated with monoclonal antibodies. Akasaka Y, Ueda H, Takayama K, Machida Y, Nagai T. Drug Des Deliv 1988 Jul; 3 (1), pp. 85–97.

Neoplasia: Delivery (Selective)/Focal Vascular Extravasation/Example: Ovarian Carcinoma *Nanoparticles/Liposomes/Hyperthermia*

Background Information: The efficacy of novel cancer therapeutics has been hampered by the ability to deliver these agents to tumors at effective concentrations. Liposomes have been used as a method to overcome some delivery issues and, in combination with hyperthermia, have been shown to increase drug delivery to tumors. Particle size has been shown to affect the delivery of liposomes, but it is not known how hyperthermia affects size dependence.
Application: Potential strategy for selective delivery to neoplastic lesions.
Route of Administration: Intended for intravascular injection (selective or non-selective).
Dosage: Dependent upon temperature and size of delivery modality.
Implementation: Evaluation of the effects of hyperthermia (42°C) on the extravasation of different-sized nanoparticles (albumin; 100 nm, 200 nm, and 400 nm liposomes) from tumor microvasculature structures.
Animal Model: Murine (e.g., mice implanted with human SKOV-3 ovarian carcinoma xenografts grown in window chambers).
Interpretation and Analysis: At 34°C, no liposomes can be detected as having extravasated into the tumor interstitium. Alternatively, hyperthermia enables extravasation of liposomes of all sizes. The magnitude of hyperthermia-induced extravasation is inversely proportional to particle size. Thus, at normothermia (34°C), the pore cutoff size for this model is between 7 and 100 nm (e.g., liposomes do not extravasate). At 42°C, the pore cutoff size is increased to $>$ 400 nm, allowing all nanoparticles to be delivered to the tumor interstitium to some degree. With hyperthermia, 100 nm liposomes experience the largest relative increase in extravasation from the tumor vasculature. Hyperthermia does not enable extravasation of 100 nm liposomes from normal vasculature, potentially allowing for tumor-specific delivery. These experiments indicate that hyperthermia can enable and augment liposomal drug delivery to tumors and potentially help target liposomes specifically to tumors.

Hyperthermia enables tumor-specific nanoparticle delivery: Effect of particle size. Kong G, Braun RD, Dewhirst MW. Cancer Res 2000 Aug 15; 60 (16), pp. 4440–5.

Neoplasia/Delivery Delineation and Validation *Fluoroscein Isothiocyanate [FITC]-Glycol-Chitosan Nanoaggregates/Correlation between Biodistribution and Antineoplastic Properties/pH Sensitive Linker*

Application: Fluoroscein isothiocyanate can be applied as a fluorescent molecular marked to characterize a variety of physiological processes or for tracing the distribution of delivery modalities (e.g., [FITC]-glycol-chitosan nanoaggregates).
Route of Administration: Intravenous (e.g., rat tail vein).
Semi-Synthetic Methods: Conjugation of FITC to glycol-chitosan-doxorubicin (GC-DOX) results in the production of nanoaggregates with a diameter of about 250 nm in aqueous media. To increase the applicability of such preparations, GC-DOX nanoaggregates can be generated that contain an acid-sensitive spacer moiety.

Preparations of GC-DOX form micelle-like nanoaggregates spontaneously in aqueous media. GC-DOX nanoaggregates have a narrow and unimodal size distribution, and their hydrodynamic diameter as measured by dynamic light scattering ranges from between 250 to 300 nm. The extent that doxorubicin can be loaded into GC-DOX nanoaggregates is reflected by a pharmaceutical content level as high as 38%, with a loading efficiency as high as 97% using a physical entrapment method.

Implementation: Characterization of the *in vivo* biodistribution of GC-DOX nanoaggregates (doxorubicin-loaded GC-DOX nanoaggregates or DOX/GC-DOX) can be facilitated by conjugation to FITC. Distribution parameters can then be correlated with the observed antineoplastic properties exerted by conjugated preparations.

Animal Model: Rat (tumor-bearing animals developed by inoculating tumor cells into the region of the dorsal back).

Interpretation and Analysis: Nanoaggregates of FTC-GC distribute mainly to the kidney, tumor, and liver with very sparse amounts observed in other tissues/organ systems. They maintain high levels for 8 days and their distribution within neoplastic lesions increases gradually. Chitosan nanoaggregates appear to accumulate passively in tumor masses due to enhanced permeability characteristics and retention (EPR) effect. Tumor growth is suppressed over a 10-day period.

Biodistribution and anti-tumor efficacy of doxorubicin-loaded glycol-chitosan nanoaggregates by EPR effect. Son YJ, Jang JS, Cho YW, Chung H, Park RW, Kwon IC, Kim IS, Park JY, Seo SB, Park CR, Jeong SY. J Control Release 2003 Aug 28; 91 (1–2), pp. 135–45.

Neoplasia/Proliferation Rate of Tumors/Tumor-Associated Macrophages/Tumor-Associated Angiogenesis

Long-Circulating Dextran-Coated Iron Oxide Particles (LCDIO)/Rhodaminated LCDIO Green Fluorescent Protein (GFP)/Hoechst 33258

Cellular/Molecular Mechanism of Action: Hoechst 33258 dye can be applied as an intravital endothelial stain. Rhodaminated LCDIO particles can preferentially localize intracellularly within certain malignant neoplastic cell types (e.g., gliosarcoma).

Application: Detection and characterization of central nervous system neoplastic lesions (e.g., gliosarcoma).

Route of Administration: Intravascular.

Implementation: Determination of the distribution of LCDIO preparation in tumors. Accumulation of LCDIO in tissue sections is evaluated using multichannel fluorescence microscopy in combination with rhodaminated LCDIO, GFP functioning as a tumor marker, and Hoechst 33258 dye serving as an intravital endothelial stain. Uptake into tumor cells is corroborated with results from immunohistochemical and cell culture uptake analyses. The effect of intratumoral LCDIO uptake on magnetic resonance imaging (MRI) signal intensity is evaluated with a 1.5-T superconducting magnet.

Animal Model: Rodent gliosarcoma.

Interpretation and Analysis: Tumoral accumulation of LCDIO is 0.11% $\pm$ 0.06 of the injected dose per gram of tissue in brain tumors and is sufficient for detection using MRI. In tumor sections, LCDIO preferentially localizes in tumor cells (49.0% $\pm$ 4.6) but is also taken up by macrophages in tumors (21.0% $\pm$ 3.1) and by endothelial cells in the areas of active angiogenesis (6.5% $\pm$ 1.4). In cell culture, LCDIO uptake strongly correlates with the growth rate of tumor cell lines. Tumoral LCDIO accumulation is not negligible and helps explain MRI signal intensity changes observed in clinical trials. Microscopically, LCDIO accumulates predominantly in tumor cells and tumor-associated macrophages. Uptake into tumor cells appears to be directly proportional to cellular proliferation rate.

Instrumentation: Magnetic resonance imaging signal intensity evaluated with a 1.5-T superconducting magnet.

Tumoral distribution of long-circulating dextran-coated iron oxide nanoparticles in a rodent model. Moore A, Marecos E, Bogdanov A Jr, Weissleder R. Radiology 2000 Feb; 214 (2), pp. 568–74.

Neoplasia: Vascular and Lymphatic Endothelium (Tumor-Associated)

Nanocrystals/Semiconductor Quantum Dots (qdots)/Tumor Vasculature-Targeting Peptides/Peptide-Coated ZnS-Capped CdSe qdots/[Nanoparticles]

Background Information: Inorganic nanostructures that interface with biological systems have recently attracted widespread interest in biology and medicine. Nanoparticles are thought to have potential as novel intravascular probes and for the delivery of both diagnostic (e.g., imaging) and therapeutic (e.g., chemotherapy) purposes. Critical issues for successful nanoparticle delivery include the ability to target specific tissues and cell types and the discovery of approaches for escaping the biological particulate filter known as the reticuloendothelial system.

Application: Detection and characterization of vascular and lymphatic structures associated with neoplastic lesions.

Route of Administration: Intravenous.

Implementation: Explore the feasibility of *in vivo* targeting by using semiconductor qdots. Qdots are small ($<$ 10 nm) inorganic nanocrystals that possess unique luminescent properties because their fluorescence emission is stable and tuned by varying the particle size or composition.

Animal Model: Murine.

Interpretation and Analysis: ZnS-capped CdSe qdots coated with a lung-targeting peptide accumulate in the lungs of mice after intravenous injection, whereas 2 other peptides specifically direct qdots to blood vessels or lymphatic vessels in tumors. Addition of poly(ethylene glycol) to the qdot coating prevents non-selective accumulation of qdots in reticuloendothelial tissues. These results encourage the construction of more complex nanostructures with capabilities such as disease sensing and drug delivery.

Nanocrystal targeting *in vivo.* Akerman ME, Chan WC, Laakkonen P, Bhatia SN, Ruoslahti E. Proc Natl Acad Sci U S A 2002 Oct 1; 99 (20), pp. 12617–21.

Ophthalmic Delivery/Corneal and Aqueous Humor

Polyacrylic Acid/Subcolloidal Nanoparticulate/[Example: Brimonidine]

Background Information: In ocular drug delivery, a major problem is providing an adequate concentration of a therapeutic agent in the precorneal area. Mucoadhesive carriers such as polyacrylic acid in subcolloidal, nanoparticulate form have great potential as candidates for ophthalmic drug delivery.

Application: Localized delivery of diagnostic or therapeutic agents to ophthalmic structures.

Route of Administration: Topical.

Semi-Synthetic Methods: A formulation of brimonidine loaded in polyacrylic acid nanoparticles can be prepared as a delivery format for ophthalmic structures. Particles are prepared by a reverse microemulsion polymerization technique and their sizes are in the range of 50 nm.

Implementation: Evaluation of cellular viability following incubation with polyacrylic acid nanoparticles over varying time periods.

***Ex Vivo* Cellular Model:** Caco-2 cells (human primary colonic tumor adenocarcinoma) and human corneal epithelial cells.
Interpretation and Analysis: In preliminary biocompatibility tests, Caco-2 and corneal epithelial cells incubated with polyacrylic acid nanoparticles retain their viability over extended time periods. The loading efficiency of the drug brimonidine into the particles is between 80 and 85% and is pH dependent. Bioadhesive polyacrylic hydrogel nanoparticles can exhibit superior loading properties for brimonidine, and such formulations are stable for more than 5 weeks. The drug is slowly released over an interval of several hours when drug-loaded nanoparticles are dispersed in phosphate buffer saline (pH = 7.4). Two-photon laser scanning microscopic studies of dye-conjugated polyacrylic acid nanoparticles can be used to demonstrate the accumulation of particles on the surface and intercellular spaces of Caco-2 cells.

Brimonidine formulation in polyacrylic acid nanoparticles for ophthalmic delivery. De TK, Rodman DJ, Holm BA, Prasad PN, Bergey EJ. J Microencapsul. 2003 May–Jun; 20 (3), pp. 361–74.

Ophthalmic Delivery/Corneal and Aqueous Humor *Nanosphere Colloidal Suspensions/[PEGylated 1,2-Distearoyl-3-Phosphatidylethanolamine]*

Cellular/Molecular Mechanism of Action: Nanospheres can function as a platform for active or passive selected targeted delivery, in addition to providing a means for delaying premature elimination and biological degradation.
Background Information: The influence of polymer molecular weight and type and concentration of various surfactants on nanosphere properties has previously been investigated.
Application: Localized delivery of diagnostic or therapeutic agents to ophthalmic structures.
Route of Administration: Topical (ophthalmic).
Semi-Synthetic Methods: Colloidal suspensions of poly-*d*,*l*-lactic acid (PLA) nanospheres can be produced by a nanoprecipitation process. The surface properties of PLA nanospheres can be changed by the incorporation of PEGylated 1,2-distearoyl-3-phosphatidylethanolamine. The mean size and zeta potential of the nanospheres can be determined by light scattering analysis.
Implementation: Evaluation of nanosphere colloidal suspensions containing acyclovir as potential ophthalmic drug delivery systems. One approach to achieving this objective can involve delineation of the *in vivo* ocular pharmacokinetics of acyclovir-loaded PLA nanoparticles compared with aqueous suspension of free drug. The loading and release of acyclovir can easily be determined (e.g., *in vitro/in vivo*).

The ocular tolerability of PLA nanospheres can be assessed applying a modified Draize test. The aqueous humor acyclovir levels are monitored for 6 hours to determine the drug's ocular bioavailability for various formulations.

Animal Model: Rabbit (New Zealand White males).
Interpretation and Analysis: A reduction in the mean size and a decrease of the absolute zeta potential of PLA nanospheres results from increasing the surfactant concentration. The higher the polymer molecular weight, the smaller the nanosphere mean size. Poly(ethylene glycol) (PEG)-coated and uncoated PLA nanospheres show sustained acyclovir release and are highly tolerated by the eye. Both types of PLA nanospheres are able to increase the aqueous levels of acyclovir and to improve pharmacokinetics profiles, but the efficacy of PEG-coated nanospheres is significantly higher than that of simple PLA nanospheres. In summary, PEG-coated PLA nanospheres can potentially function as an ophthalmic delivery system for the treatment of ocular viral infections.

Influence of preparation conditions on acyclovir-loaded poly-*d,l*-lactic acid nanospheres and effect of PEG coating on ocular drug bioavailability. Giannavola C, Bucolo C, Maltese A, Paolino D, Vandelli MA, Puglisi G, Lee VH, Fresta M. Pharm Res 2003 Apr; 20 (4), pp. 584–90.

Optical Coherence Tomography/Reflectance Confocal Microscopy/Light Microscopy *Encapsulating Microspheres with Shell or Core Nanoparticles/[Carbon-/Gold-/ Melanin-Shelled Contrast Agents]*

Background Information: Contrast agents are utilized in virtually every imaging modality to enhance diagnostic capabilities.
Application: Reflection- or scattering-based techniques such as optical coherence tomography, light microscopy, and reflectance confocal microscopy.
Route of Administration: Intravenous.
Semi-Synthetic Methods: Encapsulating microspheres that are based on nanoparticles located within the shell or core.
Implementation: Evaluation of microspheres that are based not on fluorescence but on scattering nanoparticles incorporated within the shell or core.

Animal Model: Murine.
Interpretation and Analysis: Gold-, melanin-, and carbon-shelled contrast agents demonstrate an ability to enhance optical coherence tomography images.

Engineered microsphere contrast agents for optical coherence tomography. Lee TM, Oldenburg AL, Sitafalwalla S, Marks DL, Luo W, Toublan FJ, Suslick KS, Boppart SA. Opt Lett 2003 Sep 1; 28 (17), pp. 1546–8.

Optical Detection of Neoplastic Disease/ Biomarker Recognition/Cervical Cancer *[Probe Molecules]-Gold Nanoparticles*

Cellular/Molecular Mechanism of Action: Physically bind to biomarker systems that are unique to specific neoplastic cell types.
Background Information: Recent developments in photonic technology have made it feasible to non-invasively image cells *in vivo,* and these diagnostic strategies therefore have the potential of dramatically improving the prevention, detection, and therapy of epithelial cancers. Endoscope-compatible microscopy, such as optical coherence tomography and reflectance confocal microscopy, image-reflected light in a manner that can generate 3-dimensional pictures of tissue microanatomy with excellent spatial resolution (1–10 microm). However, their ability to image molecular biomarkers associated with cancer is limited.
Application: Vital *in vivo* imaging of precancerous conditions.
Route of Administration: Intravascular.
Semi-Synthetic Methods: Development of a class of molecule-specific contrast agents suitable for vital reflectance imaging that is based on attachment of gold nanoparticles to probe molecules with high affinity for specific (unique) cellular biomarkers.
Implementation: Evaluation of the effectiveness of vital reflectance imaging of precancerous conditions using gold bioconjugated nanoparticles containing probe molecules with high affinity for specific cellular biomarkers.

***Ex Vivo* Model:** Three-dimensional cancer cell suspensions in addition to normal and neoplastic fresh cervical biopsies.
Interpretation and Analysis: Gold conjugates can be delivered topically for imaging throughout the whole epithelial surface. Such contrast agents have the potential to extend the ability of vital reflectance microscopy for *in vivo* molecular imaging. In addition, they can potentially enable combined screening, detection, and therapy of

diseases using inexpensive imaging systems. Such tools could allow mass screening of diseases such as cancer in resource-poor settings.

Real-time vital optical imaging of precancer using antiepidermal growth factor receptor antibodies conjugated to gold nanoparticles. Sokolov K, Follen M, Aaron J, Pavlova I, Malpica A, Lotan R, Richards-Kortum R. Cancer Res 2003 May 1; 63 (9), pp. 1999–2004.

Optical Fluorescent Probe Delivery
Nanospheres: Fluorescent Probe Protected Delivery/ PEBBLES: Probes Encapsulated by Biologically Localized Embedding

Cellular/Molecular Mechanism of Action: Nanospheres can influence the pharmacodynamics of a compound by delaying elimination, slowing biological degradation, and facilitating selective delivery.
Route of Administration: Intravascular injection.
Semi-Synthetic Methods: Spherical optical nanosensors, or PEBBLEs, can be produced in various sizes, including ranges between 20 nm and 200 nm (diameter). The sensors are fabricated in a microemulsion and consist of fluorescent indicators entrapped in a polyacrylamide matrix. A generalized polymerization method has been developed that permits production of sensors containing any hydrophilic dye or combination of dyes within the matrix.
Interpretation and Analysis: The PEBBLE matrix protects the fluorescent dye from interference by proteins, allowing reliable *in vivo* dye calibration. Sensor response times are less than 1 ms. Cell viability assays indicate that PEBBLEs are biocompatible and exert negligible biological effects compared to reference controls. Several sensor delivery methods have been studied, including liposomal delivery, gene gun bombardment, and *pico*-injection into single living cells.

Optical nanosensors for chemical analysis inside single living cells. 1. Fabrication, characterization, and methods for intracellular delivery of PEBBLE sensors. Clark HA, Hoyer M, Philbert MA, Kopelman R. Anal Chem 1999 Nov 1; 71 (21), pp. 4831–6.

Pharmaceutical Controlled Release
Nanoencapsulation

Cellular/Molecular Mechanism of Action: Lambda-carrageenan is a sulfated polymer isolated from algae that can function as hydrophilic matrices.
Application: Controlled release of basic pharmaceuticals.
Considerations: Atomic force microscopy is a suitable form of technology for specific on-time monitoring of interaction processes that occur in pharmaceutical systems.
Interpretation and Analysis: Because hydrophilic matrices have been proposed as a modality for controlled drug delivery, many polymeric excipients have been studied to make drug release fit desired profiles. Furthermore, the relevance of hydrophobic interactions in drug-polymer aqueous systems has been demonstrated, although no references to morphological features or to the kinetics of the formation of interaction complexes have been extensively published. Three-dimensional morphological imaging of lambda-carrageenan sulfated polymer and dexchlorpheniramine maleate (e.g., formulated at very low concentrations as a combined mixture) acquired over a 24-hour period can be achieved by the use of atomic force microscopy analysis (nanometric scale). In this fashion, it is possible to monitor topographical interactions between lambda-carrageenan and dexchlorpheniramine maleate, in order to determine how release profiles can be modified and controlled. Such analysis has demonstrated that lambda-carrageenan can nanoencapsulate spontaneously dexchlorpheniramine maleate molecules, which offers the possibility of controlling the release rate of pharmaceutical agents with no need of complex technological processes.

Self-assembly of drug-polymer complexes: A spontaneous nanoencapsulation process monitored by atomic force microscopy. Oliva M, Diez-Perez I, Gorostiza P, Lastra CF, Oliva I, Caramella C, Marino EL. J Pharm Sci 2003 Jan; 92 (1), pp. 77–83.

Radiographic Imaging/Contrast Agents
Niosomes (Iobitridol Carrier)/Polyoxyethylene Glycol 4000 Stearate/D-Alpha Tocopheryl Polyethylene Glycol 1000 Succinate/Dicetylphosphate/Cholesterol

Cellular/Molecular Mechanism of Action: Non-ionic surfactant vesicles (niosomes) can function as carriers for various types of pharmaceuticals (e.g., iobitridol).
Application: Preparation functions as a carrier modality (non-ionic surfactant vesicle). Iobitridol is a diagnostic radiographic imaging preparation.
Considerations: Niosomes (150 and 175 nm diameter) can be prepared using the film-hydration method followed by sonication. Vesicle preparations of this type can be produced with appropriate mixtures of *D*-alpha tocopheryl polyethylene glycol 1000 succinate, polyoxyethylene glycol 4000 stearate, polyoxyethylene glycol 4000 stearate, cholesterol, and dicetylphosphate. The methodology can be modified to optimize/increase the rate of encapsulation and vesicle stability. Evaluation of vesicle formulation, vesicles, physicochemical aspects, and their morphological characteristics all aid in facilitating the design of preparations that possess the most desirable functional properties.

Niosomes as carriers of radiopaque contrast agents for x-ray imaging. Muller D, Foulon M, Bonnemain B, Vandamme TF. J Microencapsul 2000 Mar–Apr; 17 (2), pp. 227–43.

Targeted Delivery/Selective Site-Specific Drug Delivery System
Polymethacrylic Nanospheres/[^{111}Indium]/[^{125}Iodine] ([^{111}In/^{125}I])-Radiolabeled Nanospheres/Nanoparticles

Cellular/Molecular Mechanism of Action: Polymethacrylic nanospheres are presumably removed from the intravascular compartment by Kupffer cells lining the hepatic sinousoids. It is uncertain if radioactivity found in the kidney during a later time frame is actually intact radiolabeled nanospheres or dissociated (“free”) radioisotopes.
Application: Site-specific drug delivery system primarily relevant to the liver with secondary excretory-based delivery to the kidney.
Route of Administration: Intravascular.
Semi-Synthetic Methods: Polymethacrylic nanospheres (mean diameter 0.25–0.30 microns) can be prepared by aqueous emulsion copolymerization. Nanoparticles can then be radiolabeled either with [^{125}I] or [^{125}I].
Implementation: Evaluation of the organ-specific distribution of polymethacrylic nanospheres.
Animal Model: Mice (single IV injection of labeled particles) for assessment of blood clearance and organ biodistribution.
Interpretation and Analysis: A rapid clearance of [^{111}In]-labeled nanoparticles from the intravascular compartment to the mononuclear phagocyte system (MPS) can be visualized using external scintigraphic imaging. From 10 to 60 minutes postinjection, radioactivity measurements in blood and organs (liver, spleen, kid-

neys, lungs, heart) reveal that [^{125}I]-labeled nanospheres are rapidly removed from the bloodstream (distribution half-life approximately 3–5 minutes) and are mainly deposited within the liver (60% of the administered dose, 10 minutes after administration). Up to 1 hour postinjection, radioactivity in heart and lungs remains insignificant, while in the kidneys, radioactivity levels increase from 8% to 11%.

Blood clearance and organ distribution of intravenously administered polymethacrylic nanoparticles in mice. Rolland A, Collet B, Le Verge R, Toujas L. J Pharm Sci 1989 Jun; 78 (6), pp. 481–4.

Targeting Strategy/Selective
Avidin-Gelatin Nanoparticles/[Biotinylated Probes]

Cellular/Molecular Mechanism of Action: Biotin has a very strong avidity for avidin that is on a magnitude that exceeds that observed for antigen/antibody complexes.
Application: Selective targeting/detection of genes, biochemical enzymes, membrane-associated receptors/antigens, and other biological entities.
Route of Administration: Intravascular.
Semi-Synthetic Methods: Gelatin nanoparticles can be prepared by a 2-step desolvation process. Functional groups at the surface of the particulate system can be quantified with site-specific reagents. The surface of the nanoparticles can then be thiolated, followed by covalent conjugation of nanoparticles to avidin utilizing a bifunctional spacer.
Implementation: Classically, a biological marker system specific for a given disease state would be "pretargeted" with a biotinylated probe or delivery modality (e.g., oligonucleotides or monoclonal antibody), followed by the administration of an avidin-conjugated nanoparticle preparation incorporated with some indicator molecule that can be detected for the various diagnostic purposes.
Interpretation and Analysis: The method allows for high levels of avidin labeling. Biotinylated peptide nucleic acid (PNA) effectively complexes with avidin-conjugated nanoparticles. Avidin-conjugated protein nanoparticles should prove effective as a potential carrier system for biotinylated derivatives for the detection of *in vivo* gene expression or for use in antisense-based gene therapy strategies.

Preparation of avidin-labeled gelatin nanoparticles as carriers for biotinylated peptide nucleic acid (PNA). Coester C, Kreuter J, von Briesen H, Langer K. Int J Pharm 2000 Mar 10; 196 (2), pp. 147–9.

MOLECULAR PLATFORMS

MICRO-SYNTHETIC AGENTS

Cardiovascular: Chronic Heart Failure (CHF)/ Adrenergic Receptor Complexes/Pharmaceutical Efficacy Evaluation
[^{123}I]-Metaiodobenzylguanidine (MIBG)

Cellular/Molecular Mechanism of Action: [^{123}I]-MIBG functions as a norepinephrine analog.
Application: Previous studies have not investigated the efficacy of angiotensin II (AII) receptor antagonists against cardiac sympathetic overactivity in cases with CHF using MIBG myocardial imaging.
Route of Administration: Intravascular.
Implementation: Evaluation of CHF in the presence of an administered AII receptor antagonist (losartan or candesartan). Image evaluation is performed with MIBG and echocardiograms before and 6 months after administration in concert with neurohumoral factors.
Human Model: Cases of CHF (n = 34) with fractional shortening of the left ventricular (LV) diameter $< 25\%$ or LV ejection fraction $< 45\%$ in echocardiogram images.
Interpretation and Analysis: MIBG imaging reveals that the antagonist does not significantly change the heart-to-mediastinum ratio. However, the washout rate falls significantly (from 32.6% + 7.6% to 28.2% + 7.5%; $p < 0.001$). No significant changes occur in LV diameter, fractional shortening, or LV ejection fraction. Circulating atrial (ANP) and brain natriuretic peptides (BNP) and aldosterone fall significantly. Changes in MIBG washout rate correlate positively with changes in BNP ($r = 0.35$, $p < 0.05$). In cases also being treated with angiotensin-converting enzyme (ACE) inhibitors (e.g., n = 19), the MIBG washout rate also falls significantly with AII antagonists, as does BNP and aldosterone. Decreases in MIBG washout and BNP in cases with CHF induced by the AII receptor antagonists suggest the efficacy of these agents in modifying cardiac sympathetic function and neurohumoral factors, even with ACE inhibition. Combination therapy with AII receptor antagonists and ACE inhibitors appears effective for CHF.

Effects of angiotensin II receptor antagonists on [^{123}I]-metaiodobenzylguanidine myocardial imaging findings and neurohumoral factors in chronic heart failure. Shinohara H, Fukuda N, Soeki T, Sakabe K, Onose Y, Tamura Y. Heart Vessels 2002 Dec; 17 (2), pp. 47–52.

Cardiovascular: Endothelin Receptor Expression: Antagonist Receptor Occupancy/Individualization of Endothelin Receptor Antagonist Dosage/Renal Failure: Acute/Cardiac Failure: Congestive
BQ-788/L-749,329/[^{125}I]ET-1/BQ-123

Cellular/Molecular Mechanism of Action: The agents BQ-123 and BQ-788 bind to and block ETA and ETB type endothelin receptor complexes (receptor antagonists). Alternatively, L-749,329 (non-peptide antagonist) has a relatively balanced affinity for each of the 2 endothelin receptor subtypes.
Physiological Mechanism of Action: Endothelin (ET) is 1 of the most potent vasoconstrictors ever identified.
Background Information: Endothelin has been implicated in various disease states, including acute renal failure and congestive heart failure. Such observations imply that these conditions can possibly be managed with endothelin receptor antagonists. However, establishing the dosages for these antagonists may be difficult because no convenient physiologic indicator of action exists and because of complexities associated with receptor function. Two receptor subtypes have been identified for which selective antagonists have been described (e.g., BQ-123 for the ETA receptor and BQ-788 for the ETB receptor). Of the 3 natural peptide hormones (ET-1, ET-2, and ET-3), ET-1 exhibits high affinity for both subtypes of the receptor.
Application: Characterization of the relative expression of 2 endothelium receptor subtypes in a manner that provides information for establishing individualized dosage schedules for endothelin receptor antagonists relevant to the management of various disease states, including acute renal failure and congestive heart failure.
Implementation: Evaluation of the *in vivo* biodistribution of [^{125}I]ET-1 with and without the presence of selective peptide antagonists and a non-peptide antagonist (L-749,329). The agent [^{125}I]ET-1 possesses binding avidity for endothelin receptor complexes.
Animal Model: Rat.
Animal Model: Primate (rhesus monkey).
Interpretation and Analysis: The agents BQ-123, BQ-788, and L-749,329 inhibit binding consistent with avidity for a single

receptor site. However, the sum of inhibition by the selective antagonist is greater than 100% (as defined by inhibition with L-749,329), which suggests (i) lower *in vivo* selectivity than determined *in vitro,* and/or (ii) receptor subtype interactions. The latter explanation is supported, in part, by *in vitro* autoradiographic studies as well as studies in isolated tissues and cells. Synthesized ET-1 labeled with [^{123}I] facilitates the acquisition of images reflecting receptor distribution in 2 *in vivo* animal models. Therefore, it is possible to visualize, via planar, non-invasive imaging, the occupancy of endothelin receptor by antagonists in both the kidney and lung. [^{123}I]ET-1 can therefore be used to determine clinical dosages of antagonist needed for receptor saturation.

Radioiodinated endothelin-1: A radiotracer for imaging endothelin receptor distribution and occupancy. Gibson RE, Fioravanti C, Francis B, Burns HD. Nucl Med Biol 1999 Feb; 26 (2), pp. 193–9.

Cardiovascular: Muscarinic Receptors/Selectivity for Cardiac M2 Muscarinic Receptor Complexes/ Minimal Affinity for Gastrointestinal Muscarinic Receptor Complexes
5H-Dibenz[b,f]Azepine Derivatives

Cellular/Molecular Mechanism of Action: 5H-Dibenz[b,f] azepine derivatives possess binding avidity for membrane-associated parasympathetic muscarinic receptor complexes.
Application: Potential diagnostic probe for evaluation of cardiac physiology parameters without exerting any major effect on gastrointestinal function.
Route of Administration: Intravascular or intraduodenal (rat, mouse, canine).
Semi-Synthetic Methods: Preparation of a series of 5H-dibenz[b,f]azepine derivatives.
Implementation: Evaluation of the relative *in vitro* selective binding affinities of 5H-dibenz[b,f]azepine derivatives for muscarinic receptors (e.g., human recombinant M1, M2, M3, and M4 muscarinic receptors). Results from *in vitro* investigations can be validated *in vivo* to determine selective effects on bradycardia (rat), analgesia (mouse), and nocturnal bradycardia (canine). Ideally, it is desired to identify compounds that have relatively higher binding avidity for cardiac muscarinc receptor complexes and significantly lower binding avidity for gastrointestinal receptor complexes.

Animal Model: Rat (acethylcholine-induced bradycardia), mouse (analgesic), and canine (nocturnal bradycardia).
Interpretation and Analysis: One compound (e.g., n = 1/8) has been identified that has high binding affinity for human recombinant M2 receptors (K_i = 2.6 nm), a low affinity for M4 receptors (39-fold less than for M2 receptors), and a very low affinity for M1 and M3 receptors (119-fold and 112-fold less than for M2 receptors, respectively). The high M2 selectivity of compound 8 may be attributed to the olefinic bond of the azepine ring. Functional experiments reveal that the 1 desirable candidate derivative can function as a competitive antagonist with high affinity for cardiac (pA2 = 7.1) and low affinity for intestinal muscarinic receptors (IC_{50} = 0.54 μM).

The selectivity of compound 8 in studies performed *in vivo* confirm parameters observed *in vitro.* Acetylcholine-induced bradycardia is dose-dependently antagonized after both intravenous and intraduodenal administration of compound 8 (rat). Cholinergic functions mediated by M1 or M3 receptors (salivary secretion, pupil diameter, gastric emptying, intestinal transit time) are not affected by the oral administration of compound 8 even at doses as high as 30 times the antibradycardic effective dose. Furthermore, compound 8 has no analgesic activity (mice), indicating poor central nervous system penetration. In dogs, nocturnal bradycardia is dose-dependently inhibited following the oral administration of compound 8 and it exerts physiological effect for 24 hours. Compound 8 appears to be a promising cardioselective antimuscarinic agent for the treatment of dysfunctions of the cardiac conduction system such as sinus or nodal bradycardia ("sick-sinus syndrome") and atrioventricular block. Based on its biological properties, the candidate compounds also has potential as a diagnostic imaging ligand .

Synthesis of new cardioselective M2 muscarinic receptor antagonists. Mandelli GR, Maiorana S, Terni P, Lamperti G, Colibretti ML, Imbimbo BP. Chem Pharm Bull (Tokyo) 2000 Nov; 48 (11), pp. 1611–22.

Cardiovascular: Sodium-Potassium ATPase (Na/K-ATPase): Myocardial
[^{125}I]-Digoxin/[^{125}I]-Digoxin-Iodohistamine (bis(O-Carboxymethyloxime))

Cellular/Molecular Mechanism of Action: Cardiac glycosides recognize and physically bind to membrane-associated myocardial Na/K-ATPase complexes.
Background Information: Cardiac glycosides have a high binding avidity for myocardial Na/K-ATPase complexes.
Implementation: Survey of radioiodinated digoxin (cardiac glycoside) derivatives as potential candidates for myocardial imaging with particular emphasis on non-invasive monitoring of cardiac glycoside therapy.

Animal Model: Canine (dog myocardial imaging analysis).
Interpretation and Analysis: The radioiodinated digoxin derivative [^{125}I]-digoxin-iodohistamine(bis(O-carboxymethyloxime)) shows a relatively high level of accumulation within the myocardium and a degree of binding avidity for Na/K-ATPase similar to digoxin itself, and resistance against ouabain displacement, as indicated by *in vivo* and *in vitro* studies. Based on these results, [^{123}I] labeling of digoxin-histamine(bis(O-carboxymethyloxime)) and imaging analysis demonstrates uptake within the myocardium.

High myocardial accumulation of radioiodinated digoxin derivative: A possible Na,K-ATPase imaging agent. Fujibayashi Y, Takemura Y, Matsumoto K, Wada K, Yonekura Y, Konishi J, Yokoyama A. J Nucl Med 1992 Apr; 33 (4), pp. 545–9.

Cardiovascular Thrombosis/Platelet GPIIb/ IIIa Receptor/Deep-Vein Thrombosis/Pulmonary Embolism/Arterial Thromboembolic Disorders/ Cerebral Vascular Stroke/Coronary Artery Thrombotic Disorders/Peripheral Artery Thromboses
Platelet GPIIb/IIIa Receptor Antagonist/ [^{99m}Technetium] ([^{99m}Tc])-DMP728/[^{3}H]-DMP728

Cellular/Molecular Mechanism of Action: The agent DMP728 functions as a GPIIb/IIIa receptor antagonist on the exterior surface membrane of platelets.
Physiological Mechanism of Action: The composition of venous thrombi is predominantly polymerized fibrin monomer in contrast to arterial thrombi that have a significantly higher platelet content.
Background Information: Either venous or arterial thrombosis is a potentially life-threatening event and existing diagnostic modalities are inadequate for detecting such lesions or determining morphological alterations that occur during evolving thrombus development. Thus development of a non-invasive imaging agent that can detect clot location remains a critical and unmet need in the field of diagnostic nuclear medicine.

Application: Detection and characterization of intravascular venous and arterial thromboses. Preparations can also function as a means of assessing the efficacy of thrombin inhibitors and other pharmaceutical candidates.
Implementation: Evaluation of artificially (*in vitro*) created venous and arterial type thrombi using the potent radiolabeled GPIIb/IIIa receptor antagonist [^{3}H]-DMP728 as detection agent. Complementary investigations can involve the *in vivo* application of [^{99m}Tc]-DMP728 to determine clot/blood biodistribution ratios (e.g., target:background ratio), as well as the application of non-invasive single photon emission computed tomography (SPECT) of venous clots in deep-vein thrombosis.
Animal Model: Canine (dogs with mixed arterial/venous or venous clots in arteriovenous shunt, in venous clot foci, and deep-vein thrombi).
Interpretation and Analysis: Radiolabeled preparations of the GPIIb/IIIa receptor antagonist DMP728 in the form of [^{3}H]-DMP728 and [^{99m}Tc]-DMP728 retain marked binding avidity for platelet GPIIb/IIIa receptor complexes. DMP728 demonstrates a relatively greater affinity for activated in contrast to non-activated human platelets, which may be essential for attaining an optimal thrombus/blood (target/background) distribution ratio and the optimal detection of small clots (i.e., greater sensitivity). Therefore, [^{99m}Tc]-GPIIb/IIIa receptor antagonists have potential utility in the diagnosis of venous clots in deep-vein thrombosis, pulmonary embolism, and arterial thromboembolic disorders including stroke and coronary and peripheral artery thrombotic disorders. Thrombin inhibitors do not appear to be as effective in this same context.

Novel technetium-99m-labeled platelet GPIIb/IIIa receptor antagonists as potential imaging agents for venous and arterial thrombosis. Mousa SA, Bozarth JM, Edwards S, Carroll T, Barrett J. Coron Artery Dis 1998; 9 (2–3), pp. 131–41.

Cardiovascular Thrombosis
[Lys-Gla-Ala-Gly-Asp-Val]-Aerosomes-Entrapped Microbubbles

Cellular/Molecular Mechanism of Action: Microbubbles can function as a means for delaying excretion, suppressing biological degradation, and enhancing site-specific accumulation of diagnostic and therapeutic pharmaceutical agents.
Application: Ultrasound can be used as a primary diagnostic technique for the detection of deep venous thrombosis. Microbubble preparations can potentially enhance the detection and characterization of intravascular thrombi.
Route of Administration: Intravascular.
Semi-Synthetic Methods: In the 1st phase of production, synthetic linear hexapeptide (lysine-glutamine-alanine-glycine-aspartate-valine) can be coupled to a lipid moiety. The targeted lipid moiety is then incorporated into a lipid blend, followed by entrapment of Aerosomes contrast agent (ImaRx) yielding perfluorobutane-entrapped microbubbles. Prior to administration microbubble preparations are then sized for uniformity.
Implementation: Evaluation of the *in vitro* capacity of sized perfluorobutane-entrapped microbubbles to (i) retain high levels of acoustic stability; (ii) recognize (bind) to blood clots; and (iii) enhance ultrasound image analysis of intravascular thromboses (blood clots).
Interpretation and Analysis: Experimental results reveal that the mean size of the specific ultrasound contrast agent (MRX-408) is about 2.0 microm. Microbubbles appear as smooth spherical structures. Microscopic analysis reveals that targeted bubbles bind to blood clots, whereas control, non-targeted bubbles do not bind to blood clots. *In vitro* acoustic studies reveal similar levels of stability for modified microbubbles compared with control microbubbles. Targeted microbubbles enhance *in vitro* blood clot visualization, whereas non-targeted microbubbles do not increase clot detection. Therefore, this new thrombus-specific ultrasound contrast agent could potentially improve the detection of thrombosis by ultrasound and may be useful for distinguishing between new and old thrombosis. Investigations performed *in vivo* have been initiated to further characterize the applicability of these preparations.

In vitro studies of a new thrombus-specific ultrasound contrast agent. Unger EC, McCreery TP, Sweitzer RH, Shen D, Wu G. Am J Cardiol 1998 Jun 18; 81 (12A), pp. 58G–61G.

Central Nervous System (CNS)/Alpha 1-Adrenoceptor
N-[3-(^{1}H-Imidazol-4-Ylmethyl)-Phenyl] Ethanesulfonamide

Cellular/Molecular Mechanism of Action: *N*-[3-(^{1}H-imidazol-4-ylmethyl)-phenyl]-ethanesulfonamide (ABT-866, 1) is a novel alpha 1-adrenoceptor ligand.
Physiological Mechanism of Action: *N*-[3-(^{1}H-imidazol-4-ylmethyl)-phenyl]ethanesulfonamide (ABT-866, 1) possesses enhanced *in vitro* and *in vivo* binding avidity profiles relative to phenylpropanolamine and midodrine. The compound has a unique profile of α_{1A} (rabbit urethra, EC_{50} = 0.60 μM) agonism with α_{1B} (rat spleen, pA_2 = 5.4) and α_{1D} (rat aorta, pA_2 = 6.2) antagonism.
Application: Evaluation of urethral function.
Route of Administration: Intravascular.
Interpretation and Analysis: In an *in vivo* canine model, compound (1) is more selective for the urethra and interacts less with the vasculature compared to A-61603 (2), ST-1059 (3), the active metabolites of midodrine, and phenylpropanolamine (4).

N-[3-(1H-imidazol-4-ylmethyl)-phenyl]ethanesulfonamide (ABT-866, 1), a novel alpha 1-adrenoceptor ligand with an enhanced *in vitro* and *in vivo* profile relative to phenylpropanolamine and midodrine. Altenbach RJ, Khilevich A, Meyer MD, Buckner SA, Milicic I, Daza AV, Brune ME, O'Neill AB, Gauvin DM, Cain JC, Nakane M, Holladay MW, Williams M, Brioni JD, Sullivan JP. J Med Chem 2002; 45(20), pp. 4395–7.

Central Nervous System (CNS)/Amyloidosis ($Beta_2$)/Microglobulin: Example Amyloidosis
[^{111}Indium] ([^{111}In])-Recombinant Human $Beta_2$Microglobulin ($Rhbeta_2$mH5)

Cellular/Molecular Mechanism of Action: $Beta_2$-microglobulin recognizes and physically binds to amyloid of $beta_2$-microglobulin ($beta_2$m) origin.
Background Information: Amyloid of $beta_2$m origin can be detected using [^{131}I]-radiolabeled-$beta_2$m scintigraphy in cases with uremia and managed with hemodialysis treatment. As the tracer $beta_2$m is isolated from another affected case, it carries the common risks, including viral infections such as hepatitis B and C and human immunodeficiency virus (HIV) that are associated with human plasma products.
Application: The *in vitro* production of recombinant human $beta_2$-microglobulin yields a protein fraction that is devoid of any potential risk of exposing recipients to various viral pathogens. Purified protein fractions can then be radiolabeled for the purpose of detecting and characterizing various conditions of amyloidosis.
Route of Administration: [^{111}In]-$rhbeta_2$mH5 (intravenous).

Semi-Synthetic Methods: Beta$_2$m-type amyloid can be produced *in vitro* as rhbeta$_2$m in *Escherichia coli* cultures. The expression vector pASK40DeltaLbeta$_2$m(His)5 can be used for such purposes due to it containing a C-terminal (His)5-tag that facilitates purification via immobilized metal ion affinity chromatography (IMAC). Size exclusion chromatography on a Superose 12 column can be used as a 2nd purification step. The isolated rhbeta$_2$mH5 reacts in an immunochemically identical manner compared to native human beta$_2$m, and can be identified as a single band of approximately 11.8 kDa utilizing Western blot immunodetection methodologies. Additionally, fractions can be visualized as a single spot in 2-dimensional gel electrophoresis (2D-PAGE: expected molecular mass = 12,415.8 Da). Uniform purity can further be proven by crystallization and N-terminal amino acid sequence analysis.
Implementation: Evaluation of beta$_2$m-amyloidosis conditions applying sterile preparations of rhbeta$_2$mH5 radiolabeled with [^{111}In] to produce [^{111}In]-rhbeta$_2$mH5.

Human Model: Cases managed with hemodialysis (± known beta$_2$m-amyloidosis).
Interpretation and Analysis: The [^{111}In]-rhbeta$_2$mH5 tracer localizes specifically within areas known to contain amyloid deposits. Recombinant rhbeta$_2$mH5 preparations therefore are suitable for the *in vivo* detection of deposits of beta$_2$m-type amyloid contained within organs, and fulfill the requirements necessary for tracer agents to be applied in clinical environments. Finally, the use of [^{111}In] instead of [^{131}I] reduces the radioactive dose and results in higher levels of lesion resolution.

Production of recombinant human beta$_2$-microglobulin for scintigraphic diagnosis of amyloidosis in uremia and hemodialysis. Linke RP, Schäeffer J, Gielow P, Lindner P, Lottspeich F, Plückthun A, Weiss EH. Eur J Biochem 2000 Feb; 267 (3), pp. 627–33.

Central Nervous System (CNS)/Gliomas
p-[^{123}I]-Iodo-L-Phenylalanine (IPA)

Cellular/Molecular Mechanism of Action: The agent IPA functions as an analogue of phenylalanine and is preferentially assimulated by certain cell types that perceive it as an amino acid mimic.
Background Information: The radiopharmaceutical IPA is highly accumulated within gliomas.
Application: Detection and characterization of gliomas within the CNS.
Dosage: *p*-[^{123}I-iodo-L-phenylalanine (average effective dose for adults is estimated to be 0.0152mSv*MBq^{-1}, leading to an effective dose of 3.8mSv in a typical brain single photo emission computed tomography [SPECT] investigation with 250 MBq IPA).
Implementation: Evaluate the feasibility of IPA to image brain tumors under routine clinical conditions using SPECT. In this fashion, it is possible to delineate whole-body kinetic profiles and brain SPECT images, in addition to plasma, urinary, and dosimetric analysis in cases of glioma following intravenous IPA injection. Results obtained by IPA SPECT can then be compared with histopathology, magnetic resonance imaging, and positron emission tomography (PET) analysis with [^{18}F]-fluorodeoxyglucose.

Human Model: Cases of glioma (n = 4).
Interpretation and Analysis: Tumor lesions can clearly be demonstrated by IPA SPECT at 30 minutes, 1 hour, and 4.5 hours postinjection, even in cases with low-grade gliomas. In glioblastoma cases, excellent visualization of the tumor is possible even at 7 hours postinjection, which is indicative of high retention of the radiopharmaceutical within cerebral gliomas. Analysis of the radioactivity in plasma and urine validate the high *in vivo* IPA stability. Blood clearance of IPA is rapid (> 65% after 10 minutes), and elimination is predominantly facilitated by renal excretion with the urinary radioactivity excretion ranging from 27% at 1 hour to 54% of injected doses at 5 hours postinjection. The IPA agent therefore appears to be a potentially valuable brain tumor–imaging agent for widespread SPECT clinical studies. Its high tumor-specific uptake and retention even in low-grade gliomas represents a major advantage compared to presently available SPECT radiopharmaceuticals. Moreover, the radiation dose estimates indicate that clinical use of IPA will result in acceptable radiation dose levels in humans.
Instrumentation: Dual- and a triple-headed SPECT camera.

Initial evaluation of the feasibility of single photon emission tomography with *p*-[^{123}I]iodo-L-phenylalanine for routine brain tumor–imaging. Samnick S, Hellwig D, Bader JB, Romeike BF, Moringlane JR, Feiden W, Kirsch CM. Nucl Med Commun 2002 Feb; 23 (2), pp. 121–30.

Central Nervous System (CNS)/Glioma and Mammary Carcinoma
T3,4BCPC

Cellular/Molecular Mechanism of Action: The exact mechanism that facilitates the selective uptake of T3,4BCPC by certain neoplastic cell types has not been precisely established.
Application: Potential application as a detectable delivery modality that selectively recognizes certain neoplastic cell types, including glioma and mammary carcinoma.
Route of Administration: T3,4BCPC (intravenous).
Dosage: T3,4BCPC (5.0 mg/kg body weight; murine fibrosarcoma model).
Semi-Synthetic Methods: Preparation of the water-soluble photosensitizer 5,10,15,20-tetrakis[3,4-bis(carboxymethyleneoxy)-phenyl]chlorin (T3,4BCPC) followed by *in vitro* characterization and then [^{99m}Tc] radiolabeled.
Implementation: Evaluation of biodistribution studies in mouse and rat tumor models for determining the comparative properties of the tumor-seeking radiopharmaceuticals [^{99m}Tc^{V}]-dimercaptosuccinic acid (DMSA), [^{201}Thallous]-chloride (TlCl), and [^{99m}Tc]-citrate using a gamma camera computer-integrated system. In the 2nd phase of evalution, *in vivo* efficacy of the compound can be determined by establishing its potential as photodynamic therapeutic agent achieved by the conduction of a preclinical photodynamic therapy (PDT) study performed in fibrosarcoma-bearing mice (postinjection of T3,4BCPC).

Animal Model: Murine (C$_3$H/J virus-induced spontaneous mammary tumors).

Animal Model: Murine (fibrosarcoma-bearing).

Animal Model: Rats (Wistar strain).

Animal Model: Rat (N-nitrosomethylurea [NMU]-induced mammary tumors).

Animal Model: Rat (transplanted C$_6$-glioma).
Interpretation and Analysis: Accumulation of imaging agent activities within the liver, kidney, bladder, and large intestine at 4 hours postinjection indicate that the labeled ligand is largely eliminated by renal excretion and partly through the hepatobiliary system. In NMU-induced rat mammary tumors, the labeled ligand shows a 5-fold tumor to muscle (T/M) ratio compared to [^{99m}Tc^{V}]-DMSA (3-fold) and [^{201}Tl]Cl (3-fold). In the case of C$_3$H/J virus-induced spontaneous mammary tumors, differences are not marked. However, in the transplanted rat C$_6$-glioma, the T/M ratio of the labeled compound is appreciably higher (4-fold) than that noted with [^{99m}Tc^{V}]-DMSA (2-fold), [^{201}Tl]Cl (3-fold), and [^{99m}Tc]-citrate (more than 3-fold). Therefore, radiolabeled T3,4BCPC may have potential utility

for detection of neoplastic disease states. Photodynamic therapy applications of T3,4BCPC in fibrosarcoma-bearing mice following delivery of a laser dose of 20 mW for 60 seconds produces an 80% level of destruction within tumor masses. The molecule may therefore be useful for PDT of cancer. The labeled agent could also be useful in monitoring the progression/regression of tumors before, during, and after chemotherapy, radiation therapy, or PDT.

Preparation and biological evaluation of the new chlorin photosensitizer T3,4BCPC for detection and treatment of tumors. Murugesan S, Shetty SJ, Srivastava TS, Samuel AM, Noronha OP. J Photochem Photobiol B 2002 Aug; 68 (1), pp. 33–8.

Central Nervous System (CNS)/Glioma/Mammary Tumors: Carcinogen-Induced
[^{99m}Technetium] ([^{99m}Tc])Field Bean Protease Inhibitor/[^{99m}Tc]-(V)Dimercaptosuccinic Acid (DMSA)/ [^{201}Thallous] Chloride (TlCl)/[$^{99m}TcO_4^-$]-Citrate

Application: Detection and characterization of glioma and possibly other neoplastic disease states.
Route of Administration: [$^{99m}TcO_4^-$]-labeled purified field bean protease inhibitor (intravenous).
Semi-Synthetic Methods: Purified field bean protease inhibitor (FBPI) can be labeled with [$^{99m}TcO_4^-$] as a tracer molecule. Labeling is done in the presence of Sn^{2+} as a reducing agent and the resulting approximately a 95% product yield. At room temperature, the product is stable for at least a 2-hour period.
Implementation: Evaluation of the biodistribution of [^{99m}Tc]-labeled purified FBPI to ascertain its ability to localize within neoplastic lesions. Biodistribution analysis can be determined at various time intervals following administration.

Animal Model: Rat (Wistar strain bearing carcinogen-induced mammary tumors or transplanted C6 glioma).
Interpretation and Analysis: Biodistribution analysis of [^{99m}Tc]-FBPI reveals that it undergoes rapid blood clearance from the systemic circulation (approximately 5 hours). The complex is predominantly eliminated through renal and hepatobiliary excretion. The tumor-to-muscle (T/M) ratios obtained with [^{99m}Tc]-FBPI in C6 glioma explants are nearly 2- to 5-fold higher than observed with several conventional tumor-seeking radiopharmaceuticals such as [$^{99m}Tc^{V}$]-DMSA, TlCl, and [^{99m}Tc]-citrate. Similarly, the T/M ratio obtained with [^{99m}Tc]-FBPI in a mammary tumor model, on the other hand, appears to be 2-fold to 3-fold higher than observed with [$^{99m}Tc^{V}$]-DMSA and TlCl. The ratio is, however, comparable with that obtained with [^{99m}Tc]-citrate. The study indicated that [^{99m}Tc]-FBPI can potentially function as a specific imaging agent for gliomas and possibly other tumor types as well.

[^{99m}Tc]-labeled field bean protease inhibitor can function as an efficient tumor-detecting agent. Murugesan S, Banerji AP, Noronha OP, Samuel AM, Fernandes AO. Indian J Exp Biol 2001 Aug; 39 (8), pp. 742–7.

Central Nervous System (CNS)/Opiate Receptor Expression
[^{18}F]-Fluorophen/Phenazocine Derivative/ Benzomorphan Opiate Agonist

Cellular/Molecular Mechanism of Action: (±)-5,9 Alpha-dimethyl-2-[2-(4-fluorophenyl)ethyl]-2′-hydroxy-6, 7-benzomorphan (fluorophen) is a fluorinated derivative of the benzomorphan opiate agonist phenazocine, which physically recognizes and binds to opiate receptor complexes (selectivity μ congruent to δ greater than κ).
Application: Detection of opiate receptor complexes. Labeled with [^{18}F], fluorophen should be sufficiently potent to be useful as a non-invasive *in vivo* probe for visualizing opiate receptors complexes.
Semi-Synthetic Methods: (±)-5,9 Alpha-dimethyl-2′-hydroxybenzomorphan can be subjected to N-acylation utilizing (*p*-fluorophenyl)-acetyl chloride, followed by diborane reduction of the resulting amide.
Interpretation and Analysis: Fluorination produces only a 2-fold opiate receptor affinity loss when measured either by bioassay or receptor binding analysis (selectivity μ congruent to delta is greater than kappa). Labeled with [^{18}F], fluorophen should be sufficiently potent to be useful as an *in vivo* probe for visualizing opiate receptors by positron emission transaxial tomography (PETT).
Instrumentation: Positron emission transaxial tomography.

Synthesis and pharmacological characterization of (±)-5,9 alpha-dimethyl-2-[2-(4-fluorophenyl)ethyl]-2′-hydroxy-6,7-benzomorphan (fluorophen), a ligand suitable for visualization of opiate receptors *in vivo*. Rice KC, Konicki PE, Quirion R, Burke TR Jr, Pert CB. J Med Chem 1983 Nov; 26 (11), pp. 1643–5.

Central Nervous System (CNS)/Parasympathetic Autonomic System/Cardiac Muscarinic Acetylcholinergic Receptors/CNS Muscarinic Acetylcholinergic Receptors/Carcinoma of the Colon
[^{123}I]-PIP/[^{125}I]-PIP

Cellular/Molecular Mechanism of Action: The agent IPIP functions as a ligand for muscarinic acetylcholinergic complexes (mAChR).
Background Information: Prior to approval for *in vivo* use in humans, organ doses for radioiodinated IPIP ligands must 1st be extensively evaluated applying *ex vivo* and *in vivo* models.
Application: Radioiodinated IPIP ligands can be applied *in vivo* for imaging mAChR using modalities like single photon emission computed tomography (SPECT).
Route of Administration: Intravascular.
Implementation: Identify the most optimum mAChR ligand-binding properties of 4 different IPIP sterioisomers facilitated by the evalatuion of their biodistribution patterns. A biokinetic model can be developed for the Z-(S)-IPIP stereoisomer to estimate the internal absorbed dose in humans based on extrapolation from an appropriate rat model.

Animal Model: Rat (IPIP biokinetic model).
Interpretation and Analysis: The thyroid is the critical organ at risk for this radiopharmaceutical, with an absorbed dose estimate of 2.4 mGy/MBq for both males and females, when labeled with [^{123}I]. Even when blocked, the thyroid is still the critical risk organ, yet with a 90% dose reduction. The heart and brain receive the next highest doses in both males and females. Effective dose estimates for the use of pure [^{123}I]-PIP in humans are 0.16 mSv/MBq for males and 0.14 mSv/MBq for females. The biodistribution studies of the Z-(S)-IPIP stereoisomer show it has the most promise as a successful agent for imaging muscarinic receptor sites in the heart and brain. IPIP can potentially be applied as a therapeutic radiopharmaceutical for certain colon carcinomas where muscarinic receptor sites are expressed in the tumor cells. These results provide preliminary data for use of IPIP in clinical studies on humans.

In vivo biodistribution of [^{125}I]-PIP and internal dosimetry of [^{123}I]-PIP radioiodinated agents selective to the muscarinic acetylcholinergic receptor complex. Breeden WK 3rd, Hamby DM, Carey JE Jr, Eckerman KF, McPherson DW, Knapp FF Jr. Med Phys 2000 Apr; 27 (4), pp. 778–86.

Central Nervous System (CNS)/Parasympathetic/ Acethylcholine Nictotinic $\alpha_4\beta_2$ Receptor Complexes/ Neurodegenerative Disease/Tobacco Dependency
S-5-[^{123}I]Iodo-3-(2-Azetidinylmethoxy)Pyridine

Cellular/Molecular Mechanism of Action: *S*-5-[^{123}I]iodo-3-(2-azetidinylmethoxy)pyridine selectively binds to $\alpha_4\beta_2$ subtype nicotinic acetylcholine receptor complexes.
Application: The iodinated analogue *S*-5-[^{123}I]iodo-3-(2-azetidinylmethoxy)pyridine of A-85380 can be used for the specific detection and characterization of $\alpha_4\beta_2$ subtype nicotinic acetylcholine receptor complexes in neurodegenerative disease states in conditions of tobacco dependence.
Route of Administration: *S*-5-[^{123}I]iodo-3-(2-azetidinylmethoxy)pyridine (intravenous).
Implementation: Accurate measurement of *S*-5-[^{123}I]iodo-3-(2-azetidinylmethoxy)pyridine plasma concentrations in order to determine their capacity to function as a "tracer" molecule for *in vivo* quantification of $\alpha_4\beta_2$ subtype nicotinic acetylcholine receptor complexes.

Human Model: Non-human and human primates.
Interpretation and Analysis: In human or non-human primate whole blood as well as in plasma, the parent compound is only stable for approximately 5 minutes, after which it decomposes. Alternatively, the radioligand is stable in the injection solution and in protein-free (> 30 KMW) plasma ultrafiltrate for at least 18 hours. To preserve the parent compound in plasma the radioactive plasma must be mixed with equal volumes of acetonitrile within 5 minutes after its collection or, alternatively, radioactive blood should be collected and mixed with sodium azide (3 mg/ml blood). The *in vivo* metabolism of [^{123}I]5-IA generates 2 distinct components including (i) a radiometabolite that is less lipophilic than the parent compound; and (ii) a polar radiometabolite that is not free radioiodide because of the absence of radioactivity accumulation within the thyroid.

Measurement of plasma metabolites of *S*-5-[^{123}I]iodo-3-(2-azetidinylmethoxy)pyridine (5-IA-85380), a nicotinic acetylcholine receptor imaging agent, in non-human primates. Zoghbi SS, Tamagnan G, Baldwin MF, Al-Tikriti MS, Amici L, Seibyl JP, Innis RB. Nucl Med Biol 2001 Jan; 28 (1), pp. 91–6.

Central Nervous System (CNS)/Parasympathetic: Nicotinic Receptors: Neurodegenerative Disease
TC-2559 [(E)-N-Methyl-4-[3-(5-Ethoxypyridin)yl]-3-Buten-1-Amine]

Cellular/Molecular Mechanism of Action: TC-2559 [(E)-*N*-methyl-4-[3-(5-ethoxypyridin)yl]-3-buten-1-amine] is a parasympathetic agonist at membrane-associated nicotinic receptor complexes.
Application: Related analogues may be capable of detecting and characterizing neurodegenerative disorders.
Implementation: Evaluation of the relative selective binding avidity of TC-2559 [(E)-*N*-methyl-4-[3-(5-ethoxypyridin)yl]-3-buten-1-amine], [^{3}H]-nicotine, and [^{125}I]-bungarotoxin for CNS nicotinic receptor complexes. Validation of laboratory results can entail detection of dopamine release from striatal synaptosomes, ion flux from thalamic synaptosomes, and ability to reduce *in vitro* glutamate-induced neurotoxicity. Evaluation of properties *in vivo* can involve characterization of behavioral changes in animal models.

Animal Model: Rat (behavioral studies).
Interpretation and Analysis: TC-2559 [(E)-*N*-methyl-4-[3-(5-ethoxypyridin)yl]-3-buten-1-amine] is markedly more selective than recently reported novel nicotinic receptor ligands (selectivity ratio for CNS to peripheral nervous system (PNS) > 4,000). In this context, TC-2559 competes effectively with [^{3}H]-nicotine binding (K_i = 5 nM) but not with [^{125}I]-bungarotoxin (> 50,000 nM). Dopamine release from striatal synaptosomes and ion flux from thalamic synaptosomes indicates that TC-2559 is potent and efficacious in the activation of CNS receptors and significantly reduces glutamate-induced *in vitro* neurotoxicity. TC-2559 has no detectable effects on muscle and ganglion-type nicotinic acetylcholine receptors at concentrations up to 1 mM.

TC-2559 significantly attenuates scopolamine-induced cognitive deficits in a step-through passive avoidance task. Acute and repeated oral dosing of TC-2559 enhances performance in a radial arm maze task. In contrast to the effects of equimolar concentrations of (-) nicotine, TC-2559 does not induce hypothermia and locomotor activity is not enhanced following repeated daily administration of 14 days. TC-2559 has a markedly enhanced CNS-PNS selectivity ratio and an intra-CNS selectivity as demonstrated by improved cognition without increased locomotor activity. Both *in vitro* and *in vivo* investigation studies suggest that TC-2559 has a desirable profile that warrants further evaluation as a potential diagnostic and therapeutic agent relevant to neurodegenerative disease processes.

TC-2559: A novel orally active ligand selective at neuronal acetylcholine receptors. Bencherif M, Bane AJ, Miller CH, Dull GM, Gatto GJ. Eur J Pharmacol 2000 Dec 1; 409 (1), pp. 45–55.

Central Nervous System (CNS)/Serotonin (5-HT_{1A}) Autoreceptors: Dorsal Raphe Nuclei (DRN)/ Pandolol Receptor Occupancy
[^{11}C]WAY 100635

Cellular/Molecular Mechanism of Action: Pandolol and [^{11}C]WAY 100635 possess binding avidity for membrane-associated serotonin (5-HT_{1A}) receptor complexes expressed by certain cell types within the CNS.
Background Information: Augmentation of selective serotonin reuptake inhibitor (SSRI) therapy by the 5-HT_{1A} receptor agent pindolol may reduce the delay between initiation of antidepressant treatment and clinical response. The hypothesis is based on the ability of pindolol to block 5-HT_{1A} autoreceptors in the DRN and to potentiate the increase in 5-HT transmission induced by SSRIs. However, placebo-controlled clinical studies of pindolol augmentation of antidepressant therapy have reported inconsistent results.
Application: The agent [^{11}C]WAY 100635 can be applied to evaluate the differential occupancy of membrane-associated somatodendritic and postsynaptic 5-HT_{1A} receptor complexes by established or prototype pharmaceutical agents (e.g., pindolol).
Route of Administration: Intravascular.
Implementation: Evaluate the occupancy of 5-HT_{1A} receptors during treatment with pindolol controlled release (CR) using [^{11}C] WAY 100635 and positron emission tomography (PET) imaging. Cases are then studied 4 times: at baseline, following 1 week of pindolol CR 7.5 mg/day (4 and 10 hours postdose), and following 1 dose of pindolol CR 30 mg (4 hours postdose).

Human Model: Healthy subjects (n = 9).
Interpretation and Analysis: Occupancy of DRN is approximately 40 ± 29%, 38 ± 26%, and 64 ± 15% (scans 2, 3, and 4, respectively). The average occupancy in all other regions is significantly lower at each dose (18 ± 5%, 12 ± 3%, and 42 ± 4%; scans 2, 3, and 4, respectively). Blockade within the DRN achieved under clinical conditions (7.5 mg/day) may be too low and variable to consistently augment the therapeutic effect of SSRIs. However, these

data indicate that pindolol exhibits *in vivo* selectivity for the DRN 5-HT_{1A} autoreceptors. As DRN selectivity is desirable for potentiation of 5-HT function, this observation represents an important proof of concept for the development of 5-HT_{1A} agents in this application.

Differential occupancy of somatodendritic and postsynaptic 5-HT_{1A} receptors by pindolol: A dose-occupancy study with [^{11}C]WAY 100635 and positron emission tomography in humans. Martinez D, Hwang D, Mawlawi O, Slifstein M, Kent J, Simpson N, Parsey RV, Hashimoto T, Huang Y, Shinn A, Van Heertum R, Abi-Dargham A, Caltabiano S, Malizia A, Cowley H, Mann JJ, Laruelle M. Neuropsychopharmacology 2001 Mar; 24 (3), pp. 209–29.

Central Nervous System (CNS)/Serotonin: 5-HT_{1A} Autoreceptor/Occupancy of Serotonin 5-HT_{1A} Autoreceptor: Dorsal Raphe Nuclei (DRN)/Dose Optimization for Serotonin 5-HT_{1A} Autoreceptor Agents

[Carbonyl-^{11}C]WAY-100635

Cellular/Molecular Mechanism of Action: The agent [carbonyl-^{11}C]WAY-100635 or [carbonyl-^{11}C] *N*-(2-(4-(2-methoxyphenyl)-1-piperazinyl)ethyl)-*N*-(2-pyridyl)cyclohexa necarboxamide, abbreviated as [^{11}C]WAY-100635, possesses binding avidity for 5-hydroxytryptamine(1A) (5-HT_{1A} or serotonin) receptor complexes.

Background Information: Preclinical studies in rodents suggest that augmentation of serotonin reuptake inhibitor (SSRI) therapy by the 5-HT_{1A} receptor agent pindolol might reduce the delay between initiation of treatment and antidepressant response. Such a hypothesis is based on the ability of pindolol to potentiate increases in serotonin (5-HT) transmission induced by SSRIs, an effect achieved by blockade of the 5-HT_{1A} autoreceptors in the DRN. However, placebo-controlled clinical studies of pindolol augmentation of antidepressant therapy have reported inconsistent results.

Application: The binding avidity of [^{11}C]WAY-100635 for 5-HT_{1A} receptor complexes can be utilized to evaluate occupancy of these membrane-associated sites. In this context, [^{11}C]WAY-100635 can effectively assess new prototype pharmaceuticals through PET imaging modalities to determine their selectivity for DRN. In this context, this strategy can be used as an investigative probe to establish appropriate doses for clinical trials.

Implementation: Evaluation of the occupancy of 5-HT_{1A} receptors following treatment with controlled release pindolol in 9 healthy volunteers with positron emission tomography (PET). Each subject is then studied 4 times, at (i) baseline (scan 1) following 1 week of orally administered pindolol CR (7.5 mg/day) at peak levels; (ii) 4 hours after the dose (scan 2); (iii) 10 hours following the dose (scan 3); and (iv) following 1 dose of pindolol CR (30 mg) at 4 hours when peak levels occur (scan 4). Pindolol occupancy of 5-HT_{1A} receptors is then evaluated in the DRN and within cortical regions as the decrease in binding potential (BP) of the selective radiolabeled 5-HT_{1A} antagonist [^{11}C]WAY-100635).

Human Model: Healthy cases (n = 9).

Interpretation and Analysis: Pindolol dose-dependently decreases [^{11}C]WAY-100635 BP. Combining all regions-of-interest, occupancy is 20 ± 8%; 14 ± 8%; and 44 ± 8% (scan 2, 3, 4 respectively). Clinical studies designed to assess the augmentation of SSRI effects exerted by pindolol at doses of 2.5 mg t.i.d. reveal that the occupancy of 5-HT_{1A} receptors is moderate but highly variable between subjects. This factor may explain the variable results obtained in clinical studies. On the other hand, at each dose tested, pindolol occupancy of 5-HT_{1A} receptors one higher in the DRN compared to cortical regions, demonstrating a significant degree of *in vivo* selectivity for DRN 5-HT_{1A} autoreceptors relative to corticolimbic postsynaptic receptors. Selectivity of this magnitude is necessary for the potentiation of 5-HT transmission, and this finding represents an important proof of concept in the development of 5-HT_{1A} agents for this application.

Positron emission tomography study of pindolol occupancy of 5-HT_{1A} receptors in humans: Preliminary analyses. Martinez D, Mawlawi O, Hwang DR, Kent J, Simpson N, Parsey RV, Hashimoto T, Slifstein M, Huang Y, Van Heertum R, Abi-Dargham A, Caltabiano S, Malizia A, Cowley H, Mann JJ, Laruelle M. Nucl Med Biol 2000 Jul; 27 (5), pp. 523–7.

Central Nervous System (CNS)/Serotonin Transporters (SERT)/Cerebral Cortex/ Hypothalamus/Hippocampus/Striatum/ [Parkinson's Disease]

[^{125}I]-ADAM/[^{123}I]-ADAM/2-((2-((Dimethylamino) Methyl)- Phenyl)Thio)-5-Iodophenylamine

Cellular/Molecular Mechanism of Action: The substances 2-((2-((dimethylamino)methyl)-phenyl)thio)-5-iodophenylamine paroxetine and (+)McN5652 all function as ligands that selectively recognize and physically bind to serotonin transporter complexes.

Application: The iodinated tracer ADAM (2-((2-((dimethylamino)methyl)-phenyl)thio)-5-iodophenylamine) can be applied to detect and characterize SERT within the CNS.

Route of Administration: [^{125}I]-ADAM (intravenous).

Implementation: Detection of SERT within the CNS using single photon emission computerized tomography (SPECT) imaging modalities utilizing [^{125}I]2-((2-((dimethylamino)methyl)-phenyl) thio)-5-iodophenylamine paroxetine and (+)McN5652.

Animal Model: Rat.

Interpretation and Analysis: Scatchard analysis of saturation binding of [^{125}I]ADAM to frontal cortical membrane homogenates (rat) produces K_d values of 0.15 ± 0.03 nM and B_{MAX} values of 194 ± 65 fmol/mg protein. Biodistribution analysis of [^{125}I]-ADAM within the brain postadministration reveals high specific binding within regions of the hypothalamus, cortex, striatum, and hippocampus, where SERT are concentrated and specific binding phenomenon peaks at 120 to 240 minutes postinjection [(hypothalamus-cerebellum)/ cerebellum = 4.3 at 120 minutes post-IV injection]. Moreover, specific hypothalamic uptake is blocked by pretreatment with SERT selective competing drugs, such as paroxetine and (+)McN5652, while other non-competing drugs, such as ketanserin, raclopride, and methylphenidate, exert no effect. Radioactive material recovered from rat brain homogenates at 120 minutes after [^{125}I]-ADAM injection is primarily the original compound (> 90%) and is a good indication of the *in vivo* stability of the agent within brain tissues. Both male and female *in vivo* models show similar and comparable patterns of organ distribution and regional brain uptake. Autoradiograms (*ex vivo*) of brain sections (120 minutes after IV injection of [^{125}I]-ADAM) detect intense signal increases in several regions (olfactory tubercle, lateral septal nucleus, hypothalamic and thalamic nuclei, globus pallidus, central gray, superior colliculus, substantia nigra, interpeduncular nucleus, dorsal and median raphes, and locus coerulus), which parallel known SERT density profiles. Such findings strongly suggest that the novel tracer ADAM is superior to the congers (i.e., IDAM) reported previously. Labeling of ADAM with [^{123}I] to produce [^{123}I]-ADAM should produce an improved and useful SPECT imaging agent for SERT within the brain.

Selective *in vitro* and *in vivo* binding of [^{125}I]-ADAM to serotonin transporters in rat brain. Choi SR, Hou C, Oya S, Mu M, Kung MP, Siciliano M, Acton PD, Kung HF. Synapse 2000 Dec 15; 38 (4), pp. 403–12.

Central Nervous System (CNS)/Serotonin Transporter (SERT)/Hypothalamus Region
[^{125}I]-ODAM/[^{125}I]-[5-iodo-2-(2-Dimethylaminomethylphenoxy)-Benzyl Alcohol]

Background Information: The SERT are the primary binding sites for selective serotonin reuptake inhibitors, which are commonly used as antidepressants (e.g., fluoxetine, sertraline, and paroxetine). Imaging of SERT with positron emission tomography (PET) and single photon emission computed tomography (SPECT) in humans would provide a useful tool for understanding how alterations of this system are related to the development of depressive illnesses and other psychiatric disorders.
Application: [^{125}I]-ODAM [(5-iodo-2-(2-dimethylaminomethylphenoxy)-benzyl alcohol, 9)] can be applied as an imaging agent for evaluating CNS SERT.
Route of Administration: [^{125}I]-ODAM (intravenous injection).
Semi-Synthetic Methods: Radioiodination and semi-synthesis of [^{125}I]-ODAM [(5-iodo-2-(2-dimethylaminomethylphenoxy)-benzyl alcohol]. A new reaction scheme has been developed for the preparation of [^{125}I]-ODAM and the corresponding tri-*n*-butyltin derivative (compound 10). Upon reacting 10 with hydrogen peroxide and sodium [^{125}I]iodide, the radiolabeling efficiency can be observed to be relatively high (95%).
Implementation: Characterization of the binding characteristics of ODAM in preparations of cortical membrane homogenates reveals a good level of affinity (K_i = 2.8 ± 0.88 nM). Using LLC-PK(1) cells specifically expressing the individual transporter (i.e., dopamine [DAT], norepinephrine [NET], and SERT, respectively), ODAM shows strong inhibition of SERT (K_i = 0.12 ± 0.02 nM). Inhibition constants for the other 2 transporters are lower (K_i = 3.9 ± 0.7 μM and 20.0 ± 1.9 nM for DAT and NET, respectively). Biodistribution following intravenous injection of [^{125}I]-ODAM (rat) shows a rapid brain uptake and washout (2.03, 1.49, 0.79, 0.27, and 0.07% dose/organ at 2, 30, 60, 120, and 240 minutes, respectively). The hypothalamus region where the serotonin neurons are located exhibits a high specific uptake. Ratios of hypothalamus-cerebellum/cerebellum based on percent dose per gram of these 2 regions reveals values of 0.35, 0.86, 0.86, 0.63, and 0.34 at 2, 30, 60, 120, and 240 minutes, post-IV injection, respectively. The specific uptake in hypothalamus can be effectively blocked by pretreatment of known SERT ligands and serves to validate the idea that this ligand displays desirable *in vitro* and *in vivo* properties as a potential SERT imaging agent.
Animal Model: Rat (cortical brain homogenates and biodistribution studies).

A novel serotonin transporter ligand: (5-iodo-2-(2-dimethylaminomethylphenoxy)-benzyl alcohol. Zhuang Z, Choi S, Hou C, Mu M, Kung M, Acton PD, Kung HF. Nucl Med Biol 2000 Feb; 27 (2), pp. 169–75.

Central Nervous System (CNS)/Stem Cell Migration: Brain/[Parkinson's Disease Research]
Gadolinium Rhodamine Dextran (GRID)/ Ex Vivo Stem Cell Labeling

Background Information: The ability to track stem cell transplants in the brain by *in vivo* neuroimaging will improve current understanding about how these cells mediate functional recovery after neural transplantation. One major challenge for the development and refinement of stem cell transplantation is to map the spatial distribution and rate of *in situ* migration.
Application: Tracking transplanted stem cells in the ischemia-damaged rat hippocampus by magnetic resonance imaging (MRI).
Route of Administration: Intravascular.
Implementation: Assessment of stem cell migration applying *in vitro* labeling of populations with the novel bifunctional contrast agent GRID prior to transplantation. Detection is achieved applying both MRI and fluorescence microscopy, or with PKH26, which can be visualized exclusively under fluorescence microscopy. At different time points following engraftment, brains are evaluated by both histology and *ex vivo* MRI.
Interpretation and Analysis: Transplanted stem cells can be identified by MRI only if prelabeled with GRID, whereas fluorescence microscopy can detect transplanted cells using either labeling reagent. Distribution of GRID-labeled stem cells established through the application of MRI corresponds with results from fluorescence microscopy analysis. Stem cells and their migration can therefore be reliably identified applying GRID-enhanced MRI methodologies.

Tracking transplanted stem cell migration using bifunctional, contrast agent-enhanced, magnetic resonance imaging. Modo M, Cash D, Mellodew K, Williams SC, Fraser SE, Meade TJ, Price J, Hodges H. Neuroimage 2002 Oct; 17 (2), pp. 803–11.

Central Nervous System (CNS)/Trauma-Induced Neurochemical Changes
[^{3}H]Glutamate/[^{3}H]MK801

Background Information: Trauma is the leading cause of death in individuals between the ages of 1 and 44 years. In the case of severe head injury, mortality can reach as high as 35–70%. Despite this fact, there has been little progress in the development of effective pharmacological agents that can provide protection in cases suffering from brain injury. To date, little is known about the mechanisms involved in neuronal cellular insult after severe head injury, especially in humans. Glutamate acts both as a primary excitatory neurotransmitter and a potential neurotoxin within the mammalian brain. Evidence indicates that hyperactivity of the glutamate system contributes to neuronal death in brain trauma. Also, in animal models of neurotrauma, such forms of neural injury are followed by gliosis, which has been linked to the severity of brain injury.
Route of Administration: Intravascular.
Implementation: Evaluate the glutamate system in conditions of brain trauma, utilizing [^{3}H]glutamate and [^{3}H]MK801 (non-competitive N-methyl-D-aspartate [NMDA]-receptor antagonist) binding and [^{3}H]glutamate uptake assays in human cerebral cortex preparations obtained from severely brain-injured and reference control victims. Additionally, Grb-2-related adaptor protein (GRAP) immunohistochemistry can be peformed to investigate gliosis following brain injury.
Interpretation and Analysis: There are no significant differences in [^{3}H]glutamate binding (affinity or density of sites) between control and head-injured subjects. In contrast, cerebral cortical [^{3}H]MK801 binding reveals both a significant increase in the density of sites (B_{MAX}) and a decrease in the dissociation constant (K_d) in the head-injured group when compared to reference controls. There are no significant differences in [^{3}H]glutamate uptake between groups. The injured brains present with an increased number of GFAP-positive astrocytes and display a more intense GFAP reaction relative to control brains. In the context of traumatic brain injury, such findings encourage further investigation into compounds capable of selectively modulating NMDA receptor subtypes in humans while also therapeutically manipulating glial cell responses following brain trauma.

Neurochemical characterization of traumatic brain injury in humans. Regner A, Alves LB, Chemale I, Costa MS, Friedman G, Achaval M, Leal L, Emanuelli T. J Neurotrauma 2001 Aug; 18 (8), pp. 783–92.

Gastrointestinal/Colon-Specific Delivery
Chitosan Powder in Hydrophobic Polymer/ Aminoalkyl Methacrylate Copolymer RS

Cellular/Molecular Mechanism of Action: A chitosan dispersed system (CDS) composed of an active ingredient reservoir and an outer drug release-regulating layer (dispersing chitosan powder in hydrophobic polymer) can collectively serve as a means of physically sequestering and protecting orally administered pharmaceutical agents until they reach the colon.
Application: Colon-specific delivery.
Implementation: An aminoalkyl methacrylate copolymer RS (Eudragit RS) is a hydrophobic polymer that has very limited solubility in acidic mediums in contrast to chitosan, which is highly soluble in low pH environments. In this context, capsules coated with chitosan dispersed hydrophobic polymer facilitate the delivery of pharmaceutical agents in a time dependent and site-specific manner. (e.g., bifunctional release characteristics).
Animal Model: Canine (e.g., beagles).
Interpretation and Analysis: The release rate of pharmaceuticals can be controlled by changing the capsule thickness. Furthermore, for colon-specific drug delivery, an additional outer enteric coating is necessary to prevent drug release from CDS capsules within the stomach, because chitosan dispersed in the layer dissolves easily under acidic conditions. The enteric-coated preparation ultimately reaches the large intestine within 1 to 3 hours after oral administration and degrades by the time of analysis at the level of the colon.

Chitosan dispersed system for colon-specific drug delivery. Shimono N, Takatori T, Ueda M, Mori M, Higashi Y, Nakamura Y. Int J Pharm 2002 Oct 1; 245 (1–2), pp. 45–54.

Gastrointestinal/Colon: Delivery
Amylose-Ethylcellulose-Coated Hydroxypropylmethylcellulose

Application: The compound 4-aminosalicylic acid can potentially be used in the treatment of diseases of the colon.
Implementation: Amylose-ethylcellulose-coated hydroxypropylmethylcellulose capsules containing 4-aminosalicylic acid Na (135 mg) and radiolabeled with [^{99m}Tc] can be utilized to delineate time release parameters when analyzed by gamma camera imaging techniques in concert with the collection of plasma and urine samples.
Considerations: The compound 4-aminosalicylic acid can potentially be used for the treatment of diseases affecting the colon. The use of amylose-ethylcellulose-coated hydroxypropylmethylcellulose capsules protects the drug until the capsule reaches the colon, where 4-aminosalicylic acid is slowly released and absorbed. Thus, such a formulation has the potential for use in the treatment of inflammatory bowel disease.
Interpretation and Analysis: Uncoated capsules break down within 10 minutes in the stomach, allowing rapid and complete absorption of the drug. In contrast, amylose-ethylcellulose-coated hydroxypropylmethylcellulose capsules remain intact in the upper gastrointestinal tract, and have a median gastric emptying time of 61 minutes (interquartile range, 77 minutes) and a median colon arrival time of 363 minutes (interquartile range, 185 minutes). In coated capsules, only the metabolite is detected in the plasma and/or urine after the capsules reaches the colon.

Colonic delivery of 4-aminosalicylic acid using amylose-ethylcellulose-coated hydroxypropylmethylcellulose capsules. Tuleu C, Basit AW, Waddington WA, Ell PJ, Newton JM. Aliment Pharmacol Ther 2002 Oct; 16 (10), pp. 1771–9.

Gastrointestinal/Colon-Selective Oral Pro-Drug Delivery/Metabolically Trapped Prodrugs/Carrier Mediated and Local Delivery
[^{125}I]UdR

Cellular/Molecular Mechanism of Action: Represents a radiopharmaceutical agent that is usually modified biochemically by a specific enzyme fraction of interest. Biochemical transformation of the parent radiopharmaceutical agent directly corresponds to local levels of the "enzyme" indicator molecule of interest. Alternatively, pro-drug forms of radiopharmaceuticals can serve as a means of delaying elimination or protecting a parent pharmaceutical compound from premature biochemical degradation prior to interaction with a desired biological target. In this context, prodrug forms of radiopharmaceuticals can accumulate or become retained within a given organ or tissue type following initial "processing." Prodrugs of several diagnostic agents can function as imaging agents, whereby their primary "targeting" strategy involves mechanisms of metabolic trapping.
Application: Selective targeting of specific cell types or tissue structures.
Synthetic Chemistry and Analysis: Design and synthesize of site-selective prodrugs for cancer radiotherapy can be derived from 5-[^{125}I]iodo-2′-deoxyuridine ([^{125}I]UdR). The prodrugs of [^{125}I]UdR designed for the purpose of targeted delivery include several derivatives with altered permeability: (i) 3′,5′-dioctanoyl; (ii) 3′,5′-dioleoyl; (iii) 3′- and 5′-*N*-alkyl-dihydropyridyl; (iv) 3′- and 5′-*N*-alkyl-dihydroisoquinolyl; (v) 3′- and 5′-*N*-alkyl-dihydroacridinyl esters of [^{125}I]-UdR; (vi) polymeric and macromolecular prodrugs of [^{125}I]-UdR for carrier-mediated or selective local delivery; (vii) metabolically trapped [^{125}I]UdR prodrugs; and (viii) glycoconjugate prodrugs for oral colon-specific delivery of [^{125}I]-UDR, [^{125}I]-UDR-5′-β-d-cellobioside, [^{125}I]-UDR-5′-β-D-glucopyranoside, [^{125}I]-UDR-5′-β-D-galactopyranoside, and [^{125}I]-UDR-5′-beta-D-glucuronide.
Considerations: A basic set of rules exist that must be utilized for the molecular design of site-selective prodrugs and various modes of their activation. Examples include the application of prodrugs and targeted delivery of radiopharmaceutical agents. Site-specific prodrugs of diagnostic radiopharmaceuticals are routinely applied in diagnostic nuclear medicine, but the instances of targeting of radiotherapeutic prodrugs are surprisingly rare.

Prodrugs in site-selective delivery of radiopharmaceuticals. Baranowska-Kortylewicz J, Kortylewicz ZP, Hoffman D, Dalrymple GV. Q J Nucl Med 1997 Jun; 41 (2), pp. 127–39.

Hematology/Macrophages: Mannosyl-Fucosyl Receptors: Macrophages
Mannosylated Liposomes

Background Information: Despite the rapid development in medicinal and pharmaceutical technology, the targeting of drugs to phagocytic cells in macrophage-related diseases still remains a major unsolved problem.

Application: Selective liposome mediated delivery to macrophage populations.
Route of Administration: Mannosylated liposomes (intravascular).
Implementation: Evaluation of liposome modalities for their ability to selectively target mannosyl-fucosyl receptors on macrophages as a potential model for targeting antileishmanial drugs encapsulated within mannosylated or fucosylated liposomes to treat leishmaniasis.
Animal Model: Hamster (experimental leishmaniasis).
Interpretation and Analysis: Mannosylated liposomes are more effective in delivering antileishmanial drugs to phagocytic cells. Liposomes loaded with an indigenous drug, andrographolide, a labdane diterpenoid isolated from Indian medicinal plant *Andrographis paniculata,* can be prepared and tested against experimental leishmaniasis in a hamster model. Mannosylated liposomes loaded with the drug are the most potent in reducing parasitic burden within the spleen as well as reducing hepatic and renal toxicity. In addition, mannosylated drug-loaded liposome-treated animals show a normal blood picture and splenic tissue histoarchitecture when compared with those treated with free drug or regular liposomal drug. Such a drug-vehicle formulation should be considered for clinical trials.

Targeting of liposomal andrographolide to L. donovani-infected macrophages *in vivo.* Sinha J, Mukhopadhyay S, Das N, Basu MK. Drug Deliv 2000 Oct–Dec; 7 (4), pp. 209–13.

Neoplasia/Carbonic Anhydrase (CA) Isoenzyme Inhibitors
Aromatic/Heterocyclic Sulfonamides

Cellular/Molecular Mechanism of Action: Carbonic anhydrase isoenzyme inhibitor.
Application: Selective inhibition of CA isoenzyme CA I.
Synthetic Chemistry and Analysis: Reaction of 20 aromatic/heterocyclic sulfonamides containing a free amino, imino, hydrazine, or hydroxyl group, with tosyl isocyanate or 3,4-dichlorophenyl isocyanate afforded 2 series of derivatives containing arylsulfonylureido or diarylureido moieties in their molecular structure, respectively.
Implementation: Molecular derivatives are assayed as inhibitors of 3 CA isozymes: CA I, II (cytosolic forms), and IV (membrane-bound form). Potent inhibition can be appreciated against all 3 isozymes but especially against CA I, which is generally 10–75 times less susceptible to inhibition by the classical sulfonamides in clinical use in contrast to the other major red cell isozyme, CA II, or membrane-bound CA IV fractions. The derivatives obtained from tosyl isocyanate are generally more potent than the corresponding ones obtained from 3,4-dichlorophenyl isocyanate.
Interpretation and Analysis: Selective inhibition of CA I can potentially lead to more selective drugs/diagnostic agents from this class of pharmacologically relevant compounds.

Carbonic anhydrase inhibitors. Inhibition of cytosolic isozymes I and II and trans-membrane, cancer-associated isozyme IX with lipophilic sulfonamides. Franchi M, Vullo D, Gallori E, Pastorek J, Russo A, Scozzafava A, Pastorekova S, Supuran CT. J Enzyme Inhib Med Chem 2003 Aug; 18 (4), pp. 333–8.

Neoplasia: Carcinoma/Pulmonary Carcinoma/Murine Lewis Lung Carcinoma
N-[2-(hydroxyethoxy)methyl]-5-[^{3}H]methyluracil (^{3}H-1)

Application: Unsuitable agent for diagnostic imaging of neoplastic disease states.
Dosage: (specific activity 188 MBq mmol-1).
Semi-Synthetic Methods: The production of tritium-labeled acyclonucleoside, *N*-[2-(hydroxyethoxy)methyl]-5-[^{3}H]methyluracil (^{3}H-3), involves synthesis from the precursor, 5-[^{3}H]-methyluracil, [^{3}H]-1, which is subsequently converted to a 2,4-bis-trimethylsilyl intermediate and then coupled with 2-acetoxyethoxymethyl bromide to yield 1-[(2-acetoxyethoxy)methyl-5-[^{3}H]methyluracil (^{3}H-2). Treatment of [^{3}H]-2 with sodium methoxide in methanol produces [^{3}H]-3 (specific activity 188 MBq/mmol).
Implementation: Evaluation of the tissue distribution of [^{3}H]-3.
Animal Model: Murine (male BDF1 mice bearing Lewis lung carcinoma).
Interpretation and Analysis: The tissue distribution of [^{3}H]-3 reveals that long bones exhibit the highest tumor-to-tissue ratios. The kidney contains the highest radioactivity level relative to tumor masses, suggesting the kidney is the major route of excretion. The primary radioactive blood component (89.21%) has a biological half-life of approximately 0.19 minutes. The title compound is unsuitable for use as a diagnostic agent for LL carcinoma because of low tumor uptake and rapid urinary elimination of injected radioactivity from the body.

Tumor uptake of radiolabeled pyrimidine bases and pyrimidine nucleosides in animal models-VIII. Synthesis and tissue distribution of *N*-[2-(hydroxyethoxy) methyl]-5-[^{3}H]methyluracil. Lee YW, Iwashina T, Gati WP, Knaus EE, Wiebe LI. Int J Appl Radiat Isot 1985 May; 36 (5), pp. 395–8.

Neoplasia/Estrogen Receptors: Mammary Carcinoma
[^{99m}Tc-N_2S_2]-Z-Aminotamoxifen/[^{99m}Tc-N_2S_2]-E-Aminotamoxifen/[Rhenium-N_2S_2]-Z-Aminotamoxifen/[Rhenium- N_2S_2]-E-Aminotamoxifen

Cellular/Molecular Mechanism of Action: Aminotamoxifen recognizes and binds to membrane-associated estrogen receptor complexes.
Application: Imaging agent for the detection and characterization of breast cancer lesions.
Route of Administration: Intravascular.
Semi-Synthetic Methods: The bifunctional chelator agent N_2S_2 is conjugated to Z- and E-aminotamoxifens through an amide linker. Both [^{99m}technetium] ([^{99m}Tc]) and rhenium can be bound to N_2S_2 through mechanisms of simple chelation.
Implementation: Detection and characterization of mammary carcinoma lesions (*in vivo*).
Interpretation and Analysis: For the Z-isomer, chelation with rhenium in the presence of sodium acetate yields a mixture of 2 isomers, anti and syn, in a 1:1 ratio. In the presence of hydroxide only the anti isomer is produced. Both the Z- and E-tamoxifen conjugates can be chelated with [^{99m}Tc] at tracer levels, yielding a single isomer product, which is assigned as anti based on chromatographic comparison to the rhenium complexes. Radiochemical yields are consistently greater than 80%, with Sep-Pak column purification yielding a final product with $>$ 99% radiochemical purity and no residual starting material. Both *in vitro* and *in vivo* biological evaluation of the tamoxifen chelates indicate very limited estrogen receptor binding.

Single isomer technetium-99m tamoxifen conjugates. Hunter DH, Luyt LG. Bioconjug Chem 2000 Mar–Apr; 11 (2), pp. 175–81.

Neoplasia/Estrogen Receptor Alpha (ERalpha): Mammary Carcinoma
4-Para-Phenylvinyl Estradiol Analogues

Cellular/Molecular Mechanism of Action: Synthetic 17α-E-(4-substituted phenyl)vinyl estradiols represent a class of ligands

that retain significant binding affinity for the ERalpha-hormone binding domain (HBD).

Application: Detection and characterization of neoplastic disease states that overexpress ERalpha-HBD applying biodistribution diagnostic procedures.

Semi-Synthetic Methods: Production of an array of 4-para-substituted phenylvinyl estradiol derivatives that can be fabricated using a combination of reagent formulations in concert with solid-phase Palladium (Pd^0)-catalyzed methods.

Interpretation and Analysis: A spectrum of compounds (e.g., n = 1 through 10) have been evaluated for binding affinity characteristics using the Eralpha-HDB isolated from transfected BL21 cell lines. Although these compounds are somewhat lower in relative binding affinity (RBA at 25°C is 1–60%) than estradiol (100%), most have higher affinity than the unsubstituted parent phenylvinyl estradiol (RBA = 9%).

Because the substituents do not generate a structure-activity relationship directly based on physicochemical properties, evaluations can be performed using molecular modeling and molecular dynamics to establish key interactions between the ligand (e.g., para substituent especially), and the protein receptor molecule. The observed relative binding affinities are directly related to the calculated binding energies. Amino acids juxtaposed to the para position play a significant but not a dominant role in binding. In particular, 4-substitution tends to increase receptor binding affinity compared to unsubstituted analogues , as exemplified by semi-synthetic product 5 (e.g., 4-$COCH_3$), which has the highest RBA value (60%) of the series of compounds. Palladium-catalyzed coupling reactions on solid support or in solution using suitably substituted iodo arenes and 17α-E-tributylstannylvinyl estradiols offer a flexible approach to preparation.

Molecular modeling studies of the receptor suggest that there exists additional ligand accessible regions within the ERalpha-HBD that can foster interactions that may enhance receptor affinity or modify efficacy in the development of new therapeutic agents. Studies to undertake modification in the properties and/or position of the aryl substituents in subsequent series to further define that role are warranted.

Synthesis and evaluation of 17alpha-20E-21-(4-substituted phenyl)-19-norpregna-1,3,5(10),20-tetraene-3,17beta-diols as probes for the estrogen receptor alpha hormone binding domain. Hanson RN, Lee CY, Friel CJ, Dilis R, Hughes A, DeSombre ER. J Med Chem 2003 Jul 3; 46 (14), pp. 2865–76.

Neoplasia/Folate Receptor Expression
Folate Liposomes

The folate receptor is a cell surface protein complex that has been identified as a tumor marker, due to its differential overexpression in several malignancies. Current research indicates that folate can be covalently attached to the surface of liposomes to mediate their selective internalization by tumor cells through the folate receptor-mediated endocytic pathway. Optimized liposome formulations, characterized by improvements in drug loading, extended residence times in the circulation, and improved drug release, have been developed to improve the biodistribution of therapeutic molecules. Theoretically, folate receptor-targeting can be combined with liposome encapsulation to synergistically affect disease outcome by enhancing the delivery of chemotherapeutic agents to neoplastic cells, while reducing systemic toxicities to normal tissues.

Folate receptor-targeted liposomes as vectors for therapeutic agents. Gosselin MA, Lee RJ. Biotechnol Annu Rev 2002; 8, pp. 103–31.

Neoplasia/Folate Receptor Expression
[^{67}Ga]Folate-DF-Folate-α/[^{67}Ga]Folate-DF-Folate-γ

Cellular/Molecular Mechanism of Action: Folate binds to its respective folate receptor complex, which is overexpressed by several neoplastic cell types. Deferoxamine functions as a chelating agent for certain radioisotopes (e.g., [$^{67}Ga^{3+}$]).

Application: Identification of folate receptor positive neoplastic lesions applying nuclear medicine imaging. In this context, folate can be used as a carrier for radioisotopes in a manner that produces an agent that can be applied as a diagnostic radiopharmaceutical. In this context, folate receptors are expressed at relatively high membrane densities by certain neoplastic cell types compared to normal cell types. Deferoxamine functions as a chelating agent for certain radioisotopes (e.g., $^{67}Ga^{3+}$).

Route of Administration: Intravascular.

Semi-Synthetic Methods: The vitamin folic acid can be covalently linked to the chelating agent deferoxamine (DF) via an amide bond using a simple carbodiimide coupling reaction. A mixture of 2 isomers, DF-folate-α and DF-folate-γ, is produced pertaining to the α- and γ-carboxyl group of folic acid, respectively. The isomers can be separated by anion-exchange chromatography and the application of NH_4HCO_3 buffer gradients.

Implementation: Evaluation of DF-folate conjugates radiolabeled with the gamma-emitting radionuclide [$^{67}Ga^{3+}$] for their ability to be internalized by cultured KB cells overexpressing folate receptor complexes.

Interpretation and Analysis: Competitive binding studies reveal that only the DF-folate-γ is recognized by the folate receptor on KB cells, which interacts with an affinity comparable to unconjugated folic acid. The cellular accumulation of [^{67}Ga]-DF-folate-γ tracer exhibits rapid uptake kinetics in cell culture with a $T_{1/2}$ of approximately 3 minutes. The KB cell association of [^{67}Ga]-DF-folate-γ is competitively blocked by free folic acid, indicating that uptake of [^{67}Ga]-DF-folate-γ is specifically mediated by the folate receptor. Because the folate receptor is overexpressed on the surfaces of many neoplastic cells, these results suggest that [^{67}Ga]-DF-folate-γ preparations might be useful as a diagnostic agent for non-invasive imaging of folate receptor-expressing tumors.

Instrumentation: Computer-integrated nuclear medicine scintigraphy imaging camera.

Preparation of ^{66}Ga- and ^{68}Ga-labeled Ga(III)-deferoxamine-folate as potential folate-receptor-targeted PET radiopharmaceuticals. Mathias CJ, Lewis MR, Reichert DE, Laforest R, Sharp TL, Lewis JS, Yang ZF, Waters DJ, Snyder PW, Low PS, Welch MJ, Green MA. Nucl Med Biol 2003 Oct; 30 (7), pp. 725–31.

Synthesis, purification, and tumor cell uptake of 67Ga-deferoxamine-folate, a potential radiopharmaceutical for tumor imaging. Wang S, Lee RJ, Mathias CJ, Green MA, Low PS. Bioconjug Chem 1996 Jan–Feb; 7 (1), pp. 56–62.

Neoplasia/Folic Acid Receptor Expression
[^{99m}Technetium] ([^{99m}Tc])-Labeled Folic Acid

Cellular/Molecular Mechanism of Action: In the context of diagnostic pharmacology, folic acid binds to folic acid receptor complexes that are variably overexpressed on the surface membrane of different neoplastic cell types.

Background Information: It is known that membrane folic acid receptors are responsible for cellular accumulation of folate and folate analogues such as methotrexate. Certain neoplastic cell types are known to overexpress folate receptors to a variable degree. In normal differentiated tissues, folate receptor expression is highly

restricted. Results of limited *in vitro* and *in vivo* animal studies suggest that folate receptors can potentially function as a targeting platform for tumor diagnostic imaging.

Application: Detection and characterization of neoplastic lesions.

Route of Administration: [^{99m}Tc]-labeled folic acid (intravenous).

Dosage: [^{99m}Tc]-labeled folic (370 KBq/rat).

Semi-Synthetic Methods: Use of ethylenedicysteine (EC) as a chelating agent for the production of [^{99m}Tc]-EC-folate.

Implementation: Evaluate the labeling efficiency of [^{99m}Tc]-labeled folic acid and its potential use as a tumor-seeking agent. Tissue distribution of [^{99m}Tc]-EC-folate can be determined by imaging at 20 minutes and 1, 2, and 4 hours (n = 3/time interval). Validation of receptor-mediated processes can be established with blocking studies utilizing the co-administration of "cold" folic acid (50 and 150 μmol/kg) in concert with [^{99m}Tc]-EC-folate in tumor-bearing *in vivo* models. Planar imaging and whole-body autoradiograms are then performed and findings compared to [^{99m}Tc]-EC (control).

Animal Model: Rats (tumor-bearing).

Interpretation and Analysis: In animal studies, tumor/blood count density ratios at 20 minutes to 4 hours increase from 0.81 ± 0.09 to 1.23 ± 0.13 with [^{99m}Tc]-EC-folate. Conversely, these values show a time-dependent decrease from 0.77 ± 0.32 to 0.65 ± 0.01 with [^{99m}Tc]-EC within the same time period. Tumor/muscle and tumor/blood count density ratios significantly decrease with folic acid co-administrations. Planar images and autoradiograms confirm that tumors can be visualized clearly with [^{99m}Tc]-EC-folate.

[^{99m}Tc]-ethylenedicysteine-folate: A new tumor-imaging agent. Synthesis, labeling, and evaluation in animals. Ilgan S, Yang DJ, Higuchi T, Zareneyrizi F, Bayhan H, Yu D, Kim EE, Podoloff DA. Cancer Biother Radiopharm 1998 Dec; 13 (6), pp. 427–35.

Neoplasia/Folic Acid Receptors/Ovarian Cancer/ Sensitivity and Specificity of Detection *[^{111}Indium] ([^{111}In])-Diethylenetriamine Pentaacetic Acid (DTPA)-Folate*

Cellular/Molecular Mechanism of Action: [^{111}In]-DTPA-folate is a radioactive chelation analogue of folic acid that binds to folate receptors.

Background Information: Folate receptor complexes are overexpressed at relatively high membrane densities by certain neoplastic cell types. The cell-membrane folate receptor is a potential molecular target for tumor-selective diagnostic and therapeutic pharmaceutical delivery.

Route of Administration: [^{111}In]-DTPA-folate (intravenous bolus).

Implementation: Evaluation of the effectiveness of [^{111}In]-DTPA-folate to selectively detect conditions of ovarian and endometrial neoplastic disease.

Applied as a diagnostic agent, whole-body images are obtained at 30 minutes, 4 hours, and (e.g., for the 1st 19 patients) 24 hours after injection; single photon emission computed tomography (SPECT) can also be performed at the delayed imaging time schedules as a validation procedure. To determine the influence of folate loading on tracer biodistribution, unlabeled "free" folic acid can be administered before injection of [^{111}In]-DTPA-folate (e.g., n = 19 cases).

Human Model: Female cases of ovarian cancer (e.g., n = 35) enrolled in a phase I/II clinical study (e.g., n = 33 completing the surgical follow-up required by the study protocol for definition of disease status). Individual cases either have a pathologically proven malignancy or are scheduled for surgery for suspected new ovarian cancer (e.g., n = 26), recurrent ovarian cancer (e.g., n = 5), or endometrial cancer (e.g., n = 2).

Interpretation and Analysis: In cases subjected to surgical intervention, slightly less than half have new or recurrent malignant tumors that can be detected (e.g., n = 14/33). A large percentage of newly diagnosed ovarian carcinomas can be identified blindly by multiple trained professionals (e.g., n = 7/7 or 100% sensitivity). Sensitivity for the detection of recurrent malignancies is approximately 38% (e.g., n = 3/7) for masked readings, compared to 85% for unmasked readings (e.g., n = 6/7), indicating that correlation with anatomic imaging studies (computed tomography) is highly important in the diagnosis of such lesions. A number of cases will be determined to have benign masses (e.g., n = 18). In the context of a limited population size, the specificity of [^{111}In]-DTPA-folate scintigraphy has been found to be approximately 76% and 82% for the masked and unmasked analyses, respectively. [^{111}In]-DTPA-folate is safe, and possibly effective, for scintigraphy differentiating between malignant and benign ovarian masses.

Evaluation of [^{111}In]-DTPA-folate as a receptor-targeted diagnostic agent for ovarian cancer: Initial clinical results. Siegel BA, Dehdashti F, Mutch DG, Podoloff DA, Wendt R, Sutton GP, Burt RW, Ellis PR, Mathias CJ, Green MA, Gershenson DM. J Nucl Med 2003 May; 44 (5), pp. 700–7.

Neoplasia/Multidrug Resistance-Associated Protein (MRP)/[Leukemia] *[^{99m}Technetium] ([^{99m}Tc])-Tetrofosmin (TF)/Verapamil*

Cellular/Molecular Mechanism of Action: Tetrofosmin is a substrate molecule for MRP expressed by certain neoplastic cell types.

Application: Detection and characterization of neoplastic cell types (e.g., leukemia) that possess resistance to chemotherapeutic intervention due to overexpression of MRP. Identification of such characteristics can provide prognostic information and the basis for the design of alternative therapeutic intervention strategies.

Route of Administration: [^{99m}Tc]-TF (intravenous).

Implementation: Evaluation of the kinetics of cellular accumulation and retention of [^{99m}Tc]-TF in leukemia wild-type cell lines and its corresponding chemotherapeutic-resistant cell line to determine if [^{99m}Tc]-TF is a substrate for MRP with and without the presence of verapamil.

Tissue Culture Model: Leukemia wild-type HL60/WT cell line and its corresponding doxorubicin-resistant HL60/DOX cell line that overexpresses MRP but without P-glycoprotein (Pgp) overexpression (37°C).

Interpretation and Analysis: [^{99m}Tc]-TF net accumulation is significantly lower in HL60/DOX (1.35 ± 0.23%) than in HL60/WT (12.79 ± 0.47%) at 60 minutes ($p < 0.001$). Three minutes after exchanging the incubation solution to the tracer-free medium, only 18.20 ± 0.34% of [^{99m}Tc]-TF remains in HL60/DOX, whereas 84.74 ± 0.65% is retained in HL60/WT ($p < 0.001$). In the presence of verapamil (10 μM), [^{99m}Tc]-TF net accumulation in HL60/DOX is 302% of the control and washout is significantly delayed. [^{99m}Tc]-TF therefore appears to be a substrate for MRP and [^{99m}Tc]-TF may be used as a functional *in vivo* imaging agent of profiling MRP expression.

Technetium-99m-tetrofosmin would be a substrate for multidrug resistance-associated protein (MRP): Comparison between a leukemia cell line with high MRP gene expression and its parental cell line. Li XF, Kinuya S, Yokoyama K, Konishi S, Ma YY, Watanabe N, Shuke N, Bunko H, Michigishi T, Tonami N. Cancer Biother Radiopharm 2001 Feb; 16 (1), pp. 17–23.

Neoplasia/Multidrug Resistance Protein (MRP)/ Predicted Chemotherapeutic Response Rate/ Osteosarcoma
[^{99m}Technetium] ([^{99m}Tc])-Methoxyisobutylisonitrile (MIBI)/[^{99m}Tc]-MIBI Washout Rate

Cellular/Molecular Mechanism of Action: [^{99m}Tc]-MIBI is a pharmaceutical substrate transported by the multidrug resistance (MDR)-related proteins.

Background Information: *In vitro* studies have demonstrated that [^{99m}Tc]-MIBI is a transport substrate of MDR-related proteins. Minimal information is available about the potential of [^{99m}Tc]-MIBI scintigraphy as a functional imaging tool for the *in vivo* detection of MRP expression in osteosarcoma, or the role of MRP and [^{99m}Tc]-MIBI imaging for the prediction of clinical outcomes.

Application: Detection and characterization of MRP expression in neoplastic disease states (e.g., osteosarcoma) in a manner that can assist in predicting response to therapeutic intervention.

Implementation: Evaluation of osteosarcoma conditions before and after initiation of chemotherapy. Tumor-to-background ratios of both early (10 minutes) and delayed (1 hour) images and the percentage washout rate (WR%) of [^{99m}Tc]-MIBI can subsequently be calculated. Immunohistochemical analysis of MRP and P-glycoprotein (Pgp) can be performed on biopsy specimens, and the response to preoperative chemotherapy assessed by histopathologic examination. In this manner, it is possible to determine if scintigraphic parameters are of any benefit in distinguishing the functional capacity of Pgp and MRP.

Human Model: Cases of osteosarcoma (n = 24).

Interpretation and Analysis: Approximately 62.5% of osteosarcomas display significant MRP expression levels (e.g., n = 15/24).

The level of MRP expression significantly correlates with WR% of [^{99m}Tc]-MIBI (r = 0.58, p = 0.003), and the WR% of [^{99m}Tc]-MIBI is significantly faster in cases with high MRP expression than in those with a low MRP score (p = 0.007). The clearance rate of [^{99m}Tc]-MIBI is significantly slower in tumor tissue samples with negative or low expression of both Pgp and MRP (16% ± 6.2%) when compared with osteosarcomas that express high levels of both proteins (31.7% ± 8.7%) (p = 0.001). There appears not to be a significant difference between the WR% of [^{99m}Tc]-MIBI in tumors with co-expression of both proteins and in tumors with high expression of either Pgp or MRP. Both the rate of MRP expression and the WR% of [^{99m}Tc]-MIBI significantly correlate with response rate. Therefore, the WR% of [^{99m}Tc]-MIBI correlates with MRP expression levels. Both the WR% of [^{99m}Tc]-MIBI and MRP expression correlate with response to therapeutic intervention. [^{99m}Tc]-MIBI, therefore, is valuable as a general probe for functional imaging of both Pgp and MRP; however, it is not capable of differentiating the functional status of either MDR-related glycoprotein.

^{99m}Tc-MIBI imaging as a predictor of therapy response in osteosarcoma compared with multidrug resistance-associated protein and P-glycoprotein expression. Burak Z, Moretti JL, Ersoy O, Sanli U, Kantar M, Tamgac F, Basdemir G. J Nucl Med 2003 Sep; 44 (9), pp. 1394–401.

Neoplasia/Multidrug Resistance Protein (MDR)/ P-Glycoprotein (PgP) Transport Activity/[Mammary Carcinoma]/[Lung Tumor]
[^{99m}Tc(CO)$_3$(MIBI)$_3$] + (Tc-CO-MIBI)/LY335979 (MDR Modulator)

Cellular/Molecular Mechanism of Action: [^{99m}Tc(CO)$_3$(MIBI)$_3$]+ (Tc-CO-MIBI) can function as a transport substrate for MDR 1 (Pgp).

Background Information: Multidrug resistance mediated by the overexpression of MDR1 Pgp is 1 of the best characterized barriers limiting chemotherapeutic intervention in conditions of neoplastic disease. Furthermore, the protective function of Pgp-mediated efflux of xenobiotics in various organs has a profound effect on the bioavailability of drugs in general. Thus, there is an expanding requirement to non-invasively interrogate Pgp transport activity *in vivo*.

Application: Detection and characterization of MDR/Pgp transport function and genetic expression. Secondary applicability includes delineation of their capacity to evaluate the efficacy of inhibitors of MDR/Pgp transport biological function and genetic expression.

Implementation: Evaluation of the recognition properties (binding avidity) of [^{99m}Tc](I)-tricarbonyl complexes in the form of [^{99m}Tc(CO)$_3$(MIBI)$_3$] + (Tc-CO-MIBI) for Pgp fractions.

***Ex Vivo* Model:** Drug sensitivity KB 3-1 cell lines; colchicine-selected drug-resistant KB 8-5 cell types; chemotherapeutic-sensitive MCF-7 mammary carcinoma cell lines; H69 lung tumor cell lines.

Animal Model: Murine (mdr1a/1b(-/-) gene deleted mice and wild-type mice.

Interpretation and Analysis: Tc-CO-MIBI has a 60-fold higher accumulation in drug-sensitive KB 3-1 cells compared to colchicine-selected drug-resistant KB 8-5 cells. In KB 8-5 cells, tracer enhancement can be achieved with the potent MDR modulator LY335979 (EC50 = 62 nM). Similar behavior can be observed using drug-sensitive MCF-7 breast adenocarcinoma cells and MCF-7/MDR1 stable transfectants, thereby confirming that Tc-CO-MIBI is specifically excluded by MDR1 Pgp overexpression. By comparison, net accumulation in control H69 lung tumor cells is 9-fold higher than in MDR-associated protein (MRP1)-expressing H69AR cells, indicating only modest transport by MRP1. Biodistribution analysis following tail vein injection of Tc-CO-MIBI shows delayed liver clearance as well as enhanced brain uptake and retention in MDR-gene-deleted mice vs wild-type mice, directly demonstrating that Tc-CO-MIBI is a functional *in vivo* probe for detecting Pgp transport activity.

Characterization of a novel [^{99m}Tc]-carbonyl complex as a functional probe of MDR1 P-glycoprotein transport activity. Dyszlewski M, Blake HM, Dahlheimer JL, Pica CM, Piwnica-Worms D. Mol Imaging 2002 Jan–Mar; 1 (1), pp. 24–35.

Neoplasia/Sigma Receptors/Mammary Carcinoma
N-(N-Benzylpiperidin-4-yl)-2-[^{18}F]-Fluorobenzamide/ Haldol

Cellular/Molecular Mechanism of Action: *N*-(*N*-benzylpiperidin-4-yl)-2-[^{18}F]-fluorobenzamide physically binds to membrane-associated sigma receptor complexes.

Background Information: Sigma receptor complexes are expressed in a relatively selective manner by human mammary carcinoma cell types.

Application: *N*-(*N*-benzylpiperidin-4-yl)-2-[^{18}F]-fluorobenzamide can potentially function as a diagnostic ligand for PET imaging of breast cancer lesions that express sigma receptor complexes at relatively high membrane densities.

Route of Administration: *N*-(*N*-benzylpiperidin-4-yl)-2-[^{18}F]-fluorobenzamide (most frequently by intravascular injection).

Implementation: Detection of mammary carcinoma neoplastic lesions *in vivo* applying *N*-(*N*-benzylpiperidin-4-yl)-2-[^{18}F]-fluorobenzamide and positron emission tomography (PET) imaging modalities.

Animal Model: Mice (severe combined immunodeficient [SCID] mice bearing MDA-MB231 tumor and native wild-type explants of human mammary carcinoma).

Interpretation and Analysis: *In vivo* studies in SCID mice bearing MDA-MB231 tumors reveal a (i) high uptake of compound 2 in neoplastic lesions (3.8%/g); and (ii) ratios of tumor/muscle and tumor/blood of approximately 6.2 and 7.0, respectively, at 1 hour postinjection. Pretreatment of SCID mice with haldol increases the uptake of compound 2 in blood, muscle, and other well-perfused organs, while decreasing its uptake by tumors. The ratios of tumor/muscle and tumor/blood decrease from 6.2 and 7.0 to 1.3 and 1.1, respectively, at 1 hour postinjection. At 2 hours postinjection, the ratios of tumor/muscle and tumor/blood decrease from 4.9 and 7.8 to 1.4 and 1.4, respectively. The tumor uptake of compound 2 in SCID mice bearing primary tumor explants from human cases of breast cancer is lower than observed with MDA-MB231 tumors (1.66%/g vs 3.78%/g), and the ratios of tumor/muscle and tumor/blood are 3.5 and 3.7, respectively, at 1 hour postinjection. These results suggest that compound 2 may be a potential ligand for PET imaging of breast cancer.

N-(*N*-benzylpiperidin-4-yl)-2-[^{18}F]fluorobenzamide: A potential ligand for PET imaging of breast cancer. Shiue C, Shiue GG, Benard F, Visonneau S, Santoli D, Alavi AA. Nucl Med Biol 2000 Nov; 27 (8), pp. 763–7.

Neoplasia/Sigma-2 Receptor Complexes (σ2-Opioid)/Mammary Adenocarcinoma *[^{99m}Technetium] ([^{99m}Tc])-Sigma-2 Receptor Ligand*

Cellular/Molecular Mechanism of Action: [^{99m}Tc]-labeled [(*N*-[2-((3′-N′-propyl-[3,3,1]aza-bicyclononan-3α yl)(2′′-methoxy-5-methyl-phenylcarbamate)(2-mercaptoethyl)amino)acetyl]-2-aminoethanethiolato] technetium(V) oxide), [^{99m}Tc]$_2$, displays specific binding avidity toward sigma-2 receptor complexes (σ2-opioid).

Note: Pentazocine is an agonist at κ-opioid receptors and a weak agonist at μ-opioid receptors and is classified as a mixed opioid because it functions as an agonist at some opioid receptors and an antagonist at other.

Application: Detection and characterization of neoplastic disease states associated with the expression of σ2-opioid receptor complexes (e.g., human mammary carcinoma).

Route of Administration: Intravenous.

Semi-Synthetic Methods: Preparation of [^{99m}Tc]$_2$ can be achieved by heating the S-protected starting material, "1," in the presence of acid, a reducing agent (stannous glucoheptonate) and sodium [^{99m}Tc]pertechnetate. The lipophilic racemic mixture can be successfully prepared at a yield of 10–50% and with a radiochemical purity of > approximately 98%. Separation of the isomers, recognized as peak A and peak B, can be successfully achieved by using a chiralpak AD column eluted with an isocratic solvent (n-hexane/isopropanol; 3:1; v/v). The peak A and peak B appear to co-elute with the isomers of the surrogate, Re-2, under the same HPLC condition.

Implementation: Conduction of *in vitro* binding assays for the rhenium surrogate of [^{99m}Tc]$_2$, determination of Re-2 binding affinity, and delineation of selectivity toward sigma-2 receptors. Biodistribution studies in conditions of mammary carcinoma.

Animal Model: Murine (mouse mammary adenocarcinoma, cell line 66 that overexpresses sigma-2 receptor complexes).

Interpretation and Analysis: *In vitro* binding assays show that rhenium (Re-2) displays excellent binding affinity and selectivity toward sigma-2 receptors (K_i = 2,723 and 22 nM for sigma-1 and sigma-2 receptor, respectively). Biodistribution studies in tumor-bearing mice (mammary adenocarcinoma) reveal that racemic [^{99m}Tc]$_2$ localizes within neoplastic lesions. Uptake in the tumor is 2.11, 1.30, and 1.11 %dose/gram at 1, 4, and 8 hours postinjection, respectively. Such findings suggest good uptake and retention within tumor cells. Tumor uptake is significantly, but incompletely, blocked (about 25–30% blockage) by co-injection of "cold" (+)pentazocine or haloperidol (1 mg/Kg). A majority of the radioactivity localizes within the tumor tissue can be extracted (> 60%), and HPLC analysis shows that it is the original parent compound (racemic [^{99m}Tc]$_2$ purity ≥ 98%). Distribution of purified HPLC peak A and HPLC peak B can be detected in the same tumor-bearing mice at 4 hours postinjection. Tumor uptake is similar for both isomers, but the blood and peripheral tissue content for the isomer in peak B is higher than that for the isomer in peak A. It is evident that the isomer in peak A possesses significantly better tumor/blood and tumor/muscle ratios. The higher rate of *in vivo* metabolism can be confirmed by the higher thyroid uptake values for the peak B isomer when compared to the peak A isomer. Therefore, the [^{99m}Tc]-labeled sigma receptor imaging agent, [^{99m}Tc]$_2$, has demonstrated the feasibility of using a [^{99m}Tc]-labeled agent for recognizing sigma receptor complexes as a means of detecting certain forms of neoplastic disease.

Development of a Tc-99m labeled sigma-2 receptor-specific ligand as a potential breast tumor–imaging agent. Choi SR, Yang B, Plossl K, Chumpradit S, Wey SP, Acton PD, Wheeler K, Mach RH, Kung HF. Nucl Med Biol 2001 Aug; 28 (6), pp. 657–66.

Neoplasia/Topoisomerase I & II/Adenocarcinoma (HT29)/Gliobastoma (U87MG)/Melanoma (A375M Antigen Positive) *[^{11}C]-9-Methoxyphenazine-1-Carboxamide/ [^{11}C]2-(4-Pyridyl)Quinoline-8-Carboxamide/ [^{11}C]DACA/[Topoisomerases I & II]*

Cellular/Molecular Mechanism of Action: The tricyclic carboxamide *N*-[2-(dimethylamino)ethyl]acridine-4-carboxamide (DACA) is a DNA-intercalating agent capable of inhibiting both topoisomerases I and II enzyme fractions.

Background Information: The tricyclic carboxamide DACA is currently in phase II clinical trials. Many related analogues have been developed, but despite their potent *in vitro* cytotoxicities, they exhibit poor extravascular distribution.

Application: Delineation of rational therapeutic drug selection.

Semi-Synthetic Methods: Each candidate compound shares a common structural feature (e.g., *N*-dimethyl side chain), which is radiolabeled with the positron-emitting radioisotope, (e.g., carbon-11).

Implementation: Evaluate the biodistribution and metabolite profiles of the prototype compound, DACA, with 3 analogues to aid rational drug selection in order to identify agents that are "minimal intercalators" with lower DNA association constants. In this fashion, promising candidates will be identified in emerging preclinical studies in animals that can ultimately be evaluated in humans using positron emission tomography (PET).

Animal Model: Murine (mice bearing human tumor xenografts).

Interpretation and Analysis: Acridine DACA, phenazine SN 23490, pyridoquinoline SN 23719, and dibenzodioxin SN 23935 are cytotoxic when evaluated applying *in vitro* assays utilizing HT29, U87MG, and A375M cell lines (IC_{50} of 1.4 of 1.8 μM, 0.4 of 0.6 μM, 1.3 of 1.6 μM, and 24 of 36 μM, respectively). *Ex vivo* biodistribution studies with [^{11}C]- radiolabeled compounds in mice bearing human tumor xenografts show rapid clearance of [^{11}C] radioactivity (parent drug and metabolites) from blood and major organs. Rapid hepatobiliary clearance and renal excretion can also be observed. There is low [< 5% of injected dose/gram (%ID/g)] and variable uptake of [^{11}C] radioactivity in 3 tumor types for all of the com-

pounds. Tumor (U87MG) to blood [^{11}C]-radioactivity ratios for [^{11}C]DACA, [^{11}C]-(9-methoxyphenazine-1-carboxamide (SN 23490), [^{11}C]2-(4-pyridyl)quinoline-8-carboxamide (SN 23719), and [^{11}C]dibenzo[1,4]dioxin-1-carboxamide (SN 23935) at 30 minutes are approximately 2.9 ± 1.1, 2.3 ± 0.6, 2.6 ± 0.6, and 0.7 ± 0.2, respectively. For SN 23719, the distribution of [^{11}C]-radioactivity in normal tissues and tumors determined *ex vivo* is in broad agreement with findings determined *in vivo* by whole-body PET scanning. [^{11}C]DACA is rapidly and extensively metabolized to several plasma metabolites and a major tumor metabolite. Alternatively, [^{11}C]SN 23935, [^{11}C]SN 23490, and [^{11}C]SN 23719 show less extensive metabolism. In tumor samples, parent [^{11}C]DACA and [^{11}C]SN 23935 is present at between 0.3 and 1.5 %ID/g, whereas [^{11}C]SN 23490 and [^{11}C]SN 23719 is present at between 1.5 and 2.8 %ID/g. Therefore, by using a strategy employing [^{11}C]-labeling, it is possible to determine the tissue distribution and metabolic stability of novel tricyclic carboxamides.

Given the objective of identifying analogues with potentially improved *in vivo* activity against solid tumors, the agents SN 23490 and SN 23719 have more favorable distribution and metabolic stability compared with DACA and SN 23935. Such observations suggest that further development and evaluation are warranted. The radiolabeling strategy used allows *ex vivo* and *in vivo* evaluation of promising anticancer agents in animals and offers the potential of rapid translation to studies in humans using PET.

Comparative biodistribution and metabolism of carbon-11-labeled *N*-[2-(dimethylamino)ethyl]acridine-4-carboxamide and DNA-intercalating analogues. Osman S, Rowlinson-Busza G, Luthra SK, Aboagye EO, Brown GD, Brady F, Myers R, Gamage SA, Denny WA, Baguley BC, Price PM. Cancer Res 2001 Apr 1; 61 (7), pp. 2935–44.

PEPTIDES, PROTEINS AND IMMUNOGLOBULINS

General Concepts: Immunoglobulin-Based Delivery Modalities/Monoclonal Antibody Production for Specific Antigens

Immunotherapy for reversal of toxicity due to poisons and drugs is not new. However, refinements in antibody isolation and purification, as well as the advancement of hybridoma technology and recombinant DNA biotechnology, has led to a new generation of immunotherapeutic and diagnostic agents. The advent of monoclonal antibody technology in 1975 heralded the new age of immunopharmacology and immunotoxicology. Monoclonal antibodies designed for a specific antigen have resolved the problem of polyclonality and cross-reactivity of traditional antibodies. Along with the production and isolation of active antibody fragments from both polyclonal and human monoclonal sources, as well as the ability to tailor-make chimeric antibodies by recombinant biotechnology, the development of novel immunotherapeutic agents has taken place. Two immunotherapeutic modalities, digoxin-specific antibody fragments (Fab) and snake antivenin, have been available for the clinician's armamentarium for years. Along the same lines of antidigoxin Fab development, application of newer antibody isolation technology has led to a purified IgG(T) antibody for snake venom poisoning, which is still in the developmental stages. Potential future developments in immunotherapeutics must overcome the clinical problems of immunogenicity and adverse reactions to the antibodies. Human monoclonal sources, active antibody fragments, and chimeric antibodies from transfectomas are all potential resolutions to these problems.

Immunotherapy in the poisoned patient. Overview of present applications and future trends. Sullivan JB Jr. Med Toxicol 1986 Jan–Feb; 1 (1), pp. 47–60.

General Concepts/Immunoglobulin: Monoclonal Antibody Delivery Platforms

Antibodies, specifically monoclonal antibodies, are potentially very useful and powerful carriers of therapeutic agents and diagnostic detection modalities to "target" tissues or lesions. The loading or charging of antibodies with agents, especially radiotracers, has been extensively described in the literature. The choice of radioisotope for immunodetection and/or immunotherapy is based on its availability, half-life, nature of the radiation emitted, and the metabolic pathways of the radionuclide in the body. Most important of all are the derivatization techniques available for labeling antibody with a given radionuclide. Isotopes of iodine and divalent metal ions are the most commonly used radionuclides. Antibodies labeled with iodine at tyrosine residues are metabolized *in vivo* rather rapidly. Such events lead to the incorporation of metabolized radioactive iodine into various tissues, mainly the thyroid gland and stomach, and to the accumulation of high levels of circulating iodine in the blood, which masks tumor uptake considerably. To overcome these limitations, the use of iodohippurate as an iodine-anchoring molecule to the protein has been considered. When divalent or multivalent metal ions are used as the preferred radionuclide, bifunctional chelating reagents such as ethylenediaminepentaacetic acid (EDTA) or diethylenetriamine pentaacetic acid (DTPA) are 1st coupled to the protein or antibody. These chelating molecules are attached to the protein by the formation of an isopeptide linkage between the carboxylate of the chelating reagent and the amino group of the protein. Several procedures are available to generate the isopeptide linkage. When the anchoring of the chelating agent through isopeptide linkage results in the inactivation of the antibody, periodate oxidation of the carbohydrate moiety of the antibody, followed by reductive coupling of chelator, could be considered as an alternative. There is still a need for better, simpler, and more direct methods for labeling antibodies with radionuclides.

Labeling of monoclonal antibodies with radionuclides. Bhargava KK, Acharya SA. Semin Nucl Med 1989 Jul; 19 (3), pp. 187–201.

Amyloidosis of Beta$_2$ (Microglobulin) *[^{111}Indium] ([^{111}In])-Rhbeta$_2$mH5*

Cellular/Molecular Mechanism of Action: Beta$_2$-microglobulin (beta$_2$m) recognizes and physically (chemically) binds to amyloid of beta$_2$m origin.

Background Information: Amyloid of beta$_2$m origin can be diagnosed using [^{131}I]-radiolabeled-beta$_2$m scintigraphy in cases with uremia and managed with hemodialysis treatment. As the tracer beta$_2$m molecule is isolated from another affected case, it carries the common risks, including viral infections such as hepatitis B and C and human immunodeficiency virus (HIV), that are known to be associated with human plasma products.

Application: The *in vitro* production of recombinant human beta$_2$m yields a protein fraction that is devoid of any potential risk of exposing recipients to various viral pathogens. Purified protein fractions can then be radiolabeled for the purpose of detecting and characterizing various conditions of amyloidosis.

Route of Administration: [^{111}In]-rhbeta$_2$mH5 (intravenous).

Semi-Synthetic Methods: Beta$_2$m-type amyloid can be produced *in vitro* as recombinant human beta$_2$m (rhbeta$_2$m) in *Escherichia coli* populations. The expression vector pASK40Delta Lbeta$_2$m(His)5 can be used due to it containing a C-terminal (His)5-tag for purification via immobilized metal ion affinity chromatography (IMAC). Size exclusion chromatography on a Superose 12 column can be used as a 2nd purification step. The isolated rhbeta$_2$mH5

reacts in an immunochemically identical manner to native human $beta_2$m, and can be identified as a single band of approximately 11.8 kDa when analyzed by Western blot immunodetection methodologies. Additionally, fractions can be visualized as a single spot in 2-dimensional gel electrophoresis (2D-PAGE: expected molecular mass = 12,415.8 Da). Uniformity can be further established by crystallization and N-terminal amino acid sequence analysis.

Implementation: Evaluation of $beta_2$m-amyloidosis conditions applying sterile preparations of rhbeta$_2$mH5 radiolabeled with [^{111}In] to produce [^{111}In]-rhbeta$_2$mH5.

Human Model: Cases managed with hemodialysis (± known $beta_2$m-amyloidosis).

Interpretation and Analysis: The [^{111}In]-rhbeta$_2$mH5 tracer localizes specifically within particular areas known to contain amyloid. Recombinant rhbeta$_2$mH5 preparations therefore are suitable for the *in vivo* detection of deposits of $beta_2$m-type amyloid contained within organs and fulfills the requirements of a tracer for common use. Finally, the use of [^{111}In] instead of [^{131}I] reduces the radioactive load and results in higher lesion resolution.

Production of recombinant human $beta_2$-microglobulin for scintigraphic diagnosis of amyloidosis in uremia and hemodialysis. Linke RP, Schäeffer J, Gielow P, Lindner P, Lottspeich F, Plückthun A, Weiss EH. Eur J Biochem 2000 Feb; 267 (3), pp. 627–33.

Cardiovascular Endothelium/E-Selectin Complexes
Liposomes: Anti-(E-Selectin) Directed/ [Immunoliposomes]/Dithionite/Pyranine

Cellular/Molecular Mechanism of Action: E-selectin is expressed on the exterior surface membrane of endothelial cell populations.

Background Information: Previous *in vitro* experiments have demonstrated that the targeting of immunoliposomes to vascular selectins is a potential strategy for selective drug delivery to sites of inflammation.

Application: Detection and characterization of vascular endothelium.

Route of Administration: Intravenous.

Implementation: Evaluation of the cellular uptake of targeted immunoliposomes by interleukin-1 activated human endothelial cells detected by utilizing spectroscopy and microscopic fluorescence techniques. In order to follow the fate of liposomes after binding to target sites, the route and degree of liposome internalization is established with the analytical focus directed toward the analysis of cell activation state or various liposomal parameters (e.g., sterical stabilization, type of antibody, or antibody coupling strategy).

Interpretation and Analysis: In attempts to further adapt the targeting strategies for physiological conditions, it has been established that E-selectin-directed immunoliposomes can cumulatively bind to target cells under simulated shear force conditions of capillary blood flow for up to 18 hours. The use of nitrobenzoxadiazole (NBD)-labeled liposomes and subsequent fluorescence quenching outside the cells with dithionite show that circa 25% of the targeted immunoliposomes become internalized. According to inhibition experiments with agents that interfere with the endocytotic pathway, it has been determined that the major mechanism of liposome entry is endocytic. Cellular entry involves, at least in part, receptor-mediated endocytosis via E-selectin, with liposome accumulation occurring within the endosomes, and their acidification has been determined using pyranine spectroscopy. Furthermore, microscopy has demonstrated that a fusion of liposomes with the cell membrane occurs, followed by a release of entrapped calcein into the cytoplasm. Such observations have provided greater insight into the behaviour of E-selectin-targeted immunoliposomes and indicate that these immunoliposomes have great potential for use as drug carriers for intracellular drug delivery at inflammatory sites.

Investigation of the cellular uptake of E-selectin-targeted immunoliposomes by activated human endothelial cells. Kessner S, Krause A, Rothe U, Bendas G. Biochim Biophys Acta 2001 Oct 1; 1514 (2), pp. 177–90.

Cardiovascular Endothelial Growth Factor (VEGF) Receptor
Vascular Endothelial Growth Factor

Cellular/Molecular Mechanism of Action: Angiogenesis is stimulated by VEGF acting via endothelial cell-specific receptors, such as VEGFR-2, that are overexpressed at sites of angiogenesis.

Background Information: Fusion protein VEGF with a large N-terminal extension retains biological activity and can facilitate the development of VEGF-based vehicles for receptor-mediated delivery modalities pertaining to both therapeutic and diagnostic agents.

Application: Selective "targeting" of vascular endothelial cell populations as a delivery modality.

Semi-Synthetic Methods: The generation of VEGF fusion proteins can be constructed in *Escherichia coli*. Purified VEGF fusion proteins containing a 158-amino acid N-terminal extension fused to human VEGF(121), VEGF(165), and VEGF(189) have been produced in this fashion.

Interpretation and Analysis: In living systems, VEGF fusion proteins induce tyrosine autophosphorylation of VEGFR-2 and its downstream targets, as well as cell contraction in cells overexpressing VEGFR-2. Although N-terminal extensions decrease the affinity of VEGF fusion proteins to VEGFR-2, at saturating concentrations these proteins are as efficient as correct size VEGF(165). It has been proposed that VEGF fusion proteins may be employed for targeting endothelial cells at the sites of angiogenesis.

Functionally active VEGF fusion proteins. Backer MV, Backer JM. Protein Expr Purif 2001 Oct; 23 (1), pp. 1–7.

Cardiovascular: Endothelium/Platelet Endothelial Cell Adhesion Molecule-1 (PECAM-1)/Pulmonary Vascular Endothelium: Selective Targeting/Cardiac Endothelium Targeting: Selective Catheter Delivery
Anti-PECAM-[Beta-Galactosidase]

Cellular/Molecular Mechanism of Action: Anti-PECAM-1 IgG or IgG fragments recognize and physically bind to membrane-associated PECAM-1 complexes expressed on the exterior surface membrane of vascular endothelial cell populations.

Background Information: Therapeutic molecules conjugated with antibodies directed against PECAM-1 accumulate in the pulmonary endothelium after IV injection (e.g., mice).

Application: Modality for selective delivery to vascular endothelium.

Route of Administration: Anti-PECAM (intravascular including via selective catheter placement within the right pulmonary artery).

Implementation: Characterization of PECAM-directed targeting of the lung and heart after local injection compared to systemic intravascular administration. Complementary investigations can entail the estimation of the effectiveness of targeting facilitated by utilization of the active reporter enzyme, beta-galatosidase in the form

of streptavidin-conjugated beta-galactosidase (beta-gal), which can subsequently be coupled to anti-PECAM or IgG (anti-PECAM/beta-gal and IgG/beta-gal). Utilization for *in vivo* investigations entails direct injection into the right coronary artery (RCA).

Animal Model: Swine.

Interpretation and Analysis: Radiolabel tracing shows that 1 hour postintravenous injection, 35% of anti-PECAM vs 2.5% of control IgG accumulates within the lung. Infusion of anti-PECAM via a catheter placed in the right pulmonary artery (RPA) results in a 3-fold elevation in uptake within the right lower lobe and 2-fold reduction of uptake in the left lobes in the lung. Cardiac uptake of anti-PECAM is negligible after intravenous and right pulmonary artery infusion. Alternatively, delivery with a catheter placed in the RCA results in a 4-fold elevation of cardiac uptake of anti-PECAM, but not IgG, compared with intravenous injection. Beta-gal activity is markedly elevated within the heart and lungs (5- and 25-fold increase, respectively) after injection of anti-PECAM/beta-gal, but not IgG/beta-gal. Endothelial targeting of anti-PECAM/beta-gal in the heart and lungs can be confirmed by imaging analysis. In summary, anti-PECAM antibody conjugates can deliver agents to the pulmonary endothelium regardless of injection route, whereas local arterial infusion permits targeting of the cardiac vasculature. This paradigm may be useful for drug targeting to endothelium in lungs, heart, and possibly other organs.

Platelet-endothelial cell adhesion molecule-1-directed immunotargeting to cardiopulmonary vasculature. Scherpereel A, Rome JJ, Wiewrodt R, Watkins SC, Harshaw DW, Alder S, Christofidou-Solomidou M, Haut E, Murciano JC, Nakada M, Albelda SM, Muzykantov VR. J Pharmacol Exp Ther 2002 Mar; 300 (3), pp. 777–86.

Cardiovascular Endothelium/Intercellular Adhesion Molecule (ICAM) Expression/Microvascular (Endothelial) Leukocyte Receptor Complex Expression
[Anti-ICAM]-Paramagnetic Liposomes

Application: The *in vivo* targeting of molecules expressed on vascular endothelium, while providing sufficient signal enhancement at these sites for detection by MRI.

Route of Administration: Intravascular.

Implementation: [Anti-ICAM]-paramagnetic liposomes (ACPL) targeted for ICAM-1 complexes administered *in vivo* for the purpose of detecting endothelial leukocyte receptor upregulation by the cerebral microvasculature during autoimmune encephalitis.

Animal Model: Mouse (autoimmune encephalitis).

Interpretation and Analysis: Fluorescence microscopy analysis reveals that fluorescently tagged ACPLs are localized within the central nervous system (CNS) microvasculature in a pattern consistent with ICAM-1 upregulation. Such findings closely correlate with immunohistochemical analyses. High-resolution magnetic resonance imaging (MRI) analysis of brains *ex vivo* demonstrates that ACPL binding patterns confer significant enhancement of signal intensity compared to reference control images. Preparations of ACPLs, therefore, appear to be a useful MRI contrast agent for visualizing specific molecules expressed on vascular endothelium during various disease states.

Instrumentation: Magnetic resonance imaging instrumentation.

ICAM-1 expression in autoimmune encephalitis visualized using magnetic resonance imaging. Sipkins DA, Gijbels K, Tropper FD, Bednarski M, Li KC, Steinman L. J Neuroimmunol 2000 Apr 3; 104 (1), pp. 1–9.

Cardiovascular Endothelium/$\alpha_V\beta_3$ Integrin Complexes
[^{99m}Technetium] ([^{99m}Tc])-(HYNIC)-Arg-Gly-Asp/ [^{99m}Tc]-(HYNIC)-RGD-4C

Cellular/Molecular Mechanism of Action: The peptides amino acid residues, Arg-Gly-Asp (RGD), in vitronectin and fibronectin possess binding affinity for cell membrane-associated $\alpha_V\beta_3$ integrin complexes.

Background Information: Three amino acid residues, Arg-Gly-Asp (RGD), in vitronectin and fibronectin show affinity for $\alpha_V\beta_3$ integrins expressed in vascular endothelial cells. That tumor growth can upregulate the expression of these integrins on tumor cells for invasion and metastasis and in tissue neovasculature suggests the potential of developing radiolabeled RGD peptides as antagonists of $\alpha_V\beta_3$ integrins for broad spectrum tumor-specific imaging. The polypeptide RGD-4C, which contains 4 cysteine residues for cyclization, has shown preferential localization on integrins at sites of tumor angiogenesis.

Application: Detection and characterization of neoplastic cell types/tumors that express relatively high $\alpha_V\beta_3$ integrin D membrane densities.

Route of Administration: Polypeptides RGD-4C and RGE (Arg-Gly-Glu)-4C (intravascular).

Semi-Synthetic Methods: The polypeptide RGD-4C and control RGE (Arg-Gly-Glu)-4C are conjugated with 6-hydrazinopyridine-3-carboxylic acid (HYNIC) to facilitate [^{99m}Tc] radiolabeling. Separation of conjugated products from residual unreacted molecular components can be achieved by C18 chromatography (e.g., Sep-Pak cartridge) applied in combination with 20% methanol solvent. Each of the peptides can be radiolabeled using tricine. For cell binding studies, both [^{99m}Tc] peptides can be further purified by SE HPLC. High specific radioactivity of labeled cyclized RGD/E of about 20 Ci/μmol can be achieved. Both [^{99m}Tc] complexes are stable in the labeling solution for over 24 hours at room temperature.

Implementation: Evaluation of the relative binding avidities of RGD-4C and RGE (Arg-Gly-Glu)-4C peptides for endothelial cell membrane preparations. Determination of such properties can be established by exposure of umbilical vein endothelial (HUVE) to RGD-4C or RGE over an incubation period of 1-hour duration (4°C) at concentrations in the picomolar to nanomolar range. Specificity can be approximated by determining at what concentration native cyclized RGD blocks 50% of the [^{99m}Tc]-labeled RGD binding to cell preparations.

***Ex Vivo* Model:** Human (umbilical vein endothelium, or HUVE).

Interpretation and Analysis: In the HUVE cell binding-avidity analyses, cell accumulation of [^{99m}Tc] in the case of RGD can be as much as 16 times greater than with RGE control peptide. Specificity analyses reveal that 7 nM of native cyclized RGD blocks 50% binding of [^{99m}Tc]-labeled RGD to cells. The binding percentage of [^{99m}Tc]-labeled RGD to purified $\alpha_V\beta_3$ integrin protein, as determined by size exclusion high-performance liquid chromatography 9HPLC), increases with integrin concentration, while [^{99m}Tc]-labeled RGE displays no binding. The association constant for [^{99m}Tc]-RGD is rather modest at $7 \times 10^6\ M^{-1}$. In both human renal adenocarcinoma (ACHN) and human colon cancer cell line (LS174T) nude mouse tumor models, the accumulation of [^{99m}Tc]-labeled RGD/E exhibits no statistical difference. In conclusion, possibly because of limited numbers of $\alpha_V\beta_3$ integrin receptors per tumor cell and low binding affinity, radiolabeled RGD peptides may have limitations as tumor-imaging agents.

In vitro and *in vivo* evaluation of a technetium-99m-labeled cyclic RGD peptide as a specific marker of $\alpha_V\beta_3$ integrin for tumor imaging. Su ZF, Liu G, Gupta S, Zhu Z, Rusckowski M, Hnatowich DJ. Bioconjug Chem 2002 May–Jun; 13 (3), pp. 561–70.

Cardiovascular/Endothelial Integrity and Lesions (Balloon Denudation)/Atherosclerotic Arterial Wall Lesions
[^{99m}Technetium] ([^{99m}Tc])-Labeled Endothelin Derivative

Implementation: Neointima of different cellularity and severity of stenosis can be induced by balloon denudation in concert with the implementation of specific dietary regimens and drug applications. Angiograms and scintigrams can be acquired after injection of a [^{99m}Tc]-labeled endothelin derivative. Validation can be achieved by dissection of the aorta for autoradiography analysis, sudan-III-staining, morphometry, and immunohistology.

Animal Model: Rabbits (e.g., n = 32) with induction of neointima injury of different cellularity and severity of stenosis using balloon denudation.

Interpretation and Analysis: Induced lesions can be detected *in vivo* (whole-body scintigram) in the vast majority of *in vivo* models 15 minutes after the injection of a [^{99m}Tc]-labeled endothelin derivative. Autoradiography analysis reveals a strong relationship between tracer accumulation and sudan-III positive staining lesions. Sites of accumulation for the endothelin derivative correlate with the number of neointimal smooth muscle cells (SMC), but not with the number of medial SMC, neointimal macrophages, and neointimal area. The *in vivo* imaging of atherosclerosis with an endothelin derivative appears to be a feasible method of detecting and characterizing atherosclerotic arterial wall lesions at early stages.

Tc-99m-labeled endothelin derivative for imaging of experimentally induced atherosclerosis. Tepe G, Duda SH, Meding J, Brehme U, Ritter J, Hanke H, Hilger CS, Claussen CD, Dinkelborg LM. Atherosclerosis 2001 Aug; 157 (2), pp. 383–92.

Cardiovascular Endothelium/Vascular Endothelial Growth Factor Receptor (VEGFR-2)
Fusion Proteins

Cellular/Molecular Mechanism of Action: Selective recognition of molecular "targets" through the design of proteins with specific binding avidities. Applying this experimental approach, a targeting molecule is expressed as a fusion protein containing a recognition tag.

Application: Function as molecular vehicles for target-mediated delivery of diagnostic agents. An example preparation is VEGF-RNase A fusion protein, designed to interact with or recognize VEGFR-2 receptors overexpressed on the exterior surface membrane of vascular endothelial cells, in a manner that can facilitate the delivery of a genetic determinant.

Route of Administration: Intravenous.

Dosage: Designed to directly establish a correlation between the specific biological activity (efficacy) of aptamer preparations and the corresponding pathological condition.

Chemical Synthesis and Analysis: Polypeptide protein in the form of a fusion protein that can non-covalently bind another peptide possessing biological activity (e.g., adapter segment). In turn, the adapter is chemically conjugated to a carrier possessing biological (diagnostic) properties. The assembled molecular delivery vehicle contains a carrier-adapter conjugate bound non-covalently to a recognition tag fused to the targeting protein. An example of a prototype fusion protein can be illustrated by VEGF fusion proteins that contain a 15-aa S-peptide fragment of RNase A as a recognition tag, using the S-protein fragment of RNase A as an adapter and polyethylenimine as a DNA carrier that can achieve selective gene delivery to cells overexpressing VEGFR-2.

Considerations: Selective targeting of therapeutic and diagnostic agents improves their efficacy and minimizes potentially adverse side effects. Existing methods for selective targeting are based on chemical conjugation of therapeutics and diagnostics, or their carriers, to cell-specific targeting molecules (e.g., growth factors, antibodies). These methods are limited by potential damage to targeting molecules that can be inflicted by the conjugation procedure. In addition, conjugation procedures have to be developed on a case-by-case basis.

Interpretation and Analysis: The advantages of this technology are (i) no chemical modification of targeting molecules, and (ii) universal, "off-the-shelf" carrier-adapter constructs that can be combined with different fusion targeting proteins. In this fashion, sensor molecules (e.g., radioisotopes, chemiluminescent moieties) can be used in a diagnostic manner to recognize various types of biological targets of interest.

Molecular vehicle for target-mediated delivery of therapeutics and diagnostics. Gaidamakova EK, Backer MV, Backer JM. J Control Release 2001 Jul 6; 74 (1–3), pp. 341–7.

Cardiovascular Thromboses: Arterial
RGD-USPIO

Cellular/Molecular Mechanism of Action: The peptide RGD recognizes and physically binds to the exterior surface of activated platelet populations. The physical orientation of iron ions becomes altered when subjected to magnetic energy fields.

Application: Detection of platelet thromboses, especially those formed with arterial vasculature that have a relatively higher platelet composition than do venous thromboses.

Semi-Synthetic Methods: Preparation of ultrasmall superparamagnetic particles of iron oxide (USPIOs) coupled to an RGD peptide (RGD-USPIO) that selectively recognizes activated platelet populations.

Implementation: Evaluation of thrombus lesions applying USPIOs coupled to an RGD peptide (RGD-USPIO) targeted for activated platelets, applied in combination with magnetic resonance (MR) imaging modalities. Thrombus visualization *ex vivo* is compared using RGD-USPIO and a non-targeted UPSIO. The influence of thrombus visualization on thrombus exposure time to RGD-USPIO (*ex vivo*) and on the spatial resolution of the MR image (*ex vivo* and *in vivo*) is then assessed.

***Ex Vivo* Model:** Thrombus (*ex vivo* and *in vivo* preparations).

Interpretation and Analysis: RGD-USPIO provides superior thrombus visualization compared to non-targeted USPIO *ex vivo*, and maximum enhancement can be achieved after approximately 1 hour exposure time of the thrombus to RGD-USPIO preparations. The ability to visualize clots is highly dependent on the spatial resolution of the image. *In vivo*, an in-plane resolution of less than 0.2×0.2 mm^2 is required for good clot visualization after contrast enhancement. Achievable resolution and sensitivity is a potential limitation to the usefulness of active vascular targeting in MRI.

A targeted contrast agent for magnetic resonance imaging of thrombus: Implications of spatial resolution. Johansson LO, Bjornerud A, Ahlstrom HK, Ladd DL, Fujii DK. J Magn Reson Imaging 2001 Apr; 13 (4), pp. 615–8.

Cardiovascular Thrombosis/ Arterial and Venous/ Deep-Vein Thrombosis/Pulmonary Embolism/ Arterial Thromboembolic Disorders/Cerebral Vascular Stroke/Coronary Artery Thrombotic Disorders/Peripheral Artery Thromboses

Platelet GPIIb/IIIa Receptor Antagonist/[^{99m}Technetium] ([^{99m}Tc])-DMP728/ [^{3}H]-DMP728

Cellular/Molecular Mechanism of Action: The agent DMP728 functions as a GPIIb/IIIa receptor antagonist on the exterior surface membrane of platelets.

Physiological Mechanism of Action: The composition of venous thrombi is predominantly polymerized fibrin polymer compared to arterial thrombi that have a higher platelet content.

Background Information: Either venous or arterial thrombosis is a potentially life-threatening event. Many existing diagnostic modalities are inadequate for establishing a definitive diagnoses or for determining the morphology of an evolving thrombus. Thus development of a non-invasive imaging agent that can detect the location of clots remains a critical and unmet need in the field of diagnostic nuclear medicine.

Application: Detection and characterization of intravascular venous and arterial thromboses.

Route of Administration: Intravascular.

Implementation: Evaluation of artificially (*in vitro*) created venous and arterial type thrombi using the potent radiolabeled GPIIb/IIIa receptor antagonist [^{3}H]-DMP728. Complementary investigation can involve the *in vivo* application of [^{99m}Tc]-DMP728 to determine the clot/blood distribution ratio (e.g., target:background ratio). In addition, non-invasive single photon emission computed tomography (SPECT) of venous clots in deep-vein thrombosis can be performed. The efficacy of thrombin inhibitors can also be evaluated applying similar strategies.

Animal Model: Canine (dogs with mixed arterial/venous clots, arteriovenous shunts with venous clot foci, and deep-vein thrombi).

Interpretation and Analysis: Radiolabeled preparations of the GPIIb/IIIa receptor antagonist DMP728 in the form of [^{3}H]-DMP728 and [^{99m}Tc]-DMP728 retain marked binding avidity for platelet GPIIb/IIIa receptor complexes. DMP728 demonstrates a relatively greater affinity for activated compared to unactivated human platelets, which may be essential for attaining an optimal thrombus/blood (target/background) biodistribution ratio to facilitate optimal detection of small clots (i.e., greater sensitivity). Therefore, [^{99m}Tc]-GPIIb/IIIa receptor antagonists have potential utility in the diagnosis of venous clots in deep-vein thrombosis, pulmonary embolism, arterial thromboembolic disorders including stroke, and coronary and peripheral artery thrombotic disorders. Thrombin inhibitors do not appear to be as effective in this same context.

Novel technetium-99m-labeled platelet GPIIb/IIIa receptor antagonists as potential imaging agents for venous and arterial thrombosis. Mousa SA, Bozarth JM, Edwards S, Carroll T, Barrett J. Coron Artery Dis 1998; 9 (2–3), pp. 131–41.

Cardiovascular/Thrombosis: Platelet Populations

RGD-USPIO (RGD Peptide)

Cellular/Molecular Mechanism of Action: The peptide RGD recognizes and physically binds to the exterior surface of activated platelet populations. The physical orientation of iron ions becomes altered when subjected to magnetic energy fields.

Application: Detection of platelet thromboses, especially those formed with arterial vascular structures, which have a relatively higher platelet composition than do venous thromboses.

Semi-Synthetic Methods: Preparation of ultrasmall superparamagnetic particles of iron oxide (USPIOs) coupled to an RGD peptide (RGD-USPIO) that selectively recognizes activated platelet populations.

Implementation: Evaluation of thrombus lesions applying USPIOs coupled to an RGD peptide (RGD-USPIO) that "targets" activated platelets. Detection *in vivo* can be established by the application of magnetic resonance (MR) imaging modalities. Thrombus visualization *ex vivo* can be compared using RGD-USPIO and a non-targeted UPSIO. The influence of thrombus visualization on thrombus exposure time to RGD-USPIO (*ex vivo*) and on the spatial resolution of the MR image (*ex vivo* and *in vivo*) can subsequently be assessed.

***Ex Vivo* Model:** Thrombus (*ex vivo* and *in vivo* preparations).

Interpretation and Analysis: RGD-USPIO provides superior thrombus visualization compared to non-targeted USPIO *ex vivo*, and maximum enhancement can be achieved after approximately a 1-hour exposure of thrombus lesions to RGD-USPIO preparations. The ability to visualize clots is highly dependent on the spatial resolution of images. *In vivo*, an in-plane resolution of less than 0.2×0.2 mm^2 is required for good clot visualization after contrast enhancement. Achievable resolution and sensitivity is a potential limitation to the usefulness of active vascular targeting in MRI.

A targeted contrast agent for magnetic resonance imaging of thrombus: Implications of spatial resolution. Johansson LO, Bjornerud A, Ahlstrom HK, Ladd DL, Fujii DK. J Magn Reson Imaging 2001 Apr; 13 (4), pp. 615–8.

Central Nervous System (CNS)/Huntington's Disease (HD)/Huntingtin RNA Genetic Targeting/ Antisense Gene Targeting: *In Vivo* Gene Expression Quantification

Antitransferrin Receptor IgG/[^{125}I]-Peptide Nucleic Acid (PNA)-[Antitransferrin Receptor IgG]

Cellular/Molecular Mechanism of Action: The PNA agent is a 16-mer PNA that is the antisense strand that corresponds to the segment around the methionine initiation codon of the huntingtin gene associated with HD. In this context, it recognizes and physically binds to huntingtin RNA (HD exon-1 messenger RNA).

Background Information: Disease-specific genes of unknown function can be imaged *in vivo* with antisense radiopharmaceuticals, providing the trans-cellular transport of these molecules is enabled with drug-targeting technology.

Application: Central nervous system targeting.

Route of Administration: [^{125}I]-PNA/8D3 conjugate (intravenous).

Semi-Synthetic Methods: Biotinylation of PNA. Covalent cross-linking strepavidin and rat 8D3 monoclonal antibody (MAb) to the mouse transferrin receptor (TfR). The latter moiety contains a tyrosine residue that can facilitate [^{125}I] radioiodination. The reformulated PNA antisense radiopharmaceutical conjugated to 8D3 MAb is designated [^{125}I]-PNA/8D3.

Implementation: Evaluation of biotinylated PNA that can be rapidly captured by conjugates of covalently cross-linked strepavidin-[antimouse transferrin receptor IgG]. Complementary *in vivo* studies in mice can be used to determine the biodistribution of the PNA analogue [^{125}I]-PNA/8D3 through harvest of tissue/organ systems 6 hours postadministration. Preparations of the brain can be frozen sectioned and quantitated applying autoradiography.

Animal Model: Murine (littermate control mice or R6/2 transgenic mice that express the exon 1 of the human HD gene).
Interpretation and Analysis: Despite covalent cross-linking of the PNA analogue [^{125}I]-PNA/8D3 to monoclonal antibody, it can gain access to endogenous transferrin transport pathways at the level of both the blood-brain barrier and the brain cell membrane, resulting in import from the blood to the brain and export from the brain into the blood mediated by TfRs. In this manner, products are able to hybridize with "target" huntingtin RNA validated by analysis from both cell-free translation assays and ribonuclease protection assays.

Approximately a 3-fold *in vivo* increase in sequestration can be appreciated for antisense [^{125}I]-PNA/8D3 radiopharmaceutical conjugates within the brains of HD transgenic *in vivo* models. Such observations are consistent with the selective *in vivo* expression of the HD exon-1 messenger RNA sequence. Therefore, gene expression *in vivo* can be quantitated with antisense radiopharmaceuticals, provided these molecules are reformulated in concert with drug-targeting technology. Drug targeting enables access of the antisense agent to endogenous transport pathways, which in turn permits passage across cellular barriers that separate blood and intracellular compartments of target tissues.

Imaging gene expression in the brain *in vivo* in a transgenic mouse model of Huntington's disease with an antisense radiopharmaceutical and drug-targeting technology. Lee HJ, Boado RJ, Braasch DA, Corey DR, Pardridge WM. J Nucl Med 2002 Jul; 43 (7), pp. 948–56.

Central Nervous System (CNS)/Opioid Receptors/ Delta-OR Receptors/μ-Opioid Receptors
Fluo-Deltorphin/d-Phe-Cys-Tyr-d-Trp-Orn-Thr-Pen-Thr-NH_2/Fentanyl Citrate

Cellular/Molecular Mechanism of Action: Fluo-deltorphin is a fluorescent compound that physically binds to deltaOR in a highly selective manner. Similarly, d-Phe-Cys-Tyr-d-Trp-Orn-Thr-Pen-Thr-NH_2 selectively binds to μ-opioid receptor complexes. Fentanyl citrate similarly binds to μ-receptors.
Physiological Mechanism of Action: Fluo-deltorphin is a highly selective deltaOR agonist. The peptide d-Phe-Cys-Tyr-d-Trp-Orn-Thr-Pen-Thr-NH_2 is a selective μ-opioid receptor antagonist. Alternatively, fentanyl citrate functions as a μ-receptor agonist.
Background Information: Opioid receptors are known to undergo complex regulatory changes in response to ligand exposure.
Application: Examination of the effect of morphine on the *in vitro* and *in vivo expression* density and trafficking of δ-opioid receptors (deltaORs).
Route of Administration: Intravascular (traditionally).
Implementation: Prolonged exposure of cortical neurons in culture to morphine (10 μm) for a period of 48 hours with and without the presence of d-Phe-Cys-Tyr-d-Trp-Orn-Thr-Pen-Thr-NH_2 or fentanyl citrate. Alterations in the expression density of membrane-associated deltaORs can then be detected applying immunogold electron microscopy.
Interpretation and Analysis: Prolonged exposure of cortical neurons to morphine results in a profound increase in the internalization of Fluo-deltorphin. Such effects are μ-mediated because it is entirely blocked by d-Phe-Cys-Tyr-d-Trp-Orn-Thr-Pen-Thr-NH_2 and can be reproduced using the selective μ agonist, fentanyl citrate. Based on results from immunogold electron microscopy analysis, marked increases in the expression density of surface membrane-associated deltaORs occur in neurons exposed to morphine and indicates that increases in Fluo-deltorphin internalization is caused by elevations in receptor availability. Prolonged morphine exposure has no effect on deltaOR protein levels, as assessed by immunocytochemistry and Western blot analysis, suggesting that an increase in bioavailable deltaORs is caused by recruitment of reserve receptors from intracellular stores and not from receptor neosynthesis. Chronic treatment of adult rats with morphine (5–15 mg/kg, subcutaneous, every 12 hours) similarly augments targeting of deltaORs to neuronal plasma membranes in the dorsal horn of the spinal cord. Such treatment markedly potentiates intrathecal d-[Ala_2]deltorphin II-induced antinociception. Therefore, prolonged *in vitro* and *in vivo* stimulation of neurons with morphine markedly increases recruitment of intracellular deltaORs on the cell surface membrane. Receptor subtype cross-mobilization of this type may widen the transduction repertoire of G-protein-coupled receptors and offer new therapeutic strategies.

Prolonged morphine treatment targets δ-opioid receptors to neuronal plasma membranes and enhances δ-mediated antinociception. Cahill CM, Morinville A, Lee MC, Vincent JP, Collier B, Beaudet A. J Neurosci 2001 Oct 1; 21 (19), pp. 7598–607.

Central Nervous System (CNS)/Opioid Receptors: Microligands/Microreceptor Peptide-Based Affinity Labels
Dermorphin/[Phe_5(p-NH_2),Lys_7]Dermorphin

Cellular/Molecular Mechanism of Action: Selective micro-opioid receptor ligands originating from amphibian skin that have been modified with various electrophiles in either the "message" or "address" sequences so they can function as potential peptide-based affinity labels for microreceptors.
Application: Opioid receptor detection/recognition.
Route of Administration: Intravascular.
Synthesis/Biosynthesis: Introduction of the electrophilic isothiocyanate and bromoacetamide groups at the para position of Phe_3 and Phe_5 can be accomplished by incorporating Fmoc-Phe(p-NHAlloc) into the peptide, followed by selective deprotection and modification. The corresponding amine-containing peptides can also be prepared.
Implementation: Evaluation of binding avidity of pure peptides for membrane-associated micro-opioid and δ-opioid receptor complexes applying radioligand binding analyses.

Tissue Culture Model: Chinese hamster ovary cells (CHO) expressing micro-opioid and d-opioid receptors.
Interpretation and Analysis: In dermorphin, introduction of the electrophilic groups in the "message" domain lowers the binding affinity by $>$ 1,000-fold; only [Phe_3(*p*-NH_2)]dermorphin retains nanomolar affinity for microreceptors. Modifications in the "address" region of both dermorphin and [Lys_7]dermorphin produces a product that is relatively well tolerated. In particular, [Phe_5(*p*-NH_2),Lys_7]dermorphin has a level of affinity similar to dermorphin and has almost a 2-fold higher selectivity for microreceptors. [Phe_5(*p*-$NHCOCH_2Br$)]- and [Phe_5(*p*-$NHCOCH_2Br$),Lys_7]dermorphin exhibit relatively high affinity (IC_{50} = 27.7 and 15.1 nm, respectively) for micro-opioid receptors. However, neither of these peptides inhibit [^{3}H]DAMGO binding in a wash-resistant manner.

Dermorphin-based potential affinity labels for μ-opioid receptors. Choi H, Murray TF, Aldrich JV. J Pept Res 2003 Jan; 61 (1), pp. 40–5.

Central Nervous System (CNS)/Opioid Receptors: Kappa Selective
Arodyn

Cellular/Molecular Mechanism of Action: The aromatic dynorphin arodyn is a unique analogue of the opioid peptide dynor-

phin-A and possesses relatively selective κ-opioid receptor ligand binding affinity (K_i = 10 nM: κ/μ/δ = 1/174/583).

Physiological Mechanism of Action: Arodyn completely reverses the agonism of dynorphin $A^{1\text{-}13}NH_2$ in a concentration-dependent manner in adenylyl cyclase assays.

Application: Arodyn is a novel κ-opioid receptor selective antagonist that will be useful in the study of this receptor type.

Identification of arodyn, a novel acetylated dynorphin $A^{1\text{-}11}$ analogue, as a κ-opioid receptor antagonist. Bennett MA, Murray TF, Aldrich JV. J Med Chem 2002 Dec 19; 45 (26), pp. 5617–9.

Immune System/Antigen Delivery: Selective and Site-Specific
Monoclonal Antibody

Cellular/Molecular Mechanism of Action: Detects and physically binds to specific epitomes corresponding to distinct segments of macromolecules (e.g., polypeptides, glycoproteins, lipoproteins, pharmaceuticals, oligosaccharides, nucleotides).

Considerations: Most monoclonal antibody preparations that have the potential of being developed into *in vivo* diagnostic and therapeutic agents are of murine or rat origin. Ideally, monoclonal antibodies intended for *in vivo* diagnostic and therapeutic purposes need to be created so that they are homologous in nature to avoid rejection or induction of aberrant immune responses in the recipient host. In this context, genetic engineering techniques have made it possible to produce immunoglobulin isotypes that are compatible with domestic animal species and man. Despite these advances, there is still an insufficient level of understanding about their functional activities or how to determine which isotype may be the most effective for a given application. Similar in concept to the alteration of the biochemical function of a given enzyme through minor changes in amino acid sequence, similar alterations in monoclonal antibody induced by site-directed mutagenesis of a single amino acid substitution can substantially modify ligand-binding properties of an immunoglobulin preparation. Additionally, immunoglobulin glycosylation is critical for full functional activity because there is a subtle interplay between the polypeptide and oligosaccharide structures in the creation of viable ligand-binding sites. Taken together, these findings suggest that it will be possible to generate "customized" antibody molecules having a predetermined profile of effector functions.

Interpretation and Analysis: It is possible to generate customized monoclonal antibodies based on the evalution and molecular characterization of the desired predetermined effector function.

Structure-function relationships in human immunoglobulins. Jefferis R. Neth J Med 1991 Oct; 39 (3–4), pp. 188–98.

Immune System/Leukocytes: *In Vivo* Labeling of Neutrophil and Macrophage Tuftsin Complexes/ Inflammation: Septic and Non-Septic/Central Nervous System (CNS): Multiple Sclerosis (MS)/ Glucocorticoid Efficacy Evaluation/Selective Delivery to Leukocytes or Sites of Inflammation/ Experimental Allergic Encephalomyelitis (EAE)
[^{99m}Technetium] ([^{99m}Tc])-RP128

Cellular/Molecular Mechanism of Action: The agent RP128 functions as a chelation agent for [^{99m}Tc] in addition to recognizing and binding to tuftsin receptors expressed by neutrophils and monocyte-macrophages.

Application: The agent [^{99m}Tc]-RP128 can be applied for the *in vivo* labeling of neutrophil and macrophage tuftsin receptor complexes for the purpose of detecting and characterizing focal sites of septic inflammation. Preparations can also potentially be applied for the detection and characterization of human MS conditions, and potentially could be applied to selectively deliver agents to macrophage and neutrophil populations.

Route of Administration: Intravascular.

Implementation: Administration of [^{99m}Tc]-RP128 for the *in vivo* detection of CNS inflammation (e.g., EAE).

Animal Model: Murine EAE (EAE as a model for human MS).

Interpretation and Analysis: The radiopharmaceutical [^{99m}Tc]-RP128 can be detected at significantly increased levels within CNS tissues in conditions of EAE at 0.5, 1.0, and 3.0 hours post-injection using a dual radioisotope technique utilized to correct for non-extravasated tracer ($p < 0.05$). Moreover, extravascular accumulation of [^{99m}Tc]-RP128 can be clearly demonstrated in inflammatory tissues with minimal loss of sensitivity when the secondary isotopic correction for blood volume is omitted. In addition, [^{99m}Tc]-RP128 can successfully monitor glucocorticoid suppression of inflammation ($p < 0.05$), detected as a typical dose response to increasing steroid concentration. Clearly, [^{99m}Tc]-RP128 can quantitatively detect CNS inflammation and assess responses to therapy, indicating potential value as an imaging agent for both clinical and research purposes. Furthermore, the rapid *in vivo* labeling by [^{99m}Tc]-RP128 of specific inflammatory cells combined with the ability to monitor the progress of anti-inflammatory therapeutics may validate the use of this cellular radiolabeling agent for detecting a variety of inflammatory conditions.

The detection and quantitation of inflammation in the central nervous system during experimental allergic encephalomyelitis using the radiopharmaceutical [^{99m}Tc]-RP128. Paul C, Peers SH, Woodhouse LE, Thornback JR, Goodbody AE, Bolton C. J Neurosci Methods 2000 May 15; 98 (1), pp. 83–90.

Immune System/Mononuclear Cell Binding: Decreased Non-Specific Mononuclear Cell Binding
IgG Fv Fragments/Modified VH/VL

Synthetic Production and Analysis: Molecular modeling technology has made it possible to identify 2 positions in conserved framework regions of antibody Fv fragments (Fvs) that are distant from complementarity-determining regions (CDRs) and potentially can be used to make recombinant Fv fragments in which the unstable VH and VL heterodimer is stabilized by an interchain disulfide bond inserted between structurally conserved regions. A disulfide bond can be introduced at 1 of these positions, VH44-VL105, and has been shown to stabilize various Fvs that retain full binding and specificity. Recombinant immunotoxins (e.g., B3(dsFv)-PE38KDEL), in which this disulfide-stabilized Fv moiety is connected to a truncated form of *Pseudomonas* exotoxin (PE; PE38KDEL) that contains translocation and adenosine diphosphate (ADP) ribosylation domains, are indistinguishable in binding and specificity from single-chain immunotoxin counterparts. Analysis of the alternative position (VH111-VL48) by predictive modeling techniques for the purpose of disulfide stabilization of monoclonal antibody (MAb) B3(Fv) can be used as a guide for the production of recombinant immunotoxin with such disulfide-stabilized (ds) Fv immunoglobulin fragments.

Interpretation and Analysis: The immunotoxin preparation is very active and retains full specificity for B3 antigen-positive cells. However, it is 2- to 3-fold less active than the VH44-VL105 dsFv-molecule. Comparison of various biochemical features of VH44-VL105 and VH111-VL48 dsFv immunotoxins with the corresponding single-chain immunotoxin reveals that dsFv immunotoxins are more stable in human serum and more resistant to thermal and

chemical denaturation than the single-chain (sc) Fv immunotoxin. Because dsFv immunotoxins and dsFvs have full activity and specificity and improved stability, they may be more useful than scFv immunotoxins as therapeutic and diagnostic agents.

Engineering interchain disulfide bonds into conserved framework regions of Fv fragments: Improved biochemical characteristics of recombinant immunotoxins containing disulfide-stabilized Fv. Reiter Y, Brinkmann U, Webber KO, Jung SH, Lee B, Pastan I. Protein Eng 1994 May; 7 (5), pp. 697–704.

Immune System/Neutrophil Leukotriene LTB_4 Receptors/Induced Myocardial Ishchemia
[^{99m}Technetium] ([^{99m}Tc])-RP517/[F]-RP517

Cellular/Molecular Mechanism of Action: In whole blood, [F]-RP517 (500 nmol/L) preferentially labels neutrophil LTB_4 receptor complexes.
Application: [^{99m}Tc]-RP517 is an LTB_4 receptor antagonist that has been developed for imaging acute inflammation or infection. A unique property of [^{99m}Tc]-RP517 is its ability to label white blood cells *in vivo* after intravenous injection.
Route of Administration: [^{99m}Tc]-RP517 (intravenous).
Implementation: Evaluate the relative [^{99m}Tc]-RP517 binding to human leukocyte subtypes and the [^{99m}Tc]-RP517 uptake pattern in myocardium with induced inflammatory lesions. One approach to assessing such conditions can involve delineation of RP517 binding to neutrophil populations *in vitro* within whole blood, and *in vivo* within the intravascular compartment. This can be achieved through the use of fluorescence-activated cell sorter analysis performed on whole human blood samples (n = 2) and isolated neutrophils (n = 4) with a fluorescent analogue of [^{99m}Tc]-RP517 referred to as [F]-RP517. Evaluation approaches *in vivo* can entail administration of [^{99m}Tc]-RP517 to determine its biodistribution within the myocardium before and after coronary occlusion. To facilitate *ex vivo* imaging of the myocardium, the left ventricle can be divided into 72 segments for flow and [^{99m}Tc]-RP517 uptake analyses.

Animal Model: Canine (n = 9 dogs; anesthetized, open-chest surgical exposure before coronary occlusion [90 minutes] and reperfusion [120 minutes]; or n = 3 dogs, before intramyocardial tumor necrosis factor-alpha (TNF-α) administration). In this context, myocardium inflammation can be induced by either coronary occlusion and reperfusion or administration by injection of TNF-α preparations.
Interpretation and Analysis: In whole blood, [F]-RP517 (500 nmol/L) preferentially labels neutrophils. In isolated neutrophil populations, [F]-RP517 (10 nmol/L) binding is inhibited by 44% in the presence of LTB_4 (400 nmol/L). In the analysis of *ex vivo* cardiac samples, an inverse exponential relationship can be detected between [^{99m}Tc]-RP517 uptake and occlusion flow (r = 0.73). In the same 15 segments, [^{99m}Tc]-RP517 uptake is highly correlated with neutrophil myeloperoxidase enzyme levels (r = 0.91). *Ex vivo* images reveal tracer uptake in the reperfused area (ischemic to normal count ratio = 2.7 ± 0.2). Therefore, it can be concluded that RP517 binds to the neutrophil LTB_4 receptor complex after intravenous injection. After reperfusion, [^{99m}Tc]-RP517 uptake correlates with myeloperoxidase levels and can be observed on *ex vivo* images, indicating that this tracer may have potential as an imaging agent for detecting inflammatory conditions.

Assessment of myocardial inflammation produced by experimental coronary occlusion and reperfusion with [^{99m}Tc]-RP517, a new leukotriene B_4 receptor antagonist that preferentially labels neutrophils *in vivo*. Riou LM, Ruiz M, Sullivan GW, Linden J, Leong-Poi H, Lindner JR, Harris TD, Beller GA, Glover DK. Circulation 2002 Jul 30; 106 (5), pp. 592–8.

Neoplasia
[^{67}Ga] Ga-2-(p-SCN-Bz)-NOTA Anti-IL-2 IgG

Cellular/Molecular Mechanism of Action: Immunoglobulin-based recognition and binding to IL-2 receptor complexes.
Application: The low molecular weight protein (LMWP) has been proposed as a candidate diagnostic agent for the detection of certain neoplastic disease states.
Semi-Synthetic Methods: The antibody fragment disulfide-linked (dsFv) to the alpha subunit of the IL-2 receptor can be radiolabeled with a [^{67}Ga] Ga-2-(p-SCN-Bz)-NOTA derivative, which is linked through an isothiocyanato group to either the epsilon-amino group of lysine or the alpha-amino group to the N-terminal amino acid.
Considerations: Because different amino acids in the dsFv are radiolabeled applying the method described, it is possible to study the relative residence times of the various catabolites.
Implementation: Evaluation of the residence time for methionine and lysine conjugates within the same kidney.
Animal Model: Murine.
Interpretation and Analysis: Approximately > 60% of the injected dose localizes within the kidney. The major catabolite (> 95%) in the kidney is the Ga-2-(p-SCN-Bz)-NOTA conjugate with either lysine or methionine, with no evidence of transchelation of [^{67}Ga]. The methionine conjugate has a significantly shorter residence time than the lysine conjugate in the same kidney. Labeling the appropriate amino acid in an LMWP may lead to reduced residence times and increased diagnostic or therapeutic ratios. Appropriately synthesized radiobiological agents of this design would preferentially accumulate within neoplastic tissues, producing a high "target-to-background" ratio that could be detected by nuclear medicine scintographic imaging.
Instrumentation: Computer-integrated nuclear medicine scintigraphy instrumentation.

Biodistribution and catabolism of Ga-67-labeled anti-Tac dsFv fragment. Wu C, Jagoda E, Brechbiel M, Webber KO, Pastan I, Gansow O, Eckelman WC. Bioconjug Chem 1997 May–Jun; 8 (3), pp. 365–9.

Neoplastic Disease/Antigen Targeting/Membrane-Associated Cancer Antigens/[^{99m}Technetium] ([^{99m}Tc])-Anti-Carcinoembryonic Antigen (CEA) Monoclonal Antibody (MAb)/Colorectal Cancer/Bladder Cancer/Thyroid Cancer
Anti-Neoplastic Antigen Monoclonal IgG/ [^{99m}Tc]-Anti-CEA MAb

Cellular/Molecular Mechanism of Action: Monoclonal antibody is used as a targeting modality for unique antigens expressed on the external surface membrane of neoplastic cell types.
Background Information: Monoclonal antibody can be produced with binding avidity for almost any protein, glycoprotein, or lipoprotein antigen greater than 10 kDA in mass. Examples of preparations other than radiolabeled anti-CEA include (i) [^{111}In]-labeled anti-MUC1 mucin for invasive bladder cancer; and (ii) [^{131}I]-MN-14 $F(ab)_2$ anti-CEA MAb for medullary thyroid cancer. Although this allows flexibility in the design of new agents, binding avidities and specificity of binding can vary between different MAb preparations.
Diagnostic Application: Detection of neoplastic disease states that express membrane-associated CEA at relatively high densities.
Route of Administration: Intravascular.
Dosage: [^{99m}Tc]-anti-CEA MAb (925 MBq).

Considerations: Intact radiolabeled IgG immunoglobulin will accumulate within the spleen and liver due to binding to Fc-receptor sites expressed on the exterior surface membrane of cell populations comprising the reticuloendothelial (e.g., mononuclear phagocytic) system. Enzymatic cleavage of the Fc fragment with either pepsin or papain results in the generation of Fab′ or Fab'_2. Such IgG molecular fragments display a significantly higher target-to-background ratio than intact IgG. Examples of radiolabeled MAbs applied for either diagnostic or therapeutic purposes include those targeted against p57 protein fractions expressed by malignant melanoma cell types.

Implementation: Evaluate the usefulness of immunoscintigraphy with an anti-CEA MAb fragment labeled with [^{99m}Tc] for early detection of colorectal cancer recurrence in patients with rising serum CEA levels. Cases are then subjected to immunoscintigraphy imaging studies (e.g., n = 8 cases; n = 59 acquired images). Immunoscintigraphy is performed after injection of anti-CEA MAb. Planar images of the thorax, abdomen, and pelvis, as well as single photon emission computed tomography (SPECT) of the abdomen and pelvis, are obtained at 4 and 24 hours after injection. Abdominal CT scans can additionally be performed prior to scintigraphic imaging. Findings are subsequently validated by histopathological analysis (e.g., n = 28 cases) or by imaging and clinical follow-up of at least 6 months following the immunoscintigraphy (e.g., n = 31 cases).

Human Model: Cases of colorectal cancer (e.g., n = 51 consecutive patients; n = 27 women, n = 24 men; population mean age 68.9 ± 10.2 years) with rising CEA levels (e.g., 16.2 ± 18.2 ng/ml).

Interpretation and Analysis: A considerable number of cases will not show recurrence during the follow-up period (e.g., n = 41). Conversely, slightly less than two-fifths of all cases will have a confirmed diagnosis of extrahepatic abdominal or pelvic disease (e.g., n = 18/51); approximately one-fifth of cases will have liver metastases (e.g., n = 11/51); slightly less than one-fifth of cases can have thoracic involvment (e.g., n = 9/51); while a relatively small number will have bone metastasis (e.g., n = 2/51). In cases with pelvic and extrahepatic abdominal disease, immunoscintigraphy will be true-positive in most instances (e.g., n = 14/18 true-positive vs n = 4/18 false-positive). Of the cases classified as true-positive, only about half are detectable by CT imaging (e.g., n = 7/14).

In the remaining cases with no detectable lesions on immunoscintigraphy images, most of these findings can be classified as true-negatives (e.g., n = 37/41 true-negative, n = 4/41 false-negative). Therefore, the sensitivity and specificity for immunoscintigraphy in extrahepatic abdominal and pelvic disease is approximately 78% and 90%, respectively. Computed tomography results show a lower sensitivity of 61% ($p < 0.05$) and specificity of 83%. Liver metastases may not be detected by CT (e.g., n = 9 cases), but such lesions may alternatively only be detected in a small number of cases utilizing immunoscintigraphy (e.g., n = 2/9). Therefore, scintigraphy with anti-CEA MAb fragment labeled with [^{99m}Tc] is superior to CT for the detection of pelvic and extrahepatic abdominal recurrence of colorectal cancer, while CT is more sensitive in the detection of liver and lung metastases. Immunoscintigraphy has a limited usefulness in the detection of distant metastases, but it may be helpful in the diagnosis of suspected colorectal recurrence in patients with non-conclusive CT findings, and when FDG-PET is not available.

Is there a role for [^{99m}Tc]-anti-CEA monoclonal antibody imaging in the diagnosis of recurrent colorectal carcinoma? Fuster D, Maurel J, Muxí A, Setoain X, Ayuso C, Martín F, Ortega ML, Fuertes S, Pons F. Q J Nucl Med 2003 Jun; 47 (2), pp. 109–15.

Neoplasia/Carcinoma of the Breast/Mammary Carcinoma
Single-Chain Anti-HER-2 Monoclonal Antibody (MAb)

Cellular/Molecular Mechanism of Action: Monoclonal antibody fragment designed to recognize and physically bind to HER-2 antigen expressed on the exterior surface membrane of (human) mammary carcinoma cell types.

Application: Selective, non-invasive *in vivo* detection, characterization, monitoring, and therapy of mammary carcinoma. Single-chain variable fragment MAb preparations that recognize and bind to HER-2 antigen also potentially have the capacity to function as a selective *in vivo* delivery format for diagnostic and therapeutic agents. Several monoclonal antibody preparations that recognize mammary carcinoma HER-2 antigen expression also inhibit the proliferation of this neoplastic cell type.

Route of Administration: Intravenous.

Semi-Synthetic Methods: To obtain a smaller immunoglobulin-based reagent possessing improved *in vivo* properties, a single-chain variable fragment (scFv) of antigen-specific monoclonal antibody (e.g., harvested from MGR6-producing hybridoma cell) can be generated applying phage display technology. Rapid purification of biologically active monoclonal IgG antibody can be obtained by applying metal affinity chromatography. Identification of epitopes on the HER-2 extracellular domain that are shared by single-chain variable fragment anti-HER-2 and intact MAb can be identified utilizing competition fluorescence-activated cell sorting (FACS) and ELISA methodologies. Based on BlAcore analysis, single-chain variable fragment anti-HER-2 can be produced that possesses characteristics very similar to the properties of intact monoclonal antibody (e.g., Koff of 9.3×10^{-4}/s).

Interpretation and Analysis: Monoclonal antibody preparations with binding avidity for HER-2 antigen have the advantage of recognizing a protein molecule expressed at relatively low levels in normal tissues and a homogeneous distribution within masses of mammary carcinoma. Relatively fast distribution and elimination half-lives of single-chain variable fragment anti-HER-2 measured following *in vivo* administration preclinical evaluations (13 minutes and 6.2 hours, respectively) represent a theoretical improvement in pharmacokinetic properties compared to intact murine MAb. Such preparations of immunoglobulin fragments, therefore, have the potential for being utilized for selectively delivering diagnostic imaging agents and therapeutics to different human carcinoma cell types overexpressing HER-2 complexes.

Production and validation of the pharmacokinetics of a single-chain Fv fragment of the MGR6 antibody for targeting of tumors expressing HER-2. Turatti F, Mezzanzanica D, Nardini E, Luison E, Maffioli L, Bambardieri E, de Lalla C, Canevari S, Figini M. Cancer Immunol Immunother 2001 Feb; 49 (12), pp. 679–86.

Neoplasia: Carcinoma of the Breast/Mammary Carcinoma/Tyrosine Kinase Her-2/neu Receptors
Streptavidin-Conjugated Iron Oxide Nanoparticles/ Biotinylated Monoclonal IgG (Anti Her-2/ neu-Receptor).

Cellular/Molecular Mechanism of Action: Monoclonal antibody designed to selectively bind to Her-2/neu-receptor complexes.

Background Information: One of the clinically relevant targets is the tyrosine kinase Her-2/neu receptor, which has importance in the staging and treatment of breast cancer.

Application: Creation of adjunct information directly relevant to the staging and treatment of breast cancer.
Route of Administration: Intravascular.
Implementation: Detection and characterization of Her-2/neu receptor expression in breast cancer cell populations that express the receptors on their exterior surface membranes at variable densities. Cell populations of interest are pre-targeted with anti-Her-2/neu monoclonal antibody followed by exposure to streptavidin-conjugated superparamagnetic nanoparticles as a strategy for selective magnetic resonance imaging of HER-2/new receptor expression.
Interpretation and Analysis: Streptavidin-conjugated superparamagnetic nanoparticles when used in combination with pretargeting strategies with biotinylated anti-Her-2/neu monoclonal IgG can function as a effective approach for detecting and characterizing the expression of these receptor complexes by magnetic resonance imaging analysis in conditions of mammary carcinoma. In this fashion, strong T_2 magnetic resonance signals can be generated by Her-2/neu-expressing cells. Furthermore, the contrast observed in MR images is proportional to the expression level of Her-2/neu receptors determined independently by fluorescence-activated cell sorting (FACS) analysis. In this context, iron oxide nanoparticles become attached to the membrane surface of mammary carcinoma cell types and they are not internalized into the cytosol, which is a major advantage for application *in vivo* as a diagnostic strategy.

MR molecular imaging of the Her-2/neu receptor in breast cancer cells using targeted iron oxide nanoparticles. Artemov D, Mori N, Okollie B, Bhujwalla ZM. Magn Reson Med. 2003 Mar; 49 (3), pp. 403–8.

Neoplasia/Carcinomas of the Breast, Colon, and Lung
Antifibroblast Activation Protein Monoclonal Antibody (MAb)

Cellular/Molecular Mechanism of Action: Represents an MAb that recognizes and physically binds to fibroblast activation protein (FAP), which is selectively expressed on activated fibroblasts residing within the tumor stroma of more than 90% of lung, breast, and colon carcinomas.
Application: Fibroblast activation protein is selectively expressed by activated fibroblasts of the tumor stroma on more than 90% of lung, breast, and colon carcinomas. The high prevalence and abundance of FAP in the stroma of these carcinoma cell types make it a promising molecule that can be used as an *in vivo* "target" for a variety of diagnostic and therapeutic agents. Specialized histological analyses (staining procedures) could be applied in the evaluation of biopsy specimens as a means of prescreening carcinomas vulnerable to such tumor stroma targeting strategies.
Route of Administration: Intravenous.
Considerations: Preparations of immunoglobulin that are completely of human origin are superior to murine or humanized antibody derivatives when applied in clinical hospital environments.
Semi-Synthetic Methods: Highly diverse IgG, IgM, and IgD isotypes comprised of heavy-chain variable domain libraries can be generated using cDNAs derived from diverse lymphoid organs of various donors types. Human single-chain antibody fragment can be converted into bivalent minibodies and expressed in eukaryotic cells to facilitate additional functional characterization.
Interpretation and Analysis: Binding-competition studies and analysis by fluorescence-activated cell sorting show that preparations have a high binding affinity (10–20 nM) for 2 clones and recognize the same epitope as the murine reference antibody. Minibodies can be successfully used for immunohistopathology analysis of a variety of human carcinoma biopsies, revealing specific staining of stromal fibroblasts. Based on the nature of these findings, immunoglobulin preparations should be suitable as a vehicle for selective *in vivo* delivery of diagnostic and therapeutic agents to neoplastic cell types.

Generation of human high-affinity antibodies specific for the fibroblast activation protein by guided selection. Schmidt A, Müller D, Mersmann M, Wüest T, Gerlach E, Garin-Chesa P, Rettig WJ, Pfizenmaier K, Moosmayer D. Eur J Biochem 2001 Mar; 268 (6), pp. 1730–8.

Neoplasia/Carcinoma of the Breast, Colon and Lung
Antifibroblast Activation Protein Monoclonal Antibody (MAb)

Cellular/Molecular Mechanism of Action: Represents an MAb that recognizes and binds to fibroblast activation protein (FAP), which is selectively expressed on activated fibroblasts residing within the tumor stroma of more than 90% of lung, breast, and colon carcinomas.
Application: The high prevalence and abundance of FAP in the stroma of carcinomas of the lung, breast, colon, and other tissue structures make it a promising molecule that can be used as an *in vivo* "target" for a variety of diagnostic and therapeutic agents. Specialized histological analyses (staining procedures) can be applied in the evaluation of biopsy specimens as a means of prescreening carcinomas that would be vulnerable to such tumor stroma targeting strategies.
Route of Administration: Intravenous.
Considerations: Investigations have described the humanization of the murine FAP-specific MAb (e.g., F19). Such preparations have been applied clinically for *in vivo* diagnostic purposes.
Semi-Synthetic Methods: Using phage-display technology and human V-repertoires, VL and VH regions of antigen-specific MAb can be replaced by analogous human V-regions while retaining the original 15-amino acid HCDR3 sequence in a manner that maintains F19 epitope specificity.
Interpretation and Analysis: The resulting human single-chain fragments of immunoglobulin variable regions (scFv 34, scFv 18) have binding affinities of 6 nM for cell membrane-bound FAP. Bivalent scFv 34 is expressed as a minibody (Mb 34). The antigen-binding characteristics of Mb 34 are comparable to the parental and a complementarity-determining region-grafted type of F19. Such characteristics can be validated by competitive binding studies, fluorescence-activated cell sorting (FACS) analyses, and immunohistochemistry on various tumor samples, including carcinomas of the breast, colon, and lung. Compared to the complementarity-determining region-grafted humanized scFv version of F19, the V-regions of selected human scFv 34 possess sequence homology with the parental antibody (Ab) only over a short, 15-amino acid long HCDR3. Thus, a largely reduced xenoantigenic potential is expected.

Human antibody derivatives against the fibroblast activation protein for tumor stroma targeting of carcinomas. Mersmann M, Schmidt A, Rippmann JF, Wüest T, Brocks B, Rettig WJ, Garin-Chesa P, Pfizenmaier K, Moosmayer D. Int J Cancer 2001 Apr 15; 92 (2), pp. 240–8.

Neoplasia/Carcinomas of the Breast, Lung (Small Cell Type), Prostate and Pancrease
[^{99m}Technetium] ([^{99m}Tc])-MAG3-Coupled Bombesin (BN) Peptide

Background Information: Several human cancers, including small cell lung, prostate, breast, gastric, colon, and pancreatic cancers, express receptors for BN-like peptides. Bombesin peptides that bind specifically to these receptors are useful for the *in vivo* detection of BN receptor-expressing cancers.

Application: Detection and characterization of neoplastic disease states, including small cell lung, prostate, breast, gastric, colon, and pancreatic cancers that express receptors for BN-like peptides at relatively high membrane densities.

Semi-Synthetic Methods: Through the use of solid-phase synthesis techniques, MAG3-coupled BN peptide (MAG3-BN) can be prepared and subsequently radiolabeled with [^{99m}Tc] using a chemical exchange methodology. The resulting product is referred to as [^{99m}Tc]-labeled-BN peptide.

Implementation: Evaluation of the *in vitro* binding avidity of [^{99m}Tc]-MAG3-BN for MDA-MB-231 and MCF-7 human breast cancer cell lines. Complementary investigations can entail determining *in vivo* radioactivity biodistribution profiles.

Animal Model: Murine (normal and nude mice bearing BN receptor-positive tumors including MCF-7 cell lines).

Interpretation and Analysis: Radiolabeling of MAG3-BN with [^{99m}Tc] produces a single radioactive species ($>$ 95%) referred to as [^{99m}Tc]-MAG3-BN peptide. *In vitro* cell-binding analyses validate the affinity and specificity of [^{99m}Tc]-MAG3-BN towards BN receptor complexes. *In vivo* biodistribution in mice reveals that [^{99m}Tc]-MAG3-BN clears rapidly from the blood and most nontargeted tissues and is excreted mainly via the kidneys. Uptake in BN receptor-positive tissues and in the tumor is low to moderate. [^{99m}Tc]-MAG3-BN displays good radiolabeling together with certain favorable biological characteristics and might be a useful peptide radiopharmaceutical in the *in vivo* detection of BN receptor-expressing cancers.

Synthesis, radiolabeling, and biological characteristics of a bombesin peptide analogue as a tumor-imaging agent. Okarvi SM, al-Jammaz I. Anticancer Res 2003 May–Jun; 23 (3B), pp. 2745–50.

Neoplasia: Carcinoma/Colon Carcinoma Cell Adhesion to Endothelium/Intravital Observation of Cancer Cell/Microcirculation Interactions
CalceinAM

Background Information: Organ-specific tumor cell adhesion within the microcirculation of host organs is an important step in the metastatic cascade. Circulating tumor cells adhere to the luminal surface of microcirculatory vessels, then quickly stabilize these adhesion interactions. Ultimately, they leave the circulation to avoid the toxic effects of hydrodynamic shear forces exerted by circulating blood.

Application: Intravital observation of colon carcinoma cell adhesion within the hepatic microcirculation.

Route of Administration: Intravascular.

Implementation: CalceinAM can be used to label colon carcinoma cell populations (e.g., HT-29 [human] and CC531 [rat]) in order to track their biodistribution following intra-arterial injection as a single-cell suspension. Intravital fluorescence microscopy can then be applied to detect the development of adhesive interactions between circulating tumor cells and vascular endothelial surfaces within the hepatic microcirculation. These interactions are then analyzed regarding their time course and site localization within the vascular tree.

Animal Model: Rats (Sprague-Dawley).

Interpretation and Analysis: Autofluorescence of liver parenchyma is sufficient to distinguish hepatic sinusoids. Intravital microscopy is capable of differentiating early events in adhesion formation within hepatic sinosoids, adhesion stabilization, and extravasation of tumor cells into the liver parenchyma. Tumor cell adhesion occurs almost exclusively within sinusoidal capillaries; however, the diameter of these vessels is usually larger than that of tumor cells, leaving remaining area of perfused capillary lumen. Colon carcinoma cells rapidly migrate into the liver parenchyma after development of adhesion interactions within the sinusoids. In contrast to common end point assays of the metastatic cascade, this particular *in vivo* model allows investigation of metastatic colon carcinoma cell adhesion phenomenon within the liver microcirculation at specific steps during the formation of hematogenous metastasis and their underlying mechanisms.

Instrumentation: Intravital fluorescence microscopy.

An intravital model to monitor steps of metastatic tumor cell adhesion within the hepatic microcirculation. Haier J, Korb T, Hotz B, Spiegel HU, Senninger N. J Gastrointest Surg 2003 May–Jun; 7 (4), pp. 507–14; discussion 514–5.

Neoplasia/Carcinoma of the Colon (LS-180 Cell Type)/Guanyl Cyclase-C Receptor
[^{125}I]-Tyr(5)-6-Ahx-Phe(19)-ST[1-19]/ [^{111}In]-DOTA-NCS-6-Ahx-Phe(19)-ST[1-19]

Cellular/Molecular Mechanism of Action: [^{111}In]-DOTA-NCS-6-Ahx-Phe$_{19}$-ST[1-19] and [^{125}I]-Tyr$_5$-6-Ahx-Phe$_{19}$-ST [1-19] both recognize and bind to guanylate cyclase-C (GC-C) receptor complexes.

Application: Detection and characterization of human colon cancer (e.g., LS-180 cell strains).

Route of Administration: [^{111}In]-DOTA-NCS-6-Ahx-Phe$_{19}$-ST[1-19] and [^{125}I]-Tyr$_5$-6-Ahx-Phe$_{19}$-ST[1-19] (intravenous).

Implementation: Evaluation of the relative *in vitro* competitive binding of [^{111}In]-DOTA-NCS-6-Ahx-Phe$_{19}$-ST[1-19] to GC-C receptor complexes expressed by human colon cancer LS-180 cells compared to [^{125}I]-Tyr$_5$-6-Ahx-Phe$_{19}$-ST[1-19].

Animal Model: Murine (tumor-bearing severe combined immunodeficient [SCID] mice [LS-180 colon cancer cells]).

Interpretation and Analysis: Competitive *in vitro* binding studies of [^{111}In]-DOTA-NCS-6-Ahx-Phe$_{19}$-ST[1-19] and [^{125}I]-Tyr$_5$-6-Ahx-Phe$_{19}$-ST[1-19] for GC-C receptors expressed by human colon cancer LS-180 cell lines reveal an IC_{50} value of 7.7 $\pm$ 0.1.6 nM. In cellular residualization studies performed *in vitro*, binding of [^{111}In]-DOTA-NCS-ST to GC-C receptors stimulates cGMP production in LS-180 cell populations and demonstrates that this peptide selectively binds to LS-180 cells in an agonistic fashion. *In vivo* biodistribution studies in mice bearing LS-180 tumors reveal that the [^{111}In]-DOTA-NCS-ST peptide targets tumors with a specific uptake of 0.94 $\pm$ 0.31 percent injected dose/gram (%ID/g) at 1 hour postinjection and approximately 23% is retained by the tumor at 4 hours postinjection. Radioactivity clears rapidly from the bloodstream with 84.5 $\pm$ 3.4 %ID at 1 hour postinjection found in the urine. High activity in urine and kidney, and minimal activity in liver and intestines, demonstrates preferential clearance of the radioactivity through renal/urinary mechanisms. The specific *in vitro* and *in vivo* accumulation of radioactivity within LS-180 human colonic cancer cells highlights the potential of radiometallated-DOTA-ST analogues as candidate diagnostic and therapeutic radiopharmaceuticals.

In vivo evaluation of a [^{111}In]-labeled ST-peptide analogue for specific targeting of human colon cancers. Gali H, Sieckman GL, Hoffman TJ, Owen NK, Chin DT, Forte LR, Volkert WA. Nucl Med Biol 2001 Nov; 28 (8), pp. 903–9.

Neoplasia: Carcinoma/Colorectal Cancer
Antiphage Protein Combinatorial Fab

Cellular/Molecular Mechanism of Action: Immunoglobulin fractions that recognize membrane-associated antigens uniquely expressed by human colorectal cancer cell types.

Application: Immuno-detection of human colorectal cancer.
Route of Administration: Intravenous.
Semi-Synthetic Methods: A combinatorial Fab phage display library can be generated from antibody variable-region genes of each of 2 BALB/c mice immunized with the human colorectal cancer cell lines SW480, SW948, and SW837. Such libraries have been shown to have diverse nucleotide sequencing and diagnostic restriction enzyme digestion fragments (fingerprinting) of individual members.
Implementation: Utilization of 2 libraries (combined) selected for binding to a suspension of formaldehyde-fixed human colorectal cancer cells in 2 successive rounds of selection and phage amplification facilitated by infection of bacteria.
Interpretation and Analysis: Analysis of the selected libraries as well as individual library clones by ELISA reveals binding to cancer cell lines in both formaldehyde-fixed and native forms of tissue sections. Fifty-five percent and 94% of library clones are positive for colorectal cancer cell binding properties after the 1st and 2nd rounds of selection, respectively. Fingerprinting of individual clones shows that the 1st selected library is very diverse, while the 2nd selected library has a more limited level of diversity. After absorption with normal human cell types, these anticancer selected libraries could be used to develop alternative therapeutic and/or diagnostic agents.

Generation of anticolorectal cancer Fab phage display libraries with a high percentage of diverse antigen-reactive clones. Williams BR, Sompuram SR, Sharon J. Comb Chem High Throughput Screen 2002 Sep; 5 (6), pp. 489–99.

Neoplasia: Carcinoma/Colorectal Carcinoma/ Human Colorectal Carcinoma Xenographs (SW1222) in Mice
Pretargeting Monoclonal Antibody (MAb) Medicated/ [^{64}Cu]-DOTA-Biotin/[^{64}Cu]-DOTA-NR-LU-10

Background Information: Pretargeting involves administration of a tumor-targeting MAb covalently linked to a molecule having a high-affinity binding site for a rapidly distributed radiolabeled effector molecule.
Application: Pretargeted [^{64}Cu]-DOTA-biotin should afford markedly superior positron emission tomography (PET) imaging contrast and therapeutic efficacy due to its extremely rapid tumor uptake and blood clearance.
Semi-Synthetic Methods: DOTA-biotin (biotinylated 1,4,7,10-tetraazacyclododecane-N,N′,N′′,N′′′-tetraacetic acid) and the intact immunoconjugate DOTA-NR-LU-10 can be labeled to high specific activities with [^{64}Cu], and the serum stabilities and target binding capabilities of each agent can be determined *in vitro* prior to application.
Implementation: Compare pretargeting strategies and conventionally labeled antibody for tumor antigens for their capcity to target neoplastic lesions following labeling with the intermediate-lived radionuclide [^{64}Cu], which has shown promise for PET imaging and radioimmunotherapy of cancer. One approach to characterizing "pretargeting" strategies can involve the evaluation of preparations in nude mice bearing SW1222 human colorectal carcinoma xenografts. Semi-synthetic preparations of [^{64}Cu]-DOTA-biotin are administered, with and without MAb-streptavidin conjugate NR-LU-10/SA pretreatement and the synthetic clearing agent Biotin-GalNAc$_{16}$, or injected with [^{64}Cu]-DOTA-NR-LU-10. Biodistributions of both agents are obtained from 5 minutes to 48 hours after injection.
Interpretation and Analysis: Both [^{64}Cu]-DOTA-biotin and [^{64}Cu]-DOTA-NR-LU-10 are 100% stable *in vitro* in serum. [^{64}Cu]-DOTA-biotin exhibits $>$ 98% specific binding to immobilized streptavidin, whereas the immunoreactivity of [^{64}Cu]-DOTA-NR-LU-10 averages nearly 80%. Biodistribution analysis in SW1222-bearing mice shows that NR-LU-10/SA-pretargeted [^{64}Cu]-DOTA-biotin attains a peak tumor uptake of 18.9% of the injected dose per gram (%ID/g) at 1 hour, with concomitant rapid disappearance from blood and renal excretion. In the absence of pretargeting, [^{64}Cu]-DOTA-biotin has very similar biodistribution and clearance properties, except with extremely low non-specific tumor uptake. Alternatively, [^{64}Cu]-DOTA-NR-LU-10 reaches 80.3 %ID/g in tumor tissue after 48 hours, whereas blood clearance is considerably slower than pretargeted [^{64}Cu]-DOTA-biotin. Comparison of the time-activity curves for tumor uptake and blood clearance of pretargeted [^{64}Cu] and the [^{64}Cu]-labeled antibody reveal that the maximum tumor accumulations of radioactivity are similar for each agent (e.g., 17.9% of injected activity per gram [%IA/g] and 20.7%IA/g, respectively). However, the tumor-to-blood ratio of areas-under-the-curve is 14 times higher for pretargeted [^{64}Cu]-DOTA-biotin because of the substantial increase in blood clearance of the small effector molecule. The extremely rapid tumor uptake and blood clearance of pretargeted [^{64}Cu]-DOTA-biotin should afford the development of a markedly superior PET imaging agent, compared to conventionally labeled [^{64}Cu]-DOTA-NR-LU-10. Further comparison of the therapeutic efficacy, toxicity, and dosimetry of these 2 agents is warranted.

In vivo evaluation of pretargeted ^{64}Cu for tumor imaging and therapy. Lewis MR, Wang M, Axworthy DB, Theodore LJ, Mallet RW, Fritzberg AR, Welch MJ, Anderson CJ. J Nucl Med 2003 Aug; 44 (8), pp. 1284–92.

Neoplasia: Carcinoma/Intestinal Microcarcinomas
Indocyanine Green (ICG)-Labeled Anti-MUC1 Mucin IgG

Cellular/Molecular Mechanism of Action: Anti-MUC1 mucin IgG possesses binding avidity for complexes expressed on the exterior surface membrane of human gastric carcinoma and colon carcinoma.
Application: Labeling of microcarcinomas to a degree sufficient for accurate and sensitive detection by videoendoscopy.
Considerations: Videoendoscopy has not significantly advanced diagnostic accuracy beyond that attainable by conventional fiberscopy, with respect to microcarcinomas of the digestive tract.
Semi-Synthetic Methods: Conjugation of ICG to anti-MUC1 mucin immunoglobulin to produce a conjugated product that has binding avidity for complexes expressed on the exterior surface membrane of intestinal carcinoma cell types.
Animal Model: Nude mice transplanted with human gastric cancer or colorectal cancer.
Interpretation and Analysis: Anti-MUC1 mucin antibody binds *in vivo* to human gastric cancer or colorectal cancer transplants in nude mice, which can be confirmed by performing immunohistochemistry analysis with a secondary antibody. The antibody labeled with an ICG derivative may therefore be clinically useful in detecting gastrointestinal microcarcinomas by videoendoscopy.
Instrumentation: Videoendoscopy.

Vital immunostaining of human gastric and colorectal cancers grafted into nude mice: A preclinical assessment of a potential adjunct to videoendoscopy. Kusaka Y, Ito S, Muguruma N, Tadatsu M, Bando T, Ii K, Irimura T, Shibamura S. J Gastroenterol 2000; 35 (10), pp. 748–52.

Neoplasia/Carcinomas of the Ovary and Breast
Anti-gp185HER-2 IgG Monoclonal Antibody (MAb)/ Tunicamicyn

Cellular/Molecular Mechanism of Action: Anti-gp185HER-2 IgG MAb recognizes and physically binds to the trans-membrane glycoprotein gp185HER-2 (185-kDa). The oncogene HER-2/neu encodes for this trans-membrane glycoprotein that is known to pos-

sess tyrosine-kinase activity. Gene amplification and high levels of gp185HER-2 expression have been found to correlate with poor clinical outcome in breast and ovarian carcinomas. (Note: Tunicamicyn functions as an inhibitor of N-linked glycosylation.)

Semi-Synthetic Methods: Given the objective of establishing efficient methods for the production of murine MAb with a high degree of antigen specificity, somatic cell hybrid fusion protocols that yield a high production frequency for hybridomas can be utilized to evaluate immune responses to the extracellular domain of gp185 glycoprotein fractions. In this manner, immunogen cell types (e.g., NIH 3T3) that express high levels of tranfected gene for (human) HER-2 can be utilized to generate monoclonal antibody preoparations that are primarily the IgG1 isotype and possess relatively high affinity for gp185 fractions (e.g., 10^7 to 10^{10} mol/L). Five distinct groups of spatially related epitopes have been identified through the application of epitope specificity analysis. Each of these segments provides different levels of immunodominancy, and all are resistant to formalin fixation. Immunoglobulins bind to epitopes localized in the protein core region of gp185HER-2 based on experimental findings observed with the application of tunicamicyn (inhibitor of N-linked glycosylation).

Interpretation and Analysis: In normal tissues, gp185HER-2 has a restricted expression and is homogenously detectable in metastatic foci of gp185 + primary tumors. Conservative speculation suggests that antibodies to this macromolecule glycoprotein potentially have *in vitro* as well as *in vivo* diagnostic, prognostic, and possibly therapeutic value.

Production and characterization of murine MAbs to the extracellular domain of human neu oncogene product GP185HER-2. Digiesi G, Giacomini P, Fraioli R, Mariani M, Nicotra MR, Segatto O, Natali PG. Hybridoma 1992 Aug; 11 (4), pp. 519–27.

Neoplasia/Carcinoma of the Ovary/HER-2/neu Overexpression
Anti-HER-2/neu Single-Chain Fv IgG

Cellular/Molecular Mechanism of Action: Anti-HER-2/neu single-chain Fv antibodies possess binding avidity for neoplastic cell HER-2/neu complexes.

Background Information: Single-chain Fv (scFv) molecules (MR 25,000) are rapidly eliminated from the circulation of immunodeficient mice, yielding highly specific retention of small quantities of scFv in human tumor xenografts.

Application: Detection and characterization of ovarian carcinoma lesions.

Route of Administration: Anti-HER-2/neu single-chain Fv antibodies (intravascular).

Implementation: Evaluation of the hypothesis that the specific retention of scFv in tumors can be enhanced by bioengineering to significantly increase the affinity of the scFv for target antigens. Affinity mutants of the human anti-HER-2/neu (c-erbB-2) scFv C6.5 can be generated by site-directed mutagenesis, which targets the same antigenic epitope with a 320-fold range in affinity (3.2×10^{-7} to 1.0×10^{-9} M).

***Ex Vivo* Model:** Human ovarian carcinoma (SK-OV-3 cell type overexpressing HER-2/neu).

Animal Model: Murine (severe combined immunodeficient [SCID] mice bearing established SK-OV-3 tumors).

Interpretation and Analysis: *In vitro*, the Kd of each scFv correlates closely with the duration of its retention on the surface of ovarian carcinoma cells. In biodistribution studies performed in tumor-bearing mice, the degree and specificity of tumor localization increases significantly with increasing affinity. At 24 hours after injection, tumor retention of the highest affinity scFv is 7-fold greater than that of a mutant with 320-fold lower affinity for HER-2/neu. Because the rapid renal clearance of scFv may blunt the impact of improved affinity on tumor targeting, the distributions can also be established in the absence of renal clearance (e.g., in mice rendered surgically anephric). In such a model, the peak tumor retentions of the 2 higher affinity scFv approximate that reported previously for IgG targeting the same SK-OV-3 tumors in SCID mice with intact kidneys. In contrast, mutants with the lowest affinity for HER-2/neu fail to accumulate within tumors, indicating the presence of an affinity threshold that must be exceeded for active *in vivo* tumor uptake to occur. These results indicate that affinity can significantly impact the *in vivo* tumor-specific retention of scFv molecules.

Increased affinity leads to improved selective tumor delivery of single-chain Fv antibodies. Adams GP, Schier R, Marshall K, Wolf EJ, McCall AM, Marks JD, Weiner LM. Cancer Res 1998 Feb 1; 58 (3), pp. 485–90.

Neoplasia/Carcinomas of the Prostate, Breast and Vascular Endothelium/Human Carcinoid Bon Cells/ Rat Pancreatic Tumor Cells (CA20948)
[^{111}In]-[c(Arg-Gly-Asp-D-Tyr-Lys)]/ [^{125}I]-[c(Arg-Gly-Asp-D-Tyr-Lys)]

Cellular/Molecular Mechanism of Action: Purified fractions of [c(Arg-Gly-Asp-D-Tyr-Lys)] appear to bind specifically and with high affinity to $\alpha_V\beta_3$ receptors on neovascular blood vessel sections of different major human cancers, including prostatic carcinoma and mammary carcinoma, that express this receptor type.

Background Information: Tumors depend on sufficient blood supply for their growth. They are able to promote new blood vessel formation (neoangiogenesis) via angiogenic factors. Inhibition of this process typically results in tumor involution or necrosis. RGD (Arg-Gly-Asp) peptides have been found to antagonize neoangiogenesis, for example, by binding to $\alpha_V\beta_3$ receptors on blood vessels.

Implementation: Evaluate the ability to visualize neoangiogenesis phenomenon in tumors *in vitro* and *in vivo*, with the RGD analogue [c(Arg-Gly-Asp-D-Tyr-Lys)], coupled to the chelator group diethyleletriame pentaacetic acid (DTPA). This analogue can subsequently be radiolabeled with both [^{111}In] and [^{125}I].

Interpretation and Analysis: In autoradiography and immunohistochemistry studies, [^{125}I]-labeled [c(Arg-Gly-Asp-D-Tyr-Lys)] appears to bind specifically and with high affinity to $\alpha_V\beta_3$ receptors on neovascular blood vessel sections of different major human cancers, including prostate and breast neoplastic conditions that express this receptor type. The radioiodinated pharmaceutical also binds to and becomes internalized in human carcinoid Bon cells and rat pancreatic CA20948 tumor cells. Internalization is receptor specific and appears to be time and temperature dependent. Administration of different peptide amounts (0.1, 0.5, and 100 μg) *in vivo* (e.g., rats) reveals that the optimum amount of the radiolabeled analogues appears to be 0.1 μg/rat, because uptake decreases with increasing peptide doses. The [^{111}In]-labeled analogue accumulates in transplantable CA20948 pancreatic tumors in a receptor-specific manner. The introduction of a DTPA group in this peptide results in renal clearance of the radiopharmaceutical, in contrast to the non-DTPA-conjugated compound that is cleared predominantly via the liver. [^{111}In] emits auger and conversion electrons besides gamma radiation, therefore this radiopharmaceutical is suitable not only for tumor scintigraphy but also has potential as a radionuclide for therapeutic purposes, including some of the major forms of human cancer. Moreover, after coupling to the chelator DOTA, the analogue can be radiolabeled in a stable manner with beta-emitters, for example, [^{90}Y] and [^{177}Lu], expanding its theoretical potential.

Evaluation of a radiolabeled cyclic DTPA-RGD analogue for tumor imaging and radionuclide therapy. van Hagen PM, Breeman WA, Bernard HF, Schaar M, Mooij CM, Srinivasan A, Schmidt MA, Krenning EP, de Jong M. Int J Cancer (Radiat. Oncol. Invest.) 2000 Aug 20; 90 (4), pp. 186–98.

Neoplasia: Carcinoma/Prostatic Carcinoma/Gene Expression Imaging
[Gd]-Anti-mRNA Oligonucleotide Strand/Trans-Membrane Carrier Peptide

Cellular/Molecular Mechanism of Action: The physical (special) orientation of gadolinium changes when placed within a magnetic field. Trans-membrane carrier proteins are transported across cell membrane structures by specific membrane-associated complexes. Oligonucleotides can be designed as complementary sequence to specific messenger RNA (mRNA) strands and the resulting cDNA/mRNA double strand effectively prevents translation of the mRNA strand. Diagnostically, complementary strands of cDNA theoretically accumulate intracellularly within cells that are actively transcribing the corresponding mRNA sequences that cDNA strands have been designed to recognize.

Background Information: The term "molecular imaging" can be broadly defined as the *in vivo* characterization and measurement of biological processes at the cellular and molecular level.

Application: Detection of *in vivo* gene expression, including neoplastic cell oncogenes, applying magnetic resonance imaging (MRI) modalities.

Route of Administration: Intravascular injection would be the most preferred method of delivery.

Semi-Synthetic Methods: Development of a novel intravital and intracellular MRI contrast agent composed of a gadolinium complex, an oligonucleotide sequence (peptide nucleic acid [PNA]), and a trans-membrane carrier peptide composed of a peptide sequence similar to that of the homeodomain of the Antennapedia protein.

Implementation: Evaluate the capacity for [Gd]-oligonucleotide complexes to accumulate in tumor cells *in vitro* and *in vivo,* and investigate whether the specificity of a PNA for the upregulated c-myc mRNA in the cell's cytoplasm has an effect on contrast agent retention within tumor cells.

Tissue Culture Models: HeLa cell lines.

Animal Model: Rat (Dunning R3327 AT1 rat prostate adenocarcinoma).

Interpretation and Analysis: Using the c-myc-specific and a c-myc-non-specific control PNA, an increase in signal intensity in tumor cells can be observed after 10 minutes *in vitro* and *in vivo* (maximum reached *in vitro* at 60 minutes in HeLa cells compared to 30 minutes *in vivo* in Dunning R3327 AT1 rat prostate adenocarcinoma cells). Such increases in signal intensity can be maintained *in vitro* in HeLa cells for only 4 hours and in Dunning R3327 AT1 rat prostate adenocarcinoma cells *in vivo* for at least for 5 hours by using the c-myc mRNA-specific PNA as a "retention" agent.

Intracellular visualization of prostate cancer using magnetic resonance imaging. Heckl S, Pipkorn R, Waldeck W, Spring H, Jenne J, von der Lieth CW, Corban-Wilhelm H, Debus J, Braun K. Cancer Res 2003 Aug 15; 63 (16), pp. 4766–72.

Neoplasia: Carcinoma/Pulmonary Small Cell Cancer
Anti-Vasopressin (VP)-Associated Neurophysin Monoclonal IgG

Cellular/Molecular Mechanism of Action: Monoclonal antibody (MAb) fractions that are designed to recognize and physically bind to the VP-associated glycoprotein segment of pro-VP polypeptide that is associated with neurophysin-related cell surface antigen.

Application: Detection of small cell lung cancer lesions based on the concept that these neoplastic cell populations have neurophysin-related cell surface antigen incorporated into their exterior surface membrane.

Route of Administration: Anti-VP-associated neurophysin MAb (intravascular).

Considerations: The VP gene is largely expressed in hypothalamic neurons, where the resultant pro-VP polypeptide is enzymatically cleaved into its peptide hormone components, including the neuropeptides VP, VP-associated neurophysin, and VP-associated glycopeptide. Small cell lung cancer tumors also express the VP gene, but the tumor pro-VP protein can remain intact and localize on the cell surface membrane.

Interpretation and Analysis: Detection of an increased uptake (binding) of radiolabeled anti-VP-associated neurophysin MAb by tissues residing within the thoracic cavity reflects positive detection of small cell lung cancer lesions.

Polyclonal antibodies directed against different regions of the pro-VP molecule bind specifically to the surface of cultured small cell lung cancer cells and recognize proteins of approximately 20-kDa in contrast to the 40-kDa antigen identified in cultured small cell lung cancer whole-cell lysates. By convention, these protein antigens have been designated neurophysin-related cell surface antigen (plasma membrane-associated complex). A MAb preparation (e.g., MAG-1) has been produced that is directed against a synthetic peptide representing the COOH-terminal sequence of VP-associated glycopeptide.

Monoclonal antibodies with these binding characteristics recognize neurophysin-related cell surface antigen expressed by small cell lung cancer cells and contained in tissue lysates based on Western blot analysis. Immunofluorescent cytometric and microscopic analyses indicate that these same MAb preparations react specifically with neurophysin-related cell surface antigen on the surface of viable small cell lung cancer cells (classical and variant subtypes). Selectivity of MAb preparations as determined by immunohistochemical analysis react with human small cell lung cancer cells, but not with normal pulmonary epithelial cells in lung tissue. Limited proteolytic Fab fragment products of MAb also possess binding avidity for neurophysin-related cell surface antigen.

Targeting the neurophysin-related cell surface antigen on small cell lung cancer cells using a monoclonal antibody against the glycopeptide region (MAG-1) of provasopressin. Keegan BP, Memoli VA, North WG. Mol Cancer Ther 2002 Nov; 1 (13), pp. 1153–9.

Neoplasia/CCK-B Receptor Expression/ Meningiomas/Gastroenteropancreatic Tumors/ Medullary Thyroid Carcinoma/Small Cell Lung Cancer/Astrocytomas/Gastrointestinal Tumors/ Stromal Ovarian Cancer
[^{111}In]-DTPA-[Nle$_{28,31}$]-CCK$_{26-33}$ (MP2286)/ DTPA-[d-Asp$_{26}$,Nle$_{28,31}$]-CCK$_{26-33}$ (MP2288)

Cellular/Molecular Mechanism of Action: [^{111}In]-labeled MP2288 and [^{111}In]-labeled MP2286 recognize and physically bind to CCK-B receptor complexes.

Background Information: Receptors for regulatory peptides such as somatostatin or vasoactive intestinal polypeptide are expressed by a number of human neoplasms and can be visualized *in vivo* with peptide receptor scintigraphy. The CCK-B receptor, which binds both gastrin and cholecystokinin with high affinity, has been found using *in vitro* methods to be overexpressed by a number of

human tumor cell types, including medullary thyroid carcinomas, small cell lung cancers, astrocytomas, gastrointestinal tumors, and stromal ovarian cancers.

Semi-Synthetic Methods: Design of a novel, unsulfated CCK octapeptide analogue linked to diethylenetriamine pentaacetic acid (DTPA) and DOTA metal chelating agents.

Implementation: Evaluation of the binding avidity of unsulfated CCK octapeptide analogues linked to the metal chelating groups DTPA and DOTA for CCK-B receptor-positive human tumor tissues.

Animal Model: Rat (biodistribution studies).

Interpretation and Analysis: Assays reveal that the most potent compounds are DTPA-[$Nle_{28,31}$]-CCK_{26-33} (MP2286) and DTPA-[d-Asp_{26},$Nle_{28,31}$]-CCK_{26-33} (MP2288) with an IC_{50} of 1.5 nM. For comparison, analogues with C-terminal DTPA, such as [$Nle_{28,31}$,$Aphe_{33}$(*p*-NH-DTPA)]-CCK_{26-33} and CCK_{26-33}-NH$(CH_2)_2$ NH-DTPA, have an IC_{50} of $>$ 100 nM. DOTA-[D-Asp_{26}, $Nle_{28,31}$]-CCK_{26-33} has an IC_{50} of 3.9 nM. The compounds are selective for CCK-B receptors, as they do not bind with high affinity to CCK-A receptors expressed in human tumors (meningiomas or gastroenteropancreatic tumors). Biodistribution studies with [^{111}In]-labeled MP2286 and MP2288 show that the primary mode of clearance is renal, and the primary sites of uptake (percent injected dose/gram [%ID/g] 24 hours postinjection) are the kidney (0.270 and 0.262, respectively) and gastrointestinal tract (rat). The CCK-B receptor-expressing gastric mucosa shows specific *in vivo* accumulation of [^{111}In]-labeled MP2288 that can be blocked by excess unlabeled MP2288. [^{111}In]-labeled MP2286 and MP2288 are also found to be stable in human plasma, whereas both compounds are degraded in urine ($>$ 40% after 3 hours at 37°C). The affinity, specificity, biodistribution, and stability of these 2 DTPA-CCK analogues indicate that these compounds hold substantial promise for use in the *in vivo* visualization of CCK-B receptor-expressing tumors.

Unsulfated DTPA- and DOTA-CCK analogues as specific high-affinity ligands for CCK-B receptor-expressing human and rat tissues *in vitro* and *in vivo*. Reubi JC, Waser B, Schaer JC, Laederach U, Erion J, Srinivasan A, Schmidt MA, Bugaj JE. Eur J Nucl Med 1998 May; 25 (5), pp. 481–90.

Neoplasia/Gastrin-Releasing Peptide (GRP) Receptors/Prostatic Carcinoma/[Mammary Carcinoma]/[Small Cell Lung Cancer]/[Pancreatic Cancer]
[^{111}In]-Bombesin/[^{111}In]-DOTA-X-BBN_{7-14}-NH_2/Beta-Ala, 5-Ava Spacer/8-Aoc Spacer

Cellular/Molecular Mechanism of Action: Bombesin has been known to bind to GRP receptors with high affinity and specificity.

Background Information: Gastrin-releasing peptide receptors have been shown to be expressed with high densities on several types of cancer cells, including prostate, breast, small cell lung, and pancreas cancers.

Application: Hydrocarbon spacer chains can effectively improve the specificity of detecting and characterizing human prostatic carcinoma cell types when employing [^{111}In]-DOTA-bombesin as a template molecule for the purpose of recognizing gastrin-releasing peptide receptor complexes.

Route of Administration: Intravascular.

Implementation: Evaluation of the relative tumor "uptake" and pharmacokinetic parameters for various [^{111}In]-labeled bombesin analogues as potential candidates for specific targeting of human prostate cancers.

***Ex Vivo* Model:** Human (PC-3 androgen-independent human prostate cancer cells).

Animal Model: Murine (PC-3 human prostate cancer-derived xenografts in CF-1 and severe combined immunodeficient [SCID] mice).

Interpretation and Analysis: *In vitro* competitive binding assays, using PC-3 androgen-independent human prostate cancer cells, reveal values $<$ 2.5 nmol/L for inhibitory concentration of 50% for analogues with beta-Ala, 5-Ava, and 8-Aoc spacers. *In vivo* biodistribution studies of [^{111}In]-DOTA-X-BBN_{7-14}-NH_2 conjugates performed on CF-1 mice at 1 hour after injection reveals that radioactivity uptake within the pancreas (Note: A GRP-receptor-expressing tissue) increases as a function of hydrocarbon spacer length (Data: 0.20 + 0.04 percentage injected dose [%ID] per gram for the analogue with no spacer to a maximum of 26.97 + 3.97 %ID/g for the analogue with 8-Aoc spacer). Radioactivity is cleared efficiently from the blood pool by excretion mainly through the renal/urinary mechanisms (e.g., 71.6 + 1.8 %ID at 1 hour postinjection for 8-Aoc spacer analog). *In vivo* pharmacokinetic studies of the [^{111}In]-DOTA-8-Aoc-BBN[7-14]NH_2 conjugate conducted with PC-3 human prostate cancer-derived xenografts in SCID mice show a specific uptake of radioactivity in tumors, with 3.63 + 1.11 %ID/g observed at 1 hour postinjection. High tumor-to-blood and tumor-to-muscle ratios of approximately 6:1 and 45:1, respectively, can be appreciated at 1 hour after injection. Relative to the radioactivity observed in the tumor at 1 hour after injection, 43%, 19%, and 9% of the radioactivity is retained respectively, at 24, 48, and 72 hours postinjection.

These studies show that radiometallated DOTA-X-$BBN_{7-14}NH_2$ constructs with hydrocarbon spacers ranging from 5 to 8 carbon atoms are feasible candidates for further development as diagnostic and therapeutic radiopharmaceuticals for GRP-positive neoplastic disease states.

Novel series of [^{111}In]-labeled bombesin analogues as potential radiopharmaceuticals for specific targeting of gastrin-releasing peptide receptors expressed on human prostate cancer cells. Hoffman TJ, Gali H, Smith CJ, Sieckman GL, Hayes DL, Owen NK, Volkert WA. J Nucl Med 2003 May; 44 (5), pp. 823–31.

Neoplasia/Gliomas/Mammary Tumors (Carcinogen-Induced)
[^{99m}Tc])Field Bean Protease Inhibitor (FBPI)/[^{99m}Tc]-(V)Dimercaptosuccinic Acid (DMSA)/[^{201}Thallous] Chloride (TlCl)/[$^{99m}TcO_4^-$]-Citrate

Application: Detection and characterization of glioma and potentially other forms of neoplastic disease.

Route of Administration: [$^{99m}TcO_4^-$]-labeled purified FBPI (intravenous).

Semi-Synthetic Methods: Purified field bean protease inhibitor can be labeled with [$^{99m}TcO_4^-$] as a tracer molecule for diagnostic purposes. Radiolabeling is done in the presence of [Sn^{2+}] functioning as a reducing agent and the resulting yield is 95% (approximately). At room temperature, the product is stable for at least a 2-hour incubation period.

Implementation: Evaluation of the biodistribution of [^{99m}Tc]-labeled purified FBPI to ascertain its ability to locate within neoplastic lesions. Biodistribution analysis can be determined at various time intervals following administration.

Animal Model: Rat (Wistar strain bearing carcinogen-induced mammary tumors or transplanted C6 glioma cell lines).

Interpretation and Analysis: Biodistribution analysis of [^{99m}Tc]-FBPI reveals that it undergoes rapid blood clearance from the systemic circulation (approximately 5 hours). The complex is predominantly eliminated through renal and hepatobiliary excretory mechanisms. The tumor to muscle (T/M) ratios obtained with

[^{99m}Tc]-FBPI in C6 glioma explants is nearly 2-fold to 5-fold higher than observed with several conventional tumor-seeking radiopharmaceuticals such as [$^{99m}Tc^{V}$]-DMSA, TlCl, or [^{99m}Tc]-citrate. Similarly, the T/M ratio obtained with [^{99m}Tc]-FBPI in an *in vivo* mammary tumor model appears to be 2-fold to 3-fold higher than observed with [$^{99m}Tc^{V}$]-DMSA and [^{201}TlCl]. The ratio is, however, comparable with that obtained with [^{99m}Tc]-citrate. Such findings indicate that [^{99m}Tc]-FBPI has the specific potential for effectively imaging gliomas and possibly other neoplastic conditions as well.

[^{99m}Tc]-labeled field bean protease inhibitor can function as an efficient tumor-detecting agent. Murugesan S, Banerji AP, Noronha OP, Samuel AM, Fernandes AO. Indian J Exp Biol 2001 Aug; 39 (8), pp. 742–7.

Neoplasia/Insulin-Like Growth Factor (IGF) Binding Proteins
[^{125}I]-Labeled-IGF

Cellular/Molecular Mechanism of Action: Insulin-like growth factors recognize and bind to membrane-associated receptor complexes (IGF binding proteins).
Application: Detection and characterization of certain neoplastic disease types.
Considerations: [^{125}I]-labeled IGF-I is degraded quite rapidly within the cytosol of some neoplastic cell types.
Semi-Synthetic Methods: Production of [^{125}I]-labeled-IGF-I by the radioiodination of IGF-I using chloramines-T reagent.
Implementation: Evaluation of the biodistribution and tumor targeting ability of radiolabeled IGFs in the form of [^{125}I]-labeled-IGF-I. Because IGF binding proteins (IGFBPs) play a critical role in modulating IGF activity, the binding properties of [^{125}I]-labeled IGF-I to IGFBPs can be investigated in both *in vitro* and *in vivo* environments. Validation of the relative specificity of uptake can in part be established by co-administration of unlabeled peptide. Delineation of the catabolism of IGF-I by tumor cells *in vitro* can also be performed because a large amount of IGF-I is catabolized *in vivo* following intravascular injection. In summary, chromatography analysis can be performed on *in vitro* and *in vivo* biological samples in order to determine the binding profile to IGFBPs and measure serum/urine catabolite concentrations.

Animal Model: Rat and mouse (tumor-bearing nude mice).
Interpretation and Analysis: Binding of radiolabeled IGF-I to IGFBPs *in vitro* occurs in a dose-dependent manner. However, there is a difference in complex formation between serum and heparinized plasma. In heparinized plasma, radioactivity shifts from a 30- to 50-kDa complex to a 150-kDa complex and to a free ligand, because the binding of heparin with IGFBPs decreases its affinity for IGF-I. In plasma prepared with acid citrate dextrose a binding pattern identical to that of serum can be observed. Moreover, there is a binding difference between mouse and rat. The [^{125}I]-labeled IGF-I is catabolized very quickly when incubated at 37°C but not at all at 4°C. In tumor-bearing nude mice, the uptake of radioactivity in normal tissues decreases quickly, particularly in the kidneys. In mice coinjected with unlabeled carrier, the radioactivity in most normal tissues is lower and the tumor uptake higher than in mice without carrier administration. [^{125}I]-labeled IGF-I is avidly bound to IGFBPs, both *in vitro* and *in vivo*. By partially saturating this binding site with unlabeled peptides, a favorable biodistribution can be achieved, including faster clearance from normal tissue and higher tumor uptake, which results in better tumor-to-nontumor ratios. Nevertheless, the rapid catabolism and release of the radiolabel from tumor tissue result in a suboptimal targeting agent.

Effects of insulin-like growth factor binding proteins on insulin-like growth factor-I biodistribution in tumor-bearing nude mice. Sun BF, Kobayashi H, Le N, Yoo TM, Drumm D, Paik CH, McAfee JG, Carrasquillo JA. J Nucl Med 2000 Feb; 41 (2), pp. 318–26.

Neoplasia/Leukemia/Jurkat Leukemia Cells (Human)
[^{99m}Tc]-Tat-Peptide 4/[Fluorescein-5-Maleimide]-Tat-Peptide

Cellular/Molecular Mechanism of Action: [Tc/Re(V)] complexes can rapidly translocate across cell membranes into intracellular cytosol. Fluorescein-5-maleimide can be used to label biological peptides.
Background Information: Development of rapid and efficient modalities for delivery of radioactive metal complexes to the cell interior would facilitate novel applications in medical imaging and radiotherapy.
Application: [^{99m}Tc]-Tat-peptide 4 can potentially be applied for diagnostic imaging of certain neoplastic disease types.
Route of Administration: [^{99m}Tc]-Tat-peptide 4 (intravascular).
Semi-Synthetic Methods: A membrane permeant peptide conjugates incorporating HIV-1 Tat transactivation protein sequences (GRKKRRQRRR) can be conjugated to an appropriate peptide-based motif (epsilon-KGC) that provides an N_3S donor core for chelating technetium or rhenium. Oxotechnetium(V) and oxorhenium(V) Tat-peptide complexes can be prepared by facile transchelation reactions with permetalates, tin chloride ($Sn^{+2}CL_2$)and sodium glucoheptonate. Reverse-phase high-pressure liquid chromatography (RP-HPLC) can detect 2 major [^{99m}Tc]-Tat-peptide species that differ in retention time by approximately 2 minutes corresponding to 2 [Re]Tat-peptide species that have identical mass. Such findings are consistent with the formation of 2 isomers, likely to be oxo-metal diastereomers. [^{99m}Tc]-Tat-peptides are stable transchelates *in vitro*. To facilitate analysis using fluorescent microscopy, the C-terminus thiol of the prototypic Tat-peptide can be labeled with fluorescein-5-maleimide (yielding conjugate 8).
Implementation: Evaluation of binding avidity and stability of [^{99m}Tc]-Tat-peptide 4 in the presence of human Jurkat cell populations.

Tissue Culture Model: Human Jurkat KB 3-1 and KB 8-5 leukemia cell types.

Animal Model: Murine (*in vivo* investigations).
Interpretation and Analysis: In human Jurkat cells, [^{99m}Tc]-Tat-peptide 4 primarily accumulates within cell populations (30-fold greater than extracellular concentrations) and is associated with rapid uptake kinetics ($t_{1/2} < 2$ min) in a diastereomeric-comparable manner. Paradoxically, uptake is enhanced at 4ºC in buffer compared to 37ºC, while depolarization of membrane potential as well as inhibition of microtubule function and vesicular trafficking show no inhibitory effect. Cells preloaded with [^{99m}Tc]-Tat-peptide species (conjugate 4) show rapid washout kinetics into peptide-free solutions. Modification of [^{99m}Tc]-Tat-peptide by the deletion of the N-terminus Gly with or without biotinylation minimally impacts net-cell uptake.

Fluorescence microscopy reveals that the [fluorescein-5-maleimide]-Tat-peptide complex (conjugate 8) can directly localize within the cytosol and nuclei (possibly nucleolus) of human Jurkat, KB 3-1 and KB 8-5 tumor cells. Preliminary *in vivo* imaging studies in mice following intravenous administration of prototypic [^{99m}Tc]-Tat-peptide (conjugate 4) reveals an initial whole-body distribution and rapid clearance by both renal and hepatobiliary excretion. Analysis of murine blood *in vivo* and human serum *ex vivo* reveals > 95% of the complex in the intact parent product, while murine urine *in vivo* contains 65% parent complex. Thus, these novel Tat-peptide chelate conjugates, capable of forming stable [Tc/Re(V)]complexes, rapidly translocate across cell membranes into intracellular compart-

ments and can be readily derivatized for further targeting applications in molecular imaging and radiotherapy.

Novel Tat-peptide chelates for direct transduction of technetium-99m and rhenium into human cells for imaging and radiotherapy. Polyakov V, Sharma V, Dahlheimer JL, Pica CM, Luker GD, Piwnica-Worms D. Bioconjug Chem 2000 Nov–Dec; 11 (6), pp. 762–71.

Neoplasia/Lymphoma: Non-Hodgkin's Lymphoma *[^{99m}Technetium] ([^{99m}Tc])-Antilymphoma IgG Fragment*

Cellular/Molecular Mechanism of Action: Antilymphoma IgG fragment detects and physically binds to membrane-associated antigens uniquely expressed on the exterior surface of neoplastic populations of this histiological cell type.

Application: Detection and characterization of non-Hodgkin's lymphoma. Administration of IgG fragments has the advantage of decreased non-specific binding to Fc receptor complexes expressed at a high density on the exterior surface membrane of the mononuclear phagocytic system (reticuloendothelial cell types) found in high concentrations within the spleen, liver, and lung.

Route of Administration: Intravenous.

Implementation: Staging of recurrent or newly diagnosed non-Hodgkin's lymphoma (NHL) applying [^{99m}Tc]-labeled antilymphoma immunoglobulin fragment, bectumomab [LymphoScan]. Assessment can be performed applying computed x-ray tomography (CT), radiogallium imaging, FDG-PET, and bone marrow biopsy (e.g., n = 117 defined sites).

Human Model: Non-Hodgkin's lymphoma (recurrent and at initial diagnosis; n = 7 cases and n = 14 cases prior to radioimmunotherapy; n = 7 low-grade, n = 11 intermediate-grade, and n = 3 high-grade histiological cell subtypes).

Interpretation and Analysis: Bectumomab reveals 56% of these sites. In some cases (e.g., n = 4) bectumomab can discover sites not evident applying conventional imaging modalities (e.g., n = 5 sites). In addition, it can detect lesions within the brain (e.g., n = 1), which is an anatomical location not addressed in the standard work-up of asymptomatic cases. Bectumomab imaging most often fails in central abdominal and thoracic locations, but excells in revealing disease affecting the head and neck. Relative to [^{67}Ga]-citrate imaging, the performance of bectumomab is variable, with no clear relation to anatomic location. However, it is capable of better targeting low and intermediate grade NHL. Radiogallium outperforms bectumomab imaging in a relatively large number of cases (e.g., n = 23), some of which are high or intermediate-grade disease states (e.g., n = 19/23). Bectumomab is superior to radiogallium at a number of sites (e.g., n = 6), some of which are associated with low-grade tumors (e.g., n = 5/6). Bectumomab shows promise as a pre-RIT probe for targeting of B-cell NHL. It excels at defining small volume, low-grade disease. However, as a purely diagnostic agent, its performance is variable.

Radioimmunoscintigraphy (RIS) with bectumomab (Tc99m labeled IMMU-LL2, Lymphoscan) in the assessment of recurrent non-Hodgkin's lymphoma (NHL). Lamonica D, Czuczman M, Nabi H, Klippenstein D, Grossman Z. Cancer Biother Radiopharm 2002 Dec; 17 (6), pp. 689–97.

Neoplasia/Melanoma (Metastatic)/Melanocyte-Stimulating Hormone Receptor Expression (MSH Receptor) *[^{111}In])-DOTA-NDP-MSH/[^{111}In]-DOTA-MSH(OCT)*

Cellular/Molecular Mechanism of Action: The peptide [Nle$_4$, D-Phe$_7$]-alpha-MSH is a very potent alpha-MSH analogue that recognizes and physically binds to melanocyte stimulating hormone receptor complexes. Similarly, [betaAla$_3$, Nle$_4$, Asp$_5$, D-Phe$_7$, Lys$_{10}$]-alpha-MSH$_{3\text{-}10}$ is an alpha-MSH octapeptide analog.

Background Information: Scintigraphic imaging of metastatic melanoma lesions requires highly tumor-specific radiolabeled compounds. Because both melanotic and amelanotic melanomas overexpress receptors for alpha-melanocyte-stimulating hormone (alpha-MSH; receptor name: melanocortin type 1 receptor, or MC1R), radiolabeled alpha-MSH analogues are potential candidate diagnostic agents for the detection and characterization of melanoma lesions.

Application: Detection and characterization of metastatic melanoma lesions including melanotic and amelanotic cell types.

Route of Administration: [^{111}In]-DOTA-NDP-MSH and [^{111}In]-DOTA-MSH(OCT) most frequently would be administered intravascularly in a clinical environment.

Semi-Synthetic Methods: Covalent conjugation of [Nle$_4$, D-Phe$_7$]-alpha-MSH (NDP-MSH) and the alpha-MSH octapeptide analog, [betaAla$_3$, Nle$_4$, Asp$_5$, D-Phe$_7$, Lys$_{10}$]-alpha-MSH$_{3\text{-}10}$ (MSH(OCT)) to the metal chelator group 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) to facilitate radiometal incorporation into conjugated complexes.

Implementation: Evaluation of the (i) potential *in vitro* binding avidity of [^{111}In]-DOTA-NDP-MSH and [^{111}In]-DOTA-MSH(OCT) for melanocortin type 1 receptor (MC1R); (ii) melanogenic activity of [^{111}In]-DOTA-NDP-MSH and [^{111}In]-DOTA-MSH(OCT) in isolated mouse B16F1 cell lines; and (iii) *in vivo* biodistribution of the hormone receptor ligands in mouse models of primary and metastatic melanoma.

Animal Model: Murine (melanoma B16F1-bearing mice).

Interpretation and Analysis: DOTA-MSH(oct) binds with high affinity (inhibitory concentration of 50% IC$_{50}$ = 9.21 nmol/L) to MC1R, although with lower potency than does DOTA-NDP-MSH (IC$_{50}$ = 0.25 nmol/L). In B16F1 melanoma-bearing mice, both [^{111}In]-DOTA-NDP-MSH and [^{111}In]-DOTA-MSH(OCT) exhibit high MC1R-mediated uptake by melanoma, which differs by a factor of only 1.5 at 4 hours postadministration. The main route of excretion for both radioconjugates is the kidneys, whereby [^{111}In]-DOTA-MSH(OCT) produces somewhat higher kidney values than does [^{111}In]-DOTA-NDP-MSH. In contrast, the latter conjugate is much more poorly cleared from other non-malignant tissues, including bone, the most radiosensitive organ. Therefore, [^{111}In]-DOTA-MSH(OCT) displays higher uptake ratios of tumor to non-target tissue (e.g., tumor-to-bone ratio at 4 hours postadministration is approximately 4.9 for [^{111}In]-DOTA-NDP-MSH and 53.9 for [^{111}In]-DOTA-MSH(OCT)). Lung and liver melanoma metastases can easily be visualized on tissue section autoradiographs after injection of [^{111}In]-DOTA-MSH(OCT). Radio-reversed-phase high-performance liquid chromatography analysis of urine samples reveals that most [^{111}In]-DOTA-MSH(OCT) is excreted intact 4 hours after injection, indicating good *in vivo* stability. Therefore, [^{111}In]-DOTA-MSH(OCT) appears to exhibit more favorable overall performance than does [^{111}In]-DOTA-NDP-MSH in murine models of primary and metastatic melanoma, making it a promising melanoma imaging agent.

A novel DOTA-alpha-melanocyte-stimulating hormone analogue for metastatic melanoma diagnosis. Froidevaux S, Calame-Christe M, Tanner H, Sumanovski L, Eberle AN. J Nucl Med 2002 Dec; 43 (12), pp. 1699–706.

Neoplasia/Melanoma/Melanoma-Stimulating Hormone Receptor Complexes (MSH Receptor) *[^{111}Indium] ([^{111}In])-DOTA-MSH(OCT)/ [^{111}In]-DOTA-NDP-MSH*

Cellular/Molecular Mechanism of Action: The octapeptide [betaAla$_3$, Nle$_4$, Asp$_5$, D-Phe$_7$, Lys$_{10}$]-alpha-MSH$_{3\text{-}10}$ referred to as

MSH(OCT) is an analogue of alpha-melanocyte-stimulating hormone.

Background Information: Scintigraphic imaging of metastatic melanoma lesions requires highly tumor-specific radiopharmaceuticals. Because both melanotic and amelanotic melanomas overexpress melanocortin-1 receptors (MC1R), radiolabeled analogues of alpha-melanocyte-stimulating hormone (alpha-MSH) are potential candidate diagnostic agents for the detection and characterization of melanoma lesions.

Application: Detection and characterization of malignant melanoma lesions.

Route of Administration: [^{111}In]-DOTA-MSH(OCT) and [^{111}In]-DOTA-NDP-MSH (intravascular).

Semi-Synthetic Methods: Molecular design of the octapeptide analogue [betaAla$_3$, Nle$_4$, Asp$_5$, D-Phe$_7$, Lys$_{10}$]-alpha-MSH$_{3\text{-}10}$ (MSH(OCT)) involves the implementation of conjugation reactions involving its N-terminal amino group to the metal chelator group 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) to enable incorporation of radiometals (e.g., ^{111}In) into peptide products.

Implementation: Evaluation of the *in vitro* ligand binding-avidity of non-radioactive DOTA-MSH(OCT) for melanocrotin-1 receptors (MC1R). Complementary investigations can involve determining the *in vivo* biodistribution of [^{111}In]-DOTA-MSH(OCT) in normal reference control and tumor-bearing mice.

Animal Model: Murine (B16-F1 melanoma tumor-bearing mice).

Interpretation and Analysis: The non-radioactive ligand DOTA-MSH(OCT) possesses a relatively high level of *in vitro* binding avidity for MC1R complexes (IC_{50} 9.21 nM). The peptide analog, [^{111}In]-DOTA-MSH(OCT) *in vivo* exhibits a favorable biodistribution profile after injection in tumor-bearing mice. The radiopeptide is rapidly cleared from the blood through the kidneys and, most importantly, accumulates preferentially within melanoma lesions. Lung and liver melanoma metastases can be clearly imaged on tissue section autoradiographs 4 hours after injection of [^{111}In]-DOTA-MSH(OCT). A comparative study evaluating the relative merits of [^{111}In]-DOTA-MSH(OCT) relative to [^{111}In]-DOTA-[Nle$_4$, D-Phe$_7$]-alpha-MSH (^{111}In-DOTA-NDP-MSH) reveals that DOTA-MSH (OCT) peptide is a superior ligand reagent, particularly with regard to the amount of radioactivity taken up by non-malignant organs, including bone, the most radiosensitive tissue exposed. Therefore, [^{111}In]-DOTA-MSH(OCT) appears to be a promising melanoma-imaging agent.

DOTA alpha-melanocyte-stimulating hormone analogues for imaging metastatic melanoma lesions. Froidevaux S, Calame-Christe M, Sumanovski L, Tanner H, Eberle AN. Ann N Y Acad Sci 2003 Jun; 994, pp. 378–83.

Neoplasia/Melanoma (Multiple Neoplasia Types)
Spermidine Analogues/N-Acetyldopamine/ Chlorambucil

Application: Selective recognition of neoplastic cell types in a manner suitable for the design of a diagnostic agent or as a delivery modality for chemotherapeutic agents.

Semi-Synthetic Methods: Spermidine can be conjugated or covalently linked to various molecular groups. Reference example spermadine analogs include the cytotoxic biopharmaceutal agents; (compound 1a) *N*-[3,4-bis(benzyloxy)phenethyl]-*N* α-(3-aminopropyl)-*L*-ornithinamide trihydrochloride; and (compound 1b) *N*-[4-]bis(2-chloroethyl)amino]phenethyl]-*N* α-(3-aminopropyl)-*L*-ornithinamide tetrahydrochloride. These compounds can be prepared from the fully protected spermidine molecule with a carboxyl group side chain (compound 8).

Implementation: Evaluation of the ability for polyamine cytotoxic agents to inhibit B16-BL6 melanoma cell growth in culture in addition to the influence of DMSO pretreatment has on the activity of the synthesized compounds.

Interpretation and Analysis: The IC_{50} values of compounds 1a and 1b are on the same order of magnitude as the control compounds, N-acetyldopamine and chlorambucil, respectively. The inhibitory activities of compounds 1a and 1b are not enhanced by pretreatment with DMSO, suggesting that depletion of intracellular polyamines does not enhance the activity of these compounds.

Synthesis and evaluation of novel spermidine derivatives as targeted cancer chemotherapeutic agents. Stark PA, Thrall BD, Meadows GG, Abdel-Monem MM. J Med Chem 1992 Nov 13; 35 (23), pp. 4264–9.

Neoplasia/Neuroectoderm-Derived Tumors
Monoclonal Antibody: Paclitaxel Conjugate

Background Information: Paclitaxel (Taxol) is a chemotherapeutic agent that prevents disassembly of microtubular polymers, thereby causing growth arrest in the G2-M phase of the cell cycle and subsequent development of apoptosis phenomenon. Paclitaxel has remarkable efficacy against fast-growing tumors but possesses major drawbacks, such as poor solubility and lack of tumor selectivity. Conversely, monoclonal antibodies usually have low therapeutic efficacy but are highly soluble and capable of selectively targeting unique tumor markers overexpressed by neoplastic cell types.

Application: Selective targeting of pharmaceutical agents for neoplastic lesions in a manner that also simultaneously reduces their potential systemic toxicity. Example: Improved therapeutic index of taxane chemotherapeutics while decreasing the high toxicity of paclitaxel following conjugation to highly selective and highly solubile monoclonal antibodies functioning as a targeting delivery platform.

Semi-Synthetic Methods: Covalent linkage of paclitaxel to monoclonal antibody fractions capable of selectively targeting neuroectoderm-derived tumors to produce paclitaxel-antibody conjugates.

Implementation: Evaluation of the relative antineoplastic activity of paclitaxel-antibody conjugates compared to "free" paclitaxel alone.

Animal Model: Mouse (xenograph tumors).

Interpretation and Analysis: Covalent cross-linking of paclitaxel to antibody to form paclitaxel-antibody conjugates provides selective toxicity toward neuroectodermal tumor cells expressing target markers for which the monoclonal IgG has been designed to recognize. Interestingly, *in vitro* cytotoxicity of preparations is greater than equimolar concentrations of free paclitaxel or free paclitaxel plus free antibody. Systemic (*in vivo*) administration of paclitaxel-antibody conjugates prevents tumor growth and prolongs survival superior to free drugs. In addition, paclitaxel-antibody conjugates are highly soluble in water and stable at −20°C for at least 3 months.

Taxane-antibody conjugates afford potent cytotoxicity, enhanced solubility, and tumor target selectivity. Guillemard V, Saragovi HU. Cancer Res 2001 Jan 15; 61 (2), pp. 694–9.

Neoplasia/Neurotensin: Adenocarcinoma/ Pancreatic Cancer
[^{111}Indium] ([^{111}In])-Diethylenetriamine Pentaacetic Acid (DTPA)-Neurotensin [Arg$_8$, Arg$_9$, and Ile$_{12}$]/Fluorescein-Neurotensin [Arg$_8$, Arg$_9$, and Ile$_{12}$]

Cellular/Molecular Mechanism of Action: Native neurotensin (NT) is a tridecapeptide that binds to neurotensin receptor (NTR) and induces tumor growth.

Background Information: The prevalence of NTR in several human tumor cell types makes it an attractive target for the delivery of cytotoxic drugs and the development of imaging agents. Unfortunately, NT has a short plasma half-life, which hinders its use for *in vivo* biomedical applications. Numerous reports suggest that Arg_8-Arg_9 and Tyr_{11}-Ile_{12} amide bonds are particularly susceptible to degradation by proteolytic enzymes.
Semi-Synthetic Methods: Substitution of Arg_8, Arg_9, and Ile_{12} amino acids with the corresponding commercially available mimics. Preparations can be conjugated to DTPA chelation groups for subsequent radiolabeling to produce [^{111}In]-DTPA or alternatively conjugated with fluorescein.

Animal Model: Mouse (severe combined immunodeficient [SCID] bearing NTR-positive human adenocarcinoma [HT29] xenografts).
Interpretation and Analysis: The surrogate amino acids are amenable to standard Fmoc peptide synthesis strategies, and the resulting compounds are stable in biological media for $>$ 4 hours and bind to NTR with a high level of affinity. Conjugation of DTPA to the synthetic peptides and subsequent labeling with [^{111}In] to produce [^{111}In]-DTPA-NTR for nuclear imaging or fluorescein-NTR for optical imaging does not diminish NTR binding avidity. Evalution of the *in vivo* biodistribution of a representative [^{111}In]-DTPA-NT peptide analogue in HT29-bearing SCID mice reveals that the conjugate is primarily retained in tumor tissue (2.2% ID/g) and the kidneys (4.8% ID/g) at 4 hours postinjection. Coinjection of cold NT and the radiolabeled NT peptide analogue inhibits tumor but not kidney uptake, and demonstrates that retention of the radiolabeled compound in tumor tissue is mediated by NTR specific uptake while it accumulates in the kidneys by a non-specific mechanism. Conjugated NT peptide analogues therefore are robust and can deliver imaging agents to NTR-positive tumors including pancreatic cancer.

Novel bioactive and stable neurotensin peptide analogues capable of delivering radiopharmaceuticals and molecular beacons to tumors. Achilefu S, Srinivasan A, Schmidt MA, Jimenez HN, Bugaj JE, Erion JL. J Med Chem 2003 Jul 17; 46 (15), pp. 3403–11.

Neoplasia/Oxytocin Receptor Complex Expression/ Endothelial Carcinoma/Mammary Carcinoma/ Glioblastoma/Neuroblastoma
[^{111}Indium] ([^{111}In])-DOTA-Lys$_8$-Vasotocin (LVT)

Cellular/Molecular Mechanism of Action: Lys_8-vasotocin is an analogue of oxytocin that possesses high binding affinity for oxytoxin receptor complexes.
Semi-Synthetic Methods: Covalent cross-linking the chelating agent 1,4,7,10-tetraazacyclododecane-N,N′,N′′,N′′′-tetraacetic acid (DOTA) to LVT.
Implementation: Evaluate the ability of the radioactive ligand [^{111}In]-DOTA-Lys_8-vasotocin to recognize and physically bind to oxytocin receptors expressed by mammary carcinoma and glioblastoma cell types.

***Ex Vivo* Model:** MCF-7 (mammary carcinoma); MOG-U-V-W (glioblastoma) and transiently transfected COS7 cell lines.

Animal Model: Murine (TS/A mouse mammary tumor).
Interpretation and Analysis: The agent DOTA-Lys_8-vasotocin (DOTA-LVT) retains high *in vitro* binding affinity for human oxytoxin receptor complexes endogenously expressed by cell lines such as MCF7 breast carcinoma and MOG-U-V-W glioblastoma cells lines, as well as to transiently transfected COS7 cells. In investigations performed *in vivo,* [^{111}In]-DOTA-Lys_8-vasotocin specifically binds to oxytoxin receptor-positive TS/A mouse mammary tumors. Based on the nature of these laboratory findings, DOTA-LVT could potentially function as a plateform for imaging and, possibly, the treatment of oxytoxin receptor-positive human tumors such as breast and endometrial carcinomas, neuroblastomas, and glioblastomas.

^{111}In-labeled 1,4,7,10-tetraazacyclododecane-N,N′,N′′,N′′′-tetraacetic acid-Lys_8-vasotocin: A new powerful radioligand for oxytocin receptor-expressing tumors. Bussolati G, Chinol M, Chini B, Nacca A, Cassoni P, Paganelli G. Cancer Res 2001 Jun 1; 61 (11), pp. 4393–7.

Neoplasia/Pheochromocytoma/[Elevated Glucagon-Receptor Expression]
Des-[His$_1$Glu$_9$]Glucagon Amide/[^{125}I-Thyr$_{10}$]Glucagon

Cellular/Molecular Mechanism of Action: [^{125}I-$Thyr_{10}$] glucagon is a radiolabeled analogue of glucagon. Des-[His_1Glu_9] glucagon amide is a glucagon receptor antagonist.
Background Information: Pheochromocytoma lesions express glucagon receptor complexes at elevated membrane densities.
Application: Acquisition of potential diagnostic parameters for detecting conditions of pheochromocytoma. Des[His_1Glu_9]glucagon amide (GR-A) abolishes the secretory response to glucagon by pheochromocytomas.
Route of Administration: Experimental (*in vitro*).
Dosage: Experimental (*in vitro*).
Implementation: Evaluation of glucagon mRNA and glucagons receptor expression in pheochromocytoma lesions.

Human *Ex Vivo* Model: Pheochromocytoma lesions (n = 3 and n = 4 normal adrenal medullas).
Interpretation and Analysis: Glucagon-receptor mRNA can be detected by reverse transcription-polymerase chain reaction in human pheochromocytomas, but not in normal adrenal medullas. Quantitative autoradiography demonstrates the presence of abundant [^{125}I-$Thyr_{10}$]glucagon binding sites in pheochromocytomas, that can be displaced by both cold glucagon and the glucagon receptor antagonist Des-[His_1Glu_9]glucagon amide (GR-A). The adrenal medulla is weakly labeled, and binding is not displaced by GR-A. Glucagon enhanced epinephrine and norepinephrine release can be detected in pheochromocytoma slices at minimal and maximal effective concentrations of 10^{-8} M and 10^{-6} M respectively. Adrenomedullary slices display a weak catecholamine response only with 10^{-5} M glucagon.

GR-A abolishes pheochromocytoma secretory responses to glucagon, but this effect is not appreciated in normal adrenal medullas. Collectively, these findings indicate that human pheochromocytomas, but not the normal adrenal medulla, express glucagon receptors and possess a marked secretory response to glucagon, thereby providing the rationale to explain the specificity of the glucagon provocative test in the diagnosis of pheochromocytoma.

Human pheochromocytomas, but not adrenal medulla, express glucagon-receptor gene and possess an *in vitro* secretory response to glucagon. Albertin G, Aragona F, Gottardo L, Malendowicz LK, Nussdorfer GG. Peptides 2001 Apr; 22 (4), pp. 597–600.

Neoplasia/Reticulosarcoma: Potential Delivery Format
Carboxymethylpullulan:Doxobrubicin

Application: Potential application for the selective delivery of diagnostic pharmaceutical agents to neoplastic cell populations.
Route of Administration: Doxorubicin:carboxymethylpullulan conjugate (CMPul-FG-DXR) is administered intravascularly.
Dosage: Doxorubicin:carboxymethylpullulan conjugate (doxorubicin dose equivalent of 10 mg/kg).
Semi-Synthetic Methods: Conjugation of doxorubicin (DXR) to carboxymethylpullulan (CMPul) using a Phe-Gly spacer (CMPul-FG-DXR)

Implementation: Evaluation of the antitumor efficacy of CMPul-FG-DXR using murine tumor models compared to DXR alone.

Animal Model: Rat (Lewis lung carcinoma).

Animal Model: Mouse (M5076 reticulosarcoma and non-solid tumor P388 leukemia).

Interpretation and Analysis: Conjugated doxorubicin:carboxymethylpullulan exhibits higher antitumor efficacy against Lewis lung carcinoma than DXR. Complete tumor regression followed by long-term tumor-free survival is frequently observed when CMPul-FG-DXR is administered intravenously 3 times at a dose equivalent to 10 mg/kg of DXR. Superior survival as well as antimetastatic effect of CMPul-FG-DXR in comparison with DXR is also evident in the M5076 murine reticulosarcoma model. Body weight loss in mice treated with the conjugate is less than that observed with doxorubicin treatment indicating lower systemic toxicity of CMPul-FG-DXR. Simply mixing CMPul with doxorubicin does not enhance the antitumor activity of doxorubicin, showing that the conjugation of DXR with CMPul improves antitumor activity. However, no enhanced antitumor efficacy of the conjugates can be appreciated against certain non-solid tumor models (e.g., P388 leukemia). The improved antitumor efficacy and reduced systemic toxicity of CMPul-FG-DXR has been effectively demonstrated. CMPul-FG-DXR may be a useful delivery platform for diagnostic pharmaceutical and biopharmaceutical agents in addition to chemotherapeutic agents with biological activity against solid tumors and metastases

Improved *in vivo* antitumor efficacy and reduced systemic toxicity of carboxymethylpullulan-peptide-doxorubicin conjugates. Nogusa H, Hamana H, Uchida N, Maekawa R, Yoshioka T. Jpn J Cancer Res 2000 Dec; 91 (12), pp. 1333–8.

Neoplasia/Somatostatin Receptors/Lymphoma and Mammary Carcinoma
Somatostatin Receptor-Avid Peptide-[Fluoroscein]/ Somatostatin Receptor-Avid Peptide-[Carbocyanine]/ Fluorescein-Bombesin/Carbocyanine-Bombesin

Cellular/Molecular Mechanism of Action: Somatostatin receptor avid peptides and bombesin peptide recognize and possess binding avidity for somatostatin receptor complexes.

Background Information: Site-specific delivery of drugs and contrast agents for tumors protects normal tissues from the cytotoxic effects of drugs and enhances the contrast between normal and pathologic tissues. One approach to achieving targeting selectivity is to direct delivery platforms at receptor complexes overexpressed on the exterior membranes of tumor cells to facilitate visualization by a non-invasive optical imaging methods.

Application: Detection and characterization of neoplastic lesions that express relatively high densities of membrane-associated somatostatin receptor complexes.

Route of Administration: Intravascular.

Implementation: Evaluation of the *in vitro* and *in vivo* characteristics of carbocyanine derivatives of somatostatin and bombesin analogues related to their binding avidity for their respective receptor complexes.

Animal Model: Rats (bearing somatostatin receptor positive and bombesin receptor positive tumors).

Semi-Synthetic Methods: The tracer dyes fluorescein and carbocyanine can be conjugated to somatostatin and bombesin receptor-avid peptides to examine their receptor binding affinities. Dual-imaging probes can also be synthesized consisting of a bioactive peptide for tumor targeting, a biocompatible dye for optical imaging, and a radioactive or paramagnetic metal chelator for scintigraphic or magnetic resonance imaging of tumors.

Interpretation and Analysis: Carbocyanine derivatives of somatostatin and bombesin analogues retain high binding avidity for their respective receptors. Further evaluation of representative molecules in rats bearing somatostatin receptor and bombesin receptor positive tumors show selective uptake of the agents by the tumor cells. Unlike carbocyanine derivatives, receptor binding of fluorescein-somatostatin peptide conjugates is highly sensitive to the type of linker and the site of fluorescein attachment on the non-receptor binding region of the peptide. In general, the presence of flexible linkers disrupts binding affinity, possibly due to the interaction of the linker's thiourea group with the peptide's cyclic disulfide bond. While the receptor binding affinity of the dual probe is not dependent on the type of chelating group utilized, it is affected by the relative positions of fluorescein and chelator on the lysine linker. For somatostatin compounds, best results are obtained when the chelator is on the alpha-amino lysine linker and fluorescein is on the epsilon-amino group. In contrast, conjugation of the chelator to epsilon- and fluorescein to the alpha-amino lysine linker of bombesin peptides results in high receptor binding. These findings indicate that despite their small size, conjugation of dyes to truncated somatostatin and bombesin peptide analogues results in the generation of promising diagnostic agents that retain high *in vitro* receptor binding activity. These contrast agents can selectively and specifically localize in receptor-positive tumors in rat models.

Synthesis, *in vitro* receptor binding, and *in vivo* evaluation of fluorescein and carbocyanine peptide-based optical contrast agents. Achilefu S, Jimenez HN, Dorshow RB, Bugaj JE, Webb EG, Wilhelm RR, Rajagopalan R, Johler J, Erion JL. J Med Chem 2002 May 9; 45 (10), pp. 2003–15.

Neoplasia/Somatostatin Receptors: Subtype 2 (sst2)/Pituitary/Pancreatic/Adrenal
[^{111}Indium] ([^{111}In])-(DTPA0,Tyr$_3$)-Octreotide/ [^{111}In]-(DOTA0,Tyr$_3$)-Octreotide/ [^{111}In]-(DTPA0)-Octreotide

Cellular/Molecular Mechanism of Action: Possess physical binding avidity for subtype 2 somatostatin receptor (sst2) complexes.

Application: Detection and characterization of pituitary, pancreatic, and adrenal neoplastic lesions that express an overabundance of sst2 complexes.

Implementation: Evaluate the potential usefulness of radiolabeled [DTPA0,Tyr$_3$]octreotide and [DOTA0,Tyr$_3$]octreotide as radiopharmaceuticals for somatostatin receptor-targeted scintigraphy and radiotherapy. Analyses involve the characterization of *in vitro* somatostatin receptor binding complemented by the determination of *in vivo* patterns of metabolism of agents compared to [^{111}In]-DTPA0-octreotide.

Animal Model: Murine (mouse AtT20 pituitary tumor membranes).

Animal Model: Rats (CA20948 tumor-bearing Lewis rats).

Interpretation and Analysis: Comparing the different peptide-chelator constructs reveals that [DTPA0,Tyr$_3$]-octreotide and [DOTA0,Tyr$_3$]octreotide have a higher affinity than [DTPA0] octreotide for subtype 2 somatostatin receptors (sst2) in preparations of mouse AtT20 pituitary tumor cell membranes (all IC_{50} values obtained are in the low nanomolar range). Studies *in vivo* in CA20948 tumor-bearing Lewis rats reveal a significantly higher uptake of both [^{111}In]-labeled [DOTA0,Tyr$_3$]octreotide and [DTPA0,Tyr$_3$]octreotide in sst2-expressing tissues than after the injection of [^{111}In]-(DTPA0)octreotide. Such observations suggest that substitution of Tyr for Phe at position 3 in octreotide results in

increased affinity for its receptor and in a higher target tissue uptake. Uptake of [^{111}In]-labeled [DTPA0]octreotide, [DTPA0,Tyr$_3$]octreotide, and [DOTA0,Tyr$_3$]octreotide in pituitary, pancreas, adrenals, and tumors is decreased to less than 7% of control by pretreatment with unlabeled octreotide (0.5 mg/rat), indicating specific binding to sst2 complexes. Comparing different radionuclides, [^{90}Y]-(DOTA0, Tyr$_3$)-octreotide has the highest uptake in sst2-positive organs, followed by [^{111}In]-(DOTA0,Tyr$_3$)-octreotide, whereas (DOTA0,[^{125}I]-Tyr$_3$)-octreotide uptake is low compared to that of the other radiobiopharmaceuticals, when measured 24 hours after injection. Renal uptake of [^{111}In]-labeled (DTPA0)-octreotide, (DTPA0,Tyr$_3$)-octreotide and (DOTA0,Tyr$_3$)-octreotide is reduced over 50% by intravenous injection of D-lysine (400 mg/kg), whereas radioactivity in blood, pancreas, and adrenals is not altered.

Pre-clinical comparison of [DTPA0] octreotide, [DTPA0,Tyr$_3$] octreotide and [DOTA0,Tyr$_3$] octreotide as carriers for somatostatin receptor-targeted scintigraphy and radionuclide therapy. De Jong M, Bakker WH, Breeman WA, Bernard BF, Hofland LJ, Visser TJ, Srinivasan A, Schmidt M, Béhé M, Mäcke HR, Krenning EP. Int J Cancer 1998 Jan 30; 75 (3), pp. 406–11.

Neoplasia/Thyroid Carcinoma/Thyroid Medullary Carcinoma/Lung Carcinoma: Small Cell/ Cholecystokinin B (CCK-B) Receptor Complexes
[^{131}I]-Labeled Gastrin-I

Cellular/Molecular Mechanism of Action: Radiolabeled [^{131}I]-human heptadecapeptide gastrin-I functions as CCK-B receptor binding ligand.
Background Information: The outstanding sensitivity of pentagastrin in detecting the presence of primary, recurrent or metastatic medullary thyroid cancer (MTC) suggests widespread expression of the corresponding receptor type in human MTC. Indeed, autoradiographic studies have demonstrated the presence of CCK-B or gastrin receptors not only in more than 90% of MTCs but also in a high percentage of small cell lung cancers, stromal ovarian cancers, astrocytomas, and several other tumor cell types.
Application: Detection and characterization of metastatic thyroid carcinoma lesions.
Route of Administration: [^{131}I]-labeled gastrin-I (intravenous).
Dosage: [^{131}I]-labeled human heptadecapeptide gastrin-I (1 μg).
Implementation: Evaluate the *in vivo* potential of radiolabeled [^{131}I]-gastrin I to target CCK-B receptor-expressing tumors assessed by determining the biodistribution profiles in conditions of metastatic MTC.

Animal Model: Murine (nude mice bearing subcutaneous xenografts of the human MTC cell line, TT).

Human Model: Cases of metastatic medullary thyroid carcinoma.
Interpretation and Analysis: At peptide amounts of approximately 1 μg, maximum tumor uptake (8.9 ± 2.9%ID/g) is observed in animals at 1 hour postinjection, with tumor-to-blood ratios as high as 6.3 ± 1.9. Physiological CCK-B receptors in the stomach, gallbladder, and pancreas of the mice are targeted as well. The major route of excretion is the kidney, but strong evidence for a biliary excretion pathway also exists. Pilot therapy studies with [^{131}I]-labeled gastrin show significant antitumor efficacy compared to untreated reference controls. In accordance with preclinical data, good receptor targeting is observed at tumor sites within the stomach, gallbladder, and pancreas of cases with metastatic MTC. Such observations suggest that gastrin and its analogues may represent a useful new class of receptor binding peptides for the diagnosis and therapy of a variety of tumor types, including MTC and small cell lung cancer. Related preclinical and clinical studies need to be performed to address in more detail the molecular features that render CCK-B receptor binding agents potentially useful candidates for *in vivo* scintigraphy and radionuclide therapy.

Targeting of cholecystokinin-B/gastrin receptors *in vivo*: Preclinical and initial clinical evaluation of the diagnostic and therapeutic potential of radiolabelled gastrin. Behr TM, Jenner N, Radetzky S, Béhe M, Gratz S, Yücekent S, Raue F, Becker W. Eur J Nucl Med 1998 Apr; 25 (4), pp. 424–30.

Neoplasia/Vascular Tumor Antigens/Prostatic Carcinoma/Prostate-Specific Membrane Antigen/ Glutamyl Carboxypeptidase/Endothelial Tumor Antigen
Prostate Specific Membrane Antigens (PSMA)/ PSMA Catalytic Site Inhibitor/Soluble Extracellular Tissue Factor (PSMA Catalytic Site)

Cellular/Molecular Mechanism of Action: Prostate-specific membrane antigen is a glutamyl-preferring carboxypeptidase.
Background Information: Prostate-specific membrane antigen is a glutamyl-preferring carboxypeptidase that is expressed by prostatic carcinoma and other carcinoma cell types present on both tumor cells and associated microvascular cells. It has been shown that the channel structures delineated by PSMA-expressing cells in human and rat prostate tumors are in functional continuity with the vasculature and thus form part of the tumor microvasculature network. The PSMA-positive cell-outlined channels are CD31 negative and mutually exclusive of CD31-positive cell-lined channels elsewhere in the tumor consistent with tumor cells adapted to a pseudoendothelial phenotype in vasculogenic mimicry.
Application: Molecular strategy for selectively targeting the microvasculature network of neoplastic masses (e.g., prostate specific membrane antigen catalytic site inhibitor).
Route of Administration: Intravascular.
Implementation: Evaluate the potential function attributes of (i) PSMA-lined microvasculature to serve as a selective *in vivo* target for diagnostic and therapeutic modalities; and (ii) selectively directed infarctive tumor therapy in the form of a soluble extracellular domain of tissue factor conjugated to a PSMA catalytic site inhibitor to create a PSMA-directed selective tumor vascular thrombogen (STVT).
Interpretation and Analysis: The semi-synthetic protein conjugate, PSMA-STVT induces selective local *in vivo* infarctive necrosis of the rat Mat Lu prostate tumor when administered intravenously. The combined administration of this STVT with low-dose doxorubicin produces a profound tumoricidal effect, resulting in complete eradication of some tumors. This is consistent with the therapeutic potential for a PSMA-directed STVT and expands the potential for selective infarctive ablation of tumors.

Prostate-specific membrane antigen directed selective thrombotic infarction of tumors. Liu C, Huang H, Doñate F, Dickinson C, Santucci R, El-Sheikh A, Vessella R, Edgington TS. Cancer Res 2002 Oct 1; 62 (19), pp. 5470–5.

Protein and Peptide Selective Delivery/ Example Application: Synovial Joint Structures
"Homing" Peptides

Cellular/Molecular Mechanism of Action: Selective "homing" peptide specific for synovial joint structures.
Application: Potentially can function as a "targeting" modality for selective delivery of agents to synovial joint structures.
Route of Administration: Intravenous (most frequently because they are protein/peptide compounds).

Dosage: Designed to directly establish a correlation between the specific biological activity (efficacy) of aptamer preparations and the corresponding pathological condition.
Biological Source and Production: Initial preparations entail the harvest of human synovium and skin samples that are then transplanted into severe combined immunodeficient (SCID) mice. A disulfide-constrained 7-amino acid peptide phage display library is then injected intravenously into the animals and synovial homing phage recovered from synovial grafts.
Considerations: Following 3–4 cycles of enrichment, DNA sequencing of homing phage clones allow the identification of specific peptides synthesized by a-fluorenylmethyloxycarbonyl chemistry and used in competitive *in vivo* assays and immunohistochemistry analyses.
Interpretation and Analysis: Isolated synovial homing phages can be produced that display specific peptides that bind to synovial but not skin or mouse microvascular endothelium (MVE). In an *in vivo* environment, they retained their tissue homing specificity independently from the phage component, the original pathology of the transplanted tissue, and the degree of human/murine graft vascularization. One such peptide (CKSTHDRLC) in capable of maintaining synovial homing specificity both when presented by the phage, and as a free synthetic peptide. The synthetic peptide also competes with and inhibits *in vivo* binding of the parent phage to the cognate synovial MVE ligand. Experimental findings of this nature represents a description of peptides with homing properties specific for human synovial MVE. The identification of such peptides opens the possibility of using these sequences to construct joint-specific drug delivery systems that may have considerable impact in the diagnosis and treatment of arthritic conditions.

Identification of synovium-specific homing *peptides by in vivo* phage display selection. Lee L, Buckley C, Blades MC, Panayi G, George AJ, Pitzalis C. Arthritis Rheum 2002 Aug; 46 (8), pp. 2109–20.

Renal/Proximal Tubule/Enhanced Proximal Renal Tubule Catabolization
Lysozyme Low Molecular Weight Protein (LMWP)/ Naproxen-Lysozyme Conjugate

Cellular/Molecular Mechanism of Action: Lysozyme is an LMWP that is mainly taken up and catabolized by the renal proximal tubule.
Background Information: A renal-specific controlled release of an active drug may enable a reduction of the required dose and serve to reduce extrarenal toxicity.
Semi-Synthetic Methods: Production of a conjugate with an average coupling degree of 2 mol naproxen per 1 mol lysozyme in which the drug is directly coupled to the protein via a peptide bond.
Implementation: Evaluate the potential to specifically target the kidney applying the LMWP lysozyme as a carrier (e.g., delivery of the non-steroidal anti-inflammatory drug [NSAID] naproxen) because it is mainly taken up and catabolized within the renal proximal tubule.
Interpretation and Analysis: Naproxen-lysozyme conjugates are predominantly and rapidly ($<$ 20 minutes) taken up by the kidney. Subsequent decreases in renal content reflect renal degradation of conjugated lysozyme and appear to be similar to that of native lysozyme with a half-life of 4 hours. Biodistribution analysis of naproxen-lysozyme reveals no detectable amounts of free naproxen present in the plasma after the administration of the conjugate in concert with the objective of reducing extrarenal side effects. Conjugation of naproxen to lysozyme results in a pronounced (70-fold) increase of naproxen accumulation within the kidney. In agreement with protein disposition studies, conjugates are rapidly taken up by the kidney and subsequently degraded. Renal selective targeting of the NSAID naproxen can be achieved by conjugation with the LMWP lysozyme. This strategy for renal drug delivery has the potential to improve drug efficacy and safety.

Drug-targeting to the kidney: Renal delivery and degradation of a naproxen-lysozyme conjugate *in vivo*. Haas M, Kluppel AC, Wartna ES, Moolenaar F, Meijer DK, de Jong PE, de Zeeuw D. Kidney Int 1997 Dec; 52 (6), pp. 1693–9.

MECHANICAL PLATFORMS

Ophthalmic Delivery: Mechanical/Ocular and Conjunctival Pharmaceutical Delivery
Ocular Inserts

Cellular/Molecular Mechanism of Action: Mechanical pharmaceutical delivery format.
Background Information: Reservoir-type ocular inserts can be fabricated using sodium alginate containing ciprofloxacin hydrochloride as the core (drug reservoir) sandwiched between Eudragit and/or polyvinylacetate films. Ocular inserts are packaged in aluminum foil and can be sterilized by gamma radiation.
Implementation: Ocular inserts can potentially function as a delivery modality for ciprofloxacin hydrochloride that is dependent upon *in vitro* rate of release, antimicrobial efficacy, *in vivo* release studies, efficacy against induced bacterial conjunctivitis, aqueous humor concentrations, and stability studies as per the International Conference on Harmonization (ICH) guidelines. Preparations can be tested for sterility according to British Pharmacopoeia (BP) guidelines.
Animal Model: Rabbit (bacterial conjunctivitis).
Interpretation and Analysis: Sterile ocular inserts display zero-order release of test pharmaceuticals in *in vitro* and *in vivo* release studies over a period of 120 hours. Pharmaceuticals are found to be active against selected microorganisms according to microbial efficacy trials. A high correlation coefficient exists between *in vitro* and *in vivo* pharmaceutical release rates. Significantly better improvement in artificially-induced bacterial conjunctivitis can be appreciated with ocular inserts compared to eye drops and reference control placebo preparations. Drug concentrations in the aqueous humor are above minimum inhibitory concentrations (MIC-90) against test microorganisms. Shelf life of the product is greater than 2 years.

Ophthalmic delivery of ciprofloxacin hydrochloride from different polymer formulations: *In vitro* and *in vivo* studies. Charoo NA, Kohli K, Ali A, Anwer A. Drug Dev Ind Pharm 2003 Feb; 29 (2), pp. 215–21.

Respiratory System/Aerosolizer
SmartMist

Cellular/Molecular Mechanism of Action: Device creates a fine mist that upon inhalation can be delivered directly into the farthest reaches of the pulmonary respiratory network (e.g., alveoli).
Application: Delivery of diagnostic or therapeutic pharmaceuticals to the respiratory tree.
Route of Administration: Pulmonary inhalation.
Dosage: Predetermined for each individual agent being administered by pulmonary inhalation.
Considerations: Non-compliance with prescribed medication is a major reason for poor therapeutic outcomes, leading to the generation of unnecessary health care costs. Poor technique in self-admin-

istration of inhalation therapy is a special type of non-compliance associated with this route of administration. However, pulmonary drug delivery has fundamental advantages for the therapeutic management of diseases affecting the respiratory tract because it is site directed. The lung is also a promising portal for drug delivery into the systemic circulation.

Interpretation and Analysis: The incorporation of microprocessors into pulmonary drug delivery systems can facilitate the implementation of sophisticated management schemes for patient compliance in conditions of chronic diseases including asthma and diabetes. Microprocessor-assisted systems afford control over administration technique during therapeutic inhalation, thus leading to efficient and reproducible regional deposition of inhaled diagnostic or therapeutic agents. SmartMist is a hand-held asthma management device that aids in optimizing the clinical use of metered dose inhalers. It also measures pulmonary lung function and provides a long-term downloadable electronic record of therapeutic and diagnostic events. The AERx pulmonary delivery system utilizes similar microprocessor capabilities; however, it employs a novel means of generating aqueous aerosols from unit dose packages, thus providing a broad inhalation technology base for delivery of a wide variety of therapeutic and diagnostic agents into the respiratory tract, and via the lung into the systemic circulation.

Inhalation delivery systems with compliance and disease management capabilities. Gonda I, Schuster JA, Rubsamen RM, Lloyd P, Cipolla D, Farr SJ. J Control Release 1998 Apr 30; 53 (1–3), pp. 269–74.

Respiratory System/Aerosol Delivery System
AERx

Background Information: AERx is a microprocessor-controlled, bolus inhalation device that is actuated by preprogrammed stimuli (e.g., inspiratory flow-rate and volume), resulting in the creation of a fine mist that upon inhalation is delivered directly into the farthest reaches of the pulmonary respiratory network (e.g., alveoli).

Application: Delivery of diagnostic or therapeutic pharmaceuticals within the respiratory tree. Example: Deposition of [^{99m}technetium]-diethylenetriamine penta-acetic acid ([^{99m}Tc]-DTPA) aqueous radioaerosols to faciliate *in vivo* (human) planar and single photon emission computed tomography (SPECT) imaging.

Route of Administration: Pulmonary inhalation.

Dosage: Predetermined for each indivudal agents being administered by pulmonary inhalation.

Considerations: AERx is a microprocessor-controlled, bolus inhalation device that is actuated at preprogrammed values of inspiratory flow rate and volume. Transmission-emission planar and tomographic images can be simultaneously acquired. Diffuse deposition of the aerosol in the lung can be appreciated using this delivery modality. The uniformity of radioisotope distributed throughout the lung is attributed to the fine particle size (mass median aerodynamic diameter of 2 μm) of the aerosol and the electronic control of aerosol inhalation by the device.

Interpretation and Analysis: Evaluation of 2 postural positions (supine vs sitting) and 2 inspiratory maneuvers (vital capacity [VC] vs "fixed volume" above functional residual capacity) on radioaerosol inhalation reveals that it is largely unaffected by inhaled volume and posture. The efficiency of the device can limit the total radiation exposure of patients and staff administering the radioaerosols, and can make it suitable for delivery of expensive drugs. Neither the breathing maneuver (inhaled respiratory volume), nor posture affects the distribution of the aerosol as measured by the ratio of the activity (counts per pixel) in the peripheral:central (penetration index, PI) or in the apex:base regions of the planar lung images ($p > 0.1$). A small, albeit statistically significant, difference in PI ($p < 0.03$) can be appreciated between VC and fixed volume sitting maneuvers with SPECT only. The PI values themselves indicate that the radioaerosol is well distributed in the lung, with the periphery having 45%-64% of the activity of that counted in the central region. Superposition of transmission SPECT lung outline on emission SPECT visually confirms the excellent peripheral deposition of the aerosol. The AERx system shows high efficiency of delivery, with approximately 50% of the extruded dose in the device deposited in the lung.

Comparison of *in vitro* and *in vivo* efficiencies of a novel unit-dose liquid aerosol generator and a pressurized metered dose inhaler. Farr SJ, Warren SJ, Lloyd P, Okikawa JK, Schuster JA, Rowe AM, Rubsamen RM, Taylor G. Int J Pharm 2000 Mar 30; 198 (1), pp. 63–70.

Respiratory System/Nebulization Strategies

Dosage: Development and use of inhalation aerosols requires an appreciation of the properties of these dynamic systems and the ways in which they interact with the anatomically and pathophysiologically complex human respiratory tract. The amounts of aerosol particles, or droplets, initially deposited at various sites in the respiratory tract will determine the intensity of local effects as well as the rate of clearance of these materials from the respiratory lumen. Activity can be modulated by suitable formulation modifications, such as presentation of the active agent in a slow releasing form carrier.

Considerations: Inhaled diagnostic aerosols are examples of mechanical targeting delivery systems that achieve high concentration in the respiratory tract (the usual target organ with these systems) while appearing in low concentrations in other parts of the human body.

Interpretation and Analysis: Extension of duration of action of inhaled drugs by such means could be possible. As more discriminating methods for location of receptors and for following the fate of inhaled drugs and their carriers are becoming available, the ultimate potential for improvement of selective toxicity of agents used in pulmonary therapy by direct delivery into the respiratory tract can be critically evaluated.

Note: If excess mucus is preventing delivery of depostion, nebulization of a mildly alkalotic aqueous solution helps dissipate mucus deposits thereby facilitating removal by the tracheal mucocilliary escalator and expectoration.

Antisense gene targeting, 435–436, 574–575, 598, 887–888
Antisense IGF-IR, 333, 438
Antisense nucleotide radiopharmaceuticals, 630
Antisense oligonucleotides, 97, 242, 420–421, 426, 428–430, 433, 436, 488, 510, 828, 838–839, 850
Antithrombin, 253
Antithrombotic properties of contrast agents, 735, 736
Anti-TNF-α, 316, 334–335, 343, 427–428
Antitransferrin receptor, 630, 887–888
Anti-vasopressin-associated neurophysin Mab, 896
Anuria, 355, 487–488
Aorta, ultrasound of, 771–773
Aortic stenosis, 51, 772–773
Aortic stent graft monitoring, 773
Aortic valve, 30–31, 772
Apomorphine, 75, 110
Apoptosis, 455–457, 504, 572–573, 582–583, 627, 818
Appendicitis, 446–447, 608–609, 616
Aprepitant, 689
Aptamers, 451
Arabian foals, 242
Arabino pyrimidine nucleosides, 649
Arachidonic acid, 382
Area X, 541–542
Arecoline, 66
Arginine, 152–154, 155–160
Arginine vasopressin (AVP), 94, 140–141, 230, 460
Arodyn, 888–889
Arrhythmia, 5–16, 576–577, 588, 679, 685, 772
Arterial phase computed tomography, 760
Arterial resistance and dilation, 114
Arteriography
  computed tomography, 753–754, 760
  magnetic resonance imaging (MRI), 530
  ultrasound, 772–777, 789, 792
Arteriovenous fistulas, 114
Arteriovenous malformations, 42–43, 70, 112–113, 743–744, 770
Arthrography, 552–553
Arthropathy, 569–570
Articular cartilage, 798
Arylamine N-acetyltransferase, 282
Aspirin, 224–225, 250–251
Aspirin-insensitive asthma, 234–235, 240–241, 384–386, 390–391
Asthma, 234–237, 240–241, 249, 264–265, 376–379, 383–397, 673
Astrocytoma, 629, 633–634, 713, 896–897
Atheroma, 774, 822
Atherosclerosis, 21, 342, 423, 466–467
  delivery modalities, 858, 863, 886
  magnetic resonance imaging (MRI), 528, 530–531
  scintigraphy, 576, 592
  ultrasound, 773, 774, 822
Atherosclerotic plaque deformation, 51–52, 774
Atopy, 247
Atopy patch test, 238–239, 337
Atrial flutter, 5
Atrioventricular (A-V) accessory conduction pathway, 5
Atrioventricular (A-V) block, 5–6
Atrioventricular nodal block induction, 6–7
Atrioventricular nodal reentrant tachycardia, 6–7
Atropine, 12–13, 29, 97, 122, 378
Attention deficit hyperactivity disorder (ADHD), 97, 326, 599
Autism, 70–71
Autoimmune disease, 229–233
  encephalitis, 528
  Graves' ophthalmology, 229
  inner ear disease, 705
  multiple sclerosis (MS), 229–230
  myasthenia gravis (MG), 230–232
  pancreatitis, 213
  rheumatoid arthritis, 232–233
  systemic lupus erythematosis (SLE), 233
  thrombocytopenia, 815
Autonomic nervous system, 61–62, 71, 600–603
Avidin, 842
Avidin-gelatin nanoparticles, 869
Axons, demyelinated, 533
Azathioprine, 94–95, 230, 282, 321

B
Balloon coronary occlusion, 586, 601–602
Barbiturate elimination, 282
Barium sulfate, 184, 518, 747–748
Basal cell carcinoma, 337, 421, 498–499
Basophil stimulation test, 234–235, 390
Bayesian methods, 281–282, 289, 313–314
Beclomethazone, 247, 249, 376–377
Bee-sting venom, 240
Behavior
  depression, 71–73
  modification, 73
  neuropsychological testing, 73
  opioid abstinence, 73–74
  panic disorder, 74
  pharmaco-electroencephalogram mapping, 74
  psychotropic side effects, 74
  schizophrenia, 74–75
  Tourette's syndrome, 75–76
Benzene, 293
Benzo-a-pyrene, 305–306
Benzoate, 356–357
Benzodiazepine receptor ligands, 76, 105
Benzomorphan, 873
Benzydamine, 312–313
Benzylpenicillin, 99, 329–330, 367
β-adrenergic blockers, 300, 322, 578, 587
Beta-amyloid precursor protein IgG, 110
Betadine, 343
β-galactosidase, 432–433, 534, 545, 818, 826, 830
11β-HSD2, 355, 459
11β-hydroxylase, 136, 142–143, 415–416
Beta-lactam antibiotics, 239
Beta-oxidation, 457–458, 707–708, 710–711
β_2-microglobulin, 358, 571
Bethanechol, 186, 189
Bicarbonate, 344, 365, 462
Bicuculline, 89, 105, 485
Bile acid transport, 268–269, 488–489
Biliary atresia, 267, 610
Biliary colic, 267, 792
Biliary dyskinesis, 267
Biliary excretion capacity, 489
Biomarker selective targeting, 37
Biotin, 630, 842, 864, 891–892

Bis (acetate), 522
Bisacodyl, 211
[bis-propanoic acid cyanine]-IgG, 408, 502–503
Bis-tetraazamacrocycle xylyl-bicyclam, 451–452
Bladder cancer, 370, 423, 500, 651, 890–891
Bladder contractions, 11–12, 370
Bladder contrast-enhanced voiding urosonography, 767
Bladder function, 76, 103–104, 370–372
Bleomycin, 615, 647–648, 649, 651, 670
Blood-brain barrier (BBB)
  diffusion, 533
  disruption, 629–630, 755
  penetration, 533, 858–859
  permeability, 533
Blood-brain cerebrospinal fluid barrier, 76
Blood flow, mismatch, 785
Blood oxygen level-dependent (BOLD), 533–534
Blood-pool agents, 526, 529–531, 539, 543, 558–559, 754–755, 822
Blood volume estimation, 473–474
BMIPP, 465, 581–582
Bolus tracking MRI, 541
Bombesin, 421, 423, 505–506, 604, 626–629, 636, 642, 677, 892–893, 897, 902
Bone
  erosion detection, 554
  growth, 341, 496
  scintigraphy, 622–625
Botulism, 62–63
Boyden chemotactic chamber, 253
BQ-123/BQ-788, 579–580, 667, 869–870
BR14, 786, 789–790
Brachial artery vasodilation, 774
Brain blood flow, 789
Brain parenchyma acoustic density, 789–790
Brain perfusion, 790–791
Brain reperfusion injury with ischemia, 531
Brain tumor, 533, 557–558, 629. *See also specific neoplasms*
Breath tests, 398–403
  hepatic system and, 276, 306, 308–310, 315, 379
  nuclear planar scintigraphy, 673–675
Brilliant blue microspheres, 495–496, 855
Brimonidine, 120, 866–867
Bromocriptine, 90, 94, 98, 133, 229–230, 233, 852
Bromophenol blue, 369, 513–514
Bromosulfophthalein (BSP), 269–272, 271, 277, 490
Bromothymol blue, 369, 513–514
Bronchial constriction response, 375–376
Bronchial hyperresponsiveness, 265
Bronchial provocation test, 389–390
Bronchospasm, 750–751
Brugada syndrome, 7–10, 576–577, 588, 678–679, 685
BSB (1-bromo-2,5-bis-(3-hydroxycarbonyl-4-hydroxy)styrylbenzene), 68, 482–483
BT-PABA, 203, 212–216
Buccal mouthwash, 335
Budd-Chiari syndrome, 792
Budesonide, 389, 852
Bumetanide, 27, 355, 477, 523–524
Bupivicaine, 62, 342, 376
Bupropion, 91
Burst ultrasound, 789
Butyrylcholinesterase, 323

C
C5a, 234–235, 253–254, 390
[^{11}C]-acetate, 604, 626, 677
[^{13}C]-acetate breath test, 185, 191, 399–400
[^{11}C]-acryloyl chloride, 719
Cadmium hepatotoxic injury, 271, 490
Cadmium selenide-zinc sulfide quantum dots, 37, 474
Caffeine, 74, 77, 80
  cerebral perfusion, 533–534
  cytochrome 450 metabolism, 295–296, 305–306
  glomerular filtration, 360
  hepatic metabolism, 288
  malignant hyperthermia, 260–263, 330–332, 344–347, 426–427, 463
  microsomal enzyme metabolizing capacity, 291–292
  N-acetyltransferase, 316
  rhabdomyolysis, 348–349
Calcein, 843
CalceinAM, 16–17, 221, 407, 411, 476, 491, 501, 812, 893
Calcitonin, 170–172, 419
Calcium
  carcinoid syndrome, 410
  gastrinoma, 129, 412–413
  hepatic neoplasia, 280
  insulin (islet cell) adenoma, 130, 414, 464–465
  pancreatic disease, 216–218
  parathyroid hormone secretion, 177
  thyroid carcinoma, 171–172, 419
  VIPoma syndrome, 130, 415
Calcium analogs, MRI and, 541–542
Calcium binding peptides, 179
Calcium chloride, 65–66, 171–172, 325, 416–417
Calcium gluconate, 171–172, 176–177, 344, 414–417, 462
Calcium gluconolactate, 176
Calcium-induced calcium release (CICR), 260–261, 262, 332, 345
[^{14}C]-allantoin, 367
Calmodulin inhibitor, 15–16
[^{13}C]-aminopyrine, 276–277
CAMP, 177
$CaNa_2EDTA$, 569
Capillary bed tolerance of small particle or liquid plastic occlusion, 38
Capillary blood flow, 37, 41, 474, 479
Capillary permeability, 474
Captopril, 82, 89, 372–373, 459–460, 591–592, 668
[1-^{14}C]-arachidonate, 691, 710–711
Carbamazepine, 80–81, 87, 845
Carbamoyl-PROXYL, 531
Carbidopa, 716–717
Carbocyanine, 109–110, 421, 423, 505–506
Carbon breath tests, 315, 398–399
Carbon dioxide, 74
  breath tests, 315, 398–399, 458, 674–675
  [$^{13}CO_2$], exhaled, 279, 401–402
  [$^{14}CO_2$], exhaled, 276, 379, 399, 402
  malignant hyperthermia, 260, 330, 345
  microbubbles, 798, 848–849
  as radiographic image-enhancing agent, 742–747, 756–757, 764
Carbonic anhydrase deficiency, 458–459
Carbonic anhydrase isoenzyme inhibitors, 878
Carbon monoxide diffusing capacity, 378–379
Carborane [Gd]-DTPA2, 555
Carboxydextran-coated maghemite, 551–552
Carboxydextran iron-oxide nanoparticles, 551
Carboxyfluorescein diacetate succinimidyl ester, 16, 124, 125, 225–226, 476, 491–492
Carboxyfluorescein (encapsulated), 484, 825
Carboxylic acid metabolism, 183, 379, 399, 459
3-carboxy-4-methyl-5-propyl-2-furanpropanoic acid, 367
Carboxymethylpullulan, 901–902
Carcinembryonic antigen (CEA), 569, 717–718
Carcinoids, 129, 216–218, 410, 628, 634, 716–717, 895–896
Cardiac catheterization, 519–520
Cardiac disease and physiology, 21–47
Cardiac failure, 52, 602, 778, 869–870
Cardiac filling and output, 35–36
Cardiac imaging, by MRI, 523–527

Cardiac output, 474, 778
Cardiac shunts, 778
Cardiac washout evaluation, 591
Cardiomyopathy, 52–54, 245–246, 577–578, 583–584, 587, 680, 683, 778–779

Melanocyte-stimulating hormone (MSH) receptor, 645–647, 899–900
Melanoma, 263–264, 337, 422, 425, 429, 431, 493, 498, 505, 640, 645–647, 660–661, 727–728, 811–812, 828–829, 837–839, 842, 882–883, 899–900
Melatonin, 105
Membrane characterization, 493–496
Membrane pore size, 494
Membrane protein-lipid interactions, 495
Ménière's disease, 127
Meningioma, 122, 599–600, 633–634, 896–897
Meningitis, 537
MEN-2 (multiple endocrine neoplasia type 2), 148, 171–172, 416–417
Mephenytoin, 282–283
Mepivicaine, 62, 342
6-mercaptopurine, 282, 320
Mesenchymal stem cells, 20, 566
Messenger RNA (mRNA), 428–430, 437–438
Metabolism, 455–470, 622, 709–712
Metaclopramide
aldosterone-producing adenoma, 135
Diamond-Blackfan anemia, 222
gastric motility, 186
gastroesophageal reflux disease (GERD), 189
hyperprolactemia, 167
infertility, 165–166
multiple sclerosis, 94, 230, 233
pheochromocytoma, 147, 148, 149, 418, 626–627
Metaiodobenzylguanidine (MIBG), 27, 50, 53, 149, 245–246, 576–579, 582, 586–589, 600–604, 626, 631–632, 677–681, 680, 685, 724, 869
Metalloproteases, 860–861
Metaproterenol, 391
Metformin, 749–750
Methacholine
asthma, 236–237, 381, 383, 386–389, 391–393, 396
bronchial response, 375–378, 391–392
immune hypersensitivity, 383, 386–389, 391–393, 396
pheochromocytoma, 148
Methimazole, 312
Methionine, 279, 315, 398–399, 401–402, 442, 458, 467
Methohexital, 42, 70, 85, 87–88, 101, 198–199
Methotrexate
blood-brain barrier disruption, 755
MTHFR and, 315–316, 334–335
rheumatoid arthritis, 232–233, 343, 427–428
TPMT and, 319–320
3-methoxymorphinan, 300
Methoxypoly(ethylene glycol)2000, 199
Methoxy-X04, 66–67, 483
Methylation, 314–316, 398–399
Methylation of RNA, 427
Methylene blue, 39, 45–46, 219, 412–413, 474, 475, 488
Methylene diphosphate, 645
Methylenetetrahydrofolate, 458
Methylergonovine maleate, 25–26
Methylglucose, 191–192, 204–208
3-0 methylglucose (3-0 MG), 194, 196, 198–199, 208
Methylphenidate, 73, 95, 326
Methylprednisolone, 118–119, 229
4-methylpyrazole, 66
Methyl 2-tetradecylglycidate, 691, 710–711
Methyl thymol blue, 552–553
Metimazol, 313
1MeTIQ (1-methyl-1,2,3,4-tetrahydroisoquinoline), 102
Metoclopramide, 351–352, 353
Metoprolol, 52, 778
Metrizamide, 116–117, 755
Metylenetetrahydrofolate (MTHFR), 315–316, 334–335
Metyrapone, 132, 136, 140–141, 143–145, 146, 604, 626, 677
MFG (milk fat globulin), 820
MGDNF gene, 818
MIBG, 27, 50, 53, 149, 245–246, 576–579, 582, 586–589, 600–604, 626, 631–632, 677–681, 680, 685, 724, 869
MIBI (methoxy-isobutyl-isonitrile), 577, 583–584, 626, 630, 648–649, 649, 662–663, 665, 716, 719, 727, 881
Microalbulimuria, 460
Microarrays, pharmacogenetics and, 288, 289
Microbubbles, 40–42, 41–42, 480, 765–773, 775–778, 780–781, 783, 785–805, 807, 845–857
Microcapsules, 845, 847
Microencapsulation, 852–853
Microglial cells, 558, 823–824
Microglobulin, 871–872, 883–884
Microparticles, 852, 854
Microsomal enzyme metabolizing capacity, 290–292
Microspheres, 44, 429, 466, 495–496, 511, 581–582, 775, 829, 840, 845–857, 851–856, 861–862
Micro-synthetic delivery agents, 869–883
Microvascular leukocyte receptor complex expression, 534
Microvascular permeability/integrity, 526
Micturating cystourethrography (MCU), 807
Midazolam, 261, 305–309, 311, 344–345, 463
Milacemide, 81–82, 88–89
MION-46L, 566, 816–817

Mitochondrial disorders, 458
Mitochondrial K/ATP channels, 477
Mitochondrial respiration uncoupling, 276, 402
Mitosis, 408, 467–468, 691–692, 711–712, 723–724
Mitotane (o,p′DDD), 153
Mitral regurgitation, 788
Mivacurium, 323
MK-0869, 689
425 MoAb-PEG-PE, 835–836
Molecular delivery platforms, 869–904
Molsidomine, 23
Mometazone, 247, 249
Monoclonal antibody, as delivery system, 889, 900. *See also specific antibodies*
Monocrystalline iron oxide nanoparticles, 539, 563
Monocytes, 245, 248–252, 749, 813
Monoethylglycinexylidide (MEGX), 269–270, 274–276, 479
Mononuclear cell function, 254, 494
Mood disorders, 285
Morphine withdrawal, 73–74, 97
Mosapride, 104, 182, 185, 210
Motion sickness, 93–94
MP2269, 543, 549–550, 552, 558–559
MP2286, 896–897
MRNA/cDNA microarrays, 249–250
MS-325, 543, 558–559
Mucosal integrity and permeability, 487
Mu-lac transducing phage, 435
Multidetector row spiral computed tomography, 756–757, 764
Multidrug resistance, 648–649, 880–881
Multiphoton *in vivo* imaging, 474
Multiple sclerosis (MS), 94–95, 133, 229–230, 533, 537–538, 889
Multistate isoproterenol tilt-table test, 35
Multitest CMI, 242, 248
Murmers, 32
Muscarinic acetylcholinergic receptors, 66, 600, 677–678, 685–686, 870, 873
Muscimol-[Alexa Fluor 532], 91–92
Musculoskeletal system, 341–349
  ex vivo, 261–263
  fluorescent and pigment dye reagents, 496
  magnetic resonance imaging (MRI), 552–555
  neoplasia, 423
  nuclear planar scintigraphy, 622–626
  pharmacogenetics, 330–332
  positron emission tomography (PET), 712–713
  sepsis and inflammation, 447–450
  ultrasonography, 798–800
Myasthenia gravis (MG), 61, 114–116, 230–232, 347–348
Mycobacterium spp., 243–244
Myelography, 520–521, 539, 747, 759
Myeloperoxidase, 252–253, 786
Myocardial akinesis, 780–781, 784
Myocardial contrast echocardiography (MCE), 767, 775–776, 780–781, 787
Myocardial dysfunction, 55–56
Myocardial function, 55–56, 683, 781–782
Myocardial hypoxia, 580–581
Myocardial infarction, 26–28, 56, 477
  echocardiography, 56, 784–785
  magnetic resonance imaging (MRI), 523–525
  nuclear scintigraphy, 26–28, 581–583, 586, 602
  prognosis, 27–28, 56
  stem cells, 817
Myocardial injury, 582–583
Myocardial ischemia, 19, 56–57, 464, 465, 466, 577, 580–584, 619, 682–683, 776, 785, 813
Myocardial Na/K ATPase, 461, 585–586, 870
Myocardial necrosis, 584
Myocardial perfusion, 57–59, 525–526, 584–585, 684, 776, 785–787
Myocardial sarcoidosis, 527
Myocyte apoptosis, 582–583
Myocyte labeling, 525
Myogenic precursor cells, 817
Myo-inositol, 367–368
Myopathy, 263, 348–349, 626
Myotonic dystrophy, 275, 379, 399

N
N-acetylcysteine, 470, 477, 519–520
N-acetyldopamine, 900
N-(4-acetyl-1-piperazinyl)-p-fluorobenzamide, 113–114
N-acetyltransferase, 316
NAD-229, 701–702
Nafamostate mesilate, 738
Nafarelin, 151, 165
Na/K ATPase, 461, 585–586, 870
Nalipride, 695
Nalorphine, 73–74
Naloxone, 73–74, 149
Naltrexone, 164–165, 166
Nanocrystals, 556
Nanoencapsulation, 868
Nanoparticles, 251, 254, 429, 473, 494, 556, 761, 787, 817, 829, 851–852, 857–869
Nanospheres, 857–869
Naphthoflavone, 291–292
Naproxen, 689, 904
Narcolepsy, 95
NAT2 inborn errors, 298–299
Natural killer cells, 811–812
NC100100, 785
NC100150, 36–37, 407, 473, 506, 528–529, 543–544, 559–560
N-[^{11}C]methylamino-4′-hydroxystilbene, 68
Near-infrared (NIF) probes, 21, 342, 407–408, 423–424, 473, 477, 494, 496, 501–503, 507
  diffuse optical tomography (DOT), 514, 555, 722–723, 807–808
  magnetic resonance imaging (MRI), 522, 555
  mammary gland differentiation, 514, 555, 722–723
Nebulization, 905
Necrosis-avid contract agents, 552
Necrotic tissue, 555
Nedocromil, 384–385
Neoplasia, 407–424. *See also specific forms*
  adrenal gland, 626–627, 661–662
  angiogenic neovascularization, 558
  apoptosis, 455–457
  bladder, 370, 423, 500, 651, 890–891
  central nervous system, 95–96, 263–264, 409–410, 542–544, 629–634, 660–661, 713–716, 872–873
  colon (colorectal), 219–220, 241–242, 410–411, 413, 420, 476, 500–501, 505, 600, 636–638, 651, 677–678, 685–686, 717–719219–220, 795–796, 834, 873, 890–894
  computed tomography (CT) image-enhancing agents, 762–763
  delivery modalities, 812, 820, 849–850, 864–866, 878–883, 890–903
  DNA intercalation, 425
  endocrine system, 415–420
  ex vivo, 263–264
  fluorescent and pigment dye reagents, 497–507
  gastrointestinal system, 190, 219–220, 241–242, 410–411, 410–415, 896–897
  gene delivery and, 429–435
  gene expression, 436–437
  glioma/gliosarcoma, 95–96, 263–264, 409, 433, 456, 485, 503–504, 510–511, 542–544, 558–560, 629–631, 660–661, 714–716, 801–802, 827, 849, 872–873, 897–898
  hepatic system, 275–276, 280, 547–548, 550–551, 638–639, 760, 762–763, 767–768, 776–777, 792–798
  immune system, 242, 250, 420–421
  integumentary, 337, 421–422
  intestine and colon, 219–220

Neoplasia, (*continued*)
liposomes as delivery system, 834–840
lung, 627–629, 633–634, 636, 649, 658, 660–661, 663–664, 726–727, 763, 828, 865, 878, 881, 892–893, 896–897, 903
lymphoma, 242, 420–421, 423, 505–506, 599–600, 641–642, 721, 899, 902
magnetic resonance imaging (MRI), 555–560
mammary, 242, 263–264, 333–334, 421, 423–424, 437–438, 497, 505–506, 555–556, 599–600, 627–629, 636, 642–645, 649–652, 659–661, 722, 800–804, 835, 864–865, 872–873, 878–879, 881–882, 891–898
melanoma, 263–264, 337, 422, 425, 429, 431, 493, 498, 505, 640, 645–647, 660–661, 727–728, 811–812, 828–829, 837–839, 842, 882–883, 899–900
metastatic, 647–648, 663–665, 713–714, 762–763, 899

Neuropeptide receptor distribution, 599
Neurophysin, 896
Neurosonography, 791
Neurotensin, 130, 415, 497–498, 653, 900–901
Neurotoxicity, 539–540, 692, 737–738
Neurotransmitter dynamics, 96, 540
Neurotrophic factor, 818
Neutrophil chemotactic activity (NCA), 234
Neutrophil leukotriene B_4 receptors, 580, 619, 813
Neutrophils
chemotaxis, 253–254
delivery modalities, 812–814, 864, 889
elastase expression, 391
ex vivo, 252–256
[^{111}In]-labeled, 223, 245, 450–451, 670–671
margination, 223
metabolism, 728–729
phagocytosis, 251, 254, 494, 864
respiratory burst activity, 251–256
[^{99m}Tc]-labeled, 446–447, 666, 814
in vivo labeling, 444–445, 621–622, 889
New methylene blue, 481–482
N-[3-(1H-imidazol-4-ylmethyl)-phenyl]ethanesulfonamide, 871
NHS-A-biotin, 443
NHS-LC-biotin, 443
N-[2-(hydroxyethoxy)methyl]-5-[^{3}H]methyluracil, 658
Niacin, 74–75
Nicotinamide, 278
Nicotinamide N-methyltransferase (NNMT), 278
Nicotine, 280–281, 297, 326
Nicotinic acetylcholine receptors, 63–64, 874
Nicotinic ligands, 63–64
Nifedipine, 23, 25–26, 750, 763
Nile blue dye, 504
Niosomes, 868
NIR96010, 506
Nitric oxide
asthma, 237, 381, 396
immune hypersensitivity, 387, 394, 396
production potential, 468
release and contrast media, 732–733
Nitric oxide synthase, 394, 548
Nitroblue tetrazolium (NBT), 251–252, 255–256
Nitrogen/dye laser, 421–422, 498–499
Nitrogen mustard (NTM), 221, 260, 425
Nitroglycerin
angina pectoris, 23–24, 50–51
brachial artery vasodilation, 774
syncope, 33–25, 106–108
vascular grafts, 44, 49, 106–107
vasodilation response, 47, 59–60
ventricular (myocardial) function, 59, 781–782
Nitroimidazole, 463–464
2-nitroimidazoles, 709
Nitroprusside, 750, 763
Nitrosamines, 293, 297
NMDA receptors, 93, 465, 710
N-2-mercaptopropionyl glycine (2-MPG), 470, 477
[^{15}N]-methacetin breath test, 673–674
N-methylation, 278
N-methyl-D-glucamine dithiocarbamate $(MGD)_2$-Fe^{+2}-NO complex, 548
N_2 microbubbles, 769
N-(1-naphthyl)-N′-(3′-[^{125}I]-iodophenyl)-N′-methylguanidine, 465, 710
N-(N-benzylpiperidin-4-yl)-2-[^{18}F]-fluorobenzamide, 643, 722, 881–882
N,N-dimethyl-2-(2-amino-4-[^{18}F]-fluorophenylthio)benzamide, 702
N-nitrosamines, 293
N-nitrosodiethylamine, 293–294
N-nitrosomethylurea (NMU), 644
Noble gases, hyperpolarized, 564–565
[^{15}NO] exhalation, 379, 402
Non-Hodgkin's lymphoma, 641–642, 721, 899
Non-steroidal anti-inflammatory drugs (NSAIDs), 42, 209–210, 327, 445–446, 607, 615–616, 625
Noonan's syndrome, 163
Norepinephrine, 91, 144
Nortriptyline, 78–79, 105, 301
N-tert-butyl-alpha-phenylnitrone, 67, 468–469, 484
N-1-tritylsulfenyl histamine, 458–459
Nuclear scintigraphy, 569–675
amyloid and amyloidosis, 569–571
angina, 47–48, 50
apoptosis, 572–573
autonomic nervous system, 600–603
breath tests, 673–675
cardiovascular, 575–595
central nervous system, 595–600
endocrine, 603–606

gastrointestinal, 606–609
gene expression, *in vivo* detection of, 573–575
general, 569
hematology, 609–611
immune system and inflammatory responses, 611–622
metabolic and metabolism, 622
musculoskeletal, 622–626
myocardial infarction, 26–28
myocardial ischemia, 57
myocardial perfusion assessment, 57–59
neoplasia, 626–665
pancreas, 666
renal, 666–669
respiratory, 669–673
thrombosis, 40
Nucleic acids
gene delivery, 826–830, 850–851
metabolism and neoplasia, 665, 718
Nucleus robustus archistriatalis, 541–542
[^{15}N]urea, 189
Nutrient drink test, 187

O
Obesity, 172–173
Octafluoropropane microbubbles, 780–781, 783
Octa-n-butoxy-substituted naphthalocyanine, 469
Octreotate, 409–410
Octreotide, 633, 659
Ocular inserts, 904
O-dianissidine dihydrochloride, 252–253
Olanzapine, 689–690687–688
Oligodendrocyte progenitor cells, 533, 816–817, 859
Oligodextran, 831
Oligonucleotides
antisense, 97, 242, 420–421, 426, 428–430, 433, 436, 488, 510, 828, 838–839, 850
CTFO (circular triple helix-forming oligonucleotides), 435
liposome-encapsulated Cy3-labeled, 429–430
magnetic bead-linked oligonucleotide probes, 438, 861
phosphoric diester-modified, 435
TFO (triple helix-forming oligonucleotides), 420–421, 426, 488, 504–505, 510
Oligouria, 355
Omeprazole, 30, 170–171, 298, 305–306, 419–420
Onchocerca volvulus, 452
Oncosis, 455–456
Oncosis, isoproterenol-induced, 573, 576
Oocyte retrieval prediction, 166–167
Ophthalmic artery dependent vision, 95–96, 122, 123
Ophthalmic delivery, 866–867, 904
Opiate peptides, 604, 626, 677
Opioid abstinence, 73–74
Opioid receptors, 96, 692–693, 873, 888–889
Opioid tolerance, 97
Optical coherence tomography, 867
OptiMARK, 543, 558–559
Optison, 765, 769, 771, 782, 784, 791, 797–798, 845
Oral cancer, 180, 413–414, 499–500
Organic anion transporter, 99, 364
Organophosphate, 97, 260, 280–281
Osteoarthritis, 554
Osteomyelitis, 444, 447–450, 608, 616–619, 623–625, 712–713
Osteopenia and osteoporosis, 341–342, 364–365
Osteosarcoma, 342, 423, 496, 625, 648–649, 881
Ouabain, 461
Ovalbumin, 240, 241, 265, 394–395
OVA-liposome, 831–832
Ovarian carcinoma, 430–431, 633–636, 654, 803, 829, 835–836, 865, 880, 894–897
Oxidases, mixed function, 314
Oxidation-activated fluorogenic probes, 67, 468–469, 484
Oxidation potential in tissues, 468–469
Oxidative stress, 250–251
Oximetry, 469
Oxotechnetium, 645
Oxotremorine, 66
Oxygen
bronchial constriction response, 375
hyperpolarized, 564
ventilation/perfusion mismatch, 380
Oxygen tension indicator, 469, 552
Oxytocin, 167
Oxytocin receptor complex expression, 650–651, 901
Oxytremorine, 280–281

P
P604, 746
P743, 744, 757
P7228, 545–546
Paclitaxel conjugate, 900
Paget's disease, 647–648
Pain and lameness disorders, 342
Pain sensation/threshold, 326–327
PAMAM-G4D-(1B4M-Gd)(64), 547
p-aminosalicyclic acid, 214
Pancreas
endocrine function, 129–130, 607–608
exocrine function, 212–216, 402, 487–488
magnetic resonance imaging (MRI), 560–562
neoplasia, 130, 212–219, 414–415, 497–498, 627–629, 634, 636, 653, 661–662, 895–897, 900–903
nuclear planar scintigraphy, 634, 636, 666
pancreatitis, 212, 214, 215, 294, 561–562, 666
ultrasonography, 804–805
Zollinger-Ellison syndrome, 212–219
Pancreolauryl test, 216, 487–488
Pandolol receptor, 874–875
Panic disorder, 74
Pannus, 555, 799
Papain-induced cartilage injury, 553
Papaverine, 352, 750, 763
PAPS, 317
Paraaminohippuric acid (PAH)
effective renal plasma flow (ERPF), 356, 362
excretion, 329–330, 366–367, 512
organic anion transporter, 99, 364
tubular absorption, 512
Paracetamol, 184–185, 202, 279
4-para-phenylvinyl estradiol analogues, 643, 878–879
Parasitology, 452–453
Parasympathic nervous system, 122, 600–601, 873–874
Parathyroid adenoma, 653, 655–656, 724–725
Parathyroid hormone, 176–177
Parkinson's disease, 70–71, 93, 97–99, 322, 486, 566, 598–599, 693–698, 815, 852, 875–876
Pars intermedia pituitary adenoma (PIPA), 145, 417
Patent blue V dye, 493
Patent ductus arteriosus, 42
PEBBLEs, 511, 860, 868
Pellegra, 74–75
Pentagastrin
achlasia, 181
carcinoid syndrome, 410
gastrinoma, 129, 217–218, 413
hepatic neoplasia, 280
thyroid carcinoma, 170–172, 416–417, 419–420, 664–665
VIPoma syndrome, 130, 415
Pentazocine, 659, 692–693
Pentobarbital, 85, 111
Pentylenetetrazol, 78–79, 82–83, 100, 105

PEO-PPO-PEO, 429
Peptide delivery, by liposomes, 840–841
Peptide nucleic acid (PNA), 435–436, 503–504, 574–575
Percuntaneous transluminal coronary angioplasty (PTCA) therapy, 581
Percutaneous computed tomography, 761
Percutaneous trans-hepatic cholangiography (PTC), 744–745
Perfluorcarbons, 565, 786, 857–858
Perfluorobutane, 789–790, 793–794, 846
Perfluorochemicals (PFCs), 523, 767–768
Perfluorodecalin (PFD), 780
Perfluorodichlorooctane (PFDCO), 780
Perfluorohexane (PFH), 780
Perfluorooctane (PFO), 780, 787
Perfluorooctyl bromide (PFOB), 780, 787
Perflutren microbubbles, 780, 784
Perfusion-metabolism mismatch, 465, 682–683
Peripheral artery disease
  arteriography, 773–774
  of lower limb, 19–20, 259
  platelets and, 259
  thrombosis, 594–595, 685, 870–871, 887
Peripheral nervous system, 62–63
Peripheral vascular disease, function and physiology, 36–47
Peritumor rim sign, 546
Permeation properties, of myocardial cells, 19
PESDA, 776
Pesticide, 102
P-glycoprotein (Pgp), 649, 881
Phage facilitated delivery, 861
Phagocyctic killing index, 251, 255
Phagocytosis, 251, 254–255, 494, 833, 863–864
Phantom studies, 518
Pharmaceutical delivery, 509–511
Pharmacogenetics
  acute lymphoblastic leukemia (ALL), 287–288
  antidepressants, 285
  attributes and perspectives, 283–285
  chemotherapeutic agents, 286
  concepts and disease examples, 281–288
  cytochrome P450, 286–287
  epilepsy, 286
  ethics and practices, 285
  extrahepatic, 322–335
  general hepatic biochemical metabolization, 289–290
  infectious disease, 286
  phase II metabolizing enzyme systems, 314–322
  phase I metabolizing enzyme systems, 290–314
  of prognosis and therapeutic response, 332–335
Pharmacogenomics, 289–290
Pharyngeal perforation, 748
Phased-array intracardiac echocardiography, 782
3-phase dynamic computed tomography, 776–777, 794–795, 800
Phase II metabolizing enzyme systems
  diagnostics, 278–279
  pharmacogenetics, 314–322
Phase I metabolizing enzyme systems
  diagnostics, 273–278
  pharmacogenetics, 290–314
Phase inversion harmonic imaging (PIHI), 797–798
Phenazocine, 873
Phenobarbital, 101–102, 290–294
Phenobarbitone, 102
Phenol red, 369, 461, 479–480, 513–514
Phenolsulfonphthalein (PSP)
  acute renal failure, 363–364
  gastrointestinal permeability, 205, 206
  glomerulonephritis, 511–512
  mucosal integrity and permeability, 487
  renal function, 361–362, 364, 366–368
  tubular absorption, 512, 513
  tubular excretion, 512–513
  tubular failure, 513
Phentolamine, 31, 62, 148
Phenylalanine, 330, 348, 355–356
Phenylbutazone, 173–174
Phenylephrine
  glaucoma, 119–120
  Horner's syndrome, 121
  long Q-T interval syndromes, 324
  myocardial glucose metabolism study, 18
  reversal with dapiprazole, 122–123
  sympathetic ophthalmic innervation, 126
  T wave lability, 13–14
Phenylethanolamide, 136
Phenylpropionic acid, 458
Phenytoin, 102, 308–309
Pheochromocytoma, 146–150, 417–418, 626–627, 632, 724, 901
Phlegmon, 791–792
Phleum pratensis, 377
Pholedrine, 120–121
Phorbol myristate acetate, 253–254
Phosphatidyl ethanolamine, 824
Phosphatidylinositol, 691
Phosphatidyl serine, 824
Phosphoric diester-modified oligonucleotides, 435
Phosphorothioate, fluorescein-labeled, 420–421, 504–505
Phosphorous excretion, 368–369
Phthalocyanine, 507
Physostigmine, 73, 92, 122
Phytohemagglutinin, 242, 247–248
Picrotoxin, 105
p-[^{123}I]-iodo-L-phenylalanine, 872
Pilocarpine
  glaucoma, 118, 119–120
  magnetic resonance imaging (MRI) and, 536–537
  parasympathic innervation, ophthalmic, 122
  pupillary response, 123
  RS 86 compared, 66
  xerostomia, 180–181
Pinacidil, 27, 477, 523–524
Piperidinyl nitroxide stable free radical derivative, 562–563
[^{18}F]-Piperidyl benzilate, 686
Piracetam, 81–82, 88–89
Piribedil, 75, 110
Piroxicam, 297
Pitressin tannate, 365
Pituitary-dependent hyperadrenocorticism (PDH), 136, 137, 143
Pituitary dwarfism, 150–151, 155, 167–168
Pituitary neoplasia, 149, 656, 661–662
Pituitary pars intermedia dysfunction, 142
Pituitary tumors, 133–134
PKH dyes, 226–227, 492
PLA nanospheres, 867
Plasmid-complexed liposomes, 801, 818, 820, 824–826, 840, 849
Plasmid DNA, 429, 432–435, 827–828
Plasmid-microspheres, 801, 820, 840, 849
Plasmids, 817
Platelet endothelial cell adhesion molecule-1 (PECAM-1), 884–885
Platelet GP IIb/IIIa receptor antagonist, 594–595, 685, 870–871, 887
Platelet GP IIb/IIIa receptor expression, 444, 579, 831
Platelets
  activation, 256–257
  adhesion, 257–258
  aggregation, 258–259
  antiplatelet properties of contrast agents, 735
  consumption, survival, 223–224
  [^{51}Cr]-labeled, 224
  delivery modalities, 814–815

endothelium interactions, 225–226, 476, 491–492
ex vivo, 256–259
fluorescent labeled, 16, 124, 125, 226, 476, 490–491
HMPAO-labeled, 594
[^{111}In]-labeled, 223–224, 593–594, 814–815
[^{99m}Tc]-labeled, 814–815
thrombasthenic, 257–258
Platelet-specific monoclonal antibody (P256), 40
PLGA, 854, 856
P7228 liposomes, 816
PMA (para-methoxyyamphetamine), 103
Pneumolysin, 249–250
Pokeweed mitogen, 242, 247–248
Polioencephalomalacia, 99–100
Poloxamine-908, 833, 858–859
Polyacrylic acid, 866–867
Polybutylcyanoacrylate nanoparticles, 859859
Polycrystalline iron oxide nanocompounds (PION), 551–552
Polycyclic aromatic hydrocarbons, 293
Polycystic kidney disease, 450, 729
Polycystic ovarian syndrome (PCOS), 166
Poly(D,L-lactic-Co-glycolic acid) multiphase microspheres, 495–496
Polyethylene glycol 400, 199
Polyethylene glycol (PEG), 26, 428–429
coated magnetite nanospheres, 798, 848, 863
ITG-PEG, 762–763
lipid-shelled microbubbles, 777–778
liposomes, 447–448, 617–618, 623, 800, 823, 834–837, 839–840, 842, 849
transferrin-PEG-polyethylenimine, 434–435
Polyethylenimine, 429, 434–435
Polyethylenimine polymers, 829, 851–852, 861–862
Polygalacturonic acid, 565–566
Poly-L-lysine, 844
Polylysine -[Gd]-DTPA, 539–540
Polymerized nanoparticle, 37
Polymer millrods, 856–857
Polyneuropathy, familial amyloid, 571, 597
Polyoxyethylene, 251, 864
Polyoxyethylene glycol 4000 stearate, 868
Polyoxypropylene, 251, 864
Polypeptide delivery, 511
Polysorbate 80, 859
Polystyrene fluorescent spheres, 514
Polyuria, 363
Poor metabolizers, 298, 305–306
Porphyrin derivatives, 429, 829, 851–852, 861–862
Portal vein, 744–745, 771–772
Portography, 759–760

immune system, 708
inflammation and sepsis, 708–709
metabolism, 709–712
musculoskeletal, 712–713
neoplasia, 713–729
special senses, 705
Potassium, 343–344, 462–463
Potassium ATP channel opener, 11
Povidone iodine dye, 179–180
PP101/PP149, 469
Pranlukast, 235, 384
Praunsnitz-Kustner (PK) test, 233
Pravastatin, 99
Prednisolone, 452
Prednisone, 118–119, 229
Premature thelarche, 168
Prinzmental's variant angina, 23–26
Prion plaques, 697
Probenecid, 368
Procainamide, 5–7, 7, 9–10, 15, 376
Progesterone, 164, 292, 329
Proguanil, 305–306
Prolactin, 72, 83, 89–90, 94, 105–106, 131, 164–168, 229, 337–338, 351–353
Promethaine, 78
Propanolol, 14–15, 36, 73, 161–162, 680
Propantheline, 186
Proparacaine, 122–123
Propidium iodine, 766, 854
Propylene glycol, 792
Prostaglandin E_2, 382
Prostate
carcinoma, 431, 556–557, 627–628, 634, 636, 657–658, 777, 804–806, 835–836, 850, 895–896, 903
ultrasonography, 777, 804, 805–806
Prostate-specific membrane antigen (PSMA), 836, 903
Protamine, 37, 777, 805
Protein C, 253
Protein kinase inhibitors, 469
Protein-losing enteropathy, 204–205
Proteoglycan depletion, 553
Provocative filling cystometry, 371
Provocative water cystometry, 370–371
Prussian blue, 566, 816–817
P-selectin, 256–257
Pseudoaneurysm, 792
Pseudohypoparathyroidism, 176–177
PS-TFO, 242
Psychosis, 327
Pteroylpolyglutamates, 201
Puberty, 168
PUFA, 383
Pullulan, 817, 861
Pulmonary artery pressure, 739–740
Pulmonary carcinoma, 658, 865, 878, 896
Pulmonary embolism, 529, 563, 594–595, 685, 756–757, 764, 870–871, 887
Pulmonary veins, 771
Pulse inversion harmonic imaging (PIHI), 792–793
Pupillary response, 123
Purkinje fiber action potential duration, 11
Pyelography, 731
Pyranine, 884
5-(3-pyridinyl)-4-azahomoadamantane 2a, 64
Pyridostigmine, 115, 160–161, 231
[^{18}F]-Pyrrolidyl benzilate, 686
Pyronin, 222
Pyruvate, 458

Q
QT-RR slope, 582, 602–603
Quantum dots (qdots), 556, 866
Quinidine, 313
Quinine, 291–292, 309, 391
Quipazine, 103

R
Raclopride, 695
Radiation-induced heaptic injury, 551–552
Radio allergosorbent test, 389–390

Radiographic image-enhancing agents, 731–764
adverse reactions, 731–741, 766
cardiovascular, 742–747
central nervous system, 747
gastrointestinal, 747–748
hepatobiliary, 748–749
monocytes and macrophages, 749
properties of agents, 741–742

Thalamus, 791
Thalassemia, 227
[^{201}Thallium], 47–48, 57–58, 575, 578, 585, 587–589, 593, 600–601, 625–626, 629–630, 638, 652–653, 655–656, 663, 681–682, 684, 715–716, 719, 724, 873
[^{201}Thallium]-pentetreotide, 629, 713
Theophylline, 135–136, 201, 294
Thiamine, 99–100
Thiobarbituric acid, 224–225, 250–251
Thioflavin dye, 570, 597
Thioflavin S, 68–69, 482–483, 483
Thioflavin T, 68, 484, 688, 689
Thiopental, 89
Thioperamide, 69
Thiopurine methyltransferase (TPMT), 319–321
Thoracic imaging, 563–564
Thrombocytopenia, 223–225
Thrombocytopenia, autoimmune, 815
Thrombosis
  deep venous, 584, 685, 870–871, 887
  delivery modalities, 847, 870–871, 886–887
  hepatic artery, 792
  magnetic resonance imaging (MRI), 531–532
  nuclear scintigraphy, 40, 584, 593–595, 814
  single photon emission computed tomography (SPECT), 685
  ultrasound, 770, 772, 780, 787, 792
Thromboxane, 258
Thrombus detection, 478
Thymidine, 442, 467
Thymidine kinase, 425–426, 467–468, 573–574, 657, 705–706, 712, 720
Thymidylate synthase, 333
Thymoma, 723
Thyroid gland
  cancer, 170–172, 173, 416–417, 419–420, 633–634, 651, 662–665, 727, 890–891, 896–897, 903
  euthyroidism, 172
  hyperthyroidism, 174
  hypothalamus, pituitary, and thyroid axis, 170–176
  hypothyroidism, 172–175
  obesity, 172–173
  scintigraphy, 604–606
  thyroid function, 173–175, 605–606
Thyroid-stimulating hormone (TSH), 111–112, 131
  chorea-acanthocytosis, 77, 131
  fatty acids influence on plasma levels, 163–164, 176
  infertility, 352–353
  recombinant, 173–174
  scleroderma, 337–338
  sclerosis, 168
  thyroid cancer, 171, 419
  thyroid function, 173–175
Thyrotoxicosis, 606, 653
Thyrotropin, recombinant, 173, 419
Thyrotropin-releasing hormone (TRH), 72, 73, 94, 337
  acromegaly, 150
  anterior pituitary function, 130–131, 133
  chorea-acanthocytosis, 77, 131
  cranial trauma, 110–111, 131–132
  Cushing's disease, 137–138, 142, 145, 146, 417
  endometriosis, 164, 351–352
  gastric ulceration, 187–188
  growth hormone and, 150, 162–163, 163–164, 176
  Hallerman-Streiff Syndrome (HSS), 132
  hyperprolactemia, 167
  hyperprolactinemia, 133
  infertility, 166, 352–353
  multiple sclerosis, 229–230
  myasthenia gravis (MG), 347
  obesity, hypothyroid/euthyroid, 172–173
  Parkinson's disease, 98
  pituitary tumors, 133–134, 417
  prolactin suppression, 167–168
  stimulation test, 175, 227
  thalassemia, 227
Thyroxine (T4), 131, 173–174
Tiaranide, 338
Tic disorders, 75–76, 110
TmDOTP^{-5}, 38
TNF-cDNA, 829–830
Tobacco dependency, 64, 600, 874
Toborinone, 288, 360
Tolbutamide, 291–292, 297–298, 308, 461
Tolcapone, 322
Topoisomerase, 425, 652–653, 727–728, 882–883
Torsade de Pointes, 15–16
Tourette's syndrome, 75–76, 110
Tramadol, 370
Trans-cardiac conductance (TCC), 36
Trans-cranial color-coded sonography (TCCS), 771, 789
Trans-cranial gray-scale harmonic imaging, 789–790
Trans-cranial sonography, 791

Trans-cutaneous delivery, 825
Trans-esophageal pacing, 577, 583–584
Transfection agents, 566–567, 816–817
Transferrin, 219–220, 413
  magnetic nanoparticles, 533, 545–546, 816, 817
  PEG liposomes, 839–840
  receptors, 435–436, 574–575, 598, 817, 829, 839–840, 859
Transferrin-PEG-PEI, 434–435, 829–830
Transforming growth factor-α (TGF-α), 183–184
Transient ischemic attack (TIA), 48–49, 704
Trans-jugular intrahepatic portosystemic shunt placement (TIPS), 744
Trans-membrane carrier peptide, 556–557, 657–658
Trans-methylation, 315, 398–399, 458
Trans-mucosal delivery, 860
Trans-placental contrast media transport, 741
Trans-sulferation capacity, hepatocyte, 279
Trans-sulfuration, 315, 398–399, 458
Transthyretin, 483
Tranylcypromine, 313
Trauma
  bladder rupture, 372
  CNS, 110–112, 603, 703, 876–877
  corneal, 117
  cranial, 131–132, 485
  intestinal, 207–208
Trazodone, 78–79, 105
TREN-Me-3,2-HOPO, 522
Triakontatetraneuropeptide, 254–255
Tricuspid regurgitation, 788
Tricyclic antidepressants, 299–300
Triglyceride, iodinated, 759–760, 762–763
Triiodothyronine (T-3), 131, 141, 173–174, 176
Trilostane, 142
17 (1,3,5-tri-n-hexyl-2,4,6-triiodobenzene), 748
Triphenyltetrazolium, 27, 28, 470, 477, 523–524
Troleandomycin, 305–310
Tropicamide, 117–118, 122–123
TRX-20, 836
Trypan blue dye, 481, 860
Trypanosoma gambiense, 452
Trypsin-induced injury, 553
Tryptase expression, 391
Tuberculin antigen, 244
Tuberculosis, 243, 244
Tubular absorption, 512
Tubular acidosis, 341–342, 364–365
Tubular excretion, 512–513
Tuftsin, 444–445, 621–622, 812–813, 889
Tumor necrosis factor-alpha (TNF-α)
  allergic reactions, 228–229
  anti-TNF-α, 316, 334–335, 343, 427–428
  cDNA, 434–435
  cyclooxygenase synthesis, 265–266
  gene delivery, 860–861
  hepatitis, 244–245, 279–280
  immune hypersensitivity, 393
  inflammatory responses, 397–398
  microspheres, 495–496, 855
  multiple sclerosis, 230
  neutrophil metabolism and, 728–729
  RANTES, 266
  rheumatoid arthritis, 232–233, 334–335, 427
  systemic lupus erythematosis (SLE), 233, 247–249
TUNEL tissue analysis, 456–457, 572–573, 627
Tunicamicyn, 894–895
T wave alternans, 13
T wave lability, 13–14
2D-PAGE, 289
Tyrosinase promoter, 828–829
Tyrosine analogues, 604, 626, 677
Tyrosine hydrolase, 136
Tyrosine kinase, 864–865136

U
Ubiquicidin, 442–443
[U-^{14}C]-palmitate, 691, 710–711
UDP-glucuronosyl transferase, 322
Ulcers, 338
Ultrasmall superparamagnetic particles of iron oxide (USPIOs), 526, 530–532, 542, 550–551, 555, 558, 562, 863–864
Ultrasonography, 765–808
  aortic stenosis, 51
  atherosclerotic plaque deformation, 51–52
  biliary colic, 267, 268
  bladder rupture, 857
  cardiovascular, 768–788
  central nervous system, 788–791
  contrast-enhancing agents, 40–41, 765–768
  gastrointestinal, 791–792
  general concepts, 765–768
  hepatic, 792–798
  immune system, 798
  musculoskeletal system, 798–800
  neoplasia, 800–804
  nitroglycerin-mediated vasodilation, 59–60
  pancreas, 804–805
  pharmaceutical delivery, 853–854
  prostate, 805–806
  renal system, 806–807
  reproduction, 807–808
  vascular blood flow, 40–42
UMB68/UMB75, 106
Urea, 750, 763
Urea cycle, 275, 277–278
Urinary bladder, 514
  cancer, 370, 423, 500, 651, 890–891
  contractions, 11–12, 370
  function, 76, 103–104, 370–372
  rupture, 807, 857
Urinary system, 355–373
  neoplasia, 423
  ultrasound, 806–807
Urine 17-OH, 132, 146
Urography, 750, 763
Urolithiasis, 372
Urticaria, 338

V
Valine metabolism, 379
Valproate, 80, 81, 84, 88–89
Varicoceles, 169–170
Vascular amyloid deposits, 570
Vascular blood flow, 40–42, 479–480, 769–772, 785–787, 800–801
Vascular blood pool, 589–590
Vascular density, 777
Vascular endothelial growth factor (VEGF), 762, 884, 886
Vascular extravasation, 46, 480–481
Vascular grafts, 44, 49–50, 106–107
Vascular hypertension, 591–592, 667
Vascular imaging, MRI, 528–532
Vascular malformations, 42–44, 43, 277–278, 281, 743–744
Vascular patency, 769
Vascular perfusion, 44–45, 112–114, 338–339, 461, 474, 479–481, 529, 563, 592–593, 703–705
Vascular permeability, 45–47, 125, 444, 479–481, 616–617, 746
Vascular spasm, 578–579
Vascular thrombosis, 584, 593–595
Vasoactive intestinal peptide, 130, 415, 604, 626, 644–645, 677, 835

Vasodilatory response, 47, 59–60
Vasopressin, 167, 363, 366
Vector-mediated gene (oligonucleotide) delivery systems, 817–820
Vecuronium, 115, 116, 231, 232
Vena cava
  cavography, 746–747, 757
  thrombosis of, 595
  ultrasound, 771–772
Ventilation/perfusion, 380, 671–673
Ventricular arrythmia, 15
Ventricular (myocardial) function, 59, 782–784
Ventricular physiology, 781–782
Ventricular wall motion, 59, 783–784
Ventricular wall motion score index (WMSI), 55, 782
Verapamil, 880
Vertebral artery, 770
Vesicoureteral reflux grading (VUR), 806–807, 857
Vestibular disease, 126–127
Vinorelbine, 648
VIPoma syndrome, 130, 415
Viral infections, 451–452
Virosomes, 835–836
Visual pathway staining, 121, 509
Vitality staining, 481–482
Vitamin B_{12}, 200–201
Vitamin D, 201–202, 203, 277
Von Willebrand's disease (vWD), 257–258
Von Willebrand's factor, 259
Von Willebrand's factor antigen (vW Fag), 227–228

W
W7, 15–16
Wada test, 43, 61, 71, 84–88, 597–598, 698
Walpole's buffer solution, 372
Warfarin, 295, 299
Water diffusion coefficients, 38–39, 476–477
Water provocative test, 118
WAY-133537, 356
Whiskey, oral, 170, 420
White blood cells, HMPAO-labeled, 441, 620
Wideband harmonic imaging (WHI), 796, 801
WIN 22181, 529–530
Wolff-Parkinson-White Syndrome, 5, 11, 14–15
WST-1, 251–252, 256
Wuchereria bancrofti, 452–453

X
X-34, 68–69, 483
Xanthene, 507
Xenobiotic metabolism, 461, 479–480
Xenon (^{129}Xe), 564–565
Xenon (^{133}Xe), 672, 673
Xenotransplants/xenografts, 632, 638, 718, 894
Xerostomia, 180–181
XR9576, 648
X-ray micro-computed tomography, 764
Xylazine, 153
Xylocaine, 112
Xylose, 191–192, 196, 203, 204–208, 212, 213

Y
[^{90}Y]-anti-CEA Mab, 569
[^{90}Y]-DOTAO-D-Phe_1-Tyr_3-octreotide (DOTATOC), 631
Yohimbine, 74

Z
ZD6169, 356
Zinc sulfate, 242–243, 866
Zollinger-Ellison syndrome, 129, 184, 208–209, 212–219, 412–413, 488
Zyn-205 linker, 811
