In most species, the secretory component is disulfide bonded to the IgA molecule, which is supported by biochemical evidence (i.e., a larger sedimentation coefficient and resistance to reduction with 2-mercaptoethanol) would suggest that IgA from these species contains a secretory component as well. Polymers of the basic 7S molecules have been demonstrated in the secretions of rats. Dog, mouse, pig, and primate (baboon, rhesus monkey) IgA appear to have properties similar to human IgA, both structurally and in the heterogeneity of electrophoretic patterns.

Serum IgA cannot bind to complement component C1q and thus cannot activate the classical pathway; however, activation of the alternate pathway seems possible.

16.2.1.4 Immunoglobulin E

Immunoglobulin E or reaginic (homocytotropic) antibody has been reported in people and in current laboratory animal species, either in their own right as in dogs (clinically relevant skin and food allergies) or as models for the study of allergic syndromes such as asthma, or the treatment thereof, including pigs (reviewed in Hammerberg, 2009; Rupa et al., 2009). IgE plays a crucial role in the type I hypersensitivity response and in the body's defense against parasites (Gould et al., 2003; Erb, 2007; Fitzsimmons et al., 2007; Duarte et al., 2007; Keir et al., 2011). The least abundant isotype found in the circulation, IgE is capable of provoking a robust inflammatory response (Winter et al., 2000). The functional properties of IgE are discussed in Section 16.3.9 and have been reviewed by Prussin and Metcalfe (2006).

The IgE molecule exists in the serum of most species as a four-chain monomer with a sedimentation coefficient of 8S, corresponding to a MW of 185–200 kDa. IgE molecules are not transferred through the placenta, do not activate complement, and are heat labile, losing their reagenic activity after exposure to 56°C for 1 hour. In blood, the half-life is between 1 and 5 days, in the skin IgE molecules persist for relatively long periods (>6 days) after passive transfer. IgE levels are lowest at birth and gradually increase up to the age of about 20 years in people, thereafter the levels decline steadily. IgE levels increase in response to infection with parasites or in conditions that include skin disease, neoplasias, and immune deficiencies. The low concentration of IgE in serum has precluded direct isolation and characterization of this molecule; therefore, most of what is known about the structure of IgE has been obtained from IgE myeloma proteins as found in certain people, dogs, mice, and rats with specific gammopathies. However, the physical and functional properties that are known for each species appear to be similar to the model IgE molecules isolated from people and mice. For a review, see Kelly and Grayson (2016).

16.2.1.5 Immunoglobulin D

This Ig represents an oddity among the isotypes in that no clear effector functions had been assigned to the IgD molecule for a long time. This is due to the extremely low concentrations of IgD found in the serum (<1 µg/mL). However, the availability of IgD myeloma proteins from mouse and people as well as the comparative study of Ig genotypes in different species has revealed recently that IgD is present in all jawed vertebrates (see reviews by Chen et al., 2009 and Sun et al., 2011).

Being expressed together with IgM as one of the first Ig in ontogeny, but also in the development of B-cell mediated immune responses, IgD is now considered an important link between native resistance to infection and the antigen-specific immune response (Chen et al., 2009). Considering that IgD-producing mature but naïve B lymphocytes mainly home to aerodigestive mucosal structures such as tonsils, adenoids, salivary and lacrimal glands, as well as the nasal mucosa undermines the importance of IgD as an early mediator in response to invading pathogens. High concentrations of IgD have also been found in mammary gland, bronchial and pancreatic secretions, in cerebrospinal and amniotic fluid, and it has been found to be produced in the fetus. In serum, the half-life of IgD is 2.8 days, with a catabolic rate comparable to IgM. IgD also exists as a transmembrane Ig receptor involved in B-lymphocyte signaling, where it complements IgM. After secretion, it can bind to myeloid cells such as basophils and mast cells, which in turn will release B-cell stimulatory mediators, such as IL-4 and IL-13. In cases of allergic skin disease, binding of IgD to neutrophils has been observed. Secreted IgD contains mostly λ light chains, which is in contrast to other Ig isotypes, and membrane bound IgD (Chen and Cerutti, 2010, 2011).

However, the exact function of membrane bound as well as secreted IgD is not yet clear. Mice deficient in IgD showed a slightly delayed antibody response and lower numbers of peripheral mature B cells, suggesting a role in B-cell homeostasis. Interestingly, IgD binds to virulence relevant antigens in pathogenic viruses and bacteria. Also, some studies showed that IgD levels were increased during infections in general, and in individuals with IgA deficiency in particular. For a detailed review, see Chen and Cerutti (2010). Finally, an age-dependent drop in IgD correlates with the reduced immunity in older individuals.

Based on current knowledge, IgD is in summary considered an important mediator for adaptive B-cell responses and antimicrobial activation of myeloid cells such as basophils (Chen et al., 2010).

The structure and biochemistry of mouse and human IgD have been extensively studied. In addition, significant advances in animal genome availability and gene identification strategies allowed lining up the respective gene sequences of the putative protein sequence of the mammalian IgD light and heavy chains in different species (see Chen and Cerutti, 2010; Ohta and Flajnik, 2006; Sun et al., 2011). Primate IgD appears to be structurally similar to human IgD, which is composed of four heavy chain domains and two light chain domains. The first and second constant-region domains are separated by a hinge region similar to that found in IgG and IgA molecules. However, IgD is unique in that this region is highly extended (64 amino acid residues) in people (Putnam et al., 1982), which makes the hinge

more susceptible to proteolytic enzymes. In contrast, mouse IgD has been shown to lack an extended hinge region and also is missing the second constant-region domain (Tucker et al., 1982). However, the molecular weight of the heavy chain reported for mouse IgD (70,000 Da) is comparable to human IgD (70,000 Da), due to a larger content of carbohydrates (Pearson et al., 1977; Sitia et al., 1977). The human IgD molecule is also known to have a single disulfide link between each of the heavy and light chain portions, as well as one disulfide link between the two heavy chains in the lower half of the hinge region. Since this region is absent from mouse IgD, Putnam et al. (1982) have hypothesized that mouse IgD does not contain an interheavy chain disulfide bridge and may exist as an HL monomer. However, strong noncovalent bonds may form a stable H2L2 molecule as well. For a review on structure and functional properties of IgD in different species, see Preud'homme et al. (2000).

16.2.2 IMMUNOGLOBULIN ALLOTYPES AND IDIOTYPES

While the basic structural characteristics of Ig are very similar, there is a substantial heterogeneity in amino acid sequences in both the constant and variable regions of the light and heavy chains. These differences often reflect only one or a few amino acid substitutions, and are most commonly detected by appropriate antisera that contain antibodies (i.e., anti-antibodies) able to recognize subtle differences among molecules. There are three major serologically and structurally defined determinants that are found on Ig of most of the species that have been studied. These markers are isotypes, allotypes, and idiotypes. Since isotypes are presented in Section 16.2.1, this section focuses on the latter two components of Ig.

16.2.2.1 Immunoglobulin Allotypes

Allotypes are inherited variants of Ig light and heavy chains that segregate in a simple Mendelian fashion among members of an outbred species. As a result, the allelic amino acid sequence of Ig can vary between individuals within a population. Many of the currently studied Ig allotypes are analogous in many respects to the allelic forms of other proteins, such as the hemoglobin chains. However, there are some interesting exceptions that have a very complex pattern of inheritance and expression. These more complex systems will be discussed later as we consider individual species differences. Several good reference articles on allotypes are available (Pandey and Li, 2013).

The genetically determined antigenic differences in the serum Ig of all of the species to be covered here are attributed to amino acid substitutions caused by mutations in the corresponding structural genes. Unlike genetic variants of other proteins, allotype variations do not appear to affect antibody specificity or any known biologic function of Ig. The fact that allotypy does not affect antibody specificity is not surprising, since most allotypic determinants are located completely within the constant region of the light or heavy chain, and the antibody combining site is, of course, completely within the variable region. The rabbit is one exception to the generalization regarding the placement of the allotypic determinant since it is now well established that several allotypes are found in the variable region of rabbit Ig heavy chains.

When animals are bred, each expressing a different allele at a given locus, the heterozygous offspring expresses both allotypes in the serum Ig. This codominant expression of allotypes is seen in all species studied and occurs with both heavy and light chain allotypes. Thus, in an animal that is heterozygous for both heavy and light chain alleles, all four alleles are seen in the serum. Since it is generally agreed that an antibody-producing cell expresses only one of two possible parental heavy chain alleles and one of two parental light chain alleles (allelic exclusion), the serum contains a mixture of symmetric Ig molecules, that is, both heavy chains have the same allotypic determinant and both light chains have the same allotypic determinant on any given antibody molecule. Genetic studies using Ig allotypes as markers revealed that genes coding for heavy chains and light chains were not linked, and that κ and λ light chain genes were also unlinked. Further, studies with rabbit heavy chain allotypes led investigators to hypothesize that the variable and constant region genes represent a gene family on the same chromosome. These conclusions based solely upon studies with allotypes have subsequently been verified by somatic cell geneticists and molecular biologists.

16.2.2.1.1 *Methods of Detecting Allotypes*

Allotypes are typically identified by antibodies that are able to recognize individual allotypic determinants. Antiallotypic antibodies are generally elicited by injecting the Ig (or antibody–antigen complexes) of a donor individual bearing the allotype into a recipient of the same species lacking the allotype. While antiallotypic antibodies can be raised by immunizing across species (i.e., mouse Ig into rabbit), one must then adsorb the rabbit antisera with mouse sera that do not contain the reference allotype. Prolonged immunization is frequently required to elicit allotype-specific antibodies, but the response can be enhanced by immunization with antibody–antigen complexes in Freund's complete adjuvant. Antisera specific for human allotypes are obtained from multiparous women, patients who have received blood transfusions, or patients recovering from various diseases.

Immunoprecipitation tests in agar gel (Oudin, 1960) can be employed for the detection of allotypic specificities in some species, particularly rabbits. Since some allotypes are manifested by only minor structural changes in the polypeptide chain, anti-allotypic antisera often detect only one or two unique antigenic determinants. In such cases, there is an insufficient development of a lattice formation that is required for an allotype–antiallotype precipitate to form. Therefore, other detection methods such as hemagglutination inhibition and radioimmunoassays (RIAs) using solid-phase adsorption or fluid phase second antibody precipitations are used (Gilman et al., 1964; Landucci-Tosi and Mage, 1970). The RIAs have a distinct advantage in that they are quantitative and one can detect the proportions of allotypic markers in test sera. Several typical RIAs have been described (Gilman et al., 1964; Landucci-Tosi and Mage, 1970).

16.2.2.1.2 *Rabbit Allotypes*

Allotypic determinants in the rabbit were first discovered in 1956. Since this original discovery, numerous allotypes have been identified and characterized (Kindt, 1975). The allotype gene loci are designated by small italicized letters (*a*, *b*, *c*, etc.), and the individual determinants (allotypes) at each locus are designated by nonitalicized letters and numbers (*a*₁, *a*₂, *a*₃, etc.). The numbers are assigned consecutively in order of their discovery, regardless of the positions of the loci coding for the determinant. Each species has a different nomenclature that will be covered as each is discussed. A representative list of the rabbit allotypes and their location within a particular heavy or light chain of Ig is presented in Table 16.5. Note that allotypes have been found in the constant region of κ (*b*) (Dray et al., 1962) and λ (*c*) (Dray et al., 1963) light chains, and the constant regions of γ (*d* and *e*, these may be identical), α ₁ (*f*), α ₂ (*g*), and μ (*n*) heavy chains. It is of particular interest that a few loci code for allotypic determinants detected in the variable region (*a*, *x*, *y*) of the rabbit heavy chain. These variable region allotypes are found on Ig of all isotypes.

The *a* and *b* loci constitute an exceptional case. These are so-called complex allotypes, since when the chains carrying these allotypes were sequenced, no single allotype-specific residue could be identified. This was the case with most other allotypes as well. The determinants coded for by the *a* and *b* loci consisted of a multitude of amino acid residues. The *a*₁, *a*₂, and *a*₃ and *b*₄, *b*₅, *b*₆, and *b*₉ loci may represent in a tightly linked cluster. If *b*₄, *b*₅, *b*₆, and *b*₉ were alleles, a single individual should not possess more than two of them, and this is true. However, several investigators have reported rabbits transiently expressing three alleles. This may occur with greater frequency after hyperimmunization with a single antigen such as ovalbumin. While the transitory and latent allotypes may be explained by regulatory genes that alter the expression of structural genes within a cluster, the issue remains currently unresolved.

Rabbits heterozygous for the *a* and *b* loci exhibit a preferential expression of each allele, that is, *a*₁₀₁ > *a*₁ > *a*₃ > *a*₂ > *a*₁₀₀ and *b*₄ > *b*₆ > *b*₅ > *b*₉. This order may change in the face of an infectious disease or after immunization with different antigens. Nearly all molecules of rabbit IgG are precipitated by a combination of anti-*b* or anti-*c* locus allotypes, indicating that if another light chain locus exists, it must code for a very small proportion of rabbit light chains (Vice et al., 1970). Since these two genes segregate independently, it was correctly speculated that they exist on separate chromosomes (Gilman-Sachs et al., 1969). It was also noted that the genes coding for the light

chain allotypes were not linked to the genes controlling markers on rabbit heavy chains (Dray et al., 1963; Kelus and Gell, 1967; Oudin, 1960).

16.2.2.1.3 *Mouse and Rat Allotypes*

The recommended nomenclature for allotypes in mice designates the loci by Igh or Ig1 (h and l for heavy and light chains, respectively) with a number assigned in the order of discovery (Igh-1, Igh-2, Igh-3, etc.). The allotypic determinants are also designated consecutively in order of their discovery and are separated from the locus by a period (Igh-1.1, Igh-1.2, Igh-1.3, etc.). Mouse heavy chain allotypes and their isotype association are listed in Table 16.6. All of the loci listed here code for determinants found in the constant region of the molecule. Most of the allotypic determinants in the mouse, however, are on the constant region, and they are restricted to a single Ig class and subclass. As noted in Table 16.7, there are exceptions, for example, determinant four is shared by IgG2a and IgG2b, and determinant eight is shared by IgG1 and IgG2a.

The heavy chain allotype loci in the mouse are closely linked genes. Specific combinations of alleles at these loci (haplotypes) are designated in Table 16.7, and the distribution of the alleles among selected inbred strains is illustrated in Table 16.8. The mouse Igh-1 locus is unusually polymorphic with 12 alleles (see Table 16.8). The allotypes at this locus are very complex and resemble those of the rabbit *a* and *b* loci.

No serologically defined allotypic variants have been identified in the κ light chains, but intra-species differences of V-regions have been detected by other means (i.e., isoelectric focusing and peptide mapping). Allotypes similar to those of inbred strains have been observed in wild mice. The wild mice, however, exhibit new haplotypes suggesting that recombinational events have occurred within the Igh locus.

Contrary to the lack of allotypic variants in the mouse κ light chain, rats exhibit two alleles of this gene. The locus in the rat is termed RI-1, and there are two allotypes: RI-1a is found in the DA-inbred strain, and RI-1b is found in the LEW strain (Gutman and Weissman, 1971). These two markers are also considered to be complex allotypes, since they differ by 11 amino acid substitutions (Gutman et al., 1975).

16.2.2.1.4 *Nonhuman Primate Allotypes*

The first human allotype was discovered using an indirect method based upon the inhibition of hemagglutination similar to the one previously described (Grubb, 1956). The genetic locus was termed Gm, since the determinant was found on the gammaglobulins. Six human heavy chain loci

have been identified: G1m, G2m, G3m, Mm, A2m, and Km, encoding allotypes on γ 1, γ 2, γ 3, μ , α 2, and κ chains, respectively. In his review, Dugoujon (1993) presented findings for Ig allotypes (Gm, Am, and Km) in nonhuman primates belonging to 72 species and subspecies of the Hominoidea, Cercopithecoidea, Ceboidea, Lorisoidea, and Tupaoidea superfamilies. The distribution of human allotypes was also presented. There were allotypes that were exclusive to people. Hominoidea,

however, demonstrated the most Gm allotypes with relatively few reported for Cercopithecoidea and Prosimians; no allotypes were reported for platyrrhinian species.

16.2.2.2 Immunoglobulin Idiotypes

Idiotypes are a group of structural variants that result from variations in the amino acid sequence of the antigenic determinants located exclusively in the variable region of the light and heavy chains. In contrast to the allotypes that are typically found on all Ig of a given isotype, the idiotypic determinants represent individual and specific markers, with each antibody or myeloma protein having its own unique set of idiotypic determinants. One may think of idiotypes on Ig as being analogous to the fingerprints of an individual, since both can be used to distinguish unique entities.

While Ig represent a relatively homogenous group of glycoproteins when compared between and within species, the heterogeneity of the amino acid sequences in the amino-terminal (variable region) of the molecule results in almost unsurpassed heterogeneity. This variability called idiotypic determinants is responsible for the almost unlimited possibility for selecting and adapting idiotypes to suit the recognition of all possible antigens an individual is confronted with. Specifically, each antibody-producing cell secretes an antibody with a single defined idio type. Only through the unique mechanisms of preexisting gene sequence recombination in the different V, D, and J regions of the Ig gene, this almost unlimited diversity is possible. This activity is controlled by recombination-activating genes RAG-1 and RAG-2 and a cellular repair mechanism. In Table 16.9, the estimated diversity levels for each V, D, and J regions are summarized. The almost unlimited combined diversity grants for the recognition of virtually any possible antigen. Through selective proliferation (clonal expansion), triggered by repeated immunization of an animal with a defined antigen, the number of specific B lymphocytes will increase and the respective titer of this particular antibody will rise.

Several excellent review articles documenting the molecular structure, the genetic regulation and the biologic and functional significance of idiotypes are available (Eichman, 1978; vanLoghem and Litwin, 1972). Therefore, our focus in this section will be limited to a few generalizations about idiotypes and anti-idiotypic antibodies that apply to all of the species that produce antibodies.

TABLE 16.9
Diversification of B-Lymphocyte Antigen Receptor Idiotypic Elements

Element	Immunoglobulin	
	Heavy Chain	κ and λ
V segments	65	70
D segments	27	–
J segments	6	5 κ and 4 λ
Number of V region combinations	3.4×10^6	3.4×10^6

Total diversity	10^{14}	10^{14}

Source: Adapted from Market, E., and Papavasiliou, F.N., *PLoS Biol*, 1, e16, 2003.

The best characterized idiotypes are those reported in mice. It has been demonstrated with conventional and monoclonal antibodies (usually by direct or indirect quantitative precipitation and RIA) that some preparations of idiotypic-specific reagents can recognize a single amino acid interchange within the variable region. In spite of this exquisite resolving power of anti-idiotypic antibodies, one cannot draw conclusions regarding structural identity of antibodies based solely upon the binding of the antibody to two separate antibody samples. Remarkably, antibodies of different isotypes may share a common idiotypic, and antibodies with the same isotype may share only partial identity with any particular idiotypic (i.e., microheterogeneity within the V-region).

Idiotypes have been divided into private and public idiotypes, based upon their distribution within a species. Originally, it was thought that an idiotypic was unique and restricted to a single antibody clone derived from a single individual. This type of idiotypic also referred to as a minor, individual, or private idiotypic, does exist, at least in principle. However, it is now recognized that other idiotypes can be shared among individuals, called public, major, or cross-reactive idiotypes. The private idiotypic may represent a single clonal product, whereas a public idiotypic may be a manifestation of an entire family of related antibodies that differ at various positions throughout the V-region of the light or heavy chain. Both private and public idiotypes may be inherited from generation to generation. Idiotypic sharing among individuals is therefore much more frequent within inbred strains than within outbred animals. All animals of a given strain may produce antibodies, a portion of which cross-reacts idiotypically in response to a given antigen, but antibodies from another strain specific for the same antigen may show little or no cross-reactivity.

The concept of idiotypic has led to a number of valuable contributions regarding the genetics and biology of antibodies and antibody-producing cells. These contributions include (1) their use as markers, with which one can quantitatively follow the expression of an individual clone or a family of related clones of antibody producing cells within a heterogeneous population of antibody-producing cells, (2) the recognition that a clone of cells can switch from IgM to IgG secretion (isotype switching), (3) the broad range of idiotypic specificities of antibody directed against a single antigen or hapten has reflected a great diversity within the antibody repertoire, (4) alterations in the degree of idiotypic cross-reactivity in an antibody population as a function of time after immunization has led to the recognition that somatic mutations occur during an immune response, and (5) B- or T-lymphocyte recognition of idiotypes displayed on the membrane of immunocompetent cells plays a role in immune regulation (clonal deletion) (Nemazee and Hogquist, 2003; Nemazee, 2006).

16.2.2.3 Structural and Genetic Studies of Immunoglobulins in Swine

Significant progress has been made in recent years to understand immune system ontogeny in swine, not lastly due to its suitability as a model for a number of experimental systems to study xenotransplantation, cystic fibrosis, and developmental immunity including allergenicity (reviewed in Butler et al., 2009; Dearman and Kimber, 2009). A particular focus is on the mechanisms of maternal transfer and development of mucosal immunity (Butler et al., 2009 a and b, 2011; Cervenak and Kacs Kovics, 2009).

Like other vertebrate species, swine have all five isotypes of Ig (Butler et al., 2009a). Their concentrations in various body fluids, the location of the respective secreting plasma cells throughout the body, and their transport to lacteal secretions and absorption by the gut of the newborn piglet have been well studied (Butler et al., 2011; Butler and Brown, 1994). Like people, swine have both κ and λ light chains. Nucleotide sequencing of cDNA's encoding κ and λ light chains revealed a high degree of homology with other species (Lammers et al., 1991). The constant region lengths are 105 amino acids for λ and 108 amino acids for κ light chains. The frequency of κ and λ expression in swine is similar to that observed in people.

IgG comprises about 88% of serum Igs, and recent molecular genetic studies reveal that swine have the largest number of IgG subclass genes of all species tested so far. Sequences of six different IgG subclasses IgG1(a), IgG2(a), IgG3(a), IgG4(a), IgG5(a), and IgG(a), and their respective predicted functional properties in terms of C1q or Protein A binding are now available (Kloep et al., 2012; Butler and Brown, 1994; Butler et al., 1996), and as many as 11 copies of the C γ gene have been recognized (Butler et al., 2009a). Swine have only a single gene for IgA that occurs in two allelic forms that differ in hinge length. Swine also contain single genes encoding the constant regions of C μ (Bosch et al., 1992) and C ϵ . IgG3 accounts for about 80% of the Ig in neonates but <5% in adults, whereas IgG1 is high in adults (with IgG4 being the lowest) (Kloep et al., 2012).

Newborn piglets are virtually agammaglobulinemic as the epitheliochorial placenta of sows does not allow Ig transfer. Consequently, passive transfer of Ig from colostrum and milk by subsequent uptake in the neonatal gut is indispensable for the offspring (Butler et al., 2009; Salmon et al., 2009; see also Section 16.3.3). Ig G comprises about 80% of all Igs in colostrum (Rejnek et al., 1965, 1966). Importantly, the composition of the lacteal secretions changes dramatically during the first week, as IgG is substituted by IgA. Thus, mature milk in both swine and people transfers the local (mucosal) immunologic experience of the mother, that is, IgA, to the neonate, while the colostrum of swine is also the vehicle for transfer of maternal systemic immunity, that is, IgG antibodies (Butler and Brown, 1994).

Swine represent a valuable model for the hypothesis-based study of immunoontogeny in general and mucosal immunity in particular. Both the influences of maternal regulatory factors as well as intestinal gut flora can be experimentally controlled. Thus, instead of extrapolating from mice to human beings, swine represent a species deserving further studies in its own right and also as a very valuable model for human disease (Butler et al., 2009a and b).

16.3 PHYSIOLOGY AND EFFECTOR ACTIVITY OF IMMUNOGLOBULINS

The function of antibodies has been investigated for over 100 years and their importance in protection from infectious pathogens has been known since the very beginning. Fundamental mechanisms of Ig functions and their correlation to Ig structural components were established with a number of models *in vitro* and *in vivo*. The following sections reflect these conventional antibody functions in health and disease. More recently, more complex aspects in antibody-mediated immunity have emerged. For a review, see Casadevall and Pirofski (2012).

16.3.1 NEUTRALIZATION OF VIRULENCE

One of the key effector functions of antibodies is the neutralization of virulence-related proteins or components in toxins (e.g., tetanus toxin), viruses (e.g., rabies), bacteria, and parasites (Bachmann and Zinkernagel, 1997; Childers et al., 1989; Norrby-Teglund et al., 2006). By binding to such antigenic determinants, the toxic invader is prevented from binding to target surfaces and cells, from eliciting pathophysiological reactions and from killing target cells. Ultimately, this will inhibit successful multiplication of an infectious organism and prevent the actual infectious process as such. Further functions of antibodies listed below will assist the primary goal of the antigen-specific defense reaction mediated by antibodies.

16.3.2 CYTOPHILIC AND OPSONIZING ACTIVITY

Antibodies that are cytophilic for macrophages presumably function to focus on the phagocytic activities of macrophages on the intruding organism or particle (opsonic activity) (Childers et al., 1989; Ravetch and Clynes, 1998; Tizard, 2013). IgG2 exhibits more opsonic activity than the IgG1 subclass. In contrast, only the IgG2 subclass of mice is cytophilic for macrophages (Boyden, 1964), while all four human IgG subclasses (Huber and Fudenberg, 1968) bind to macrophages (IgG1, IgG3 > IgG2, IgG4). The murine and human IgM isotype has also been shown to have opsonic activity when complexed with complement.

16.3.3 PLACENTAL/GUT TRANSFER OF IMMUNOGLOBULINS

Passive transfer of Ig from the mother to the fetus or the newborn is an important mechanism of protection from infectious disease. Ig may be transferred either prenatally, postnatally, or both. Ig transfer differs among species due to the different types of placenta. In addition, Ig isotypes and their transfer mechanisms vary according to the stage of pregnancy and lactation. Ig transfer occurs through the yolk sac in rabbits, whereas it is transplacental in the other listed species including people. Only postnatal transfer occurs in swine (reviewed in Salmon et al., 2009).

The transport of IgG from mother to fetus depends on a specific transport protein in the placenta, termed the neonatal Fc receptor (FcRn). Although the structure of FcRn is closely related in structure to MHC Class I molecules (Raghavan and Bjorkman, 1996; Simister et al., 1997), the binding to FC is different. Essentially, two molecules of FcRn bind to one molecule of IgG, enabling its transport across the placenta into the vascular space in the fetus.

Postnatal transfer of maternal IgG across the intestinal epithelium occurs in rat, mouse, and dog up to 21, 16, and 10 days following birth, respectively (Brambell, 1966; Halliday, 1955; Morris, 1964). Again, the postnatal transfer of maternal IgG is mediated by binding to the FcRn on the brush border of the proximal small intestine. After delivery to the vascular circulation and tissues of the neonate, it can be recycled to the gut lumen for mucosal protection. The FcRn is found only in the fetus (suggesting also uptake of IgG from amniotic fluid) and in early postnatal life in rodents, whereas in people it is also expressed in adults (Israel et al., 1997; Shah et al. 2003; reviewed by Roopenian and Akilesh, 2007). Besides IgG, there is also transfer of IgA (people, piglets) and IgM (rabbits) from mother to offspring (Waldmann and Strober, 1969; Butler et al., 2009). There are likely differences in the transfer efficiency of certain IgG subclasses, depending upon the species investigated (Cervenak and Kacsokovics, 2009). Mouse IgG3 is transferred much more readily than the other IgG subclasses (Grey et al., 1971), while all IgG subclasses are transferred equally well in people (Spiegelberg, 1974). Importantly, FcRn is expected to play a role in the development of the induction of oral tolerance and immune surveillance (Israel et al., 1997; Bailey et al., 2005).

16.3.4 COMPLEMENT FIXATION

Fixation of complement by Ig is an important property of antibody molecules that may lead to cell lysis, Arthus reaction, and/or enhanced opsonic activity and cytophilic binding. The classic pathway for complement activation uses all nine components (1, 4, 2, 3, 5–9, respectively), while the alternative pathway involves activation of the third and fifth to ninth components, respectively (for review on these pathways, see Sarma and Ward, 2011). The IgG and IgM isotypes of all species appear to fix complement by the classic pathway, though there may be subclass differences. Complement fixation requires Ig to be either polymeric (as IgM) or complexed with antigen. Human IgG4 and mouse IgG1 and IgG3 do not fix complement via this pathway. In addition, a subpopulation of noncomplement-fixing IgM has been described for people and the rabbit (Spiegelberg, 1974). The IgA, IgE, and IgD isotypes also do not fix complement via the classic pathway for any of the species considered here.

The alternative pathway of complement activation in people involves only the two IgA subclasses, while the other isotypes are not able to fix complement via this pathway. In contrast, IgG1 in mice and rabbits can fix complement via the alternative pathway (Spiegelberg, 1974). Aggregated IgD and IgE in many species also activate the alternative pathway.

16.3.5 ANTIBODY-DEPENDENT CELL-MEDIATED CYTOTOXICITY

Stimulated by Ig binding, antibody-dependent cell-mediated cytotoxicity (ADCC) is the killing of antibody-coated target cells by cytotoxic effector cells (e.g., natural killer cells, neutrophils, eosinophils, monocytes, macrophages) using nonphagocytic processes involving the release of cytotoxic granules or the expression and release of mediators of cell death (e.g., tumor necrosis factor, reactive oxygen species, perforin) (Teillaud, 2012). ADCC of virus-infected cells has been shown in HIV-infected patients (Ahmad and Menezes, 1996). Furthermore, ADCC is an important mechanism in the area of therapeutic antibodies and also in the area of organ transplantation (Alderson and Sondel, 2011; Singh et al., 2009).

16.3.6 PROTEIN A BINDING

Staphylococcal protein A has been shown to bind to IgG from a variety of mammalian species (Langone, 1978). The protein A molecule is known to have four binding sites available for interaction with the Fc portion of Ig molecules, and can therefore form immune complexes of protein A and antibody in the serum. These immune complexes have been shown to fix complement as well as classic antigen–antibody complexes in serum (Forsgren and Sjoquist, 1966, 1967). The relative effectiveness of protein A binding to IgG from different species is shown in Table 16.10. In addition to IgG, the IgA2 subclass of human Ig and IgM from human, rabbit, mouse, and rat also exhibit low levels of binding to protein A (Goding, 1978). Within the IgG subclasses of different species, there may also be heterogeneity in the affinity of binding to protein A. The murine IgG1 subclass and human IgG3 subclass do not bind to protein A. Presumably, protein A binding can play a physiologic role in protection against disease, though there is no direct evidence for this.

16.3.7 MONOCLONAL AND THERAPEUTIC ANTIBODIES

An excellent review on the development and types of therapeutic antibodies is the one by Nissim and Chernajovsky (2008). The concept of monoclonal antibodies, based on hybridoma formation of mouse myeloma cells with clonal antigen-specific lymphocytes almost 40 years ago by Milstein and Köhler set the ground for a rapidly growing number of biologic therapeutic modalities, especially in oncology but also in the area of chronic debilitating diseases such as

TABLE 16.10
Relative Binding Affinity of IgG Antibody to Protein A

Species	Relative Binding Affinity of IgG Antibody to Protein A ^a
Human	1
Rabbit	1
Dog	0.21
Mouse	1.33×10^{-2}
Rat	$<6.0 \times 10^{-4}$

^a Numbers based on the amount of IgG required to inhibit binding of 125I-labeled protein A to immobilized rabbit IgG.

rheumatoid arthritis. Advanced molecular biology technologies and transgenic mouse models are being used to develop an ever growing number of chimeric or humanized therapeutic antibodies that target growth receptors, cytokines or their receptors, and other biologically relevant key determinants (for reviews, see also Bodey et al., 2000; Majidi et al., 2009; and Maurer and Gruber, 2012).

16.3.8 IMMUNOMODULATION BY FC γ -RECEPTORS

The long-term outcome of multiple minor and major immune responses taking place in an organism over time is regulated by checks and balances at every step of the process. The binding of antibody–antigen complexes (or immune complexes) to the different types of Fc receptors by the Fc portion of the antibody component is considered an important link between the antigen-specific response and effector cells of nonspecific defense functions, that is, granulocytes, monocytes, mast cells, and macrophages (reviewed by Nimmerjahn and Ravetch, 2007). Essentially, studies with human and murine IgG have shown two important variables. One is the Fc γ –receptor-binding affinity (Fc γ RI = high affinity, Fc γ RII, Fc γ RIII, and Fc γ RIV = low affinity), the other one is the nature of the signals transferred to the respective target cells. Signal transduction is influenced by the (cytokine) environment, where TGF- β and interleukin-4 (IL-4) are inhibitory while IFN- γ , TNF- α , and molecules such as lipopolysaccharide (LPS) or C5a are activating. In addition, the types of sugar residues on the Fc part of the IgG molecule play a role, and the complexity of the FC γ R-regulated system is underscored by the presence of over 30 different types of IgG Fc–glycovariants in human serum.

Importantly, the balance between activating and inhibitory signals will influence for instance, the tolerance to autoantigens and can thus contribute to antibody-mediated autoimmune diseases such as arthritis, multiple sclerosis, and systemic lupus erythematosus (Nimmerjahn and Ravetch, 2007).

Finally, the neonatal Fc receptor FcRn has been shown to play an important role in antibody metabolization in people, including adults (but not rodents). Whether this is true for other species has so far mostly been addressed in neonates. For a review, see Roopenian and Akilesh (2007).

IgG and IgG-receptor (i.e., Fc receptor) interactions demonstrate differences between primate species. For example, there are cynomolgus monkey IgG subclasses that have greater Fc receptor-binding affinity and a more pronounced effector function than human IgG (Warncke et al., 2012).

16.3.9 HYPERSENSITIVITY REACTIONS

Hypersensitivity-type reactions are a collection of unwanted, harmful, and potentially life-threatening responses that occur in an affected individual or animal as a sequela of the normal function of the immune system. There are essentially four classes, or groups, of hypersensitivity reactions (labeled as type I through type IV). A fifth type (Type V) has been described but may be more appropriately considered a subclassification of Type II hypersensitivity (Rajan, 2003). Types I, II, III (and V) are mediated through the binding of antigens to Ig that, in general, either stimulate the release of vasoactive compounds (type I), induces cytotoxicity (type II) or results in immune complex-induced inflammatory reactions (type III); type IV reactions occur through an Ig-independent, cell-mediated mechanism.

16.3.9.1 Type I Hypersensitivity

Immediate type I hypersensitivity, or allergic reactions, is mediated through the action of IgE and can be further subclassified as “early-” or “late-phase” reactions. This class of hypersensitivity reactions is mediated by IgE bound to high-affinity IgE receptors called FcεRI on the surface of mast cells and basophilic granulocytes. After crosslinking of surface-bound IgE by an antigen (also known as allergen) or an anti-IgE antibody, FcεRI-mediated signaling results in exocytosis or degranulation of histamine, eicosanoids, and other cytokines from such activated mast cells. Early-phase type I responses occur within seconds to minutes; the late-phase response occurs within 8–12 hours. Depending on the location of the immediate-type response, there will be itching, reddening (due to vasodilation), and swelling (due to increased vascular permeability) in the skin, airway constriction due to smooth muscle contraction resulting in wheezing and shortness of breath in the lung, while systemic reactions can ultimately result in shock due to a rapid hypotonic vascular crisis. Peanut-induced food anaphylaxis of people is an example of an IgE-mediated type I reaction.

Reaginic or IgE antibody can be demonstrated by the prick test, that is an epidermal application of an allergen after a superficial needle prick. Alternatively, serum IgE can be determined by enzyme-linked immunosorbent assay (ELISA), either with anti-IgE antibodies or a specific allergen. However, serum levels of IgE may not correlate with the local presence of allergen-specific reactivity, respectively, the real allergy status of an individual.

IgE is heat labile at 56°C in the skin, but it is long lived (11–15 days), as was demonstrated after passive transfer. Besides of people, all laboratory animal species exhibit reaginic reactivity.

Mast cells have also a receptor for IgG, called FcγRIII, a low-affinity receptor. Local IgG is heat stable but has a short half-life (<1 day) in the skin after passive transfer. In the rat and mouse, this antibody belongs to the IgG1 subclass (Spiegelberg, 1974). For a review of IgE and its interaction with basophils, mast cells, and eosinophils, see Prussin and Metcalfe (2006). For a review on different animal models of protein allergenicity, see Dearman and Kimber (2009).

16.3.9.2 Type II Hypersensitivity

Type II hypersensitivity (or cytotoxic hypersensitivity) occurs as a consequence of antibody binding to membrane-bound antigen resulting in a complement-mediated cytotoxicity or opsonization/inflammation (Tizard, 2013; Baldo and Pham, 2013). Type II reactions can occur within minutes to hours and are mediated through IgM or IgG, either by complement fixation or ADCC mechanisms. Immune-mediated hemolytic anemia is an example of a type II hypersensitivity response.

16.3.9.3 Type III Hypersensitivity

Type III reactions (or immune complex hypersensitivity) occur when Ig (primarily IgG, but occasionally IgM) bind to soluble antigens to form immune complexes (Tizard, 2013; Baldo and Pham, 2013). The soluble antigen–antibody immune complexes are deposited and accumulate in tissues resulting in the induction of a localized inflammatory process, including recruitment of leukocytes.

This type of response can occur within hours and is typified by the intradermal Arthus reaction in rabbits or farmer's lung (an Arthus-type response in people).

16.4 CIRCULATING CONCENTRATIONS OF IMMUNOGLOBULINS

16.4.1 NORMAL LEVELS

Reported normal serum concentrations and half-life of immunoglobulins are presented for a number of laboratory animals (Tables 16.11 through 16.15). The differences in serum concentrations among species reflect differences of Ig synthesis and catabolism in these animals. In a normal antigenic environment, Ig synthesis in people (Birke et al., 1963; Solomon et al., 1963) ranges from 25 to 35 mg/kg/day, while mice (Bell and Fahey, 1964; Fahey et al., 1965; Humphrey and Fahey, 1961), rats (Kekki and Eisalo, 1964), and rabbits (Andersen and Bjorneboe, 1964; Catsoulis et al., 1964) synthesize from 50 to 130 mg/kg/day. In addition, the half-life of IgG in serum appears to be more variable among species than other isotypes. The reported half-time survival of IgG in mouse serum (Bell and Fahey, 1964; Humphrey and Fahey, 1961) is 4.5 days, 5.5 days in rats (Kekki and Eisalo, 1964), 6 days in rabbits (Catsoulis et al., 1964), 6.6 days in

^a The predominant form in serum is 7S, while polymeric forms of IgA can be found in the secretions.

^b Electrophoretic mobility increases slightly from G2a to G2c.

^c The half-life was determined for rat IgG only and therefore mainly reflects catabolism of the predominant IgG subclass (G2a).

^d The serum concentration of this subclass is highly variable and may reach levels 10 times those reported after immunization or appear naturally in certain strains (i.e., Wistar).

^e N.D. means not detected by the assay procedure used.

^f Passive cutaneous anaphylaxis.

^g There appears to be a controversy as to the ability of this subclass to mediate a homologous PCA reaction, though it does compete with IgE for cellular binding.

^h These three subclasses were not separated when assayed and were simply referred to as IgG2.

ⁱ The heterologous reaction was performed using guinea pigs as recipients.

^j Rat IgG as a whole exhibits only weak binding, and no distinction is made between the subclasses. IgM binds more weakly than IgG.

^e The heterologous reaction was performed using guinea pigs as recipients.

^f IgM binding is much weaker than IgG binding

rhesus monkeys (Dixon et al., 1952), 8 days in dogs (Dixon et al., 1952), 12 days in baboons (Cohen, 1956), and 20–25 days in humans (Birke et al., 1963; Solomon et al., 1963). Differences in metabolism also exist among the various classes and subclasses of immunoglobulin. IgM has a predominantly intravascular distribution and a decreased survival rate in the serum (1/10–1/2 the half-time survival rate of IgG). Similarly, IgA in mice has a half-time survival rate 1/4 that of IgG (Fahey and Sell, 1965). Subclass variations in the serum survival rate of mouse IgG (Fahey and Sell, 1965), similar to that found within the human IgG subclasses, also exist in other species. In general, reference ranges of Ig levels in normal healthy animals should preferably be determined in a defined environment in a particular species and strain and with validated laboratory methods. Additionally, Stein et al. (1977) have described statistical methods utilizing tolerance limits instead of the familiar but considered incorrect confidence limits, for the determination of the range of normal values of serum Ig in any population, including the conversion of those values or ranges from milligram per milliliter (mg/mL) to World Health Organization International Units.

One factor that can alter the catabolic rate of Ig is the preexisting serum concentration (Bell and Fahey, 1964; Fahey and Robinson, 1963; Fahey and Sell, 1965; Humphrey and Fahey, 1961; Lippincott et al., 1960; Rogentine et al., 1966; Solomon et al., 1963; Wiener, 1951). For instance, the catabolic rate of IgG class of Ig in both people and mice goes up with increasing serum levels, while for IgA there is no correlation between serum level and catabolism (Barth et al., 1964; Fahey and Sell, 1965; Solomon and Tomasi, 1964; Spiegelberg et al., 1968; Strober et al., 1968). In contrast, the catabolic rate of human IgD has been found to be inversely proportional to its serum concentration (Rogentine et al., 1966). Thus, as the concentration of IgD increases, the catabolic rate decreases.

TABLE 16.13
Properties of Nonhuman Primate Immunoglobulins

		Immunoglobulin Class/Subclass				
		IgG	IgA	IgM	IgE	IgD

^a Polymeric forms of IgA can be found as in human serum and secretions.

^b Four subclasses have been identified in apes using antihuman IgG subclass antiserum. In the baboon, determinants cross-reactive with the antihuman antisera were not identified, though four structural forms of IgG could be identified using antibaboon IgG antisera.

^c Two subclasses have been defined in the rhesus monkey.

^d N.D. means not detected by the assay procedure used.

^e Passive cutaneous anaphylaxis.

^f The heterologous reaction was performed using guinea pigs as recipients.

Catsoulis et al. (1964) reported an increased catabolic rate of IgG in hyperimmunized rabbits, while in neonatal rabbits with low levels of serum IgG, the survival time of this isotype in their serum was longer when compared with adult values (Humphrey, 1961).

Finally, in people and in contrast to rodents the neonatal Fc receptor FcRn has been shown to play an important role in stabilizing IgG levels by preventing metabolization (reviewed by Roopenian and Akilesh, 2007).

16.4.2 ANTIGENIC STIMULATION

The major overall factor affecting the concentrations of serum Ig is antigenic stimulation, while isotype expression is influenced by the type of antigen—presenting cell and potential T-lymphocyte help and the respective cytokines (see below). At one extreme are animals that have been raised in a germ-free environment. These animals are “immunologically virgin” and express very low concentrations of Ig in their serum. At the opposite extreme are animals that have been exposed to an environment high in pathogens, or have been hyperimmunized. These animals may have serum concentrations of Ig that are 5–10 times the concentrations found in normal animals.

Specific classes or subclasses of Ig may be preferentially elicited by different antigenic stimuli or disease states. Expression of the IgG3 subclass in mice and IgG2 subclass in people has been predominantly associated with anticarbohydrate or antibacterial immunity (Perlmutter et al., 1978; Riesen et al., 1976; Yount et al., 1968). The IgG2 isotype found in mice often increases more rapidly

^a Serum IgA has a slightly lower molecular weight than the secreted IgA although similar.

^b The IgG subclasses were not differentiated in the study; therefore, the values given probably refer mainly to the predominant subclasses IgG1 and IgG2a, b.

^c No distinction was made between IgG2a and IgG2b.

^d N.D. means not detected by the assay procedure used.

^e Passive cutaneous anaphylaxis.

than IgG1 after antigenic stimulation of the animals with protein antigens. IgM antibody typically appears in the serum early and for several weeks following a primary exposure to antigen.

The circulating levels of IgE are often found to be elevated in animals infected with parasites or afflicted with a variety of allergic disorders (for reviews, see Becker, 1971; Bloch, 1967; Patterson, 1969). Protein antigens, when injected with the appropriate adjuvant, will also elicit high titers of reaginic antibody (Vaz et al., 1971).

The mechanism(s) by which different antigens preferentially elicit expression of one isotype over another is mediated by cytokines such as IL-4 and IL-12 (Kaplan et al., 1996; Lee et al., 1999). For a review, see Romagnani (2000). Most of what is known about the regulation of isotype switching by helper T cells (TH) has come from experiments in which mouse B cells are stimulated with LPS and purified cytokines in vitro. These studies suggest that selected cytokines can induce, augment, or inhibit the production of certain heavy chain isotypes. For example, IL-4 induces the production of both IgG1 and IgE, but inhibits IgM, IgG3, and IgG2a (Janeway and Travers, 1997). The inhibitory effect of a cytokine is likely due to the result of directly switching to a different isotype. Another example of a cytokine influence over isotype expression is interferon gamma (INF- γ) inducing IgG3 and IgG2a and inhibiting IgM, IgG1, and IgE. The isotype switching is dependent upon T cells. TH cells include at least two different subsets, that is, TH1 and TH2. TH1 cells produce cytokines such as INF- γ that induces switching to IgG2a and IgG3, while TH2 helper subsets release IL-4 and IL-5, which favor the switch to IgG1, IgA, and IgE isotypes. For reviews on the role of antigenic stimulation and mechanisms of isotype switching and idiotype selection, see Bouvet and Fischetti (1999), Manz et al. (2005), and Borghesi and Milcarek (2006).

TABLE 16.15
Properties of Mouse Immunoglobulins

		Immunoglobulin Class/Subclass							
		IgG1	IgG2a	IgG2b	IgG3	IgA	IgM	IgE	IgD
Sedimentation coefficient		7S	7S	7S	7S	7S–13S ^a	18S	8S	8S
Molecular weight		150K	150K	150K	150K	≥150K	900K	190K	180K
Electrophoretic mobility		Fast γ	Slow γ	Slow γ	Slow γ	β	Mid γ	–	–
Half-life in serum (in days)		4	5	2	4	1	1	–	–
Concentration	Serum (mg/mL) ^b	6.5	4.2	1.2	0.1–0.2	0.7	1	<0.01	<0.01
	Placental transfer (prenatal)		+	+	+	N.D. ^c	N.D.	N.D.	N.D.

	Heterologous ^e	N.D.	+	N.D.	N.D.	N.D.	N.D.	+	N.D.

^a Monomeric and polymeric forms of IgA exist in the secretions.

^b Serum concentrations for a normal BALB/c mouse.

^c N.D. means not detected by the assay procedure used.

^d Passive cutaneous anaphylaxis.

^e The heterologous reaction was performed using guinea pigs as recipients.

16.4.3 GAMMOPATHIES

The most significant shift in serum immunoglobulin concentration occurs with various monoclonal gammopathies such as multiple myeloma, a common neoplastic condition in people, nonhuman primates, dogs, mice, and rats. Gammopathies result in expansion of a single clone of neoplastic B cells secreting copious amounts of antibody. Often, the monoclonal antibody product may represent >90% of the total Ig present in serum. Monoclonal gammopathy is demonstrated by cellulose acetate electrophoresis of serum proteins. The normally diffuse banding region occupied by Ig will contain a single, darkly stained band (representing the neoplastic product) and a fainter, diffusely stained region (representing the normal Ig in the serum). The large amounts of pure antibody that can be isolated from such serum have allowed a variety of biochemical and functional analyses on specific isotypes that are normally expressed only at low levels (i.e., IgE and IgD) and have thus proven to be extremely useful to immunologists.

16.5 QUANTIFICATION OF IMMUNOGLOBULIN CLASSES AND SUBCLASSES

Numerous protocols for immunologic methods in general and analytic procedures for and with Ig in particular can be found in the series immunology protocols (e.g., immunoblotting and immunodetection, Gallagher et al., 2008). The isolation of IgG and IgM from animal serum has classically been performed using a combination of ion-exchange and gel permeation chromatography, often on an Ig fraction precipitated from the serum with either ammonium or sodium sulfate (Herbert, 1974; Herbert et al., 1973; Williams et al., 2004). A good separation of rabbit IgG/IgM can be obtained

by these procedures, including separation of the IgG subclasses. Mouse (Fahey, 1962; Fahey and McLaughlin, 1963) and rat (Binaghi and Boussac-Aron, 1975; McGhee et al., 1975) IgG and IgM can be separated by similar procedures, although incomplete separation of the IgG subclasses may occur, especially with the IgG2a and IgG2b subclasses of the mouse, which are similar in structure (Fahey et al., 1964a, b). The IgA class can also be isolated by similar techniques and elutes later than IgG from a Diethylaminoethylcellulose (DEAE) ion-exchange column. However, due to the low concentration of IgA in the serum, colostrum, milk, or other secretion products are often used as the starting material for IgA isolation (Cebra and Robbins, 1966). IgE and IgD cannot be isolated in pure form from the serum due to their low concentrations, and elution properties from DEAE and gel permeation columns that are common with the other isotypes (Halliwell et al., 1975; Ishizaka et al., 1969; Spiegelberg, 1972). Consequently, these IgE and IgD have been isolated in pure form mostly in cases of specific gammopathies (i.e., IgE or IgD myelomas), where relatively high serum isotype titers occur in affected animals.

Immuno- or γ -globulins can be quantitated by standard electrophoresis. Basically, after measuring the concentration of total proteins in serum, the relative areas of migration occupied by albumin and α -, β -, and γ -globulins are determined, and the final concentrations for each group are then calculated. For the quantitation of classes and subclasses, specific antisera for detecting the various isotypes are necessary. Thus, the ability to quantitate Ig from different species is dependent upon the availability of species-specific anti-Ig antisera. These antisera are prepared by purifying the Ig class or subclass of interest, and immunizing a second species of animal (i.e., a rabbit or goat) with the product. The antisera are made isotype specific by adsorbing the unwanted specificities on an affinity column conjugated with Ig containing all of the known light and heavy chain isotypes except for the relevant isotype. The specificity of these adsorbed antisera is checked against a battery of known isotype standards in the assay system of interest. Often myeloma proteins are used in place of the normal serum Igs, since myeloma proteins are more easily isolated and can be obtained in larger quantities. These proteins have proven to be extremely useful for developing antiserum to the rare isotypes (i.e., IgE and IgD). However, myelomas have not been described in all species for all of the different classes and subclasses of Ig. Complete sets of myeloma proteins have been described for people, mice, and rats (with the exception of an IgD myeloma in rats), while other species of laboratory animals lack more than one myeloma protein representing a specific class or subclass of Ig.

A quantification of the major isotypes (IgG, IgM) in the serum can be accomplished using a variety of immunoassay techniques since the concentration of these isotypes is reasonably high and, therefore, assay sensitivity is not a prime consideration (for the sensitivity range of various techniques, see Table 16.11). Quantitative immunoprecipitation and radial immunodiffusion may be used for the analysis of these Ig isotypes. Of these two assays, radial immunodiffusion is the more sensitive technique, and methods for extending its range of sensitivity by adding a radiolabeled second antibody or enhancing the contrast and intensity of precipitin lines in the gel (Harrington et al., 1971; Sieber and Becker, 1974) have been described. These enhancements have allowed the detection of IgD and IgE in serum. The quantitative precipitation assays are capable of detecting 50–100 μg of Ig per mL. Typically, the radial immunodiffusion is able to detect as little as 1–10 $\mu\text{g}/\text{mL}$. Both assays are far less sensitive than the current RIAs or enzyme immunoassays (EIAs).

Rocket immunoelectrophoresis, another popular technique used for quantitation of antibodies to a variety of different antigens, is a less useful technique for the quantitation of Ig isotypes. This assay involves electrophoresing the antigen preparation into an agar gel containing anti-antigen antibody. The technique relies on selecting an optimal pH of the buffer system, which allows migration of the antigen into the gel while maintaining a neutral net charge on the anti-antigen antibodies and thus preventing their migration into the gel. In this way, precipitin arcs can form in the agar. However, for the quantitation of isotypes, both the antigen and antibody in the assay system are Ig, and thus optimizing conditions for electrophoresis that would allow migration into the gel of one Ig species (i.e., the Ig isotype of interest) while maintaining a neutral charge on the second Ig species (i.e., the anti-isotype antisera in the agar) would be very difficult, if not impossible.

RIAs and EIAs offer more sensitivity in detecting the various Ig classes and subclasses than the previously discussed techniques. This increase in sensitivity may be necessary when assaying for the presence of certain Ig isotypes (i.e., IgE, IgD) that are normally present in very low concentration in the serum. These assays are also advantageous when a large number of different samples are to be assayed. As with the previously mentioned assays, the quality and sensitivity of the RIA and EIA are dependent upon the specificity and affinity of the isotype-specific antisera used in the assay and also the detecting label (Fan et al., 2009). These include new color and enzymatic reagents as they are being used with chemoluminescence platforms. These not only allow enhanced sensitivity but also the simultaneous analysis of multiple isotypes in very small sample volumes in a high throughput format. Basically, the isotype of interest is quantitated by assaying the ability of an unknown isotype sample to inhibit the binding between a labeled Ig isotype standard and an anti-isotype antiserum. These results are then compared with a standard curve to obtain the quantity of isotype in the assay sample. Both the RIA and EIA are able to detect Ig in the low nanogram per milliliter range (ng/mL) (Fan et al., 2009).

As many new technologies such as chemoluminescence-related methods are evolving rapidly the importance of proper method validation cannot be overstated. Specifically, testing formats must previously be checked for their precision, accuracy, and bias with well-established reference methods for each species in question. Availability for species-specific Ig isotype reagents has to be checked with current commercial providers (Findlay et al., 2000).

ACKNOWLEDGMENT

We wish to thank Richard B. Bankert and Paul K. Mazzaferro, authors of this chapter from the second edition of this book, for their vision and contributions to this chapter.

17.1 INTRODUCTION

The complement system is composed of 30 or more chemically and immunologically distinct proteins capable of interacting with each other, antibodies, certain bacterial products, and cell membranes (Walport, 2001a). Each protein of the complement system is normally present in the circulation as a functionally inactive molecule. Together these proteins make up approximately 15% (wt/wt) of the human plasma globulin fraction. It has been shown, however, that the placenta of human beings, rodents, and ungulates is an effective barrier in preventing the passage of complement either to or from the fetus (Colten, 1976).

Once activated, complement proteins function as part of the innate immune system acting as a primary effector mechanism of antibody-mediated immunity. In general, the complement system has three physiologic activities (Walport, 2001a, b). First, it acts in the host defense against infection (e.g., by facilitating opsonization, leukocyte chemotaxis, and lysis of bacteria). Second, it acts as an interface between innate and adaptive immunity (e.g., by enhancing response to antibodies). Finally, it plays a role in the clearance of waste products of inflammation and apoptotic cells generated during normal cell turnover (e.g., supporting removal of immune complexes) (Merle et al., 2015).

The activation of complement is a highly regulated process consisting of a sequential series of enzymatic reactions resulting in the formation of peptide fragments, or anaphylatoxins (e.g., C3a and C5a), that are potent inducers of multiple physiologic responses ranging from chemoattraction to apoptosis (Sarma and Ward, 2011). Three series of enzymatic activation reactions (aka. complement activation pathways) have been described, specifically, the alternative pathway, the classic pathway, and the lectin pathway. Being elicited by different mechanisms they all lead ultimately to the activation of the terminal, biologically important effector portion of the complement cascade, the membrane attack complex (MAC), unless being abbreviated by inhibitory mechanisms (Merle et al., 2015). Production of the MAC results in the ability to lyse target cell membranes establishing the complement system as a primary mediator of antibody-dependent cellular cytotoxicity (ADCC) (Sarma and Ward, 2011; Tizard, 2013).

Besides its role in innate and adaptive immunity, complement also appears to be involved with tissue regeneration and tumor growth (Qu et al., 2009), and human pathologic states such as atypical hemolytic uremic syndrome and age-related macular degeneration (Wagner and Frank, 2010).

Therefore, the investigation into therapeutic approaches and the interaction with the complement system have become an important area of research and development (Merle et al., 2015).

As mentioned in the Introduction, there are three complement activation pathways that result in the formation of the MAC. These pathways are termed the classic, alternative (or properdin), and lectin pathway, and are triggered by different substances (Sarma and Ward, 2011; Merle et al., 2015). All three pathways have been demonstrated in human beings and mammals in which they have been investigated (Zhang et al., 1999). The activating sequence for complement consists of four steps: triggering, amplification, feedback loop, and lysis (Liszewski et al., 1996; Merle et al., 2015). Amplification is a rapid process, with millions of copies of C3b being deposited on a target membrane in less than 5 minutes. The spread of this reaction into the fluid phase is prevented by feedback and other regulatory mechanisms that include the spontaneous decay of activated proteins, destabilization or inhibition of activation complexes, and proteolytic cleavage of activated components. In addition to their role as effectors of cell membrane lysis, many of the biologically active split products of complement proteins contribute to the pathogenesis of inflammatory reactions (Sundsmo and Fair, 1983; Merle et al., 2015). The physiology, biochemistry, and measurement of these split products, as well as of the specific cellular receptors they are binding to, have been reviewed and will not be covered extensively in this section (see Aegerter-Shaw et al., 1987; Cooper et al., 1983; Dierich and Schultz, 1983; Hugli, 1981; Weigle et al., 1983; Barrington et al., 2001; Ricklin and Lambris, 2013; Merle et al., 2015).

17.1.1 NOMENCLATURE

The nomenclature of the complement cascade-related proteins and receptors has been an evolving process. For example, in 1963, it became generally accepted that the components of complement in serum were to be designated by the letter “C” followed by the prime symbol and the component number (e.g., C'1 for the first component of complement) (Rapp and Borsos, 1963). Further, activated products were designated by the letter “a” added to the symbols (e.g., C'1a). By the late 1960s, the prime symbol was dropped and the importance of proteolytic fragmentation of components was recognized (Karlson et al., 1981). To designate these fragments, letters (e.g., a, b, and c) were added to the native component from which the fragment was generated (e.g., C3a and C3b from component C3). At the time, this fragmentation process resulted in the need to identify the activated components, and the use of a bar over the activated component or complex name was used to indicate that it was in an activated form (e.g., C'1 for C1a and EAC1423 for the activated complex). By 1981, another pathway of complement activation and its component proteins (different from the original or “classical” pathway) had been described. Moreover, a subcommittee of the Nomenclature Committee of the International Union of Immunological Societies formalized the nomenclature for this “alternative” pathway (Alper et al., 1981). Components of the alternative pathway were identified with letters (i.e., B, D, H, I, and P), plus C3 and active complexes were represented as component and fragment combinations (e.g., C3b, Bb or C3b, Bb, C3b, P). With the recognition of the lectin pathway of complement activation in 1990 (Evans-Osses et al., 2013), and the continued discovery of cellular receptors for the different activation fragments, the nomenclature process is still developing. In the continued effort to harmonize nomenclature, a Complement Nomenclature Committee (under the backing of the International Complement Society and the European Complement Network) convened and was charged with conducting the first formal evaluation of complement nomenclature since 1981. Though more progress required, Table 17.1 outlines their initial set of recommendations for the nomenclature of the components of complement cascade.

17.2 COMPLEMENT ACTIVATION PATHWAYS

Recently, the three distinct pathways of complement activation (i.e., classic, alternative, and lectin) have been investigated in detail, and excellent reviews are available (Figure 17.1) (Gál and Ambrus,

2001; Walport, 2001a, b; Sarma and Ward, 2011, Barrington et al., 2001; Ricklin and Lambris, 2013; Osses et al., 2013; Merle et al., 2015).

17.2.1 CLASSIC PATHWAY

The classic pathway (Figure 17.1) is initiated by the pattern recognition molecule C1q produced in immature dendritic cells, macrophages and monocytes, and interacting with a target structure such as immune complexes or pathogen-associated molecular patterns including lipopolysaccharide (LPS) and bacterial porins, and molecules exposed on the surface of dying cells (phosphatidylserine, double stranded DNA, glyceraldehyde-3-phosphate dehydrogenase, annexins A2 and

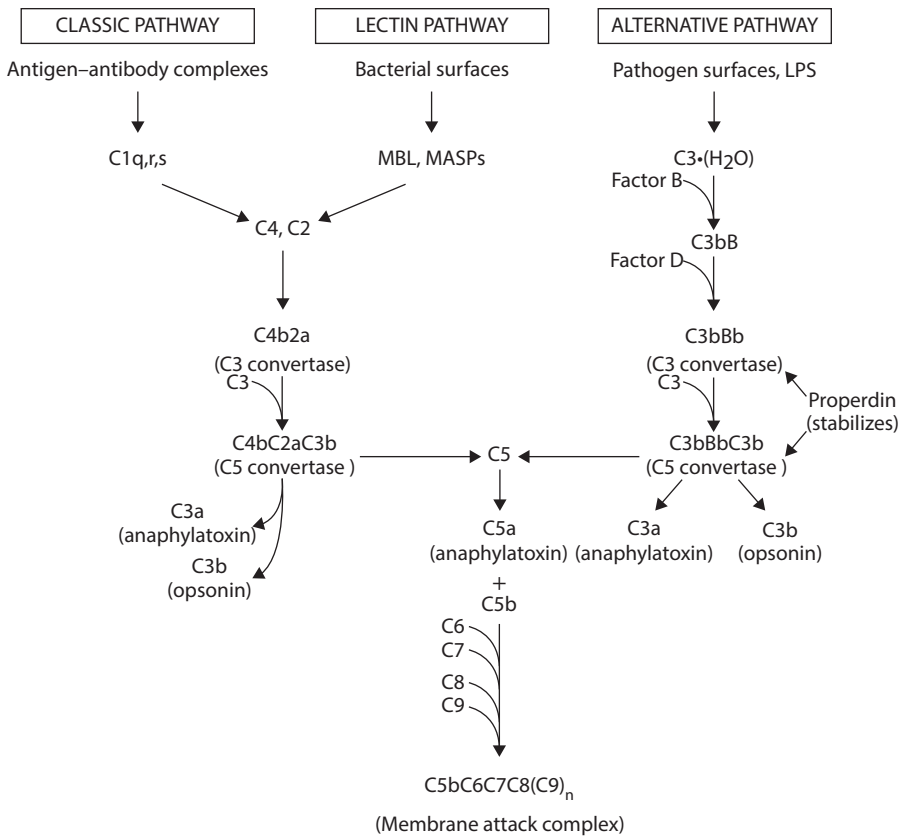

FIGURE 17.1 Illustration of complement activation of classic, lectin, and alternative pathways. (Adapted from Sarma, J.V. and Ward, P.A., *Cell Tissue Res*, 343, 227–235, 2011; Drawing by David Sabio.)

A5, and calreticulin) (Merle et al., 2015). In addition, older studies listed trypsin-like enzymes, staphylococcal protein A, teichoic acids and C-reactive protein (CRP), a number of polyanions, DNA precipitates, heparin, dextran sulfate, kallikrein, plasmin and amyloid β -protein, and certain RNA tumor viruses as initiating recognition structures (Atkinson and Frank, 1980; Burger et al., 1977; Fevereiro et al., 1992; Muller-Eberhard, 1975; Sundsmo and Fair, 1983; Velazquez et al., 1997). Recently, more details on the stoichiometry between C1q and IgM and IgG/antigen complexes have been reviewed (Merle et al., 2015). Essentially, the activation process begins with the binding of the C1q subcomponent of C1 to the Fc portion of antigen-bound IgM or IgG molecules (Sim and Reid, 1991). Once bound, C1q provides a noncovalent binding site for the C1 subcomponents C1r and C1s. A C1 complex consisting of C1q, C1r, and C1s molecules is formed. Ultimately, there is formation of a multimeric, calcium- and magnesium-dependent (Atkinson and Frank, 1980) serine protease tetramer, C1s–C1r–C1r–C1s (Gál and Ambrus, 2001). C1r undergoes self-cleavage and modifies C1s, leading to the active C4-cleavage enzyme. C1, by limited proteolysis of C4 and C2, generates the C3 convertase, named C4b2a. The potential of C1 to split several hundred C4 molecules results in a tremendous amplification process. Activated C4b2a interacts with C3 to generate C4b2a3b named C5 convertase, as well as several biologically active C3 split products such as C3a and C3b. The interaction of C4b2a3b complex with C5 results in cleavage of the C5 molecule into C5a and C5b.

17.2.2 TERMINAL COMPLEMENT PATHWAY

Attachment of C5b to the cell membrane through a C5b membrane-binding site initiates the formation of the MAC by interaction with C6 (forming C5b6, without cleavage of C6), and subsequent assembly of C7, C8, and C9 (without molecular cleavage). The MAC C5b6789 is composed of one molecule each of C5, C6, C7, and C8, with a variable number of C9 molecules. The participating molecules integrate into the membrane lipid bilayer and polymerize into a ring structure forming an inner hydrophilic channel or core, surrounded by a hydrophobic rim (Muller-Eberhard, 1975), permitting water and ions to pass into the cell through this core or hole. The result is cellular swelling and eventually total lysis of the target cell (Hobart, 1984). Depending on membrane fluidity, partial leaks may be initiated by C5b67 or C5b678 (Muller-Eberhard, 1975; Morgan, 1995). Furthermore, liposome and viral membranes, as well as bacterial cell walls, may be disassembled by the MAC independent of the formation of transmembrane channels.

17.2.3 ALTERNATIVE PATHWAY

The alternative, or properdin, pathway (Figure 17.1) is characterized by three areas of activity: silent elimination of apoptotic cells (without danger signal), elimination of pathogens (80% of terminal complement activity during pathogen recognition is provided by the alternative pathway), and maintenance of a low level of activated C3 (tick-over) kept in check by complement inhibitors in the absence of need (Merle et al., 2015). The alternative pathway can be initiated directly by a variety of nonimmunologic molecules including proteins, LPS, staphylococcal peptidoglycans, cobra venom factor (CoF), and zymosan (Walport, 2001a; Harboe et al., 2006; Kimura et al., 2008; Spitzer et al., 2007; Xu et al., 2008). In addition, viruses, bacteria, parasites, and certain eukaryotic cells (Gorman, 1984) activate the alternative pathway. Though the alternative pathway does not require specific antibody for its activation, heat-aggregated immunoglobulins and certain monomeric immunoglobulins can initiate alternative pathway activation (Gotze and Muller-Eberhard, 1976), as can IgA immune precipitates in some species (Rits et al., 1987), and under experimental conditions.

The current hypothesis for the activation of the alternative pathway is that certain surfaces, such as bacterial cell walls, fungi, and helminth cuticles, contain carbohydrate-rich polymers that allow binding of C3b but impair the binding of factor H. This allows the rapid formation of surface-bound C3bBb. Other substances containing polyanions bind and sequester factor H directly, allowing the C3bBb complex to develop into C5 convertase. Although the alternative pathway does not require specific antibody for its activation, it appears quite effective in deactivating a wide variety of infectious agents, suggesting it evolved earlier in ontogeny (Egwegang and Befus, 1984).

Besides direct triggering, the alternative pathway is slowly and spontaneously activated by hydrolysis of C3 (Harboe and Mollnes, 2008). Native C3 in plasma possesses a thioester bond that spontaneously and continuously hydrolyzes, forming C3a and C3b. Factor C3b binds to the cell surface, where it complexes with factor B. Complex C3bB is split (in the presence of magnesium) by the enzymatic factor D, to form C3bBb, a C3 convertase (Muller-Eberhard and Schreiber, 1980). C3 convertase (C3bBb) self-amplifies the cleavage of C3 and leads to the generation of the C5 convertase, C3bBbC3b. Approximately 10% of the C3b so released may bind activator surfaces, resulting in amplification of the sequence.

The C3Bb complex, however, is unstable, with a reported half-life of 90 seconds (Pangburn and Muller-Eberhard, 1986a, b). Released by activated neutrophils, the protein properdin stabilizes the C3Bb complex; properdin is also found in macrophages and T cells (Kemper et al., 2010). Properdin (P) associates with C3Bb, forming a stable (C3b)₂BbP complex (aka C5 convertase) (Fearon, 1979). This molecular complex recognizes and activates C5 (similar to C4b2a3b complex in the classic pathway). Additionally, the properdin-stabilized complex is protected against spontaneous and factor H-mediated decay and inhibits the cleavage of C3b by factor I. Properdin is the only known regulator of complement that enhances activation (Harboe and Mollnes, 2008).

17.2.4 LECTIN PATHWAY

In the absence of immune complexes, the lectin pathway (Figure 17.1) is initiated by the binding of a lectin pathway activation complex to pathogen-associated molecules (primarily carbohydrate moieties) found on microorganisms such as yeast, bacteria, parasites, and viruses (Fujita, 2002; Petersen et al., 2000; Dahl et al., 2001; Youssif et al., 2012; Zhang et al., 1999). Additionally, irregular glycocalyx structures on apoptotic, necrotic, malignant, or oxygen-deprived cells can activate the lectin pathway (Fujita, 2002; Schwaeble et al., 2002).

Specifically, the pattern recognition molecules of the lectin pathway include the mannose-binding lectin (MBL), collectins, as well as ficolins H, L, and M. The LP-pattern recognition molecules have an N-terminal collagenous region similar to C1q; however, their C-terminal domains differ from gC1q. Collectins contain carbohydrate recognition domains, which recognize sugar patterns frequently expressed on bacteria, viruses, and dying cells, but usually not host cells. MBL, which belongs to the collectin family, recognizes terminal monosaccharide exposing horizontal 3'- and 4'-OH groups (glucose, mannose, and N-acetyl-glucosamine) in a Ca-dependent manner. In general, the lectin pathway is activated when mannan- or MBL, or ficolin bind to the surfaces of microorganisms resulting in neutralization, opsonization, and cytotoxic reactions (Sarma and Ward, 2011; Youssif et al., 2012; Zhang et al., 1999; Merle et al., 2015). Once MBL binds to mannose, it allows for the binding of C1r/C1s with subsequent complement activation (Holmskov et al., 1994; Sato et al., 1994). Both MBL and ficolin circulate in the serum as complexes with MBL-associated proteins, or MASP (Wallis, 2007; Sørensen et al., 2005). In human beings, circulating lectin pathway recognition molecules consist of one MBL (the product of MBL2 gene), collectin-11 (CL-11), collectin kidney 1 (CL-K1), and three ficolins (M-ficolin, or FCN1; L-ficolin, or FCN2; and H-ficolin, or FCN3) (Fujita, 2002; Liu et al., 2005; Hansen et al., 2010). In rodents, four recognition molecules have been described, including two mannan-binding lectins (MBL-A and MBL-C), CL-11, and ficolin A (Schwaeble et al., 2011). A second murine ficolin, ficolin B, linked to monocytes and macrophages, does not activate complement in mice, but may do so in rats (Girija et al., 2011). MASP-1, -2, and -3, and truncated, nonenzymatic products of MASP2 and MASP1/3 genes (i.e., MAp19 and MAp44, respectively) have been reported in human beings and mice (Sørensen et al., 2005; Ali et al., 2012).

Since neither MASP-1 nor MASP-3 can cleave C4, MASP-2 is a vital and required component for the formation of the C3 and C5 convertases (i.e., C4b2a and C4b2a(C3b)n, respectively) by the lectin pathway (Schwaeble et al., 2011; Ali et al., 2012). The binding to pathogens leads to a conformational change resulting in the activation of MASP-2. Similar to C1s, activated MASP-2 cleaves C4 to form C4a and C4b. The C4b attaches to the surface of the pathogen and to C2. The bound C2 is then cleaved by MASP-2 to form C2a and C2b. Together, C4b with the bound C2a forms the enzymatically active C3 convertase (C4bC2a). The exact role of the other MASP is presently unknown although MASP-1 can cleave C2 but not C4 (Wallis, 2007) and thus help in enhancing complement activation by the bound complexes.

17.2.5 MEMBRANE ATTACK COMPLEX

Formation of the MAC results from activation of the terminal complement pathway and C5 cleavage into C5b by the C5 convertase, inducing a dramatic conformational change. Interaction of C5b with C6, C7, C8, and multiple copies of C9 results in MAC formation. The lipophilic portion of C5b-7 binds to the cell membrane, and C8 is the first component to penetrate the lipid bilayer upon interaction with the forming MAC tubular channel. A single MAC contains up to 18 C9 molecules but one or two C9 molecules are sufficient to form a functional pore. One MAC is sufficient to lyse the membrane of metabolically inert cells, like erythrocytes or liposomes by colloid osmosis, and in coordination with calcium flux and poorly understood signal transduction in target cells can be

activated leading to cell proliferation or apoptosis, which is dependent on the targeted cell type and experimental conditions (Merle et al., 2015).

In summary, the described mechanisms of activation of the three complement pathways rely on the versatility of the target pattern recognition molecules (C1q, MBL, and ficolins) that can discriminate between self and nonself and bind to pathogen- or danger-associated molecules. These molecular patterns result from specific conformational changes, such as with IgM or IgG-antigen clustering, CRP, or pathogen-associated carbohydrates. Complement activation is thus driven by conformational changes following a recognition process, leading to the subsequent activation or modulation of downstream complement components (Merle et al., 2015) involved in phagocytosis, opsonization, inflammatory and immune reactions including antibody production, and actual cell/pathogen lysis and elimination (Merle et al., 2015).

17.2.6 PATHWAY REGULATION

While the activation of classic and lectin pathways is, in general, dependent on foreign components, both pathways can be activated under some other situations (e.g., tissue ischemia/reperfusion injury) and cause injury to the host. Further, there are complement-related diseases in which deposition of C3b after activation and amplification of the alternative pathway, without proper regulation, results in host cell injury. Thus, in view of the damage that unchecked complement activation can cause on host cells, it makes biologic sense that mechanisms are in place to limit complement activation (Sarma and Ward, 2001; Noris and Remuzzi, 2013). Consequently, human beings and mammals have a variety of regulatory soluble and membrane-bound proteins that participate in the control of complement activity (Table 17.2 and Figure 17.2).

TABLE 17.2
Complement Regulatory Proteins, and Their Functions, Demonstrated in Plasma or Bound to Cell-Membranes

Plasma

C1 inhibitor (C1INH)	Inactivates C1r and C1s, MASP-1, and MASP-2
C4 binding protein (C4BP)	Binds to C4b; decay accelerating and cofactor activity
Factor H	Binds to C3b; has decay accelerating activity of the AP C3 and C5 convertases and cofactor activity
Factor I	Degrades C3b and C4b aided by cofactors
S-protein (vitronectin)	Binds to C5b-7 and inhibits C9 polymerization
Clusterin (SP-40,40)	Binds to C5b-7 and inhibits generation of C5b-9

Membrane-Bound

MCP	Cofactor for factor I-mediated cleavage of C3b and C4b
DAF	Destabilizes C3/C5 convertases of the CP and AP (decay accelerating activity)
CR1	Decay accelerating activity as well as cofactor activity for factor I-mediated cleavage of C3b and C4b
Thrombomodulin	Increases CFH cofactor activity, activates TAFI-mediated C3a and C5a inactivation
Factor I	Degrades C3b and C4b aided by cofactors
CD59	Blocks the C9 association with C5b-8 to prevent C5b-9 formation on host cells

TAFI, thrombin activatable fibrinolysis inhibitor.

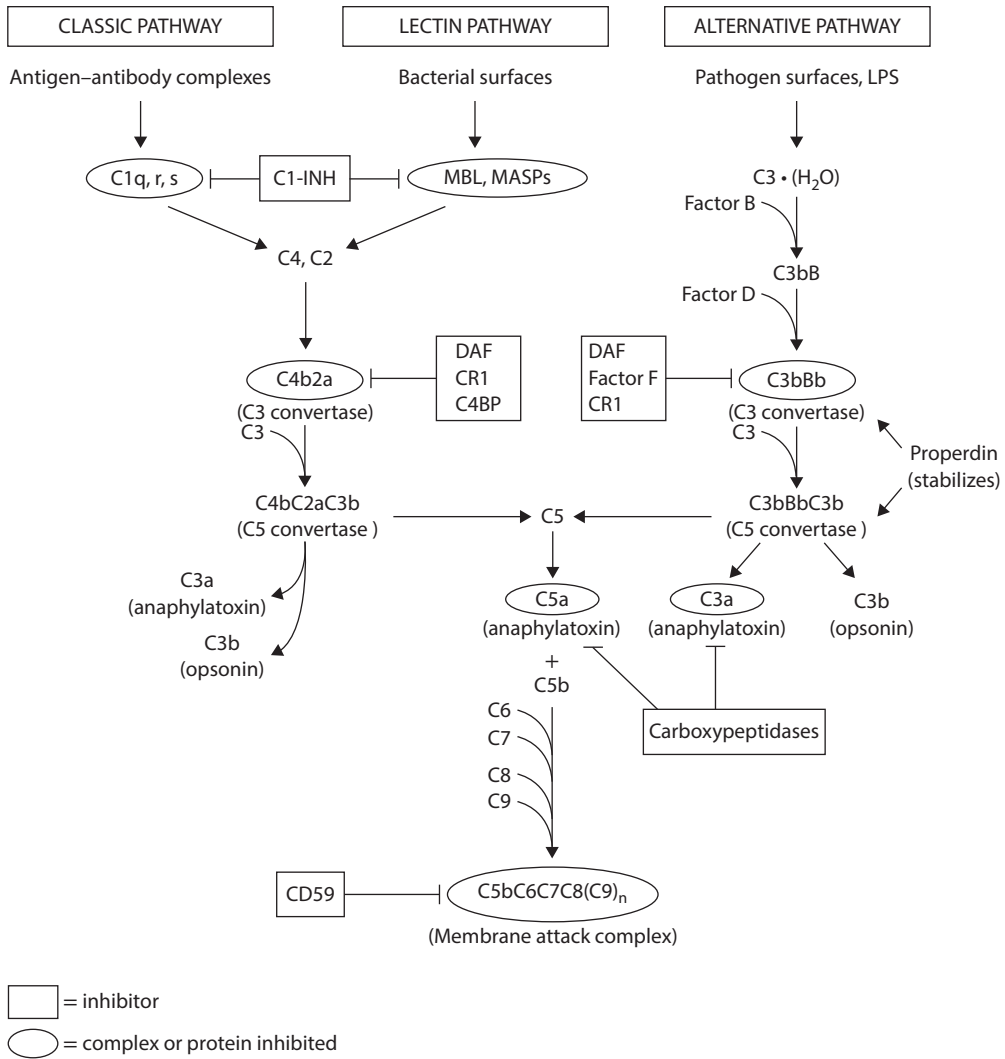

FIGURE 17.2 Illustrated representation of complement pathway regulation involving soluble or cell membrane-bound inhibitory factors. (Adapted from Sarma, J.V. and Ward, P.A., *Cell Tissue Res*, 343, 227–235, 2011; Drawing by David Sabio.)

17.2.6.1 Soluble Factors

Circulating carboxypeptidases, by cleaving the C-terminal Arginine, attenuate the inflammatory capacity of the anaphylatoxins C3a and C5a (Sarma and Ward, 2011). The resulting C3a des-Arg and C5a des-Arg have markedly reduced biologic activity (<10% of their original activity).

C1 inhibitor (C1INH, SERPING1) is a circulating serine protease inhibitor that irreversibly binds to the C1r and C1s of the C1q–C1r–C1s complex of the classic pathway. This binding blocks the active sites of C1r and C1s, allowing dissociation from C1q (Liszewski et al., 1996). Further, C1INH can bind MASP-1 and -2 of the lectin pathway (Noris and Remuzzi, 2013). Thus, the initiating steps of these pathways are inhibited. In addition to its action as an inhibitor of complement activity, C1INH plays a role as an inhibitor of the contact system of coagulation by inhibiting factor

XIIa and kallikrein. A deficiency of C1INH results in excess generation of bradykinin leading to increased vascular permeability, and angioedema (Cugno et al., 2009).

Circulating proteins such as factors H and I both inhibit complement activation (Noris and Remuzzi, 2013). Factor H (FH) is a large glycoprotein (155 kDa) that provides regulatory control of the complement system by multiple mechanisms. Acting as a primary inhibitor of the alternative pathway, the binding of FH to C3b obstructs the interaction of C3b with both Factor B (Pangburn, 2000) and C5 (Isenman et al., 1980), and causes displacement of the Bb fragment of Factor B from active C3 and C5 convertases of the alternative pathway (Weiler et al., 1976). Additionally, FH acts as a cofactor for the serine proteinase factor I (FI), which cleaves C3b into inactive C3b (iC3b), thus inhibiting the action of C3b in all complement pathways (Pangburn et al., 1977). Since FH binds to glycosaminoglycans (molecules generally found on the membranes of mammalian cells), FH protects host cells and surfaces but not the surfaces of pathogens (e.g., viruses and bacteria) (Pangburn, 2000).

As mentioned earlier, FI (aka C3b/C4b inhibitor) is a serine proteinase that, in the presence of cofactors (FH or C4b-binding protein), rapidly inactivates C3b and C4b by proteolytic cleavage into the fragments, inactive C3b (iC3b), C3dg, C3c, C4c, and C4d (Sarma and Ward, 2001; Noris and Remuzzi, 2013). Factor I cleaves C3b in the presence of factor H by hydrolysis of its α -polypeptide resulting in the prevention of C3 convertase formation. The C4b component of complement is cleaved by FI in the presence of the plasma cofactor C4b-binding protein.

C4b-binding protein (C4BP) is a potent circulating soluble inhibitor of the classic and lectin pathways of complement (Blom et al., 2004). Through its interaction with C4b, C4BP acts on the complement system in at least three ways. First, C4BP acts as a cofactor to FI, for the proteolytic inactivation of C4b, preventing the formation of C3 convertase (C4bC2a) (Scharfstein et al., 1978). How C4BP functions as a cofactor to FI is not understood, but it appears to involve a conformational change of C4b following binding to C4BP, thus becoming more susceptible to cleavage by FI. Second, C4BP physically prevents the assembly of C3 convertase by binding nascent C4b. Third, C4BP, accelerates the natural decay of the C3-convertase complex (Gigli et al., 1979). Finally, C4BP can also act as a cofactor to FI in the cleavage of C3b in the fluid phase thereby providing some inhibition of the alternative pathway of complement activation as well (Blom et al., 2003; Seya et al., 1985; Seya et al., 1995). However, since it does not inhibit the fluid phase C3 convertase of the alternative pathway, it appears that C4BP does not inhibit assembled C3 convertase (Seya et al., 1985). Furthermore, unless it is present in very high concentrations, C4BP does not reduce the hemolytic activity of cell-bound C3b (Blom et al., 2003). Thus, C4BP is not able to fully replace the major fluid phase inhibitor of the alternative pathway, factor H.

Other factors that protect against the fluid phase activation of the MAC include S Protein (vitronectin) and clusterin (SP40, 40, cytolysis inhibitor), both of which inhibit the terminal complement pathway after the formation of C5b-7 (Liszewski et al., 1996).

17.2.6.2 Membrane-Bound Factors

The membrane-bound decay-accelerating factor (DAF, CD55) is named for its ability to accelerate the decay of C3 convertase (C4b2a) of the classic and lectin pathways, and the C3bBb complex of the alternative pathway (Pangburn et al., 1983). It functions by releasing C2a from its binding site on C4b (classic) and Bb from C3b (alternative). Its actions are limited to C3 convertases assembled on the same cell expressing DAF (Medof et al., 1984). DAF is expressed on all hematopoietic cells, endothelial and epithelial cells, at the fetomaternal interface of the placenta, and as a soluble molecule in plasma and other body fluids. Expression of human DAF on swine xenografts protects them against hyperacute rejection by nonhuman primates (McCurry et al., 1995).

Membrane cofactor protein (MCP; also known as CD46, measles virus receptor) is a membrane-bound complement regulator that serves as a cofactor for factor I-induced degradation of C3b and C4b. MCP and its analogs in other species are widely expressed on tissues throughout the body, and

its expression on endothelium in transgenic pigs aids in the prevention of acute (antibody-mediated) rejection of swine xenografts (Rooney et al., 1993).

Complement receptors type 1 (CR1; C3b/C4b receptor, immune adherence receptor, CD35) and type 2 (CR2; C3d receptor, Epstein–Barre Virus (EBV) receptor, CD21), found on circulating cell membranes, bind ligands, including derivatives of C3 (CR1 and CR2) and/or C4 (CR1), and immune complexes (Hourcade et al., 1989). While CR1 facilitates both complement regulation and immune complex processing, CR2 interacts only with C3b-derived ligands degraded by other regulators, and as such makes only a minor contribution to complement regulation. Although CR1 has decay accelerating and cofactor activities, its principal role is to reduce complement activity after immune complexes containing C3b/C4b adhere to cells. In the blood, CR1 is found mainly on erythrocytes. Soluble CR1 (recombinant) (SCR1) infused into animal models blocked inflammation and reduced the extent of myocardial necrosis in models of myocardial infarction, suggesting that complement may play an important role in the removal of dead and dying tissues and may promote healing (Moore, 1994). Infusion of SCR1 into rats transplanted with renal allografts delayed complement activation, prolonged graft survival, and down regulated B cell antibody synthesis (Pratt et al., 1997).

MAC-inhibitory protein (CD59, MAC-IP) is a membrane-bound glycoprotein that inhibits the formation of MAC on membranes by inhibiting C9 from associating with C5b-8 and preventing the polymerization of C9 on the membrane (Huang et al., 2006; Liszewski et al., 1996; Noris and Remuzzi, 2013). Analogs of human CD59 have been documented in rats, sheep, and pigs, and appear to be effective in the control of experimental glomerulonephritis and other inflammatory conditions (Hughes et al., 1992; van den Berg and Morgan, 1994).

17.2.7 ATYPICAL PATHWAYS OF COMPLEMENT ACTIVATION

Other atypical routes can lead to complement activation. A number of molecules can directly bind and activate C1 without involving antibody, leading to activation by the classic pathway. The acute phase reactants CRP and serum amyloid-P component (SAP) bind to damaged cells and nuclear constituents as well as microorganisms and, once bound, bind C1, allowing for complement activation and enhancing phagocytosis of inflammatory debris (Jiang et al., 1991; Hicks et al., 1992; Vaith et al., 1996). Additionally, damaged mitochondria and myelin (Moore, 1994), proteases from neutrophils and macrophages (Ward and Zvaifler, 1973; Huber-Lang et al., 2002), and coagulation factors resulting from the activation of the coagulation cascade (i.e., kallikrein, plasmin, factors IXa, Xa, XIa, XIIa, plasmin, and thrombin) (Huber-Lang et al., 2006; Sarma and Ward, 2011) can generate complement activation products (Merle et al., 2015).

17.3 METHODS OF ANALYSIS

It has been shown that alterations in the complement system can be part of direct or indirect pathophysiologic mechanisms of a number of diseases and pathologic conditions such as autoimmune disease, infections, cancer, allogeneic and xenogeneic transplantation, and inflammation (Figuroa and Densen, 1991; Nilsson and Ekdahl, 2012; Ricklin and Lambris, 2013; Morgan and Harris, 2015). To characterize the alterations, complement analyses have been performed on these conditions in both prospective and retrospective studies, and in experimental settings in human beings and animals (Figuroa and Densen, 1991; Kirschfink and Mollnes, 2003; Mollnes et al., 2007). Further, it has been considered that the indications for serologic diagnostic complement analysis be divided into three primary types: (a) acquired and inherited complement deficiencies; (b) disorders of complement activation; (c) inherited and acquired C1INH deficiencies (Nilsson and Ekdahl, 2012).

The various components of the complement system are quantitated by assays designed to measure either the functional properties of these proteins or the presence of their antigens. Additionally, functional assays measure the ability of the total classic, lectin or alternative pathway, or individual components to lyse (hemolyze) antibody-coated (sensitized) or noncoated (for alternative pathway) red blood cells in suspension or in agarose gel (Porcel et al., 1993). Functional assays are both precise and sensitive (Atkinson and Frank, 1980). Tests designed to measure complement factor antigens generally are simpler, less subject to error due to mishandling of serum, and less expensive. However, they have the disadvantage of measuring both active and inactive forms of these proteins and therefore may not necessarily correlate well with the functionally active protein concentration. As with most immunologic assays, specificity and sensitivity are enhanced when species-specific antisera are employed. Methods of complement analysis have been comprehensively reviewed (Kirschfink and Mollnes, 2003; Mollnes et al., 2007; Nilsson and Ekdahl, 2012).

17.3.1 FUNCTIONAL ASSAYS

Using functional assays has been a traditional method for the evaluation of the integrity of the complement system. They have proven useful as a screening tool for the detection of complement deficiencies or monitoring dysfunction (Kirschfink and Mollnes, 2003; Nilsson and Ekdahl, 2012). Potential deficiencies can be subsequently analyzed quantitatively for specific components using component-specific immunoassays, with and/or without procedures in which the test sample is reconstituted with the relevant component protein. The addition of this follow-up, confirmatory-type testing provides information as to whether it is an actual or functional deficiency (Kirschfink and Mollnes, 2003).

17.3.1.1 The Hemolytic Assay

Since the 1930s, the complement fixation hemolytic assay has been a useful functional screening test for assessment of complement activity of whole serum or plasma (Atkinson and Frank, 1980; Nilsson and Nilsson, 1984; Porcel et al., 1993; Costabile, 2010). Because calcium and magnesium are required components of the assay buffer, the use of chelating agents such as ethylenediaminetetraacetic acid (EDTA) should be avoided. In general, most complement component assays are performed using serum rather than plasma. In the hemolytic assay, the degree of hemolysis is measured spectrophotometrically as the absorbance of released hemoglobin can be directly related to the number of lysed red blood cells. The hemolytic complement activity is estimated as the amount of complement required to achieve 50% hemolysis and is referred to as the CH_{50} .

17.3.1.1.1 Evaluation of Pathway Activation

As a screening assay for the activation of the classic complement pathway, the CH_{50} is sensitive to the reduction or absence and/or inactivity of any component of the pathway. In general, it tests the functional capability of the complement components in the serum to lyse sheep red blood cells, precoated (sensitized) with rabbit antisheep red blood cell antibody (hemolysin). When antibody-coated sheep red blood cells are incubated with test serum, the classic pathway of complement is activated and hemolysis results.

The amount of complement activity is determined by examining the ability of various dilutions of test serum to lyse the sensitized sheep red blood cells. Thus, a fixed volume of the red blood cells is added to each serum dilution. The mixture is incubated, then centrifuged, and the degree of hemolysis is determined by measuring the absorbance of the hemoglobin released at 540 nm. The percentage of red blood cell lysis in a standardized system follows an S-shaped curve when plotted against increasing amounts of added complement. In the midregion of the curve, there is nearly a linear relationship between the degree of hemolysis and the amount of complement added. The amount of complement required to achieve 50% hemolysis is the CH_{50} . When human or animal serum is

submitted to this procedure, a whole complement titer is measured, and the titer is expressed as the reciprocal of the serum dilution that lyses 50% of a standard suspension of erythrocytes.

For the alternative pathway, fresh human serum is capable of lysing unsensitized rabbit erythrocytes in the presence of Mg-EDTA by the alternative pathway (Atkinson and Frank, 1980). This assay has been used to measure alternative pathway components (ACH_{50}) in 25 species of mammals; while rabbit red cells served as targets for alternative pathway activation in 18 of 20 species, the red cells of other mammals were frequently more sensitive. Sialic acid concentration of the red cell membrane correlated with ACH_{50} (Ish et al., 1993; Menger and Aston, 1984; Naka et al., 1997; Olahu-Mukani et al., 1994).

17.3.1.1.2 *Measurement of Individual Complement Components*

The hemolytic assay can also be used to measure individual complement components. Target red cells with membrane-bound components are prepared by producing antibody-sensitized sheep red cells (EA), and incubating them in purified guinea pig or human C1. This reaction mixture yields EAC1. Incubation of EAC1 with fresh human serum in EDTA yields EAC14 and EAC4. The application of EAC1 to test serum allows for the rapid binding of C4, which in the presence of fresh guinea pig serum, containing C3–C9, will result in hemolysis limited only by the concentration of C4 in the test sample. Likewise, the application of the cellular intermediate EAC14 to test serum allows for the binding of C2 from the test serum, which in the presence of fresh guinea pig serum allows for hemolysis limited only by the concentration of C2 in the test serum.

The use of cellular intermediates and purified components for the measurement of all nine classic pathway components was reviewed for use in human (Gaither and Frank, 1979) and other animal samples (Barta and Barta, 1973a). Testing animal complement components using commercially available reagents for human beings has produced acceptable results for the measurement of C1 and C5 through C9; however, the results obtained when measuring C4, C2, and C3 are generally much lower in domestic animals than in human beings or the guinea pig (Barta and Hubbert, 1978). For this reason, the purification of C4, C2, and C3 from each species and their use in a homologous assay is encouraged. The hemolytic assay for individual components using cellular intermediates was used to measure C1 through C7 in rats (Arroyave et al., 1977; Sakamoto et al., 1981), C1 through C9 in rabbits (Menger and Aston, 1984), C1 through C9 and factor B in nonhuman primates (McMahan, 1982; Schur et al., 1975), C1 through C9 in guinea pigs (Bitter-Suermann et al., 1981; Nelson et al., 1966), and C1 through C6 in the mouse (Nilsson and Muller-Eberhard, 1967).

Several modifications to the hemolytic assay have been made for the measurement of individual components in human beings and animals. In one modification, the EA cells are incubated with test serum or serum from animals that have a genetically related deficiency in one complement component. In addition, a number of animals with genetically related deficiencies of individual complement components including, C2-, C3-, or C4-deficient guinea pigs, C3-deficient dogs, C1q-, C3-, C4-, C5- and factor B-deficient mice, and C6-deficient rats and rabbits have been described (Rother and Rother, 1986; Botto, 1998; Barrington et al., 2001; Tuzun et al., 2003). An often-used assay employs sera from C4-deficient guinea pigs, and has been used to measure C4 in human beings, mice, and rats (Arroyave et al., 1977; Atkinson et al., 1980; Gaither and Frank, 1979). Similarly, human C2-deficient sera and rabbit C6-deficient sera have been used to measure levels of these components in human and animal serum (Atkinson et al., 1980; Bitter-Suermann et al., 1981; Gaither and Frank, 1979). In a second modification, Pepys (1974) measured murine C3 by observing rosette formation where EAC142^{SP} (isolated components of guinea pig origin) bound to C3 on mouse mesenteric lymph node cells.

Yamamoto et al. (1995) developed a liposome-based assay to measure total complement activity in human beings. When liposomes had glucose-6-phosphate dehydrogenase entrapped in their core and dinitrophenyl integrated in the outer membrane, a fully automated complement assay could be quantitated following the binding of anti-DNP as the initiator.

17.3.1.1.3 Testing Sensitivity

Since hemolysis will be lowered proportionally to the consumption of complement, these types of complement evaluations can be used to assess the effect of complement inhibition by a certain substance or agent or as a semiquantitative estimator of complement activation under controlled conditions. If any single component of the classic pathway is missing, hemolysis will not occur. The total absence of a component, however, is rare in most clinical situations. Problems with the assay may include complex mathematical and or technical manipulations, lack of objectivity, and poor sensitivity. These have been addressed somewhat in a modification of the tube assay involving microtiter plates and an enzyme-linked immunosorbant assay (ELISA) reader (measuring hemolysis), and a computer program for calculation of values (Blann et al., 1990; Costabile, 2010).

17.3.1.1.4 Species-Specific Considerations

Though hemolytic assays can be designed for any species, in some instances a comprehensive analysis of complement is limited due to the lack of appropriate reagents and procedures (Kirschfink and Mollnes, 2003). For example, in a previously unstudied species, the selection of a relevant target cell is a considerable factor. Thus, when testing animal serum, determining the optimum conditions for hemolysis for the individual species is critical and factors such as target red cell, buffer pH, buffer ionic strength, and concentration of calcium ions must all be carefully selected (Barta and Barta, 1984). In general, serum for all animal species should be harvested within 60 minutes of blood collection and either tested immediately or stored frozen at -70°C until tested. Swine and chicken complement, however, are relatively unstable even when frozen at -70°C (Barta and Barta, 1984). Since the resultant hemolytic titers are influenced by the source and quality of erythrocyte-specific antibodies, comparison of pathway activity between different species can be difficult to assess (Higgins and Langley, 1985). It appears, however, when the assay has been optimized, activity of the classic and the alternative pathways can be demonstrated in essentially any species of laboratory and domestic animal (Barta, 1978; Ish et al., 1993; Tanaka et al., 1987). Finally, techniques have been thoroughly reviewed for both human (Alper and Rosen, 1975; Gaither and Frank, 1979) and animal assays (Barta and Barta, 1984; Grant, 1977).

Using the basic technique, the total hemolytic complement of animals was measured in dogs (Barta and Barta, 1973a; Madewell, 1978; Trail et al., 1984; Wolfe and Halliwell, 1980), rats (Naka et al., 1997; Sakamoto et al., 1981), mice (Nilsson and Muller-Eberhard, 1967), guinea pigs (Thurston et al., 1980), nonhuman primates (Ellingsworth et al., 1983; Rommel et al., 1980), rabbits (Nelson and Biro, 1968), sheep (Jonas and Stankiewicz, 1981; Stankiewicz and Jonas, 1981), goats (Oyekan and Barta, 1980), swine (Oyekan and Barta, 1980), cats (Barta and Oyekan, 1981), hamsters (Yang et al., 1974), horses (Barta and Barta, 1973b), and chickens (Barta and Barta, 1975). It has been reported that many mouse strains have low complement activity relative to human beings, rats, guinea pigs, and rabbits (Ong and Mattes, 1989). Of 43 mouse strains evaluated, only 8 strains demonstrated complement activity levels comparable to those of other mammals.

Modifications to the hemolytic assay have been made to measure hemolytic complement in bovine milk (Poutrel and Caffin, 1984). A test for measuring cytotoxic complement in rabbits using murine lymphocytes and alloantisera in a microtiter system has been reported (Fox and Cherry, 1978; Fox et al., 1978, 1979).

17.3.1.2 Evaluation of Complement Activation by Immunoassay

Methods using a solid-phase enzyme immunoassay (ELISA or EIA) format have been described for screening the activation of all three (classic, alternative, and lectin) pathways (Fredrikson et al., 1993; Seelen et al., 2005). One assay (Seelen et al., 2005) includes three separate EIA assessing all three activation pathways simultaneously in human samples; it is commercially available (Wieslab, Euro Diagnostica, Malmö, Sweden). For this method, IgM (for the classic

pathway), mannan or acetylated bovine serum albumin (for the lectin pathway), and LPS (for the alternative pathway) are used as the specific recognition molecules for the immunoassay. In general, the recognition molecules are coated onto microtiter plate wells. The test serum is added and incubated under conditions in which only one pathway is activated. Complement activation is then detected using a monoclonal antibody against either a C9 neoepitope (classic pathway) or an antibody against properdin (alternative pathway). To create a lectin pathway-specific assay, the other activation pathways must be blocked. This blockade is achieved by the use of a monoclonal anti-C1q antibody inhibiting classic pathway activation (Roos et al., 2005).

The solid-phase immunoassay format has advantages compared with the hemolytic assays. For example, as an EIA, it is easily performed, it is not dependent on erythrocyte availability, and the alternative pathway assay can detect a properdin deficiency. These assays can be used in combination with the measurement of C3 and C4 and, if a complement deficiency is suggested, could be supplemented by measurement of an activation product assay to distinguish primary from secondary complement deficiency (Seelen et al., 2005). Recently, ELISA methods for measuring functional complement pathways in rats, mice and some old world monkeys, similar to the human assays outlined in Section 17.3.1, have been described (TECOmedical Group, 2010; Kotimaa et al., 2014; Kotimaa et al., 2015; van der Pol et al., 2012).

17.3.2 IMMUNOCHEMICAL ASSAYS

Individual complement components, irrespective of functional activity, can be measured by a variety of methods that rely on the formation of antigen–antibody complexes as the test principle. For example, antigenic assays including radial immunodiffusion, electroimmunodiffusion (rocket electrophoresis), automated immunoprecipitation (measured nephelometrically), crossed immunoelectrophoresis (Lewis and Picut, 1989; Mancini et al., 1965), time-resolved immunofluorometric assay (Moller Kristensen et al., 2003), radioimmunoassay (Guiguet et al., 1987), and ELISA (Porcel et al., 1993) have all been used to measure complement components in human beings and other animals. A brief description follows for some of the listed methods.

17.3.2.1 Radial Immunodiffusion

A widely used method, radial immunodiffusion, is based on the principle that a quantitative relationship exists between the amount of antigen placed in a well cut in the agar antibody plate and the resulting ring of precipitation. The assay may be conducted using one of two methods. In the Mancini method (Mancini et al., 1965), specific antibody raised against the complement component to be measured is added to agar so that the antibody is in excess (relative to the concentration of the complement component in test sera). In this assay, the incubation time is not critical.

The Fahey method (Fahey and McKelvey, 1965) employs antibody that is not in excess, and therefore, the time of incubation is critical. In both assays, a standard curve is first generated using purified complement components, and the diameter of the precipitin ring is directly related to antigen (complement) concentration through a logarithmic relationship. When universal reference standards or chemically pure components are unavailable, a standard reference serum may be used in which the exact concentration of the specific complement component is known. The radial immunodiffusion assay should be run on fresh or fresh frozen (-70°C) serum and, as in all complement assay methods, bacterial contamination of the test serum must be avoided. Reference standards should be frozen as aliquots because repeated freeze–thawing may influence the results. The radial immunodiffusion assay has been used successfully to measure various complement components in guinea pigs (Thurston et al., 1980), cattle (Table et al., 1983), mice (Ferreira and Nussenzweig, 1975; Karp et al., 1982a), and nonhuman primates (Holmberg et al., 1977).

17.3.2.2 Electroimmunodiffusion

The electroimmunodiffusion (rocket electrophoresis) assay is based on the principle of electrophoresis of antigen (complement) into antiserum-containing agarose. In this assay, the peak heights of rocket-shaped precipitin bands are measured and compared with those of standards used for quantitation of antigen in the test sample. This method is both sensitive and rapid, but it requires some special equipment. Rocket electrophoresis has been used to quantitate complement components in nonhuman primates (Alper et al., 1971; McMahan, 1982), dogs (Feldman et al., 1981), mice (Ferreira and Nussenzweig, 1975; Natsuume-Sakai et al., 1978; Pepys et al., 1977), and guinea pigs (Bitter-Suermann et al., 1981).

A modification of the rocket electrophoresis, used for rapid qualitative assessment of complement components, was described by Natsuume-Sakai et al. (1978). In this procedure, wells are cut from agarose-coated glass slides, and antigen is first isolated by charge using constant voltage. After a period of time, a trough is cut between two wells, and specific antiserum is added. Precipitin bands occur when antigen and antiserum reach equivalence by double diffusion. This technique is useful to detect the presence or absence of a component and to observe charge variation in components. It has been used to evaluate complement in such divergent species as mice (Natsuume-Sakai et al., 1980) and cattle (Table et al., 1983).

17.3.2.3 Crossed Immunelectrophoresis

Crossed immunelectrophoresis is a variant of immunelectrophoresis and is more sensitive. It allows precise measurement of the amount of each antigen present in a mixture. Antigens placed in the sample slot are electrophoresed in agarose. A central strip of agarose containing all of the isolated components is then removed and placed on a second slab of agarose, which contains the antisera (Laurell, 1972). This assay has the advantage of providing quantitative estimations of complement component conversion, and therefore complements activation that occurred *in vivo* (Alper and Rosen, 1975). Crossed immunelectrophoresis has been used successfully to quantitate complement components in dogs (Gorman et al., 1981a), cats (Gorman et al., 1981b), nonhuman primates (Ziegler et al., 1975b), and mice (Pepys et al., 1977).

17.3.2.4 Quantitative Immunoassays

The availability of monoclonal antibodies that bind neopeptides present on the split products of individual human complement components allows for the initial binding of the split product (and its removal from serum or plasma), and later quantitation with an enzyme-linked (ELISA-type assay) or radio-labeled (RIA-type assay) secondary antibody. These types of assays can be specific, sensitive, and conducive to automation. Currently, antibodies exist to measure human C4b, C4c, C4d, Ba, Bb, C3dg, and C4BP (Porcel et al., 1993; Coppola et al., 1995; Pavlov et al., 2011). When C4d, Bb, and iC3b (quantitated by ELISA) were compared to levels of C3 and C4 (by radial immunodiffusion) and CH_{50} , good agreement was found between human patients and controls for all levels except iC3b, which was elevated compared to CH_{50} . The authors attributed these elevated iC3b levels in patients to a decreased iC3b clearance, an increased C3 synthesis, or an enhanced C3 cleavage by nonimmune mechanisms (Goldberg et al., 1997).

17.3.2.4.1 Measurement of Anaphylatoxins

Tests for total hemolytic complement and components are indirect measures of activation tests that are capable of directly detecting and quantitating complement activation. In each of these assays, *in vitro* activation must be prevented, therefore, blood is collected into EDTA tubes containing nafamostat mesylate (to stabilize components), and the plasma should be separated as soon as possible. A sensitive radioimmunoassay was developed to measure the anaphylatoxins C3a, C4a, and C5a (Wagner and Hugli, 1984); however, this procedure first requires precipitation of the native molecules (C3, C4, and C5) from plasma. The detection of false plasma elevations due to complement

activation *in vitro* is a major limiting factor in all anaphylatoxin assays. This radioimmunoassay could be used to detect anaphylatoxins in rhesus monkey and baboon serum; however, the test appears to be no more than 10% efficient in measuring C3a in nonhuman primate samples.

17.3.2.4.2 Species Cross-Reactivity

While numerous specific assays have been described for human complement activation, only a few are available for animal studies. Tests developed specifically for animals include assays based on monoclonal antibodies to guinea pig C5a (Link et al., 1999) and C3 activation products (Hawlich et al., 2000), rabbit C5a (Bergh and Iversen, 1989), and rat C5b-9 (Schulze et al., 1989). A double antibody radioimmunoassay specific for rat C3 was developed and utilized for quantifying C3 in cell culture media (Guiguet et al., 1987). There are examples of human epitope-specific assays that cross-react with other species including baboon C3bc (Hiramatsu et al., 1997); baboon C3bc, C5a, and C5b-9 (Mollnes et al., 1993); baboon C4d, C3a, Bb, and C5b-9 (Fung et al., 2001); and porcine C5b-9 (Jansen et al., 1993). Further, using a human assay of complement activation, potential species cross-reactivity can be assessed by activating the serum from the respective species and comparing it to the nonactivated sample. If the signal is stronger in the activated serum compared to the nonactivated serum, the assay cross-reacts to some level with that species.

17.4 SPECIFIC COMPONENTS OF THE COMPLEMENT CASCADE

The complement system is an indispensable host defense mechanism against external pathogens. However, several perturbations of this defense apparatus are related to a variety of diseases. For example, unregulated activation of complement significantly contributes to inflammation-mediated tissue damage, and inherited or acquired complement deficiencies can contribute to the development of autoimmunity (Markiewski and Lambris, 2007; Ram et al., 2010; Nilsson and Ekdahl, 2012). Additionally, alterations of complement activity can play a role for such pathologic conditions as transplantation reactions, infections, and cancer (Nilsson and Ekdahl, 2012). Moreover, complement analyses including quantification of complement activity and complement activation products, and genetic methods for the detection of deficiencies, mutations, and polymorphisms, have been performed on many of these conditions in human and experimental animal studies (Kirschfink and Mollnes, 2003; Mollnes et al., 2007).

Basic indications for diagnostic complement analysis have been divided into three major categories: (1) acquired and inherited complement deficiencies; (2) disorders with complement activation; (3) inherited and acquired C1INH deficiencies (Nilsson and Ekdahl, 2012). Animal models of acquired complement inhibition (e.g., CoF) have been used (Frank, 1995). Additionally, a variety of animals (e.g., mouse, rat, guinea pig, dog, rabbit, and swine) with spontaneous or genetically engineered overexpression or deficiency of individual components have enabled investigators to study the role of complement in a focused manner (Frank, 1995; Botto et al., 1998; Linton, 2001; Hanafusa et al., 2002; Loeffler, 2004; Markiewski and Lambris, 2007; Ram et al., 2010). The following section highlights some of the information regarding specific components of complement and associated animal models.

17.4.1 THIRD COMPONENT OF COMPLEMENT (C3)

17.4.1.1 Physical, Chemical, and Genetic Properties of C3

The third component of complement (C3) is a secreted glycoprotein with the electrophoretic migration properties of a β -globulin (Colten, 1976). It is present in human serum in concentrations higher than any other component, and was the first isolated in pure form. The molecules of C3,

C4, and C5 have common structural and functional properties, and it has therefore been postulated that they may all have arisen from a common ancestral molecule (Muller-Eberhard, 1975). The molecular weight of secreted human C3 is 180,000 Daltons (Da) (Budzko et al., 1971). It consists of two chains linked by disulfide bonds (Nilsson and Mapes, 1973; Tack and Prahl, 1976). The C3 α -chain weighs 110 kDa, and the C3 β -chain weighs 70 kDa. Both chains are part of a large intracellular polypeptide, pro-C3, which in the mouse and guinea pig has the subunit arrangement NH_2 - β - α -COOH (Goldberger et al., 1981). The pro-C3 subunits are linked by four arginine residues that must be cleaved to produce the native two-chain molecule (Fey et al., 1983). The secreted two-chain molecule undergoes extracellular enzymatic cleavage that selectively affects the larger α -chain. Cleavage of the chain leads to generation of the C3a and C3b fragments, each with biologic activity. Further cleavage of the C3b fragment of the α -chain leads to production of C3c, C3d, and C3e (Muller-Eberhard, 1975). Rat C3 has a molecular weight of 187 kDa (Daha et al., 1979) and consists of two polypeptide chains weighing 125 and 73 kDa (Guiguet et al., 1987). Swine C3 α -chain has a molecular weight of 110 kDa and the C3 β -chain is 60 Da (Storm et al., 1992).

Three electrophoretic variants of C3 have been described in the rhesus monkey. The three alleles have been designated C3^S, C3^F, and C3^{F1}, with a gene frequency of 0.66, 0.33, and 0.01 among 81 rhesus monkeys (Alper et al., 1971). Using high voltage electrophoresis, Gorman et al. (1981a, b) described three allotypes of canine C3, designated F, FS, and S. Family studies in dogs demonstrated that the C3F and C3S alleles are codominantly expressed at a single autosomal locus. The canine C3 genetic locus was not linked to the major histocompatibility complex (MHC).

Human C3 α - and C3 β -chains are both glycosylated, whereas only the C3 β -chain is glycosylated in the mouse (Fey et al., 1983). It is also known that the mouse C3 β -chain is 9 kDa smaller than the human C3 β -chain due to a difference in the amino acid chain length. A number of rare variants of the S and F alleles have been described in human beings; however, they are all functionally identical (Colten, 1983b; Colten and Alper, 1972).

The amino acid sequence of the C3 chain is known for the mouse and man (Fey et al., 1983). In addition, the sequence of C3a (anaphylatoxin) is also known for the rat (Jacobs et al., 1978) and pig (Corbin and Hugli, 1976). Mouse C3a shares 92% amino acid homology with rat C3a, 70% with rabbit C3a, 67% homology with human C3a, and 65% homology with swine C3a (Becherer et al., 1989; Hugli, 1975; Karp et al., 1982a). All 10 amino acid residues common to the thioester bond region of human C2, C4, and α -macroglobulin (the thioester bond is considered essential for function) are also identical to those in mouse C3. Structural characteristics of cattle, avian, reptilian, amphibian, and fish C3 have been published (Becherer et al., 1989; DiCarlo et al., 1997).

The human and murine C3 gene has been cloned (Hobart, 1984). A single gene in both species codes C3, and strong homologies are seen in the primary structure of each C3 gene. The gene for human C3 is located on chromosome 19, unlinked to the MHC (Fey et al., 1983). The murine C3 gene is linked to the MHC on chromosome 17 but maps outside the MHC, at a recombination distance of 12 centimorgans. Mice have three alleles encoding different electrophoretic variants (da Silva et al., 1978). The C3a allele determines a protein with an isoelectric point (pI) of 6.0 and an intermediate migration rate on cellulose acetate electrophoresis. C3b determines a protein of pI 6.1 and slow(S) migration; it is found in C57BL/6, BALB/c, CBA/J, and many other murine strains. C3c determines a protein with a pI of 6.0 but is antigenically different from the C3a protein; it migrates fast (F) and is found in SWR/J, WB/Re, SF/Cam, SJL and other murine strains (da Silva et al., 1978). The alleles responsible for these variants in both species are codominantly expressed (Natsuume-Sakai et al., 1978), and the allotypic determinants are located on the C3c fragment (as part of the primary structure). Antigenic variants in murine C3 have been demonstrated using specific alloantisera (Natsuume-Sakai et al., 1979). Constitutive and cytokine-induced expression of the C3 gene requires both *cis*- and *trans*-acting elements (Kawamura et al., 1992).

17.4.1.2 Function of C3

Due to its central position in both the alternative and classic pathways, C3 is of paramount importance in the generation of both the MAC and biologically active split products. The initial extracellular enzymatic cleavage of C3 occurs in the α -chain by C3 convertase (either classic or alternative), yielding a small molecular weight (9 kDa) C3a, and the large C3b fragments. The biologic activities of C3a include receptor binding and histamine release from mast cells (Johnson et al., 1975), polymorphonuclear leukocyte chemotaxis (Muller-Eberhard, 1975), and contraction of bronchial smooth muscle and hypotension (Bokisch and Muller-Eberhard, 1970; Regal et al., 1993).

The C3b fragment has a binding site, allowing for its attachment to other acceptor molecules. Once bound, C3b has a second binding site, allowing it to react with the immune adherence receptor on a variety of cells (Morgan, 1995; Muller-Eberhard, 1975). The binding of C3b to these receptors allows polymorphonuclear leukocytes/granulocytes and macrophages to engage in phagocytosis (Gigli and Nelson, 1968). The binding sites of human C3 for properdin, factor H, CR1, CR2, factor B, and MCP have all been identified (Sahu et al., 1998).

The C3b fragment is also subject to enzymatic cleavage by the C3 inactivator, which also occurs on the α -chain (Bokisch et al., 1975). During this cleavage, a small peptide, C3d, remains attached to the cell, while a larger molecule, C3c, is released (Ruddy and Austen, 1971). The C3c fragment maintains an intact β -chain, but during fission from C3b it loses another small fragment (16 kDa), C3e (Bokisch et al., 1975). The membrane-bound C3b combines with classic pathway C3 convertase to yield the trimolecular complex C4b2a3b, which acts as a C5 convertase, cleaves C5, and initiates the assembly of the MAC, C5b-C9 (Kolb et al., 1972). Likewise, the alternative pathway C3 convertase, C3bBb, may initiate a similar sequence, resulting in the activation of C3-C9 (Fearon et al., 1973). There is some evidence that the C4b2a3b complex of rabbits is a much more efficient C5 convertase than that of human beings or guinea pig (Ong et al., 1996).

Another interesting feature of C3 is that its blood concentrations increase during acute and chronic inflammation, and after tissue injury (Kusher, 1982; Muller-Eberhard, 1975). Although the acute phase reactants CRP and serum amyloid A protein rise rapidly within hours after injury, C3 levels rise more slowly (2–10 days) and often parallel ceruloplasmin concentrations. The concentration of C3 in the blood often increases by 50% during this acute phase response, whereas other acute phase reactants, such as CRP and serum amyloid A protein increase by hundred or thousand folds. Although most acute phase reactants of hepatic origin are induced by interleukin-1, glucocorticoids are the only well-characterized C3 regulators (Fey et al., 1983). Extracellular phosphorylation of C3 occurs under several pathologic conditions and renders C3 less susceptible to cleavage by either the classic or alternative pathways (Ekdahl et al., 1997).

17.4.1.3 Synthesis and Catabolism of C3

Estimates of C3 synthetic rates in human beings range between 0.45 and 2.7 mg/kg/h (Alper and Rosen, 1967; Peters et al., 1972; Sliwinski and Zvaifler, 1972). C3, like most of the C proteins, is synthesized early in fetal life (Hirschfeld and Lunell, 1962). Gitlin and Biasucci (1969) demonstrated fetal C3 synthesis in as early as the fourth week of human gestation. In normal human adults, the liver was shown to be the principal site of C3 synthesis (Alper et al., 1969a). However, small amounts of C3 have been produced in short-term cultures of human monocytes, lymphoid cells, and certain epithelial cells (Fey et al., 1983), and C3 synthesis by glomerular epithelial and mesangial cells in the kidney has been documented during human membranous nephropathy and Heymann nephritis in rats (Sasaki et al., 1997).

Hepatocytes of adult rats and mice failed to synthesize C3 *in vitro* except after endotoxin stimulation; however, C3 synthesis was easily demonstrated in unstimulated hepatocytes from juvenile animals. In mice, a locus that maps in the MHC locus controls the serum levels of C3 in the newborn, while no significant differences in C3 concentrations are seen in adults (Ferreira and Nussenzweig,

1975, 1976). Induction of hepatic C3 synthesis may be mediated by IL-1, IL-6, or tumor necrosis factor (TNF) (Singer et al., 1994).

Several investigators (Stecher and Thorbecke, 1967; Strunk et al., 1975) have shown that hydrocortisone increases the synthesis of C3 *in vitro*; however, injection of cortisone acetate into experimental animals has yielded contradictory results (Atkinson and Frank, 1973). In one study, periorbital abscesses secondary to blood sampling procedures abolished the expected depression of the C3–C9 complex (Colten, 1976). C3 expression in the mouse can be suppressed by anti-C3 antibody, and CD4⁺ and CD8⁺ T-lymphocytes are required for suppression (Goldman et al., 1992).

C3a is inactivated in serum by carboxypeptidase B, an α -globulin that removes the COOH-terminal arginine residue from C3a and neutralizes its activity. The trimolecular complex C4b2a3b decays with the dissociation of the C2 fragment. C3b inactivator splits cell-bound or soluble C3b into two fragments, C3c and C3d, and the function of C3b is thus abolished (Muller-Eberhard and Gotze, 1972; Tamura and Nelson, 1967). In man, mouse, and several other species, C3 turnover is regulated by CR1, CR2, DAF, and MCP binding proteins (Holers et al., 1992).

17.4.1.4 Analysis of C3

Serum concentrations of C3 were measured by hemolytic assay using cellular intermediates in eight species of nonhuman primates. The hemolytic titers for C3 were equivalent to those in human beings for five species of Old World nonhuman primates; however, both antigenic and functional assays were inadequate in several New World primates (Quimby, 1999). C3 was also measured by rocket electrophoresis in four species of Old World primates (Alper et al., 1971; McMahan, 1982) and by radial immunodiffusion using human antiserum in nine nonhuman primates. In all of these studies, Old World primates had strong cross-reactivity with human reagents (rhesus monkey is nearly identical to human sequence) while prosimians had no detectable reactivity (Holmberg et al., 1977).

In rabbits, rats, guinea pigs, and mice, C3 was measured by immunoelectrophoresis, double diffusion in agar, and immune adherence (Cochrane et al., 1970). Both rocket electrophoresis and crossed electrophoresis were used successfully to quantitate C3 in the mouse (Natsuume-Sakai et al., 1978; Pepys et al., 1977). C3 was also quantitated in dogs, rabbits, and swine using radial immunodiffusion (Kalowski et al., 1975; Molleda et al., 1993; Storm et al., 1992; Ulevitch and Cochrane, 1977). Canine C3 has been measured by rocket electrophoresis (Feldman et al., 1981; Gorman et al., 1981a, b). A double antibody radioimmunoassay has been developed to measure C3 in the rat (Guiguet et al., 1987).

As with all other C-component assays, the lack of universal reference standards in animals makes comparison between laboratories impossible. These and other technical considerations when testing laboratory animal species were reviewed by Barta and Barta (1984).

Assays designed to measure antigenic determinants on the split products of C3 have been developed for human beings and guinea pig (Regal et al., 1993; Sinosich et al., 1982). Cross immunoelectrophoresis of swine C3 does not elucidate the C3b/iC3b/c3c fragments as seen with human C3 (Storm et al., 1992).

17.4.1.5 Clinical Significance of C3 Concentrations

When measured by radial immunodiffusion, the adult levels of C3 in human beings are 1–2 mg/mL (Fey et al., 1983). Levels of serum C3 in women are known to increase during late pregnancy (Propp and Alper, 1968). No differences were reported in the levels of C3 between male and female dogs; however, higher levels were observed in older dogs (Molleda et al., 1993). Human beings with obstructive jaundice have an increase in C3 (Colten, 1976), and patients with membranoproliferative glomerulonephritis have a decrease in serum C3 (Alper et al., 1966; Peters et al., 1972). Because liver samples from two patients with membranoproliferative glomerulonephritis failed to produce C3 in culture, it was postulated that the decrease in C3 seen in this condition is due to both decreased synthesis as well as increased catabolism (Colten et al., 1973). Decreased serum C3 due

to increased catabolism is also seen in patients with diseases characterized by circulating immune complexes, such as systemic lupus erythematosus and lupus nephritis (Levo and Pick, 1974; Swaak et al., 1986).

The concentrations of total hemolytic complement (CH_{50}) and C3 were significantly depressed in dogs with acute necrotizing pancreatitis (Feldman et al., 1981) and in rats fed a protein-deficient (0.5%) diet (Schaller et al., 1977). Rabbits developing disseminated intravascular coagulation had significantly depressed levels of C3 and CH_{50} ; a relationship between clotting and complement activation was demonstrated, indicating that platelets were partially responsible for complement activation (Kalowski et al., 1975). C3 concentrations are elevated in the cerebrospinal fluid of mice with bacterial meningitis (Stahel et al., 1997). The role of C3 in hyperacute xenograft rejection has been studied in monkeys, rats, guinea pigs, and dogs (Braidley et al., 1994; Cable et al., 1997; McCurry et al., 1995; Tanaka et al., 1996).

CoF has been widely used in experimental animals to evaluate the role of complement in various biologic systems. CoF is composed of two anticomplementary factors: a low molecular weight factor (140 kDa), which activates both C3 and C5, and a high molecular weight factor (10^6 Da), which is anticomplementary for the early complement components only (Ballou and Cochrane, 1969). The effect of CoF has been studied in rats, rabbits, guinea pigs, hamsters, and mice (Cochrane et al., 1970; Roxvall et al., 1990). In these studies, C3, as measured by immunoelectrophoresis, double diffusion, and immune adherence, was depressed to <10% normal in all animals after treatment with CoF. Furthermore, complement-depleted animals undergoing acute nephrotoxic nephritis had fewer neutrophils infiltrating the glomeruli. CoF was also shown to inhibit the Arthus reaction, thus demonstrating an important pathologic effect associated with C3 activation.

Mice depleted of C3 by CoF treatment had no change in the rate of clearance of preformed immune complexes in vivo (Bockow and Mannik, 1981), but had a significantly prolonged survival of *Trypanosoma lewisi* (Albright and Albright, 1985). These investigators concluded that resistance to *T. lewisi* involved activation and binding of C3b by uncoated trypanosomes (Desai et al., 1987).

Rabbits treated with CoF and depleted of C3 (measured by radial immunodiffusion) had rapid C3-dependent depression of platelet function and blood pressure. The hypotensive effects could be blocked by a histamine H₂-receptor antagonist (Trail et al., 1984). Mathison and Ulevitch (1981) also showed that thrombocytopenia associated with endotoxemia in rabbits could be abrogated if the animals were depleted of C3. However, despite the abrogation of this early reaction, CoF had no effect on the final development of hypotension and disseminated intravascular coagulation in these animals.

Genetic deficiencies in C3, though rare, have been described in human beings (Alper et al., 1969b), dogs (Winkelstein et al., 1981, 1982), guinea pigs (Burger et al., 1986; Moore, 1919), rabbits (Komatsu et al., 1988), and mice (Pekna et al., 1998; Prodeus et al., 1997; Singer et al., 1994). Total (homozygous) C3 deficiency in human beings is characterized by the complete absence of C3 in the serum, and it is usually associated with recurrent pyogenic infections and the development of membranous glomerulonephritis. Many individuals with total C3 deficiency die in childhood. Transfusion with normal plasma gives patients transient relief from systemic infections. Sera from these patients lack the typical complement-mediated biologic functions, such as hemolytic activity, opsonization of endotoxin-coated particles, and chemotactic and bactericidal activities (Alper et al., 1972c, 1976). Dogs with total C3 deficiency display similar signs and a lack of normal complement-mediated functions.

In both human beings and dogs, the defect is inherited as an autosomal recessive trait, and heterozygotes have half the normal C3 concentrations. The first report of a complement defect in a laboratory animal was published by Moore (1919). He studied a guinea pig strain whose serum failed to lyse antibody-sensitized horse erythrocytes. This guinea pig serum showed reduced opsonization capacity, and affected guinea pigs were more susceptible to infection with *Bacillus cholerae suis* (*Salmonella cholerae suis*). This colony was decimated by an infectious disease; therefore, the true

nature of the defect will never be known. The defect was transmitted as a simple Mendelian recessive trait.

Partial deficiencies also have been described in human beings. These deficiencies may be due to either a partially inactive gene product or partially reduced synthesis of a normal product from at least one defective allele. Carriers of a partial deficiency are generally healthy (Fey et al., 1983).

Burger et al. (1986) also described a colony of guinea pigs with C3 deficiency. Animals homozygous for the deficiency had markedly reduced hemolytic activity, reduced antigenic activity (6% normal), reduced bactericidal activity, and impaired antibody responses (Bottger et al., 1986a, b; Burger et al., 1986). The defect in guinea pigs is inherited in a codominant autosomal fashion and is not linked to the MHC locus (Burger et al., 1986).

Rabbits displaying 6%–12% serum levels of C3 were found in a colony of C8 deficient rabbits (Komatsu et al., 1988). The C3-hypocomplementemic rabbits had no alteration in C3 conversion, antigenicity, or catabolism, and no C3 inhibitors were detected. C3 hypocomplementemia was inherited in a simple codominant fashion, and serum from these rabbits had lower bactericidal activity compared to normal serum. Unlike rabbits with C8 deficiency, C3 hypocomplementemic rabbits had no decrease in body weight; however, they did have poor survival rates (Komatsru et al., 1988).

Mice homozygous for a targeted mutation of the C3 gene have been developed, and they have no detectable levels of circulating C3 (Pekna et al., 1998). C3 deficient mice have increased mortality following cecal perforation and exhibit decreased peritoneal mast cell degranulation, production of TNF- α , neutrophil infiltration, and clearance of bacteria (Prodeus et al., 1997). C3 knockout mice have also been used to demonstrate the critical role of complement in antiglomerular basement membrane-induced nephritis (Sheerin et al., 1997).

17.4.2 FOURTH COMPONENT OF COMPLEMENT (C4)

17.4.2.1 Physical, Chemical, and Genetic Properties of C4

The fourth component of complement (C4) was first described by Gordon et al. (1926) but was not isolated until 1963 (Muller-Eberhard and Biro, 1963). Human C4 is a glycoprotein weighing 209 kDa and containing 8% carbohydrate residues. It migrates electrophoretically as a β -protein. Human C4 is composed of three unequal, covalently linked polypeptide chains designated as α , β , and γ with molecular weights of 93, 78 and 33 kDa, respectively (Schreiber and Muller-Eberhard, 1974). Guinea pig and mouse C4 have a similar molecular weight and three-chain structure (Hall and Colten, 1977). The mouse has two C4-like molecules, each coded by a separate gene in the S-region of the MHC (Shreffler, 1982); however, only one of these molecules (formerly known as Ss protein) is the functional homologue of guinea pig and human C4 (Ferreira et al., 1977). C4 has been identified in the rat, and amino acid sequence homology (derived from a cDNA clone) was 81.7% and 86.6% for murine and human C4, respectively (Fimmel et al., 1996). A molecule having C4-like functional activity has also been described in the hamster, but this protein has not been isolated and characterized (Arroyave et al., 1977). Canine C4 containing three polypeptide subunit chains has also been described (O'Neill et al., 1984). The order of subunit composition in human beings, mice, and guinea pigs is β - α - γ (Chan et al., 1984; Morris et al., 1982; Odink et al., 1981). In mice and human beings, the carbohydrate moiety is found on the α - and β -chains only (Chan et al., 1984).

There are two C4 structural gene loci in human beings, C4A (acidic) and C4B (basic) (O'Neill et al., 1978), with allelic variants described for each locus (Awdeh and Alper, 1980). Complement 4 variants have been identified in the mouse and are linked to the S-region (Ferreira et al., 1977; Natsume-Sakai et al., 1980). The product of one locus, *Slp*, is hormone regulated (Shreffler, 1982). There is some evidence that the two C4 loci of human beings and mice arose by gene duplication (Shreffler, 1982). Despite duplication of the C4 gene in mice, only one gene product is hemolytically

active (Ss protein). The product of the second C4 gene, *Slp*, contains a thioester site in a different portion of the molecule, preventing it from being cleaved by C1 (Hobart, 1984); however, this gene may regulate the expression of a closely linked *Cyp2 1a1* gene and play a role in a third complement pathway in mice (Milstone et al., 1992; van den Berg et al., 1992).

While only a single C4 gene has been identified in guinea pigs, linked to the MHC (Shevach et al., 1976), three variants of guinea pig C4, called C4-F, C4-S, and C4-S1, have been identified by electrophoresis (Bitter-Suermann et al., 1977). These variants are under the control of three codominant alleles at the single C4 locus (Bitter-Suermann et al., 1977).

The dog appears to have only a single C4 structural gene linked to the MHC/dog leukocyte antigen complex (DLA), which has at least five codominantly expressed alleles (Day et al., 1985). They arise from the combination of two allelic products in both the α - and γ -chains (O'Neill et al., 1984). The two allelic products of the canine C4 α -chain also differ in molecular weight (in contrast to the human gene products, which are of identical molecular weight). As in the mouse, the dog C4 γ -chain variant also shows molecular heterogeneity (Ferreira et al., 1980).

Two structural genes encoding C4 appear to be present in certain nonhuman primates (Mevag et al., 1983). Two isoforms of C4 have been reported in the rat (Galibert et al., 1993).

The structural genes for C4, C2, and factor B have all been mapped to the MHC region in guinea pig, mouse, and human beings and are referred to as MHC *class III genes* (Bitter-Suermann et al., 1981; Kronke et al., 1977; Parker et al., 1979; Roos and Demant, 1982; Shreffler and Owen, 1963). The DNA sequence of the various murine and human complement component genes is 5'-C2-Bf-C4-3'. The *Slp* gene of mice is closer to Bf than to C4. Similarly, the C4A gene of human beings is closer to the Bf gene than it is to the C4B gene (Hobart, 1984). The observation of frequent gene deletion and variations in the number of C4 genes in both mouse and man suggests that this MHC class III region is not genetically stable and may still be undergoing gene expansion and contraction (Shiroishi et al., 1987).

17.4.2.2 Function of C4

During activation of the classic pathway, C4 is cleaved by C1 to produce two split products, C4a and C4b. In human beings, C4a has a molecular weight of 10 kDa and acts as a weak anaphylatoxin. The human C4b fragment is much larger at 190 kDa and covalently binds the biologic material. This bound C4b fragment combines with activated C2 to form a C3 convertase capable of completing the classic pathway of activation (Morgan, 1995; Muller-Eberhard and Biro, 1963). A similar role has been proposed for functionally active C4 of all other species.

Mouse C4 is known to have poor hemolytic activity compared to other species. Molecular analysis of murine C4 identified a short amino acid segment in the β -chain that differed from the human sequence and was responsible for the compromised C5 convertase subunit activity of mouse C4 (Ebanks and Isenman, 1996).

C4BP regulates the classic pathway of complement activation by binding C4b, enhancing degradation of C4b, and accelerating the decay of C3 convertase. Molecular cloning of rat C4BP and an evaluation of the functional relationships among human, bovine, rabbit, mouse, and rat C4BP have been reviewed (Hillarp et al., 1997).

17.4.2.3 Synthesis and Catabolism of C4

Using immunologic methods, C4 biosynthesis has been demonstrated for macrophages and hepatocytes (Colten, 1976). In vitro production of functionally active guinea pig C4 has been demonstrated using cultures of bone marrow, spleen, and liver (Siboo and Vas, 1965), and again the cell type responsible for production of C4 was a phagocytic cell (Ilgen and Burkholder, 1974; Littleton et al., 1970). In contrast, using allogeneic bone marrow chimeras established in mice, Geng et al. (1986) found that circulating C4 in the blood was not primarily synthesized by descendants of bone marrow cells. Recent studies using cell-free biosynthetic systems have shown that guinea pig (Hall and

Colten, 1977), mouse (Parker et al., 1979), and human (Gigli, 1978) C4 is synthesized from a single stranded precursor protein (pro-C4) (Karp et al., 1981) that undergoes intracellular processing, including the cleavage of two proteolytic bonds, sulfation and glycosylation, subsequent to secretion as native C4 (Whitehead et al., 1983), known as C4s (s designates the secreted form). Approximately 8% of the circulating C4 of mouse and man is C4s (Chan and Atkinson, 1983; Karp et al., 1982b); the remaining C4 circulates as C4p, a molecule produced by extracellular proteolytic cleavage.

Both C4s and C4p are active in the fluid phase of blood and respond to regulatory enzymes. The combination of posttranslational intracellular processing, as well as extracellular cleavage, is responsible for as many as 20 structural variants of plasma C4 in a single human being (Chan et al., 1984). Each of the major intracellular and extracellular cleavage products has also been demonstrated in murine biosynthetic systems.

Control of C4 biosynthesis in guinea pigs has been shown to involve a specific feedback mechanism involving C4 itself (Auerbach et al., 1983). This feedback control of synthesis appears to be directed at the level of transcription or is a function of the stability of C4-specific mRNA. No similar feedback control of C4 biosynthesis, using similar systems, has been detected in mice (Newell and Atkinson, 1983). *In vitro* culture systems have also identified specific antibody and a lymphoid cell as suppressors of guinea pig macrophage C4 production (McMannis et al., 1987). Rat hepatic stellate cell cultures have been used to study the induction of C4 mRNA by interferon- γ . *In vivo* stellate cells were induced to transcribe C4 by iron overload. C4 production by hepatocytes was unchanged during this procedure (Fimmel et al., 1996).

In normal human beings, approximately 2% of the plasma pool of C4 turns over each hour; therefore, 50% of the plasma pool must be newly synthesized daily (Atkinson and Frank, 1980). When Ruddy et al. (1975) compared fractional catabolic or synthetic rates for C4 in normal human beings based on serum concentrations, it was concluded that the primary determinant of serum concentrations was the synthetic rate. The turnover rate for other animal species is not known.

17.4.2.4 Analysis of C4

The fourth component of complement may be measured using radial immunodiffusion, electroimmunodiffusion (rocket electrophoresis), automated immunoprecipitation, and sheep red cell hemolysis using C4-deficient guinea pig serum. Electroimmunodiffusion is an extremely sensitive assay for human C4 and requires less total time. Universal reference standards for human C4 are available for calibration of all immunologic methods. When C4-deficient guinea pig serum is available, the hemolytic assay is simple and accurate; however, care must be taken to use only fresh or frozen guinea pig serum to prevent the loss of complement activity (Cooper et al., 1983; Gaither and Frank, 1979; Mancini et al., 1965). One benefit of the hemolytic assay is that unlike immunologic assays, functionally active C4 is measured. Human C4 is measured in a hemolytic assay with antibody-sensitized sheep erythrocytes and C1; however, this cellular intermediate, while commercially available using purified guinea pig or human C1, is unreliable for testing many animal sera for C4. Therefore, purification of homologous C1 is usually necessary (Barta and Barta, 1984).

Rats have been successfully evaluated for C4 using the hemolytic assay and the cellular intermediate EAC1^{sp}, and adding human C2. Hemolysis was expressed as a percentage of the maximum hemolysis obtained by substituting purified human C4 in the reaction mixture (Arroyave et al., 1977). Using a similar technique, Sakamoto et al. (1981) expressed the results of C4 as the reciprocal of the end titer serum dilution giving 50% hemolysis. The values for normal rats were 419 ± 93 (SD).

Mouse C4 has been successfully quantitated by a sensitive one-step hemolytic assay with sensitized sheep red blood cells and C4-deficient guinea pig sera in the reaction mixture (Atkinson et al., 1980). Results of this assay were expressed in arbitrary hemolytic units in which B10.D2 mouse serum was used as the positive control. These investigators found that the addition of purified human C2 to the assay increased hemolytic titers twofold. They speculate that the human C2 helped to overcome a partial incompatibility between guinea pig C2 and mouse C4. More recent analyses found that

several amino acid substitutions in the mouse C4 β -chain abolished C5 convertase subunit activity, and "humanizing" this segment replenished convertase activity (Ebanks and Isenman, 1996). Murine C4 also has been measured using agarose electrophoresis coupled with immunodiffusion (Natsuume-Sakai et al., 1980). In this case, alloantisera specific for each C4 allotype were prepared by injecting mice that did not express the allotype with purified mouse C4. The method for purification of mouse C4 closely followed the method described for human C4 (Bolotin et al., 1977). Heterologous anti-mouse C4 has also been prepared for immunoprecipitation assays (Passmore and Beisel, 1977).

Immunoprecipitation procedures using heterologous goat antihuman C4 have been described for canine C4 (Kay and Dawkins, 1984).

Taking advantage of the absolute C4 deficiency of C4D guinea pigs (Co-4), Ellman et al. (1970) were able to develop an antiguinea pig C4 antiserum that was effective in precipitating guinea pig C4 by gel diffusion. This principle of immunoprecipitation has been used by others to develop an effective radial immunodiffusion technique for guinea pigs (Thurston et al., 1980). In addition, guinea pig C4 can be quantitated in a hemolytic assay using the cellular intermediate EAC1, with human C1 (Ellman et al., 1970).

Rabbit C4 has been measured in the hemolytic assay using the EAC1 cellular intermediate with C1 of guinea pig origin. After initial incubation of intermediate cells with rabbit test sera, normal guinea pig serum in EDTA is added to complete the reaction (Nelson and Biro, 1968).

The sera of various nonhuman primates have been evaluated for detection of C4 by double immunodiffusion using goat antihuman C4. Although cross-reactivity was observed between rhesus, stump-tail, and cynomolgus macaques, as well as Patas and African green monkeys, differences in migration distances, lengths of arcs, and spur formation suggested molecular differences in the proteins among species. Although this method may be useful in detecting genetic polymorphic forms of C4 among nonhuman primates, purified homologous C4 is necessary to quantitate this complement component (McMahan, 1982). Baboon C4 was measured using cellular intermediates prepared with human purified complement components.

In most studies performed to evaluate C4 in various animals, internal laboratory standards rather than commercially available reference standards were used; therefore, a direct comparison between laboratories is often difficult. A more complete discussion of the various methods is presented elsewhere in this chapter, and the technical aspects of the hemolytic assays for various domestic species have previously been reviewed (Barta and Barta, 1984).

As in man, the assays for native C4 have been particularly useful in the detection of genetic C4 deficiency in the guinea pig and rat as well as the quantitative deficiency in mice (Arroyave et al., 1977; Ellman et al., 1970; Kunstmann and Mauff, 1980).

17.4.2.4.1 Analysis of C4 Activation

The fourth component of complement is activated by limited proteolysis to produce a large (C4b) and a small cleavage product (C4a). Because the charge of C4b differs from that of the parent molecule, activation can be detected by immunoelectrophoresis (Cooper et al., 1983). C4b is broken down in human serum to C4d, a smaller fragment that is antigenically different from C4. Immunoelectrophoresis in agarose allows for the simultaneous quantitation of C4 and C4d. This method has been particularly useful in the assessment of such clinical conditions as rheumatoid arthritis, hereditary angioedema, and systemic lupus erythematosus (Milgrom et al., 1980). Extremely sensitive radioimmunoassays have been developed to detect the smaller C4a fragment; however, though as little as 10 ng/mL of C4a can be detected in human plasma, the plasma must first be treated for selective precipitation of the native C4 molecule before application of the radioimmunoassay (Gorski, 1981; Wagner and Hugli, 1984). Measurement of C4a has been a particularly sensitive marker of classic pathway activation in systemic lupus erythematosus (Wagner and Hugli, 1984). ELISA assays for rat, mouse and bovine and possibly other species may be found on the internet (http://www.biocompare.com/pfu/110627/soids/9361/ELISA_Kit/Complement_C4a).

17.4.2.5 Clinical Significance of C4 Concentrations

In human beings, serum C4 concentrations of 200–800 µg/mL (as measured by radial immunodiffusion) are considered normal (Agnello, 1978). However, as previously mentioned, the use of different techniques and the lack of reference standards prevent a comparison of C4 concentrations (in animal species) among the various laboratories. The serum C4 concentrations in human beings and animals increase from birth to sexual maturity, and levels in women increase during pregnancy (Atkinson and Frank, 1980; Barta and Barta, 1984).

In human beings, C4 acts as an acute phase reactant with levels increasing two- to threefold during acute inflammation. Elevations in C4 are also parallel increased corticosteroids. However, C4 levels are decreased during infections associated with the development of antigen–antibody complexes such as malaria and poststreptococcal glomerulonephritis (Atkinson and Frank, 1980). Further, marked depression of C4 is seen during exacerbations of systemic lupus erythematosus in human beings (Swaak et al., 1986). Increased catabolism is the suspected cause of the lower C4 levels seen in hereditary angioedema, systemic lupus erythematosus, and complement-mediated anemias (Alper and Rosen, 1975; Atkinson and Frank, 1980; Swaak et al., 1986).

Few attempts have been made to measure C4 during rheumatic and infectious disease in animals. Whereas total hemolytic complement activity is decreased during certain rheumatic diseases in dogs, the levels of specific components have not been measured (Barta and Barta, 1984; Wolfe and Halliwell, 1980). It is of interest that the inheritance of two disorders in dogs, idiopathic cardiomyopathy and systemic lupus erythematosus, are associated with a particular C4 allele (Day, 1996; Day et al., 1985).

Depression of C4 has been associated with acute aflatoxicosis in guinea pigs (Thurston et al., 1980) and dietary protein restriction in rats (Sakamoto et al., 1981). Sex-limited protein (Slp), the nonfunctional homologue of C4 in mice, has an androgen-dependent inducible synthesis in some strains (Passmore and Shreffler, 1970), and a constitutive, androgen-independent synthesis in others (Hansen and Shreffler, 1976).

Recent studies suggest that hormonal regulation of the Slp gene product is associated with DNase I-hypersensitive sites in the 5' regions of the Slp gene (Hemenway and Robins, 1987). Strains showing androgen-independent expression of Slp have C4-Slp recombinant genes with the 5' region derived from the C4 gene (Nakayama et al., 1987). No other differences in circulating C4 have been described in animals of different sexes, in association with natural cycles, or in response to specific drugs.

A genetic deficiency of C4 has been described in guinea pigs, Wistar strain rats, and human beings, and a quantitative reduction in the hemolytic activity of C4 has been described in mice (Karp et al., 1982a). In human beings, guinea pigs and rats, C4 deficiency is inherited as an autosomal recessive trait, with heterozygotes expressing intermediate levels of C4 (Arroyave et al., 1977; Ellman et al., 1970; Ochs et al., 1977; Schaller et al., 1977). Homozygotes in all three species cannot activate complement through the classic pathway.

The deficiency in guinea pigs has been studied extensively. C4 deficiency is thought to have arisen from a mutation in the C4-F allele, which is designated Co-4. Deficient guinea pig cells have no detectable intracellular pro-C4 (Colten and Frank, 1972); however, a C4 precursor RNA was detected using a cDNA probe for the fourth component of complement (Whitehead et al., 1983). These authors speculate that the basis for the C4 deficiency in guinea pigs is a posttranscriptional defect in the processing of C4 precursor RNA to mature C4 mRNA. Affected guinea pigs are more susceptible to experimental infection with *S. cholerae suis* or injection of endotoxin, and they had markedly impaired antibody responses to certain T-lymphocyte-dependent antigens (May et al., 1972; Moore, 1919; Ochs et al., 1978, 1983), serologic evidence for polyclonal B-cell activation (Bottger et al., 1986a), and an absence of glomerulonephritis (Foltz et al., 1994).

Mice expressing the H-2^{w7} MHC haplotype have C4 (Ss), which has only 30% of the functional activity of other strains (24). In affected mice, the C4 α-chain has a lower molecular weight due to

a difference in its carbohydrate content (Karp et al., 1982b). This genetic variation in glycosylation was shown to affect the hemolytic activity of the C4 molecule directly. Quantitative differences in the circulating levels of C4 have been demonstrated in certain strains of mice. The Ss locus is directly involved with 20-fold reduced levels of C4 being expressed in low (Ss-L) level mice. These quantitative differences in C4 are linked to the H-2^k haplotype. Despite these low levels of C4, Ss-L mice have an intact classic pathway for the activation of complement, and are not prone to infectious disease (Shreffler and Owen, 1963); however, they do have a greatly prolonged contact sensitivity reaction to picryl chloride (Dieli and Salerno, 1986).

Mice were rendered C4 deficient by homologous recombination and shown to have no circulating C4. When these mice were injected with antiglomerular basement membrane antibody, there was a significant (but not total) attenuation of nephritis, leading the authors to speculate that both classic and alternative complement pathways contributed to this disease (Sheerin et al., 1997).

17.4.3 SECOND COMPONENT OF COMPLEMENT (C2)

17.4.3.1 Physical, Chemical, and Genetic Properties of C2

In human beings, the second component of complement is a single-chain glycoprotein with a molecular weight of 117 kDa (Colten, 1983a). Human C2 migrates as a β_1 -globulin with a sedimentation constant of 6S (Colten, 1976). The C2 molecule has two free reactive SH groups that are positioned in close proximity to form an intramolecular disulfide bond on oxidation with iodine. This reaction allows for an extraordinary increase in hemolytic activity (Muller-Eberhard, 1975; Polley and Muller-Eberhard, 1967). Guinea pig C2 has a molecular weight of 130 kDa (Colten, 1976).

Factor B, C2, and C4 are linked with the MHC in human beings, guinea pig, and mouse (Ishikawa et al., 1990). In human beings, C2 and Bf genes are very close and separated from C4 genes by 50 kilobases (Hobart, 1984). Based on the structure of the C2 and factor B genes in mice, it was determined that they had arisen by a duplication that preceded the development of the alternative and classic pathways (Tosi et al., 1985).

Genetic polymorphism of C2 has been described in human beings (Alper, 1976; Hobart and Lachmann, 1976), who have one main C2 allotype and two rare allotypic variants. In contrast, guinea pigs have six C2 phenotypes resulting from three alleles occurring with equal gene frequency. The three allotypic variants are known as C2b (basic), C2a, and C2a1, the latter two both being acidic variants. These variants of a single structural C2 gene behave as autosomal codominant traits (Bitter-Suermann et al., 1981). In mice, studies have established that the multiple transcripts of C2 and factor B are expressed but the molecular mechanisms were not elucidated (Ishikawa et al., 1990).

17.4.3.2 Function of C2

C2 is a serine protease found normally as a trace protein in serum, and it is one of the two precursor molecules of the complex enzyme C3 convertase (Muller-Eberhard, 1975). C3 convertase (C4b2a) is assembled by the enzyme C1s. The cleavage products of C2 are C2a (80 kDa) and C2b (37 kDa). C3 convertase is then capable of activating C3 and continuing the classic pathway (Morgan, 1995).

17.4.3.3 Synthesis and Catabolism of C2

A variety of studies have demonstrated that monocytes and tissue macrophages are the cellular sites of C2 synthesis in human beings and guinea pigs (Colten, 1976). Human monocytes in culture generally require 3 days of incubation *in vitro* before C2 synthesis is detected. This delay in C2 secretion can be shortened by adding a lymphokine to the culture medium (Littman and Ruddy, 1977). Human bronchoalveolar macrophages incubated *in vitro* initiate C2 synthesis without this 3-day lag period (Cole et al., 1982). Likewise, differences are seen in the rate of C2 synthesis by guinea pig macrophages; however, in this species, the proportion of tissue macrophages bound to synthesize C2 varies from 2% for bronchoalveolar macrophages to 45% for peritoneal or splenic macrophages (Alpert et al., 1983).

The plasma levels of C2 vary greatly among the strains of mice, and the genes outside the MHC are thought to be involved in the transcriptional control of C2 (Falus et al., 1987; Ishikawa et al., 1990). In addition, exogenous IL-1 has been shown to increase specific C2 mRNA levels in murine kidney and lung (Falus et al., 1987; Perlmutter et al., 1986). In healthy human beings, approximately 2% of the plasma pool of C2 turns over each hour (Atkinson and Frank, 1980). The human C3 convertase, C4b2a, has a half-life of 10 minutes at 37°C.

17.4.3.4 Analysis of C2

Guinea pig C2 may be quantitated using the cellular intermediate EAC14gp and guinea pig serum diluted 1:10 in Veronal Buffered Saline-EDTA as a source of C3–C9 (Bitter-Suermann et al., 1981). Similarly, C2-deficient guinea pig serum may be used in a one-step hemolytic assay. Quantitative estimates for guinea pig C2 have also been conducted by rocket immunoelectrophoresis using homologous antiguinea pig C2 antibody (Bitter-Suermann et al., 1981).

The hemolytic assay using sheep red blood cells sensitized in C4 deficient guinea pig serum was used to quantitate hemolytic rat C2. However, when EAC1gp red blood cells were used to quantitate rat hemolytic complement, much weaker hemolytic activity was observed at 37°C than at 20°C. It was found that at 37°C, the natural decay of rat C2a from C3 convertase was much faster compared to rates of decay for guinea pig or human C2 (Naito and Okada, 1997).

Mouse C2 has been quantitated by hemolytic assay using the cellular intermediate EAC1gp4h (Goldman and Goldman, 1976). Rat and rabbit C2 have been quantitated similarly, with cellular intermediates made from purified guinea pig C1 and C4 (Nelson and Biro, 1968; Sakamoto et al., 1981).

Schur et al. (1975) quantitated the hemolytic activity for individual complement components in eight species of nonhuman primates using cellular intermediates prepared from purified human components. The C2 hemolytic titers of chimpanzees and gibbon ape were roughly the same as those of the human. The C2 hemolytic titers of *Papio anubis* (baboon), *Macaca fascicularis* (crab-eating macaque), *Ateles geoffroyi* (spider monkey), and *Cebus albifrons* (cebus monkey) were all greater than those of the human, and the titer of *Galago crassicaudatus* (greater bush baby), a prosimian, was approximately one tenth that of the human (Schur et al., 1975).

17.4.3.5 Clinical Significance of C2 Concentrations

Healthy human beings have 25 µg/mL of C2 in serum as measured by radial immunodiffusion (Muller-Eberhard, 1975). The hemolytic titer of C2 measured in Old World nonhuman primates and Great Apes is similar to human titers when purified human components are used as intermediates. The concentration of C2 in other species varies with methodology and the laboratory standard used.

Studies of 26 families with homozygous C2 deficiency (C2D) probands demonstrated that 23 of 38 C2D patients had diseases of the autoimmune type. Fourteen (37%) had systemic lupus erythematosus or discoid lupus erythematosus (Agnello, 1978). Only 2 of 38 patients had recurrent infections. As a primary clinical problem, however, an increased susceptibility to infections is thought to occur in all C2D homozygotes. The disease manifestations in C2D patients with systemic lupus erythematosus are different from those of “classic” systemic lupus erythematosus because C2D patients do not have anti-DNA antibodies and have reduced immunoglobulins deposited in skin, a low incidence of renal disease, and an increased frequency of discoid lesions, suggesting that certain genes controlling the disposition to these lesions may be missing in C2D patients. A similar systemic lupus erythematosus-like syndrome has not been described in the C2D guinea pig; however, circulating immune complexes are seen in these animals (Bottger et al., 1986a).

In several cases of C2D in human beings, there has also been a partial deficiency in factor B (Newman et al., 1978). These patients suffer from repeated *Streptococcus pneumoniae* infections. Because clearance of this organism is thought to depend on C3b-induced opsonization, an inability

to activate C3 through the alternative pathway appears to predispose these individuals to streptococcal infection.

Human beings affected by autoimmune disorders characterized by antibody–antigen binding and activation of the classic pathway of complement, such as systemic lupus erythematosus and autoimmune hemolytic anemia, characteristically have sharp depressions in serum C2 (and most other classic components). Although not specifically studied, it is assumed that C2 levels are lower in animals that develop spontaneous systemic lupus erythematosus and autoimmune hemolytic anemia, similar to markedly decreased total hemolytic complement in susceptible strains of mice exhibiting comparable diseases (Andrews et al., 1978).

In human beings infected with malaria, there is rapid activation of the classic pathway and a resultant sharp decline in serum C1, C4, C2, and C3 levels concomitant with schizont rupture and intravascular release of malaria antigens (Atkinson and Frank, 1980). Patients affected by cutaneous necrotizing vasculitis and disseminated intravascular coagulation also have lower serum C2 levels. A similar reduction may be expected in animals with disseminated intravascular coagulation.

C2, like C1, C4, C3, and factor B, acts as acute phase reactants, increasing two- to fourfold during a systemic inflammatory response in human beings. C2 levels are also elevated in women during pregnancy; however, similar findings in animals have not been reported.

Finally, there has been some speculation that the pathogenesis of the edema in human hereditary angioedema (C1 esterase inhibitor deficiency) is mediated by a cleavage product of C2 with kinin-like activity (Donaldson et al., 1969). Serum C2 levels are also known to be very low during acute episodes of this disease. No equivalent deficiency has been described in animals.

The functional levels of C2 were found to vary among inbred strains of mice (Goldman and Goldman, 1976). Serum C2 levels in mice appear to be controlled by genes closely linked to the Ss locus. Rats maintained on protein-deficient diets (0.5 vs. 18%) for 8 weeks had a 58% depression in serum C2 activity (Sakamoto et al., 1981). In addition, normal Sprague-Dawley pathogen-free rats challenged with an intradermal inoculation of 2×10^9 *Staphylococcus aureus* organisms had a 100% elevation in serum C2, which remained elevated 14 days following inoculation (Sakamoto et al., 1981). An extract of *Ephedra sinica* used in the treatment of nephritis contains a fraction called complement-inhibiting component, which is composed of a polyanionic carbohydrate. Incubation of this fraction with serum from human beings, pig, guinea pig, rat, or rabbit was associated with inhibition of the classic pathway of complement, likely due to carbohydrate binding to C2, thus preventing binding to EAC1^{hu4hu} (Ling et al., 1995).

Deficiency of C2 occurs in 1 in 10,000 individuals, making it the most common human complement deficiency (Glass et al., 1976). Macrophages from C2 deficient human beings function normally but are incapable of secreting C2 (Colten, 1983a). Recently, Cole et al. (1985), using a combination of protein radiolabeling, immunoprecipitation, and Northern and Southern blot analyses, discovered that C2-deficient human beings do not have a major gene deletion or rearrangement, but instead have a specific and selective pretranslational regulatory defect in C2 gene expression. This leads to a lack of detectable C2 mRNA and a lack of C2 synthesis.

The C2D in guinea pigs was the first C2D described in an animal (Hammer et al., 1981). Homozygous deficient guinea pigs have no detectable hemolytic activity, whereas heterozygotes have 50%–70% hemolytic activity (Bitter-Suermann et al., 1981). These C2-deficient guinea pigs show no C1s-induced vascular permeability (Strang et al., 1986), have impaired humoral immunity (Bottger et al., 1985), and demonstrate characteristics of immune complex disease (Bottger et al., 1986a). Guinea pigs homozygous for C2D synthesize a C2-like protein that can be detected immunologically within the cytoplasm of monocytes, but it is not secreted. Extracellular fluid from in vitro cultured C2-deficient macrophages contained reduced amounts of C2 antigen, which consisted of small molecular weight molecules (14–15 kDa). These studies suggested that C2-deficient guinea pig macrophages produce a structurally abnormal C2 protein, but they could not distinguish between a block in secretion or secretion of an unstable C2 protein (Goldberger et al., 1982). The C2^o allele of C2 deficient guinea pigs appears to be a silent C2^B allele.

17.4.4 FIFTH COMPONENT OF COMPLEMENT (C5)

17.4.4.1 Physical, Chemical, and Genetic Properties of C5

Human C5 has a molecular weight of 180 kDa and is a β_1 -globulin. The human C5 glycoprotein contains approximately 20% carbohydrate moieties. The C5 molecule is a two-chained structure linked by disulfide bonds (Nilsson and Mapes, 1973). The approximate molecular weights of α - and β -chains are 110 and 70 kDa, respectively (Muller-Eberhard, 1975). A protein immunochemically defined as C5 in the mouse was previously called MuB1. In mice, plasma C5 consists of two chains of unequal size, an α -chain (115 kDa) and a β -chain (82 kDa) structurally similar to those of both human beings and guinea pig C5 (Patel and Minta, 1979).

17.4.4.2 Function of C5

When C5 is subjected to enzymatic attack by C5 convertase (C4b2a3b) or (C3bBb), the resulting product, C5b, serves as the focus for a self-assembling process leading to the stable C5b-9 complex (Kolb et al., 1972). The entire MAC is composed of one molecule each of C5, C6, C7, and C8 and a variable number (8–18) of C9 molecules (Hobart, 1984). This large molecular complex is assembled without the need for enzymatic activity following C5 convertase (Morgan, 1995; Muller-Eberhard, 1975). One report (Kitamura et al., 1984) suggests that C5 may compensate for the lack of C3, at least in some cases of human C3 deficiency. These investigators provide evidence for the direct activation of C5 by the C3 convertase (C4b2a), resulting in the formation of the MAC C5b-9.

C5a biological behavior is very similar to C3a, causing the release of histamine from mast cells, eliciting chemotaxis of neutrophils, and triggering contraction of smooth muscle. The C5a of pig, rat, and guinea pig differs from human C5a in that their COOH-terminus is susceptible to inactivation by serum carboxypeptidase B, which forces a conformational change on this molecule that results in reactivation and resistance to carboxypeptidase B (Hugli et al., 1975; Vogt et al., 1971; Weigle et al., 1983). C5a and C3a bind to specific receptors on lymphocytes and macrophages, and are potent regulators of the immune response (Weigle et al., 1983). Human C5a triggers a wide variety of neutrophil responses after binding to the neutrophil receptor (Hugli, 1981). Murine C5a binds to specific receptors on murine macrophages, but murine lymphocyte C5a receptors have not been identified. Purified C5a, given in physiologic doses, was shown to enhance the primary murine anti-sheep red blood cell response *in vitro* by induction of cytokine secretion by macrophages (Goodman et al., 1982) including interleukin-1 (Weigle et al., 1983).

17.4.4.3 Synthesis and Catabolism of C5

Evidence from several studies suggests that C5 may be synthesized in many human tissues, including lung, liver, spleen, thymus, placenta, peritoneal cells, bone marrow, and fetal intestine (Colten, 1974; Kohler, 1973). In the mouse, splenic macrophages were shown to be a site of C5 synthesis by one group (Colten, 1976), whereas another group found that circulating C5 was not synthesized by descendants of bone marrow cells (Geng et al., 1986). Studies of murine C5 synthesis in C5-deficient (C5D) strains have demonstrated the presence of a 200 kDa single polypeptide located intracellularly, though no extracellular C5 was detected. These authors suggested that C5D strains produce a nonglycosylated pro-C5 molecule intracellularly that is not secreted (Ooi and Colten, 1979). Studies conducted in mice have shown that C5 is synthesized in the fetus at 10–12 days of gestation, and that passive transfer of C5 from mother to fetus does not occur (Tachibana and Rosenberg, 1966).

C5 convertase (C4b2a3b or C3bBb) cleaves a small fragment (molecular weight 17 kDa) from the α -chain called C5a, leaving a slightly smaller biologically active C5b molecule (molecular weight 163 kDa). The C5b molecule is inactivated by a second enzymatic cleavage also of the α -chain, which yields a small C5d fragment. The biologically active C5a, like C3a and C4b, binds to surface receptors on white blood cells. It has been shown that both human and murine neutrophils and macrophages are capable of degrading C5a following its specific receptor binding (Weigle et al., 1983).

17.4.4.4 Analysis of C5

The hemolytic assay for murine C5 is conducted using the EAC1a,4,^{oxy}2a3b intermediate derived from purified human components. The use of oxidized C2 resulted in 10 times greater stability of the complex (Nilsson and Muller-Eberhard, 1967). The cellular intermediate can also be induced using certain purified guinea pig components (Terry et al., 1964). Qualitative determination for the presence or absence of murine C5 has been assayed using immunodiffusion with antihuman C5 (Parrish et al., 1984).

The hemolytic titers of porcine C5 were very low when measured using cellular intermediates constructed from human components; therefore, the isolation of autologous components for accurate testing is required (Barta and Hubbert, 1978).

Hemolytic titers for C5 can be measured accurately in guinea pigs using cellular intermediates derived from either guinea pig or human purified components (Lachmann, 1970; Nelson and Biro, 1968). Rat C5a has been quantitated using a double antibody ELISA (Schmid et al., 1997).

17.4.4.5 Clinical Significance of C5 Concentrations

The average human serum concentration of C5 is 80 $\mu\text{g}/\text{mL}$ as measured by radial immunodiffusion (Muller-Eberhard, 1975). The mouse was once considered to have particularly low amounts of hemolytically active complement until it was realized that many inbred strains and outbred mice are deficient in the C5 (Herzenberg et al., 1963). An early attempt to develop a more sensitive assay using radioactive chromium-labeled sheep erythrocytes was described by Rosenberg and Tachibana (1962). However, the development of cellular intermediates from purified components and specific antisera against C5 has rectified this situation. Many Hc^0 homozygous strains have been described (Staats, 1985). Cinader et al. (1964) and Dubiski and Cinader (1966) showed that adult female mice have only two-thirds the concentration of C5 (MuB1) found in adult C5-sufficient males.

The kinin, coagulation, and fibrinolytic systems share important interactions with the complement system. In particular, the activation of the coagulation cascade, for example, in experimental endotoxemia may result in metabolites that activate certain complement proteins, including C5 (Sundsmo and Fair, 1983). Furthermore, conditions leading to the activation of C3 and the production of C5 convertase will result in decreased concentrations of C5 (and other late phase components) in the serum. Direct measurement of C5 concentrations in diseased animals has not been extensively reported; however, it is assumed that changes in C5 concentration in most mammalian species will parallel changes seen in similar human conditions (Agnello, 1978; Alper and Rosen, 1975; Atkinson and Frank, 1980).

In rats, either intrapulmonary deposition of IgG immune complexes or systemic activation of complement by CoF leads to inflammatory lung injury mediated by neutrophil infiltration. While C6-deficient rats were still susceptible, pretreatment of rats with anti-C5a antibody protected against increased pulmonary vascular permeability (Mulligan et al., 1996). Later, it was shown that serum levels of C5a were directly proportional to the amount of CoF infused, and that peak serum C5a correlated with peak neutrophil chemotactic activity and upregulation of CD11b on neutrophil cell membrane. Treatment with anti-C5a was associated with down regulation of pulmonary vascular intercellular adhesion molecule (ICAM). Thus, C5a in the rat appears to upregulate both the pulmonary vascular and neutrophil adhesion molecules, allowing neutrophils to form intravascular aggregates that damage the pulmonary endothelium and cause lung injury (Schmid et al., 1997).

Human beings with both total deficiency of C5 and C5 dysfunction have been described. Related clinical disease is rare, but has been associated with the absence of C5 (immunogenic and hemolytic), and an increased susceptibility to infection, particularly pneumococcal pneumonia, and systemic lupus erythematosus. One patient with C5D and systemic lupus erythematosus had typical serologic and dermal manifestations of systemic lupus erythematosus, but the renal disease was

not progressive (Rosenfeld et al., 1976a). In vitro studies with C5D serum demonstrated impaired cytolytic and bactericidal activities. Deficient sera could not generate chemotactic factor, but they could provide normal opsonization of Baker's yeast (Rosenfeld et al., 1976b). C5D is transmitted as an autosomal trait in which heterozygotes have half-normal levels.

Several reports have described family members with normal antigenic and hemolytic C5 levels that are predisposed to infections. A functional defect in C5 in these individuals is postulated because purified C5 corrects the opsonization defect but C5D serum does not. These patients have Leiner's disease, which is characterized by eczema and secondary infections in infants (Miller and Nilsson, 1970). Because the defect in opsonization is not seen in homozygous C5-deficient serum, another factor may be responsible for the dysfunction.

Mice deficient in the fifth component of complement were first described by Rosenberg and Tachibana (1966), who were able to show that two strains, DBA/2 and B10.D2 (old), were lacking in vitro hemolytic activity. They also demonstrated that the defect was inherited as a single Mendelian recessive trait, the locus of which was designated as Hc (Herzenberg et al., 1963; Tachibana et al., 1963). By immunizing DBA/2 mice with serum from other normal mice, two groups of investigators independently discovered a new serum β -globulin (formerly called MuB1) that was present only in mice with normal hemolytic activity (Cinader and Dubiski, 1963; Erickson et al., 1964). Homologous and heterologous antibody to MuB1 reacted with the serum of many mammalian species, demonstrating common antigenic determinants among them (Cinader and Dubiski, 1964). Later, a protein contaminant of murine β 1c, β 1F glycoprotein, was characterized as the fifth component of complement (Nilsson and Muller-Eberhard, 1965) and shown to be the same as MuB1 (Nilsson and Muller-Eberhard, 1967). Because purified human C5 was able to reconstitute mice bearing the homozygous Hc^o (deficient) gene, it was concluded that the Hc locus controlled the production of C5 in mice. As in human beings, there is no linkage between the Hc gene and the MHC-H-2 in mice. There is some evidence that the molecular basis for C5 deficiency in mice involves an abnormal primary transcript of the C5 gene, retarding the processing of C5 mRNA and resulting in an abnormal C5 protein (Wheat et al., 1987).

The availability of two coisogenic lines of mice, one deficient in C5 (B10.D2/oSn) and the other (B10.D2/nSn) containing normal levels of C5, has allowed investigations concerning the role of C5 in a variety of experimental situations. The ability to reject large numbers of sarcoma tumor cells was shown to require the presence of C5 (Phillips et al., 1968). Two groups demonstrated that C5D strains of mice were deficient in rejecting skin allografts after treatment with antilymphocyte serum (Cinader et al., 1971; Weitzel and Rother, 1970). Lindberg and Rosenberg (1968) found that C5-sufficient (B10.D2/nSn) strains were at risk of developing experimental nephritis; however, C5D strains of mice were more susceptible to the development of experimental thyroiditis (Nakamura and Weigle, 1968). C5D mice are less susceptible to development of experimental autoimmune myasthenia gravis because the MAC is necessary to destroy acetylcholine receptors (Christadoss, 1988).

The importance of C5 in resistance to experimental bacterial infections has been studied extensively. Killing of *Escherichia coli* but not phagocytosis (Glynn and Medhurst, 1967), in vivo and in vitro defense against *S. pneumoniae* (Shin et al., 1969), opsonization of *S. aureus* (Easmon and Glynn, 1976), and the early attraction of neutrophils against *Listeria monocytogenes* (Lawrence and Schell, 1978) all required C5 for maximum activity. Later studies showed that C5 yields important neutrophil chemotaxins during the early period after intrapulmonary inoculation with *S. pneumoniae*, and that pulmonary clearance of the organism is impaired in C5D mice (Toews and Vial, 1984). Similar findings regarding pulmonary clearance of aerosolized *S. aureus* have also been reported (Cerquetti et al., 1983).

Morelli and Rosenberg (1971) demonstrated that normal mice survived longer than C5D mice after injection with *Candida albicans*. Moreover, infection of C5D mice with *Mycoplasma pulmonis* resulted in a more severe and persistent arthritis than that seen in normal mice (Keystone et al., 1978). Finally, the incidence of pulmonary consolidation and mortality seen in mice inoculated with the influenza virus was much higher in C5D mice (Hicks et al., 1978).

17.4.5 COMPLEMENT COMPONENTS OF THE TERMINAL ATTACK COMPLEX (C6–C9)

17.4.5.1 Physical, Chemical, and Genetic Properties of C6–C9

The sixth component of human complement is a β -globulin with a molecular weight of 111 kDa (Podack et al., 1976). Homogenous preparation of C6 from rabbit and guinea pig serum revealed proteins of similar molecular weight and structure (Arroyave and Muller-Eberhard, 1971). Murine C6 is also a single peptide chain with a molecular weight slightly larger than that of human C6 (140 kDa); the PI range of murine C6 is more basic than that of human C6 (Hayakawa et al., 1984). The location of the epitope on human C6 responsible for binding C5b was identified using monoclonal antibody WU6–4. The Src homology domain containing (SHC) is encoded by the third thrombospondin repeat (of C6 α -chain), and a similar epitope is found on rabbit C6 (Wurzner et al., 1995).

Purified human C7 has a molecular weight of 102 kDa and an electrophoretic mobility identical to that of C6. Both C6 and C7 are single polypeptide chains (Podack et al., 1976). Additional investigations showed similarities between C6 and C7 in both amino acid and carbohydrate content, and trypsinization studies suggest similar tertiary structures (Podack et al., 1979).

Both human C6 and C7 show polymorphisms in isoelectric focusing (Hobart et al., 1975). Polymorphisms have also been demonstrated for C6 of rhesus monkey (Hall and Alper, 1977), chimpanzee (Raum et al., 1980), rabbit (Kunstmann and Mauff, 1980), dog (Anderson et al., 1983; Eldridge et al., 1983), and mouse (Hayakawa et al., 1984). Canine C7, like human C7, is polymorphic (Eldridge et al., 1983).

Murine C6 occurs as two major protein bands by isoelectric focusing, with molecular weights of 90 and 100 kDa. All inbred strains belong to one of four haplotypes: *C6Aa* encodes the 90 kDa molecule ($pI < 6.3$), which occurs in A/J, BALB/c, DBA/2, and C57BL/6 strains; *C6Am* encodes a 90 kDa molecule ($pI < 6.2$), which occurs in *Mus musculus molossinus*; *C6AaBa* encodes both 90 and 100 kDa molecules with pIs such as *C6A^a* and occurs in CBA/Ca; and haplotype *C6AaBb* determines both 90 and 100 kDa with the acidic pIs and occurs in AKR mice (Orren et al., 1988). Each protein band is also associated with one or more minor acidic bands. Two common variants of human C6 were also described by isoelectric focusing, and they are designated as the A and B variants. Individuals may express any of three phenotypes, C6A, C6B, and C6AB, which occur with frequencies 37%, 14%, and 45%, respectively (Hobart et al., 1975). Studies by Hobart et al. (1977a) showed that the gene responsible for C6 deficiency in human beings is not linked to the human leukocyte antigen (HLA) complex, but is closely linked to the gene for C7. In the rat, the C6 gene has been used to isolate full-length transcripts of rat C6 mRNA (Bhole and Stahl, 2004). Sequence analysis demonstrated that the amino acid sequence for rat C6 was highly homologous to the human and murine sequence.

It has been determined that C7 is a single-chain plasma glycoprotein that is encoded by a gene containing 18 exons and spanning 80 kb (Hobart et al., 1995). Products of three codominant alleles at an autosomal locus, there are three structural forms of C7 in humans (Hobart et al., 1978). In human beings, the genes C6 and C7, along with C9, are closely linked and located on chromosome 5 (Coto et al., 1991). In mice, C7 is encoded by a genetic locus with two alleles. *C7^b* encodes peptides that display five bands on isoelectric focusing, while *C7^a* has all five plus an extra cathodal band. AKR mice carry the *C7^b* allele, while 26 other murine strains each carry the *C7^a* allele (Orren et al., 1985).

The structure and function of C8 has been reviewed Sodetz (1988). In general, C8 is a serum protein consisting of three nonidentical subunits (α , β , γ) arranged asymmetrically as a C8 α -C8 γ disulfide-linked dimer noncovalently associated, with a C8 β subunit; each subunit is encoded by a different gene (Kolb and Muller-Eberhard, 1976; Ng et al., 1987). The human C8 α gene consists of at least 11 exons, spanning approximately 70 kb of DNA, and the genomic organization is very similar to that of C6, C8 β , and C9. While the C8 α - and β -chains show an overall sequence homology to

C6, C7, and C9, the C8 γ -chain was found to have a structural homology to the α -1-microglobulin/bikunin precursor, protein HC (Haefliger et al., 1987; Hunt et al., 1987). The crystal structure of the C8 α component domain of the MAC perforin demonstrated that it was structurally homologous to the bacterial, pore-forming, cholesterol-dependent cytolysins (Hadders et al., 2007). Two wild-derived strains of mice were found to lack C8, but hemolytic activity could be restored with purified human C8. Backcrosses between DBA and the wild strain (MSM) indicated that inheritance was at a single locus called *C8b*. Mice carrying C8b1 have lytic activity, whereas those carrying C8b0 lack hemolytic activity (Tanaka et al., 1991).

Complement component 9 (C9) is the major constituent of the MAC and, while single molecules of C5b, C6, C7, and C8 are needed for MAC formation, multiple molecules of C9 are recruited and assembled (DiScipio et al., 1984). In contrast to homologous proteins that require the membrane for oligomerisation (e.g., perforin and cholesterol-dependent cytolysins), soluble C9 assembles directly onto the MAC (Dudkina et al., 2016). In a recent report, Dudkina et al. (2016) showed an 8 Å cryo-EM structure of the soluble form of poly-C9. Additionally, they demonstrated a 22-fold symmetrical arrangement of C9 molecules resulting in an 88-strand pore-forming β -barrel. Facilitating this solution-based oligomerisation was an N-terminal thrombospondin-1 (TSP1) domain, and the authors suggested that these TSP1 interactions might explain how additional C9 subunits are recruited to the expanding MAC subsequent to membrane insertion. It has been demonstrated that the genetic locus for C9 is tightly linked to the C6 and C7 loci (Coto et al., 1991). However, while it was determined that the C6 and C7 genes are contained in the same NotI fragment of 500 kb, no evidence was found for a physical linkage between C9 and C6 or C7 (Setien et al., 1993).

17.4.5.2 Function of C6–C9

Regardless of which pathway is activated, C5 convertase cleaves C5 to produce C5b, which attacks the membrane at a third topologically distinct site (Muller-Eberhard, 1975). The final MAC C5–C9 is assembled by the sequential addition of one molecule each of C5b, C6, C7, with C8 attaching to the cell surface, and a variable number of C9 molecules inserting themselves into the lipid bilayer and polymerizing into a ring with a central channel (DiScipio et al., 1984; Hobart, 1984). The attachment of late-acting complement components (C6–C9) takes place spontaneously without the necessity for enzymatic cleavage (Morgan, 1995; Muller-Eberhard, 1975). Following the lytic phase, the soluble C5–C9 complex circulates in the fluid phase with a molecular weight of 10400 kDa (Kolb and Muller-Eberhard, 1973).

17.4.5.3 Synthesis and Catabolism of C6–C9

It is considered that the liver is the major site of synthesis of C6, C8, and C9 (Hobart et al., 1977b; Alper et al., 1980; Adinolfi and Lehner, 1988). However, while C7 cDNA sequence analysis has been successfully performed on liver-derived cDNA (DiScipio et al., 1984), implying that C7 is also synthesized by hepatocytes, the liver does not appear to be the primary site for C7 synthesis. For example, C7 is not an acute phase reactant similar to C6 and C9 (Pepys, 1992). It has also been demonstrated that small amounts of C6 and trace amounts of C8, but not C7, were secreted by a human hepatoma-derived cell line, HepG2 (Morris et al., 1982). Further, in a study of liver transplantation patients, serum C7 evaluations demonstrated that there was a $\leq 50\%$ contribution of the transplanted liver toward the C7 concentrations at 2–3 weeks posttransplantation (Wurzner et al., 1994). That contribution decreased with time to approximately 10% at 6 weeks after transplantation. The authors concluded that C7 is the only terminal complement component not predominantly synthesized by hepatocytes. Moreover, since cells such as monocytes, peritoneal macrophages, and alveolar macrophages are known to synthesize C7 *in vitro*, they suggested that C7 synthesis was attributable to the cells of the mononuclear phagocyte lineage. Monocytes also produce C5, C6, C8, and C9 *in vitro* (Hetland et al., 1986).

The half-life ($t^{1/2}$) of rabbit C6, calculated by infusion of plasma from normal into C6D rabbits, is 30 hours (Biro and Ortega, 1966).

17.4.5.4 Analysis of C6–C9

Hemolytic assays designed to measure C6 in various animals have taken advantage of the availability of human and rabbit C6D serum for simple one-step assays to quantitate C6 activity in the hamster (Yang et al., 1974), dog (Eldridge et al., 1983), rabbit (Goldman et al., 1982), mouse (Nilsson and Muller-Eberhard, 1967), and rat (Van Dixhoorn et al., 1997). The quantitation of both rabbit (Nelson and Biro, 1968) and mouse (Nilsson and Muller-Eberhard, 1967) C6 and C7 using cellular intermediates and purified components has been documented. The details for measuring C6 and C7 in human beings and nine animal species using purified components derived from cellular intermediates were given by Barta and Hubbert (1978). The hemolytic titers for both C6 and C7 for seven nonhuman primate species were published by Schur et al. (1975). Immunologic techniques have been employed for the measurement of C6 in mouse (Hayakawa et al., 1984) and rabbit (Goldman et al., 1982).

17.4.5.5 Clinical Significance of C6–C9 Concentrations

The levels of antigenic C6 and C7 in human serum average 60 $\mu\text{g/mL}$ (Atkinson and Frank, 1980). As with most complement components, the measurement of C6 and C7 in animals varies between laboratories according to the methodology used, therefore direct comparisons between laboratories are difficult.

Deficiency of C6 (C6D) has been described in human beings who lack antigenic and functional levels of C6 in their plasma. The disease is transmitted in families with an autosomal codominant pattern of inheritance (Agnello, 1978). Heterozygotes for the C6D gene have half-normal antigenic levels of C6 but normal CH_{50} levels. Although some C6D patients appear to be normal, others have been described with Raynaud's syndrome, recurrent gonococcal septicemia, and recurrent meningococcal meningitis (Atkinson and Frank, 1980).

A biologically normal individual was found who had a partial genetic deficiency of both C6 and C7. Plasma levels of C6 were low, and the molecular size of the C6 was smaller than normal. A structural mutation in the C6 gene causing hyposynthesis of C6 and C7 was hypothesized (Glass et al., 1978; Lachmann et al., 1978). In most instances, however, human C6 deficiency is not associated with reduced C7 (Leddy et al., 1974; Lim et al., 1976). In addition, C6D rabbits have normal levels of C7 (Nelson and Biro, 1968). A simultaneous deficiency of C6 and C2 occurred in three members of a single family; however, the deficient genes segregated independently, indicating separate genetic events (Delage et al., 1979).

At least three separate instances of spontaneous C6 deficiency have occurred among different strains of rabbits. In each instance, C6D rabbits had little or no hemolytic C6 in their serum. The hemolytic activity of serum was reconstituted in one C6D strain by adding purified human or rabbit C6 (Rother et al., 1966) and purified guinea pig C6 in another C6D strain (Nelson and Biro, 1968). Lachmann (1970) showed that C6D rabbits had no circulating antigenic C6. Given the fact that these deficiencies occurred in different strains of rabbits in England, Mexico, and Germany, it is assumed that the defect in C6 synthesis in this species is fairly common. The defect in C6 synthesis in rabbits was shown to be transmitted as a single autosomal recessive trait with heterozygotes containing half-normal serum levels of C6 (Lachmann, 1970).

C6D rabbits appear to withstand common infections well and have normal antibody production. Abnormal coagulation, as measured by prolonged whole blood clotting time and reduced prothrombin consumption, was observed in C6D rabbits and corrected by adding purified C6 to deficient blood (Zimmerman et al., 1971). Experimental polyneuropathy induced by the injection

of IgM antimyelin-associated glycoprotein was abolished in C6D rabbits, suggesting that the MAC acted as effector for the development of disease (Monaco et al., 1995).

In rodents, C6 deficiency has been reported in the rats, mice, and Syrian hamster (Yang et al., 1974; Bhole and Stahl, 2004; Spicer et al., 2007). Rats with complete deficiency of C6 have been identified in the PVG/c strain (Spicer et al., 2007). While a C6 mRNA transcript was found in the liver of deficient rats, its expression was 100-fold less than in sufficient rats. Since Northern blot analysis failed to reveal a large deletion in C6 DNA of C6D rats, the authors attributed deficiency to mRNA instability or a point mutation resulting in aberrant transcription (Van Dixhoorn et al., 1997). In an experimental model of thrombotic microangiopathy, antibodies to glomerular endothelial cells infused in rats produce glomerular endothelial cell injury, platelet aggregation, fibrin deposition, acute renal failure, tubular necrosis, and interstitial inflammation. The C6D rat was protected against this disease (Nangaku et al., 1997). Bhole and Stahl (2004) identified a 31 bp deletion in exon 10 of the C6 gene that leads to C6 deficiency in the PVG rats (PVG/c-) and developed a polymerase chain reaction (PCR)-based genotyping test. An unexpected finding from this study was a coagulation defect in the C6 deficient mice and rats.

In the Syrian hamster, serum from C6D hamsters could not reconstitute C6D serum from human beings or rabbits (Yang et al., 1974). However, normal hamster serum could. Although no differences between C6D and normal hamster sera were noted in induction of immune adherence or phagocytosis, this colony was extremely susceptible to proliferative enteritis and was subsequently lost.

While a rare occurrence in western countries, a high incidence of C9 deficiency has been observed in Korea and is the most common complement deficiency in Japan (Kang et al., 2005; Miura et al., 2011). It has been linked with immune complex-associated glomerulonephritis, but not systemic lupus erythematosus, and is related to an Arg95Stop mutation of the C9 gene (Kanemitsu et al., 2000; Miura et al., 2011).

17.4.6 ALTERNATE PATHWAY COMPONENTS (FACTORS B AND H)

17.4.6.1 Physical, Chemical, and Genetic Properties of Factors B and H

In human beings, factor B is a single chain glycoprotein with a molecular weight of 95 kDa (Christie et al., 1980) migrating as a β -globulin (Muller-Eberhard and Schreiber, 1980). This thermolabile glycoprotein is composed of 7.3% carbohydrate (Curman et al., 1977), and its amino acid composition is known (Lesavre et al., 1979). Murine factor B has a molecular weight of approximately 100 kDa (Natsuume-Sakai et al., 1983; Roos and Demant, 1982).

The intact human factor B is cleaved by factor D into Ba and Bb fragments of 30 kDa and 61 kDa molecular weight, respectively (Morgan, 1995). The Ba and Bb fragments of murine factor B have similar molecular weights (Roos and Demant, 1982).

Multiple alleles of *Bf* (the factor B structural gene) have been described in human beings (Alper et al., 1972b), mouse (Natsuume-Sakai et al., 1983; Roos and Demant, 1982), guinea pig (Bitter-Suermann et al., 1977), and rhesus monkey (Ziegler et al., 1975a). Multiple alleles in all species are codominantly expressed. Four allelic variants have been found in mice (Natsuume-Sakai et al., 1983), two variants in guinea pigs (Bitter-Suermann et al., 1977), and six in the rhesus monkey (Ziegler et al., 1975b).

The gene for human factor B is closely linked to the gene for C2 (Alper et al., 1972a; Bitter-Suermann et al., 1977), C4 (Awdeh and Alper, 1980), and the MHC locus (Allen, 1974; Raum et al., 1981). Linkage between Bf, C2, C4, and the MHC has also been demonstrated for the rhesus monkey (Ziegler et al., 1975a), guinea pig (Kronke et al., 1977), and mouse (Natsuume-Sakai et al., 1980; Roos and Demant, 1982). Restriction map analysis of the genomic clone and total genomic DNA have elucidated a single Bf gene (per haploid) spanning more than 5.5 kb. Using a human factor B cDNA probe, a murine cDNA clone that has 85% homology with the human cDNA was isolated (Colten, 1983a). Restriction enzyme analysis of multiple human and murine cDNA clones failed to reveal differences in the DNA sequence among members of the same species.

In mice, the structural gene for factor H, *cfh*, is found on chromosome 1 and has two alleles, *cfh* and *cfh*² (formerly called *Sas*¹ and *Sas*⁰ or Mud1 and Mud2 [D'Eustachio et al., 1986]). Polymorphisms of factor H identified by electrophoresis and alloantisera were determined by the *cfhe* locus where allele *cfhe*^a occurs in BALB/c, A/J, and C57BL/10 (and most other) strains and allele *cfhe*^b occurs in the STR strain. Another allele *cfhe*^c has been identified on the BFM/2Ms strain derived from European wild mice (Natsuume-Sakai et al., 1985). The *cfhe* locus maps to chromosome 2. Three allotypes of mouse factor H have been purified and their functional properties investigated (Okada et al., 1993).

17.4.6.2 Function of Factors B and H

As mentioned previously, when factor B (bound to C3b) is cleaved by factor D (in the presence of Mg²⁺), it generates C3bBb, an unstable C3 cleaving enzyme. This cleaving enzyme is stabilized by the addition of properdin (P) to form C3 and C5 convertases (Colten, 1983a). Because Bb can hydrolyze the synthetic ester, acetyl-glycyl-lysine methyl ester, in a form unassociated with C3b, it is classified as a serine protease (Cooper, 1971). Two short consensus repeat (SCR) regions, SCR-2 and SCR-3, were shown to impart the ability of factor B to bind fluid phase C3b (Hourcade et al., 1995). Control over the amplification of convertases in the fluid phase is mediated in part by C4BP, which acts as a cofactor (with factor I) in the cleavage of C3b in the convertase (Morgan, 1995).

Schreiber et al. (1979) found that the mixture of isolated alternative pathway proteins and the isolated membrane attack pathway proteins constitutes an intact cytolytic pathway capable of killing bacteria in the absence of antibody. The activated alternative pathway appears to be effective in the lysis of some virus-infected cells (Schreiber et al., 1980), inactivation of viruses (Cooper, 1979), killing of certain parasites (Flemmings and Diggs, 1978), and influencing many host cellular functions. Guinea pig Ba has neutrophil chemotactic activity (Hamuro et al., 1978); however, human Ba does not (Lesavre et al., 1979).

17.4.6.3 Synthesis and Catabolism of Factors B and H

Human factor B is synthesized by macrophages (Brade et al., 1978; Whaley, 1980), fibroblasts (Watanabe et al., 1995), and lymphocytes (Halbwachs and Lachmann, 1976), and it accounts for 0.1% of the total protein synthesized by the liver (Hobart and Lachmann, 1976). Similarities between factor B and C2 have been seen in biosynthesis, postsynthetic processing, and secretion (Matthews et al., 1982). Like C2, factor B synthesis may be induced by interferon- γ via a protein kinase c dependent pathway (Watanabe et al., 1995).

Factor B is activated by enzymatic cleavage into fragments Ba (the N-terminal component that behaves electrophoretically as an α -globulin) and Bb, which behaves as a γ -globulin. Under physiologic activation, Bb remains complexed to C3b (forming an alternative pathway C3 convertase), and Ba is released. The maintenance of stable C3bBb and the formation of C3/C5 convertase require an activator that prevents the interaction of C3b with factor H. Many such activators are known, including LPS, viruses, fungi, bacteria, parasites, and some animal cells; however, the critical feature of their structure that inhibits the C3b-factor H interaction is not known. Increased catabolism of factor B has been observed in human patients with immune complex-mediated diseases (Charlesworth et al., 1974).

Factor H can be synthesized by a variety of tissues, including liver and skeletal muscle. Unlike most complement components, where synthesis is induced by interleukin-1, TNF, and interferon- γ , IL-1 is not involved with the synthesis of factor H (Legoedec et al., 1995).

17.4.6.4 Analysis of Factors B and H

In man, factor B is routinely measured using the radial immunodiffusion assay (Gaither and Frank, 1979). Erythrocytes of some animal species are sensitive to alternative

complement pathway-mediated lysis by fresh heterologous sera in the presence of magnesium and ethyleneglycol-bis-(2-aminoethyl)-tetra-acetic acid (EGTA). The proper target red cell for 12 animal species has been reported (Van Dijk et al., 1983). Antigenic analysis using specific antifactor B antisera has been published for guinea pig (Bitter-Suermann et al., 1977) and mice (Natsuume-Sakai et al., 1983).

Factor B has been measured in cattle using a hemolytic diffusion plate assay and radial immunodiffusion, with poor concordance between these assays (Table et al., 1983). The investigators suggest that because hemolytic activity depends on the concentration of other complement components, it is not as reliable as radial immunodiffusion. Rocket immunoelectrophoresis has been developed for measuring consumption of factor B after activation with zymosan (Table et al., 1983).

Schur et al. (1975) demonstrated lines of identity between factor B of six nonhuman primate species and antihuman factor B. This observation was confirmed by McMahan (1982) and used as a basis for crossed electrophoresis to measure rhesus monkey factor B (Ziegler et al., 1975a).

Factor H has been measured in human beings both by double antibody ELISA and by their capacity to cleave ^{125}I -labeled C3b analyzed by electrophoresis and autoradiography (Legoedec et al., 1995).

17.4.6.5 Clinical Significance of Factors B and H Concentrations

The serum concentrations of factor B in healthy human beings average 200 $\mu\text{g}/\text{mL}$ (Muller-Eberhard and Schreiber, 1980) and range from 180 to 230 $\mu\text{g}/\text{mL}$ (Adinolfi and Beck, 1975; Nagaki et al., 1980). In cattle, mean factor B levels in serum were 34 mg/dL (Table et al., 1983). In mice, sexual dimorphism is seen in the expression of factor B variants, with female mice lacking several anodal bands present in males; however, no differences in total factor B were seen using radial immunodiffusion or rocket immunoelectrophoresis (Roos and Demant, 1982). Strain-specific differences in plasma levels of factor B have been documented with 10-fold differences seen between B10.WR and B10.SM strains (Falus et al., 1987). Factor B levels are commonly elevated in inflammatory disorders, leaving some to classify factor B as an acute phase reactant (Atkinson and Frank, 1980). In both man and mouse, interleukin-1 has been shown to modulate factor B gene expression, resulting in increased mRNA levels in tissues and factor B in plasma (Falus et al., 1987; Perlmutter et al., 1986).

Membranoproliferative glomerulonephritis occurs in factor H-deficient human beings (Rougier et al., 1998). Similarly, an inherited deficiency in factor H has been described in Yorkshire pigs. In these pigs, there is continuous activation of C3 through the alternative pathway, resulting in renal deposition and complement-mediated kidney injury (Frank, 1995; Jansen et al., 1993). Pickering et al. (2002) demonstrated that mice, deficient in factor H (*Cfh*^{-/-} mice), spontaneously developed a membranoproliferative glomerulonephritis and were highly susceptible to developing immune complex-related renal injury. With the addition of a second mutation in the gene encoding complement factor B, thereby, preventing the *in vivo* turnover of C3, the authors abrogated the phenotype of *Cfh*^{-/-} mice. Thus, they demonstrated that uncontrolled C3 activation was essential for the development of renal injury associated with factor H deficiency.

17.5 CONCLUSIONS

Complement is a powerful immune modulating system that is not only based on lytic activities, but also on pathogen recognition components and important interactions with antigen-specific and nonspecific inflammatory host components. Recent elucidation of pathogenic hereditary deficiencies and dysfunctions have also lead to potential therapeutic interventions, by affecting the unique enzymatic reactions and the resulting conformational changes thus limiting the potential harmful host pathology such as that encountered in Lupus erythematosus, cancer, transplantation medicine, and atypical hemolytic uremic syndrome (Merle et al., 2015).

ACKNOWLEDGMENT

I wish to thank Fred W. Quimby, the author of this chapter from the second edition of this book, for his vision and contributions to the current chapter.

18.1 INTRODUCTION

In most of the animal species, plasma proteins make up approximately 7% of the total plasma. These nitrogenous compounds are often unique and specific for individual species. Most plasma proteins have specific functions as, for example, enzymes, blood coagulation factors, hormones, antibodies, or transport compounds. Most transport proteins in humans and many in animals have been well characterized. The major transport proteins covered in this chapter include albumin, transthyretin (TTR), thyroid hormone-binding proteins, haptoglobin, group-specific components (Gc), hemopexin, transferrin, and corticosteroid-binding globulin. Many of these proteins have multiple roles and can be classified differently depending on the subject matter. In this text, ceruloplasmin has been included in Chapter 19 due to its role in inflammation.

18.2 ALBUMIN

18.2.1 PROPERTIES

Serum albumin (SA) is the most abundant protein in the circulation and the most prominent component on electrophoresis. Albumin is a single peptide chain of over 580 amino acid residues. The amino acid composition and sequence of albumin have been determined in many domestic and laboratory animals, including cattle, horse, rat, mouse, pig, and sheep (Brown, 1976; Brown et al., 1971; Carter and Ho, 1994; Peters, 1977; Peters and Reed, 1980). The complete amino acid sequence of human and bovine albumin has been described (Behrens et al., 1975; Brown, 1975; Meloun et al., 1975). The molecular weights of human and bovine albumin calculated from the sequences are 66,500 and 66,210 Da, respectively. The proposed structure for both human and bovine albumin consists of three repeating units or domains (domains I, II, and III). Each domain is composed of two large double loops and one small double loop (loops 1–9) (Behrens et al., 1975; Brown, 1975; Carter and Ho, 1994). The double loops are formed by disulfide bonds between the 34 half-cystine residues. Only 20% of the amino acid residues differ between human and bovine albumin. Sequence homologies between equine and bovine SAs and equine and rat SAs are 73% and 76%, respectively (Carter and Ho, 1994).

18.2.2 ROLE/FUNCTION

Albumin serves many functions. It binds and transports large organic anions that are normally insoluble in aqueous fluid, for example, bilirubin and long-chain fatty acids, poorly soluble hormones, such as steroid and thyroid hormones, and virtually all constituents of plasma not bound and transported by specific proteins. Albumin is a major contributor to the plasma osmotic pressure and accounts for 75% of total osmotic activity. It plays a minor nutritive role, acting as reservoir and contributing approximately 5% of amino acids used in peripheral tissues. It is also involved in the binding of heavy metals (Grant and Kachmar, 1976; Peters, 1977). Ligand-binding locations for several substances have also been reported (Peters, 1977; Reed et al., 1975). Copper and nickel bind at the amino terminus. Cystine and glutathione bind near the first thiol group, and normally two fatty acids bind on loops 4–6 and 7. Furthermore, the efficacy, distribution, and metabolism of many drugs are affected by their affinity to SA. In different species of SA, single changes in relevant sequence were found to significantly alter their binding selectivity (Titlebach and Gilpin, 1995). Structural differences in the binding sites between rat and human SA have been reported (Massolini et al., 1996).

During the acute phase response, the concentration of albumin is decreased due to either, a decrease in its synthesis due to inflammatory cytokines, or by a negative feedback mechanism involving an oncotic pressure receptor on the hepatocytes. Hypoalbuminemia is observed when inflammation has lasted up to 1 week. Four factors are responsible for the reduction in albumin:

- Hemodilution
- Loss into the extravascular space, as vascular permeability increases in the areas of inflammation
- Increased catabolism due to localized cell consumption
- Decreased synthesis as the result of direct inhibition by cytokines, for example, IL-1, IL-6, and TNF- α , and an increased colloidal osmotic pressure (Gentry, 1999; Nassir et al., 2002; Stockham and Scott, 2008)

The synthesis of albumin involves an intracellular precursor form, proalbumin. Rat studies in the rat have shown that proalbumin, formed by the microsomes, contains a basic hexapeptide extension at the amino terminus. Proalbumin binds bilirubin and palmitate as effectively as albumin. Although the role of proalbumin is unknown, it has been suggested that the hexapeptide extension on proalbumin serves to channel the nascent albumin through the liver cell and to regulate albumin synthesis (Peters, 1977; Peters and Davidson, 1982, 1986; Peters and Reed, 1980).

Overall rates of albumin catabolism have been determined for various animal species by conventional protein tracer techniques, such as radioiodination (Allison, 1960; Dixon et al., 1953; Mattheeuws et al., 1966). The rate of catabolism varies with the species, and is frequently measured as the time in which one half the serum concentration disappears ($T_{1/2}$). There appears to be a direct correlation between albumin turnover and body size. The $T_{1/2}$ for albumin in various species is listed in Table 18.1.

The tissue sites for albumin catabolism have been studied using nondegradable radioactive tracers that accumulate in tissues following protein degradation. Studies in rabbits using (^{14}C) sucrose-labeled albumin suggested that all tissues catabolized albumin, with no tissue of predominant importance. The most active tissues were those with fenestrated or discontinuous capillary beds, suggesting that exposure to high concentrations of albumin was an important determinant in albumin degradation (Yedgar et al., 1983). Similar studies in rats showed that the major fraction of albumin catabolism occurs in muscle and skin (Baynes and Thorpe, 1981).

18.2.3 PATHOPHYSIOLOGICAL SIGNIFICANCE

Genetic polymorphism has been observed in many species, including domestic fowl, pig, cattle, horse, and toad (Tarnoky, 1980). Breeding experiments with inbred lines of brown leghorns, white leghorns, and Rhode Island Red chickens have shown three phenotypes of albumin controlled by

TABLE 18.1
Albumin Turnover in Animals

Species	$T_{1/2}$ (days)	Reference
Mouse	1.9	Allison (1960)
Rat	2.5	Allison (1960)
Guinea pig	2.8	Allison (1960)
Rabbit	5.7	Dixon et al. (1953)
Dog	8.2	Dixon et al. (1953)
Man	15.0	Dixon et al. (1953)
Baboon	16.0	Cohen (1956)

two codominant autosomal alleles: a homozygous fast, a homozygous slow, and a heterozygous fast-slow combination type (McIndoe, 1962). Patterns of albumin polymorphism similar to those of chickens are also observed in turkeys (Quinteros et al., 1964) and horses (Stormont and Suzuki, 1963). In pigs, the genetic control of albumin phenotypes appears to involve three codominant alleles (Kristjansson, 1966). Eleven albumin alleles present in 29 phenotypes were found in the American toad (*Bufo americanus*) (Constans and Viau, 1977). Genetic variants have also been described in cattle (Soos, 1971).

Measurement of SA is of considerable diagnostic value, as it relates to (a) general nutritional status, (b) the integrity of the vascular system, and (c) liver function. SA concentrations for most laboratory animal species are between 2.42 and 4.19 g/dL, and reference values for each laboratory animal species have been reported (Mitruka and Rawnsley, 1977). In man, the rate of albumin synthesis by the liver is approximately 14 g per day (Putman, 1975b). In 5- to 7-week old rats, it is 3.13 mg/100 g of body weight per hour (Peters and Peters, 1972).

Fasting rats for 18 hours caused a 40% reduction in the rate of albumin synthesis (Peters and Peters, 1972). Circadian fluctuation of plasma protein and albumin levels in rats maintained on a 12-hour light-dark cycle has been reported, with highest levels observed at 0100 and 0800 hours, and lowest levels observed at 1800 (Scheving et al., 1968). A significant decrease in SA levels in late gestation has been reported in rhesus monkeys (Golub and Kaaekuahiwi, 1997). The formation of albumin decreases with increasing age (Jeffrey, 1960); however, the properties and composition of SA from adult and aging mice are identical (Schofield, 1980). Increased albumin production, has not been known to occur in animals. An increase in the SA concentration is usually interpreted as consistent with dehydration. Hypoalbuminemia may result from (a) impaired synthesis, as in malnutrition or chronic liver disease; (b) loss through urine and feces, as in renal and intestinal disease; (c) increased catabolism, as in neoplastic conditions and acute phase reaction (albumin is a "negative" acute phase reactant); and (d) changes in distribution between intra- and extravascular compartments (Grant and Kachmar, 1976; Kalberg et al., 1983; Kurosky et al., 1980). Interestingly, a strategy for hepatocyte transplantation, using retrorsine and partial hepatectomy, has been demonstrated to restore albumin synthesis and physiological function of the liver, suggesting its potential use as a method to treat genetic-based or acquired liver diseases (Oren et al., 1999).

18.2.4 ANALYTICAL METHODS

Currently used procedures for estimation of SA are based on one of the following principles: (a) salt precipitation, (b) dye binding, (c) electrophoretic mobility, and (d) antigenicity (Grant and Kachmar, 1976; Peters, 1977).

The most commonly used salts for precipitation are sodium and ammonium sulfate. Serum globulins can be removed selectively by salt precipitation, and the remaining albumin assayed by the biuret method.

Albumin has the tendency to bind certain dyes, such as BG, methyl orange, and 2-(4'-hydroxyazobenzene) benzoic acid (HABA). This characteristic has been used to measure albumin directly. HABA binds very poorly to albumin of domestic animals and is susceptible to bilirubin interference. The use of BG appears to be quite accurate when compared to electrophoresis and is less affected by pigment interference. For example, measurement of rabbit albumin by unmodified dye binding with either BG or bromocresol purple yields falsely elevated values if human or bovine albumin is used to calibrate the assay. If determined this way, the measured concentration of rabbit albumin may exceed the concentration of total protein. This may be related to the configuration of the binding sites of rabbit albumin. The error may be overcome by using rabbit albumin as the calibrator for the measurement of rabbit albumin. The opposite is true for birds where avian

albumin binds BG with less affinity, therefore, if a bovine albumin is used as the standard, all avian values will be falsely decreased (Hall, 1992).

The assay of albumin using electrophoresis and protein staining has frequently been used as the reference against which other procedures are judged. However, there is no convincing evidence that the staining intensity is linear to protein concentration.

Immunochemical techniques for albumin determination such as radial immunodiffusion and immunonephelometry are gaining popularity (Peters, 1977). Immunologic cross-reactivity between SA from various species has been studied and correlated with the phylogenetic relatedness between species. Cross-reactivity between human SA and those of several primate species, as well as cross-reactivity among SAs of various domestic and laboratory animals, has been reported (Kamiyama, 1976; Rangel, 1965; Sakata and Atassi, 1979; Sarich and Wilson, 1966; Weigle, 1961). In these studies, rabbit anti-bovine SA antibodies will cross-react most strongly with sheep and goat albumin and less so with pig, horse, rodent, and chicken albumin in decreasing order. A species-specific standard if available should be used. If unavailable, alternative standards can be selected and tested for cross-reactivity or alternatively the protein can be measured by serum protein electrophoresis or the biuret method.

18.3 CORTICOSTEROID-BINDING GLOBULIN

18.3.1 PROPERTIES

Corticosteroid-binding globulin (CBG), or transcortin, a member of the superfamily of serine protease inhibitors, is a plasma carrier protein of obscure biologic function. Human and animal CBGs are α -globulins of similar size. The amino acid composition and carbohydrate content of CBG in rats, rabbits, and guinea pigs have been reported (Chader and Westphal, 1968a, b; Mickelson and Westphal, 1979; Rosner and Hochberg, 1972). Rat and rabbit CBG has more cystine than does human CBG. Cystine is involved in the maintenance of the conformational structure of CBG; therefore, higher cystine content found in rat CBG may be related to its greater tendency to form polymeric structures after removal of corticosterone (Westphal, 1971). The number of corticosteroid-binding sites per molecule of CBG is one in all species tested (Mickelson and Westphal, 1979; Rosner, 1972; Rosner and Hochberg, 1972). The partial amino acid sequence analysis of mouse CBG shows a low overall homology (60%) to human CBG (Nyberg et al., 1990). Sequence homologies between hamster CBG and rat and human CBGs are 70% and 59%, respectively (Lin et al., 1990). Squirrel monkey (*Saimiri sciureus*) CBG has a molecular weight of approximately 42,000 Da and, as expected, shows high sequence identity (86%) with human CBG (Hammond et al., 1994).

CBG, like other glycoproteins, is synthesized mainly in the liver, but a small amount is probably produced in other tissues such as the kidney, lung, and spleen (Allison, 1960; Scrocchi et al., 1993; Seralini et al., 1990). CBG receptors on plasma membranes of a variety of cells have been shown. CBG, when exposed to a serine protease, is cleaved and releases all or most of its bound cortisol (Rosner, 1991).

18.3.2 ROLE/FUNCTION

It is generally accepted that CBG protects the corticosteroids from peripheral metabolism and loss through the kidney, and therefore helps maintain relatively constant plasma corticosteroid levels; however, firm evidence supporting this hypothesis is lacking. CBG has been found in all vertebrate species examined. The CBG binding capacities of 131 vertebrate species have been determined by Seal and Doe (Seal and Doe, 1963, 1965, 1966). A comprehensive review of the CBG of various animal species was made by Westphal (1971).

18.3.3 PATHOPHYSIOLOGICAL SIGNIFICANCE

Normal CBG reference values for practically all vertebrate species have been compiled by Westphal (1971). The female rat has a higher CBG level than does the male; however, there is no change in CBG concentration during estrus or pregnancy (Gala and Westphal, 1965a, b; Grunder, 1966). The CBG activity of female mice is three times that of the male. In contrast to that in rats, pregnancy in mice results in a 13-fold increase in CBG activity (Gala and Westphal, 1967). This increase during pregnancy is also observed in the rabbit, guinea pig, and hamster (Gala and Westphal, 1967; Lin et al., 1990). The rise in guinea pig plasma CBG during gestation is as dramatic as that seen in the mouse, with peak values of 900 μg of CBG/mL of plasma (compared to 75–155 μg /mL in nonpregnant animals) (Goodman et al., 1981). Pregnant baboons have only a moderate increase in CBG during pregnancy (59 ± 6.4 μg of cortisol/100 mL of plasma in pregnant animals compared to 33.4 ± 5.5 μg /100 mL in nonpregnant animals) (Oakey, 1975). The CBG levels in fetuses are higher than those in neonates, and newborn animals have much lower levels of CBG than do adults (Ballard et al., 1982; Beamer et al., 1973; D'Agostino and Henning, 1982). The development and synthesis of CBG are probably regulated through the pituitary-adrenal and pituitary-thyroid axes (Ballard et al., 1982; D'Agostino and Henning, 1982; Rosenthal et al., 1974; Sakly and Koch, 1983). Estrogen administration caused a marked increase in CBG activity in rats and monkeys (Barbosa et al., 1970; Cody, 1980; Coe et al., 1986). This effect was not observed in hypophysectomized rats, suggesting that thyroid-stimulating hormone is involved in the estrogen effect, because it is the only pituitary hormone that influences CBG activity. Conversely, testosterone administration depresses CBG activity in the rat. Testosterone also depresses CBG activity in monkeys, though not significantly (Barbosa et al., 1971). Testosterone did not seem to have a depressive effect on CBG in badgers (Audy et al., 1982). In Peking ducks, in which males have higher CBG levels than do females, testosterone was found to stimulate CBG production without altering thyroxine levels (Daniel et al., 1981).

Diurnal variations in CBG levels have been observed in the guinea pig, rat, and mouse. The guinea pig has a maximum CBG binding capacity at 1600 hours (9 hours of light per day cycle, and lights on at 0800 hours) and the lowest binding capacity at 1200 and 2400 hours (Fujieda et al., 1982). Biphasic circadian rhythm for CBG has been observed in the rat. D'Agostino et al. (1982) observed two distinct peaks, one during the light phase and the other during the dark phase, which were sustained for almost the entire dark period. Other investigators (Ottenweller et al., 1979) found both peaks in the light period. The CBG rhythm in the mouse is monophasic, with peak levels found during the dark phase (Ottenweller et al., 1979).

Pathologic variations in CBG levels in man have been reviewed (Brien, 1981). Altered values have been reported in liver disease, nephrosis, and other protein-losing conditions, thyroid disease, adrenal diseases (including Cushing's syndrome and Addison's disease), mental illness, and stress. Sows and gilts subjected to stress (heat and crowding) during midgestation had lower CBG levels (Kattesh et al., 1980). Acute inflammation induced by subcutaneous injection of turpentine produced an average threefold decrease in serum corticosterone and CBG levels in both pregnant and nonpregnant rats (Savu et al., 1980). CBG may represent one of the "negative" acute phase proteins like transferrin and albumin.

18.3.4 ANALYTICAL METHODS

Plasma CBG can be measured indirectly by determining the cortisol or corticosterone-binding capacity, and is expressed as micrograms of cortisol or of corticosterone per 100 mL of plasma. The most commonly used methods for indirect measurement are equilibrium dialysis, competitive binding analysis, and gel filtration (Westphal, 1971). The CBG can be measured directly

using radial immunodiffusion (Van Baelan and De Moor, 1974) and radioimmunoassay (Bernutz et al., 1977). The results obtained by homologous radioimmunoassay for rat CBG were consistently 0.25 μM lower than those obtained by the steroid-binding method (Ramoure and Kuhn, 1983). Chemical alterations of the protein and radioisotope decay are inherent problems in the radioimmunoassay for guinea pig CBG (Rosenthal et al., 1974). The CBG concentrations calculated by radial immunodiffusion are in good agreement with estimates made by equilibrium dialysis (Goodman et al., 1981).

18.4 GROUP-SPECIFIC COMPONENT

18.4.1 PROPERTIES

Gc was first discovered in human serum by Hirschfeld in 1959 (Hirschfeld, 1959). It is an α_2 -globulin with an electrophoretic mobility similar to but distinct from that of haptoglobin. The protein was later isolated and characterized, and its amino acid composition was determined by various investigators (Cleve et al., 1963; Simons and Bearn, 1967). The total amino acid composition and molecular weight of the major human Gc phenotypes are very similar. They have a molecular weight of about 50,800 Da and appear to be a single polypeptide chain. Gc in various animal species, including primate, cattle, pig, horse, rodent, and rabbit, has also been reported (Ashton, 1963b; Cinader and Dubinski, 1963; Cleve and Patutschnick, 1979; Reinskou, 1968; Weitkamp, 1978). Mouse and rat Gc have been well characterized, and their amino acid sequences have been determined (Yang et al., 1990; Borke et al., 1988; Yamamoto et al., 1997). Their molecular weights are estimated at 49,000 and 52,000 Da, respectively. The amino acid sequence of mouse Gc is 78% identical to human and 91% identical to rat Gc.

Variants of human Gc are controlled by some 30 different alleles (Constans, 1976), but the three most common phenotypes are Gc 1-1, Gc 2-1, and Gc 2-2, controlled by codominant alleles Gc 1 and Gc 2. Gc 1 consists of two suballeles, Gc 1F (fast) and Gc 1S (slow) (Cleve and Patutschnick, 1979). Antiserum specific to human Gc was found to cross-react with serum from horse, cow, rhesus monkey, chimpanzee, goat, sheep, rat, and mouse (Daiger et al., 1975; Reinskou, 1968), but not with rabbit and guinea pig serum (Courtoy et al., 1981a). In many species, Gc appears as single-band components on electrophoresis. However, genetic polymorphism of Gc has been observed in cattle (Ashton, 1963b), mouse (Cinader and Dubinski, 1963), horse (Weitkamp, 1978), and primate (Cleve and Patutschnick, 1979). In the horse, Gc polymorphism is apparently under the control of two autosomal codominant alleles, with three different phenotypes found in standard bred, thoroughbred, and Arabian horses as well as the Shetland pony (Weitkamp, 1978). Kitchin and Beam (1965) studied Gc polymorphism in chimpanzees, orangutans, rhesus monkeys, and a gorilla, and found genetic variations only in orangutans. Cleve and Patutschnick (1979) observed two phenotypes in a group of 78 chimpanzees and postulated that two alleles controlled the genetic variation in chimpanzee Gc. Two phenotypes, Gc pan 1-1 and Gc pan 2-1, were found, but the third phenotype, Gc pan 2-2, was not observed.

18.4.2 ROLE/FUNCTION

The Gc system has been used for individual identification and parentage exclusion. Gc has affinity for actin and is known to bind vitamin D and its metabolites (Constans, 1992; Daiger et al., 1975; Daiger and Cavalli-Sforza, 1977; Rodriguez et al., 1997). Additionally, Gc may have a function in vitamin D transport and may also act as a buffer to prevent the toxic effects of vitamin D at the tissue level (Daiger et al., 1975). Data collated by Goldschmidt-Clermont et al. (1988) suggest a crucial role for Gc in the sequestration and clearance of released cellular actin. The biologic function of Gc is largely unknown.

18.4.3 PATHOPHYSIOLOGICAL SIGNIFICANCE

Increased levels of Gc were observed in subjects with asthma, therefore the neutralization of the Gc protein could be a therapeutic strategy for asthma (Lee et al., 2011). Also, Gc complexes are drastically increased where tissue necrosis is present, such as in hepatic failure (Goldschmidt-Clermont et al. 1988).

18.4.4 ANALYTICAL METHODS

Demonstration and quantitation of Gc components can be conducted using various methods, such as electrophoresis, isoelectrofocusing, and immunoprecipitation (Constans, 1976; Reinskou, 1968). High doses of vitamin D, hemolysis, and bacterial contamination may induce modification of the Gc electrophoretic pattern (Constans, 1976).

18.5 HAPTOGLOBIN (SEROMUCOID α_2)

18.5.1 PROPERTIES

Haptoglobin (Hp) was first identified in 1939 as a serum component responsible for enhancing the peroxidase activity associated with hemoglobin (Hb) (Polonovski and Jayle, 1939). It is a serum α_2 -glycoprotein present in man and animals that can bind free Hb, forming a stable complex. This complex has a pink color and can be visualized after electrophoresis or chromatography. Hp is synthesized in the liver and has a plasma half-life of about 3 days (Koj, 1974). Hp appears to exhibit little species specificity in binding to Hb. Human Hp can bind Hb from numerous animals; however, very distantly related Hbs only bind weakly (Cohen-Dix et al., 1973; Makinen et al., 1972). Chicken Hp has a narrow specificity and binds only avian and reptilian Hb (Musquera et al., 1979).

Human Hp has a tetrachain structure with two α chains and two β chains. The α and β chains are covalently linked by disulfide bonds (Kurosky et al., 1980). The covalent disulfide linking of the α and the β chains is observed in most mammals, except in the dog and probably other carnivores, where the two chains are joined by noncovalent interaction (Mominoki et al., 1995). The Hp β subunit shows substantial homology to the chymotrypsinogen family of serine proteases. Evolution from a common ancestral molecule is suggested; however, no proteolytic activity remains in the case of Hp (Kurosky et al., 1980).

The dissociation of Hb tetramers into dimers is a prerequisite for binding to Hp. This suggests that the $\alpha_1\beta_2$ contact region between Hb dimers is the binding site for Hp (Benesch et al., 1976; Makinen et al., 1972). Evidence has also been presented that Hb binds to Hp as intact $\alpha_1\beta_1$ dimers and that the primary region of Hb involved in the intermolecular contact is the $\alpha_1\beta_2$ interface (Hwang and Greer, 1980). Binding sites on the Hb α - and β -subunit interacting surfaces have been localized (Kazim and Atassi, 1981; Yedgar et al., 1983; Yoshioka and Atassi, 1986).

Hp has been found in the sera of all vertebrates studied (Javid, 1978; Putman, 1975a). Hp isolated from most nonhuman species resembles human Hp 1 on gel electrophoresis and appears as a single component. Hp forms similar to human Hp 2 and Hp 2-1 have been observed in members of the Bovidae and Cervidae families, such as goat, sheep, and cattle (Bradshaw et al., 1985; Ritter and Smith, 1971; Runnegar et al., 1997; Tranz et al., 1975; Van Der Walt and van Jaarsveld, 1978). Despite an extensive search in several species of nonhuman primates (Blumberg, 1960; Shim and Bearm, 1965), dogs (Shifrine and Stortmont, 1973), rabbits (Grunder, 1966), and swine (Kristjansson, 1961), there is no convincing evidence that polymorphism exists in any animals other than man (Bowman and Kurosky, 1982; Buettner-Janusch, 1970). Other variations in the Hp structure have been observed in the chicken and dog. Chicken Hp is composed of only two chains with a molecular weight of 3,000 and 54,000 Da (Lombart et al., 1979).

18.5.2 ROLE/FUNCTION

One known function of Hp is to protect the kidneys from tissue destruction by binding free Hb after hemolysis (Bowman and Kurosky, 1982). The formation of Hp-Hb complexes may also be beneficial by decreasing the availability of Hb iron to support bacterial growth at sites of septic inflammation (Eaton et al., 1982; Murata et al., 2004; Mahmud et al., 2007). Another possible role of Hp is stimulation of angiogenesis (Cid et al., 1993).

Hb binds to the β chain of Hp, and the α chain does not directly participate in the binding (Bowman and Kurosky, 1982; Gordon and Beam, 1966). The stable Hp-Hb complex, once formed in the blood stream following hemolysis, is rapidly cleared from the plasma and accumulates in the liver. When cats were injected intravenously with Hb in quantities sufficient to bind all circulating Hp, unbound Hp was not present after 3 hours, and the Hp-Hb complexes were cleared in as little as 6 hours (Harvey and Gaskin, 1978). Studies using solubilization and assay of the hepatic receptor for the Hp-Hb complex suggest that the carbohydrate moiety of haptoglobin did not appear to participate in the binding of the Hp-Hb complex to its receptors (Lowe and Ashwell, 1982). These complexes are also beneficial as they decrease the availability of hemoglobin iron that supports bacterial growth at sites of septic inflammation (Parra et al., 2005; Mahmud et al., 2007). The complexes are recognized and scavenged via CD163, the specific surface receptor on macrophages and scavenged by phagocytes. The immunomodulation is partly mediated through binding of haptoglobin to the CD11/CD18 receptor of effector cells (Murata et al., 2004). Hp also inhibits prostaglandin synthesis by blocking catalytic effect of the heme moiety of hemoglobin on the cyclooxygenase enzymes. Furthermore, haptoglobin may also have an important role in the host defense to infections and neoplasms by withholding iron from invading pathogens and tumor cells, by modulating angiogenesis and other local inflammatory processes (Mahmud et al., 2007).

Hp is a major extracellular protein that protects against protein misfolding and assisting in the preservation of cell function. It is elevated in pregnancy, myocardial infarction, and obesity as these conditions are characterized by tissue growth and repair that require anti-inflammatory responses (Quaye, 2008).

18.5.3 PATHOPHYSIOLOGICAL SIGNIFICANCE

Genetic studies showed that Hp polymorphism in man is controlled by three codominant alleles coding for the α chain, that is, Hp α 1F (fast), Hp α 1S (slow), and Hp α 2. These three major alleles are responsible for the six common phenotypes observed (Smithies et al., 1962). Other rare variants of human Hp have also been reported (Bowman and Kurosky, 1982). The simplest phenotypic form, Hp 1-1, is monomeric, whereas phenotypes Hp 2-1 and Hp 2-2 are polymeric and appear as several bands on electrophoresis. Complete amino acid sequences of the α - and β -chains of human haptoglobin type 1-1 have been determined (Kurosky et al., 1980). In humans, haptoglobin is expressed by a genetic polymorphism as three phenotypes: Hp1-1, Hp2-1, and Hp2-2 (Burbea et al., 2004). Structural and functional differences between the three major Hp phenotypes have been demonstrated to have biological consequences, such as hemoglobin binding and antioxidative activity. Purified Hp2-2, *in vitro*, shows less inhibition of hemoglobin-induced oxidation of low-density lipoprotein than purified Hp1-1, which indicates that Hp2-2 has lower antioxidative activity than Hp1-1 and Hp 2-1. As the neutralization activity of Hp2-2 is weaker than that of the other Hp phenotypes, concentrations of free nonhaptoglobin bound hemoglobin are increased in this phenotype (Lee et al., 2004; Mahmud et al., 2007; Quaye, 2008). Hp is synthesized in the liver during granulocyte differentiation and stored for release when neutrophils are activated. It has a plasma half-life of approximately 3 days and appears to exhibit little species specificity in binding to hemoglobin (Quaye, 2008).

TABLE 18.2
Normal Haptoglobin Levels of Some Animal Species

Species	Serum Haptoglobin		References
	mg/100 mL of Serum	mg Hb bound/100 mL of Serum	
African green monkey (<i>Cercopithecus aethiops</i>)	—	21–105	Barbosa et al. (1973)
Cattle	— 2.2–4.7	0–50 —	Bremner (1966) Salonen et al. (1996)
Rabbit	10–30	—	Lombart et al. (1965)
Rat			
Unspecified	10–30	—	Lombart et al. (1965)
Unspecified	30–60	—	Akaiwa (1982)
Unspecified	50	—	Courtoy et al. (1981b)
Sprague-Dawley	100	—	Baglia et al. (1981)
Mouse—DBA/2	—	50–150	Peacock et al. (1967)
	—	45–55	Palmer (1976)
Dog	—	14–252	Harvey (1976)
Cat	—	31–216	Harvey (1976)
Horse	—	19–177	Harvey (1976)

Amino acid compositions of dog, rat, and rabbit Hps have also been reported (Hanley et al., 1983; Kurosky et al., 1979; Lombart et al., 1965). Strain-dependent variation in Hp concentration was reported among 11 strains of mice examined (Peacock et al., 1967). The DBA/2 and AKR strains represent the extremes of this variation, with serum Hp levels of 50–150 and 5–10 mg of hemoglobin-binding capacity (HbBC) per 100 mL, respectively. No reports were found regarding gender-related differences in Hp levels in animals. In contrast to the unchanged concentration reported in pregnant women, Hp was increased in pregnant C57BL/10 mice (Waites et al., 1983). The increase was of greater degree and duration in allogeneic than in syngeneic pregnancy. Levels returned to normal by 8 days postpartum (Waites et al., 1983). Age also has an effect on baseline levels in mice. Normal Hp levels of some animal species are listed in Table 18.2.

Baseline Hp levels in human serum are influenced by genetic factors, gender, and age (Putman, 1975a; Sutton, 1970). Hp is one of the major acute-phase reactants (Koj, 1974). Concentrations in serum increase during inflammation and decrease after hemolysis. Raised levels are noted with acute or chronic inflammatory conditions and with neoplastic disease. Absence or a low level of Hp indicates hemolysis or severe liver diseases (Grant and Kachmar, 1976).

In animals, changes in Hp levels associated with various pathologic processes are similar to those seen in humans. Decreased Hp levels were documented in cats with experimental and spontaneous hemolytic anemias (Harvey and Gaskin, 1978) and in some rats with induced hepatic cirrhosis (Courtoy et al., 1981a). Increased concentrations are seen in bacterial and viral infections, inflammatory conditions (Cid et al., 1993; Eckersall et al., 1996; Francisco et al., 1996; Godson et al., 1996; Salonen et al., 1996), and tissue injuries, including those caused by irradiation (Magic et al., 1995). Absence or a low level of Hp indicates hemolysis or acute hepatocellular damage (Grant and Kachmar, 1976). In newborn DBA/2 mice, serum Hp was about 50% of the adult levels (Polonovski and Jayle, 1939). The levels then dropped quickly and remained at only 10%–30% of the adult range during the first 2 weeks of life.

18.5.4 ANALYTICAL METHODS

Dog Hp under standard gel electrophoretic conditions appears similar to human Hp 1 in both charge and size, with a molecular weight of approximately 100,000 Da. However, under denaturing

conditions employing 6 M urea or 0.1% sodium lauryl sulfate, the molecular weight is that of a Hp $\alpha\beta$ subunit, which is 48,500 Da (Kurosky et al., 1979). Hp typing by vertical electrophoresis conducted on 47 blood samples from three breeds of dogs (Doberman, German shepherd, and pit bullterrier) revealed two common phenotypes that could not be used to differentiate among them (Harrington et al., 1991).

Several methods for purifying and quantitating serum Hp have been described. The quantitating procedures include measuring enhancement of peroxidase activity, changes in electrophoretic mobility, rivanol precipitation, and immunochemical techniques (Young et al., 1995). In most methods, an excess of Hb is added to the serum to saturate the Hp. The amount of Hp-Hb complex is then estimated by peroxidase activity. The complex can also be separated from free Hb by electrophoresis or gel filtration, and the proportion of Hb bound to Hp is then calculated. Immunotechniques may be complicated, depending on the heterogeneity and the degree of polymerization of Hp. Immunochemical methods that have been used to measure Hp in animals include rocket electroimmunoassay (Palmer, 1976; Voelkel et al., 1978), immunonephelometry (Courtoy et al., 1981b), enzyme linked immunosorbent assay (ELISA) (Baker, 1967; Mominoki et al., 1995), radial immunodiffusion (Baglia et al., 1981), and fluoroimmunoassay using monoclonal antibodies (McNair et al., 1995). A high-performance liquid chromatography (HPLC) method has also been described (Salonen et al., 1996). Some degree of interspecies cross-reactivity does occur. Antiserum against human Hp was found to produce clear rockets when used in electroimmunoassay to measure rabbit (Voelkel et al., 1978) and mouse (Waites et al., 1983) haptoglobin. Hemolysis in samples does not affect Hp estimation, but hyperlipidemia may give high results (Bowman and Kurosky, 1982; Grant and Kachmar, 1976).

18.6 HEMOPEXIN

18.6.1 PROPERTIES

Hemopexin (Hx) is a β -glycoprotein and is synthesized by the liver. Human and rabbit Hx have been found to be very similar (Hrkal and Muller-Eberhard, 1971; Seery et al., 1972). They both have a molecular weight of approximately $57,000 \pm 3,000$ Da and appear to consist of a single polypeptide chain. The carbohydrate content is about 20% and consists of sialic acid, mannose, galactose, and glucosamine. The amino acid composition of both human and rabbit Hx has been determined (Hrkal and Muller-Eberhard, 1971), and complete amino acid sequence of human Hx has been reported (Takahashi et al., 1985b). Pig Hx has been isolated in almost pure form and has a molecular weight ranging from 57,000 to 62,000 daltons (Majuri, 1982; Van Gelder et al., 1995). Mouse Hx was reported as a β -2-III globulin with a molecular weight of approximately 65,000 Da (Witz and Gross, 1965). Bovine Hx migrates as a β_1 -globulin (Bremner, 1966). Rat and guinea pig heme-Hx complexes have also been reported to migrate with β -globulins (Hughes-Jones et al., 1961). Rhesus monkey Hx purified by the wheat-germ lectin-sepharose method has a molecular weight of 60,000 Da (Foidart et al., 1982). Sheep Hx has a molecular weight of 56,000 Da, and its chemical composition has been reported (Stratil et al., 1984a).

Studies on the immunologic cross-reactivity of serum Hx from 64 vertebrates representing many different phylogenetic orders revealed that many antigenic determinants are shared by the Eutherian mammals but not by the non-Eutherian mammals and lower animals. The Hx of apes and man appears to be identical (Cox et al., 1978). Rat Hx shows a 76% amino acid sequence homology with human Hx (Nikkila et al., 1991).

18.6.2 ROLE/FUNCTION

During intravascular hemolysis, Hb is released into the circulation and cleared by glomerular filtration or hepatocellular uptake. Hp, albumin, and Hx are the three plasma proteins associated with the

transport of circulating Hb and heme (heme in this discussion is defined as ferriprotoporphyrin IX). In man, haptoglobin binds Hb but not heme, and Hx and albumin bind heme but not Hb (Hershko, 1975; Muller-Eberhard, 1970, 1978). Mouse Hx has been reported to bind both heme and Hb (Witz and Gross, 1965).

The Hx molecule has two non-disulfide-linked domains, an N-terminal domain (domain I) that binds heme, and a C-terminal domain (domain II) that does not (Wu and Morgan, 1995). Hx binds heme specifically and carries circulating heme to the liver for uptake and breakdown (Muller-Eberhard, 1978; Wu and Morgan, 1995). Radiolabeled heme-Hx complex given intravenously was found exclusively in the liver parenchymal cells, whereas spleen, kidney, lung, and bone marrow cells remained free of radiolabeled material. This finding suggests that plasma heme is eliminated as a heme-Hx complex by the hepatocyte (Lane et al., 1973; Muller-Eberhard et al., 1970). It appears that the delivery of heme to the liver cells is a receptor-mediated process and that Hx is degraded or returned intact into the circulation, depending on the physiological conditions (Potter et al., 1993; Wu and Morgan, 1995). Hx has also been found in neurons and glial cells, and it is believed to play a role in neuronal iron homeostasis (Morris et al., 1993).

18.6.3 PATHOPHYSIOLOGICAL SIGNIFICANCE

Genetic polymorphism of Hx has been described in rabbits, pigs, and sheep. Studies in rabbits (Grunder, 1968; Hagen et al., 1978) suggest that rabbit Hx is controlled by four codominant autosomal alleles and that the Hx locus is located between the color locus (c) and the Hq blood group locus (Linkage Group I). American and European pigs are reported to have a Hx system under the control of seven alleles (Hpx^o, Hpx¹, Hpx^{1F}, Hpx², Hpx³, Hpx^{3F}, and Hpx⁴) (Baker, 1967, 1968). A new allele, Hpx⁵, was described in East Asian pigs (Ohmini miniature pigs) (Oishi et al., 1980). The Hpx locus in pigs appears to be linked to the K blood group system (Andersen, 1966; Hagen et al., 1968). In sheep and probably goats, Hx is genetically controlled from a single locus by two codominant alleles, and three phenotypes, Hpx A, Hpx AB, and Hpx B, have been described (Stratil et al., 1984a).

The normal plasma concentration of Hx in New Zealand white rabbits is 31–52 mg/100 mL (Lane et al., 1973). As in humans, neonatal rabbits have much lower levels of Hx than adults, and adult rabbit Hx values are reached at about 30–60 days of age (Muller-Eberhard, 1970). Rhesus monkeys have serum Hx levels of 53.3 ± 2.8 U/100 mL (1 unit represents the amount of monkey Hx equivalent to 1.0 mg/mL of human serum) (Foidart et al., 1982).

In man, decreased serum levels of Hx are associated with severe hemolytic diseases or fulminant rhabdomyolysis (Adornato et al., 1978a; Muller-Eberhard et al., 1968; Sears, 1968). Increased Hx levels have been observed in certain heme deficiency and chronic neuromuscular diseases in which small amounts of heme are released from increased circulating myoglobin (Adornato et al., 1978b; Lamon et al., 1978). The most important factor controlling the plasma level of Hx is heme (Muller-Eberhard et al., 1968; Sears, 1968). Unlike haptoglobin and other acute phase reactants, Hx levels are rarely and only minimally affected by nonspecific stimuli such as acute inflammation, connective tissue disease, surgical procedures, and fractures. Hyperoxia has been shown to induce the expression of Hx gene in the liver in vivo (Kietzmann et al., 1995; Nikkila et al., 1991). Serum Hx is probably a more reliable measurement of the severity of hemolysis than haptoglobin or other acute phase reactants (Kusher et al., 1972).

Experiments in calves, however, have shown that turpentine injection produced a marked increase in plasma Hx (Bremner, 1966). The same investigator also reported the disappearance of Hx from the plasma of calves during the hemolytic crisis of babesiosis. In rabbits receiving varying amounts of heme, the level of Hx was lowest 4–6 hours after injection. Thereafter, plasma Hx concentration rose slowly in rabbits injected with large amounts of heme. These observations suggest that the administration of heme may stimulate Hx synthesis, mobilize it

from the extravascular site, or both (Muller-Eberhard et al., 1969). Heterologous Hxs from rabbits and man maintain the heme transport function when injected into rats (Liem, 1976). In the rhesus monkey, small doses of heme administered intravenously elevated serum Hx to 150% of control levels with a 76% increase in the net rate of Hx synthesis, whereas large doses of heme caused a 60% decrease in the serum Hx level, and intermediate doses of heme produced no change in the circulating Hx levels (Foidart et al., 1982). The changes observed following heme administration appeared to be specific for Hx, because serum haptoglobin and transferrin levels were unaffected by heme administration.

18.6.4 ANALYTICAL METHODS

Several methods for Hx purification and serum level determination, including preparative electrophoresis, affinity and ion-exchange chromatography, rivanol precipitation, immunoelectrophoresis, and immunodiffusion, have been described (Foidart et al., 1982; Hrkal and Muller-Eberhard, 1971; Majuri, 1982; Takahashi et al., 1985a; Van Gelder et al., 1995).

18.7 THYROID HORMONE-BINDING PROTEINS

18.7.1 PROPERTIES

In plasma, there are three proteins that regulate the circulation of thyroid hormones: (a) thyroxine-binding globulin (TBG), the most important and transports the major part of T_4 in most animals; (b) thyroxine-binding prealbumin (PA) (see TTR); and (c) SA, which usually plays a minor role in thyroid hormone transport (see albumin). In addition, lipoproteins also carry minor quantities of thyroxine, but their importance is unknown. These serum proteins may store thyroxine in a nondiffusible form in the extrathyroidal space, and they may serve to carry thyroxine from the circulation to target cells (Cody, 1980; Horn and Gartner, 1979; Robbins et al., 1978).

Human TBG is a single polypeptide chain with a molecular weight of 54,000–63,000 Da (Horn and Gartner, 1979; Robbins et al., 1978). It is an acidic inter- α -globulin rich in sialic acid and shares a high degree of homology with two serpin antiproteases, alpha-1-antichymotrypsin and alpha-1-antitrypsin (Bartalena et al., 1992). Bovine TBG has a molecular weight of 54,000 Da and a carbohydrate content similar to that of human TBG (Van Der Walt and van Jaarsveld, 1978). TBG is synthesized by the liver (Glinoe et al., 1970, 1977a).

18.7.2 ROLE/FUNCTION

In man, TBG is responsible for the transport of 75% of the thyroxine, thyroxine-binding prealbumin (TBPA) 15%, and albumin, despite its abundance in plasma, transports only about 10% of the plasma thyroxine.

TBG has the highest affinity for T_4 and binds most of the circulating T_4 , with over one-third of the binding sites on the protein occupied.

18.7.3 PATHOPHYSIOLOGICAL SIGNIFICANCE

In the rhesus monkey, the serum TBG concentration is approximately 20 $\mu\text{g/mL}$, and the synthesis rate of TBG in the rat is approximately 2 mg/day/kg of body weight (Glinoe et al., 1979; McGuire et al., 1982). The biologic significance of a given serum TBG concentration is not completely understood.

In humans with normal thyroid function, the T_4 /TBG ratio remains constant. Elevation in the T_4 /TBG ratio is found in hyperthyroidism, and a decreased T_4 /TBG ratio is seen in hypothyroidism (Horn and Gartner, 1979). Abnormalities in thyroxine-binding proteins must be suspected when abnormally elevated or diminished total thyroid hormone concentrations are encountered in clinically euthyroid subjects to avoid misinterpretation of the thyroid condition (Bartalena and Robbins, 1993). Many xenobiotics such as dioxan and polychlorinated biphenyls (PCBs) alter the binding of T_4 to carrier proteins. PCBs, specifically 3, 4, 3', 4' tetrachlorobiphenyl, bind to and displace rat T_4 from TTR but not albumin (Brouwer, 1989; McKinney and Waller, 1994; Rickenbacher et al., 1986).

18.7.4 ANALYTICAL METHODS

With the use of agarose gel electrophoresis, rhesus monkey T_4 may be found bound to the inter-alpha, PA, and albumin zones; T_3 is bound to the interalpha and albumin zones only. The inter-alpha protein in rhesus monkey migrates slightly more slowly than does human TBG. Baboon and chimpanzee have thyroxine-binding patterns similar to those of rhesus monkey, but TBPA and its polymorphic variations have only been seen in mandrills and macaques (Farer et al., 1962; Refetoff et al., 1970; Weiss et al., 1971). In the dog and cat, T_4 is bound to the interalpha and albumin zones, and there is no binding to a PA area. In the mouse, T_4 is bound to albumin and α -globulin; however, there appears to be some interstrain variation in the electrophoretic mobility of these proteins. Mouse TTR does not bind T_4 . In the rat, T_4 is bound to TTR and albumin. Postalbumin TBG was reported by some investigators (Davis et al., 1970) but not confirmed by others (Farer et al., 1962; Refetoff et al., 1970; Shutherland and Brandon, 1976). TTR in the rat was found to be the major T_4 transport protein, carrying 55% of the total T_4 compared to 15% and 18% by albumin and TBG, respectively (Davis et al., 1970). Rabbit T_4 binds similarly to albumin and postalbumin, and a small amount is also bound to TTR (271). In the guinea pig, thyroxine seems to be associated only with albumin. In cattle, sheep, and goat, T_3 and T_4 are bound in postalbumin and albumin zones. In the horse and chicken, a PA zone (in addition to the albumin and postalbumin zones) is also found to bind T_4 (Farer et al., 1962; Refetoff et al., 1970). In many animal species, the thyroxine carrier proteins reported in the literature are unspecific and poorly characterized, and TBG probably does not exist in a number of species, including the cat, rat, rabbit, frog, and chicken (Larsson et al., 1985).

TBG may be isolated and purified using immunoprecipitation, affinity chromatography (throxine-coupled agarose), anion-exchange chromatography, and gel filtration. Serum TBG concentrations can also be measured using radioimmunoassay methodology (Glinoyer et al., 1977b, 1979; Horn and Gartner, 1979).

18.8 TRANSFERRIN

18.8.1 PROPERTIES

Transferrin (formerly called siderophilin), the major component of β -globulin, is the iron-transporting protein of plasma. The molecular weight of human transferrin ranges from 75,000 to 80,000 Da, as estimated by sedimentation equilibrium and diffusion (Mann et al., 1970; Roberts et al., 1966). The molecular weight of most animal transferrin also falls within this range, whereas turtle and hagfish transferrin have molecular weights of 92,000 and 44,000 Da, respectively (Hudson et al., 1973; Palmour and Sutton, 1971; Schreiber et al., 1979; Spooner et al., 1974; Van Gelder et al., 1995).

The structure and composition of transferrin have been studied in several species. Generally, it is a glycoprotein consisting of a single peptide chain with a varying number of heteropolysaccharide units attached to it (Aisen and Brown, 1977; Greene and Feeney, 1968; Hudson et al., 1973; Palmour and Sutton, 1971; Richardson et al., 1973). Rabbit transferrin was reported to contain two heterosaccharide units per molecule by some investigators (Hudson et al., 1973), and only 1 U by

others (Heaphy and Williams, 1978; Leger et al., 1978). Most serum transferrin molecules in the rabbit contain two sialic acid residues. Transferrin isolated from rabbit milk appears to be identical to serum transferrin, except that most milk transferrin molecules contain only one sialic acid residue (Baker et al., 1968). Analysis of pooled plasma from 116 rats revealed that one third of the total transferrin contains three moles of sialic acid, and two-thirds contain 2 mol of sialic acid per mole of transferrin (Schreiber et al., 1979). The N-terminal sequences of rabbit and rat transferrins show clear homology with human transferrin (Heaphy and Williams, 1978; MacGillivray et al., 1977; Schreiber et al., 1979).

Sheep transferrin has an amino acid composition similar to that of cattle. Individual components of two variants of sheep transferrin containing three to four sialic acid residues have been isolated. However, there is no evidence for pairs of bands with the same number of sialic acid residues, as seen in cattle (Spooner et al., 1974). Transferrin in carp (*Cyprinus carpio* L.) contains no sialic acid (Valenta et al., 1976). The sialic acid content may be of importance in transferrin catabolism. The catabolic rate of asialotransferrin in rabbits was found to be higher than the corresponding value for normal transferrin (Regoeczi et al., 1974).

Although transferrin may be synthesized by tissues other than the liver, such as testes, lung, brain, hematopoietic, and mammary tissues, the liver is the major site of transferrin synthesis in adult animals (Bradshaw et al., 1985; Focht et al., 1997; Idzerda et al., 1986; Meek and Adamson, 1985; Yang et al., 1997). In the rat and rabbit, the rate of transferrin production is about 95 and 27 mg/kg of body weight per day, respectively. In the rat, the rate of transferrin synthesis is one-fifth the rate of albumin synthesis (Morgan and Peters, 1971a). In mouse embryos, transferrin can be detected by immunoperoxidase staining in the egg cylinders from the seventh day of gestation onward and in the visceral yolk sac at all gestational stages (Adamson, 1982). Thus, transferrin can be produced by both mature and immature hepatocytes. Fasting decreases transferrin synthesis, while reduced ambient temperature increases it (Gardiner and Morgan, 1981).

Precise information about the site of transferrin catabolism is unavailable. It is probably taken up by the cells of many tissues and enzymatically degraded intracellularly (Aisen and Brown, 1977). Studies of transferrin turnover in 11 mammalian species showed that the turnover rate closely correlated with species size (Regoeczi and Hatton, 1980).

18.8.2 ROLE/FUNCTION

Each transferrin molecule has two active sites for iron binding, with the exception of hagfish transferrin, which has only one (Palmour and Sutton, 1971). Sequence studies of human and rabbit transferrin polypeptide chains revealed two regions of internal homology (MacGillivray et al., 1977; Strickland and Hudson, 1978). This internal homology reflects a doubling of an ancestral structural gene responsible for the production of a transferrin with two metal-binding sites from a precursor with a single metal-binding site (MacGillivray et al., 1977). There are definite physicochemical differences between the two iron-binding sites (Aisen et al., 1978; Delaney et al., 1982); however, it is unclear whether functional differences exist. Several investigators have observed functional heterogeneity of the two iron-binding sites (Awai et al., 1979; Baarlen et al., 1980; Fletcher and Huehns, 1968), whereas others have not (Delaney et al., 1982; Hudson et al., 1973; Young, 1982).

Transferrin carries iron from cells involved with the absorption or storage of iron to cells that utilize iron, as in Hb synthesis (erythroblasts and reticulocytes), the incorporation into cytochromes involved with electron transfer, or as a component of an enzyme system. Transferrin may also play a role in the regulation of iron absorption in the intestine (Forth and Rummel, 1973; Huebers et al., 1982, 1983). More recently, it has been suggested that transferrin may serve as a physiologic regulator of granulocyte maturation (Evans et al., 1986). It is now generally accepted that transferrin is transported across the cell membrane by receptor-mediated endocytosis (Runnegar et al., 1997).

Transferrin receptors on reticulocyte and hepatocyte membranes in rat, rabbit, and mouse have been studied extensively (Van Der Heul et al., 1982; Goodman et al., 1965; Kamiyama, 1976; Massolini et al., 1996; Van Gelder et al., 1995; Weiss et al., 1971). Transferrin receptors of rabbit mammary gland cells and placenta have also been described (Ballard et al., 1982; Moutafchicv et al., 1983; Navab et al., 1977b).

18.8.3 PATHOPHYSIOLOGICAL SIGNIFICANCE

Transferrin polymorphism has been observed in man as well as many animal species (Buettner-Janusch, 1970; Giblett et al., 1959; Giblett, 1969). In man, at least 18 genetic variants have been described; however, only 28 phenotypes have been observed (Giblett, 1969). All genetic variants appear to be compatible with good health. In animals, transferrin polymorphism has been observed in many species, including nonhuman primates, cattle, sheep, swine, fish, and toad. Of the nonhuman primates, the chimpanzee has the greatest variation of transferrin phenotypes, while a remarkable number of variants are observed in baboons and macaques. The genus *Macaca* has at least 11 variants; of the 66 possible phenotypes, 34 have been described (Goodman et al., 1965). The transferrins of prosimians are extremely complex, particularly in lemurs, where 22 alleles are described. Some monkeys, such as the *Erythrocebus patas*, appear to have no transferrin variants (Buettner-Janusch, 1970). Certain transferrin variants such as Tf-D and Tf-G in rhesus monkeys may be responsible for or associated with lower infant growth rates and decreased fertility (Smith, 1982).

In cattle, transferrin polymorphism is under the control of four alleles: Tf^A, Tf^{D1}, Tf^{D2}, and Tf^E (Ashton, 1963a; Kristjansson and Hickman, 1965; Smithies and Hickman, 1958; Spooner and Baxter, 1969). In addition, polymorphic variation in the amount of sialic acid attached to bovine transferrin is believed to be controlled by a recessive epistatic gene with two alleles: Tfs A and Tfs a. Thus, Tfs a/a cattle are lacking the two faster transferrin bands from the four bands normally observed in any Tf allele. Tfs A/a and Tfs A/A animals have a full complement of phenotypes (Spooner et al., 1977). The Tf and Tfs loci are apparently not linked.

There are 10 known transferrin variants in horses (D, F1, F2, F3, G, H, J, M, O, and R), of which the F variant is the most common (Chung and McKenzie, 1985; Stratil and Glasnak, 1981; Stratil et al., 1984b). More new variants have been found recently (Bell et al., 1995). As in cattle, equine transferrin is highly heterogeneous. Transferrin polymorphism has also been observed in Duroc and Hampshire pigs (Baker, 1968), the American toad (*B. americanus*) (Guttman and Wilson, 1973), and carp (*C. carpio*) (Valenta et al., 1976). In the toad, 13 transferrin alleles are present, and 36 phenotypes have been described. Seven variants (A, B, C, D, E, F, and G) are found in the carp. Shifrine and Stormont (1973) studied variants of transferrin in 100 samples of plasma from beagles and found a single phenotype with a three-band pattern. Other transferrin variants in the dog have been reported (Braend, 1966).

The average concentration of transferrin in human plasma is about 290 mg/100 mL (about 30 $\mu\text{mol/L}$) or, in terms of total iron-binding capacity (TIBC), about 300 $\mu\text{g}/100\text{ mL}$ (60 $\mu\text{mol/L}$) (Grant and Kachmar, 1976). There are no sex differences or diurnal variation, but there is a tendency for the transferrin level to fall with age (Bernat, 1983). Serum transferrin concentrations of many animal species, such as baboon, goat, mouse, rabbit, and sheep, fall within a broad range of 250–350 mg/100 mL. The pig and rat have higher mean concentrations, that is, 593 and 458 mg/100 mL, respectively, whereas the dog and guinea pig have somewhat lower mean levels, that is, 192 and 187 mg/100 mL, respectively (Regoeczi and Hatton, 1980). Adult male hamsters have a TIBC level of 104.5 $\mu\text{mol/L}$ with 44% transferrin saturation (Rennie et al., 1981). Increased serum transferrin levels have been observed in pregnancy (Grant and Kachmar, 1976; Hofvander, 1968), iron-deficiency anemia (Morton and Tavill, 1975), and cortisol and estrogen administration (Horne et al., 1971; Jeejeebhoy et al., 1972). Low levels, usually accompanied by low albumin, are found in many diseases and are due either to impaired synthesis, as in cirrhosis, starvation, and chronic infection, or

to increased excretion as in the nephrotic syndrome (Grant and Kachmar, 1976; Jarnum and Lassen, 1961; Morgan and Peters, 1971b).

18.8.4 ANALYTICAL METHODS

Bovine transferrin exhibits a very complex heterogeneity on starch-gel electrophoresis. In addition to genetic polymorphism, each homozygous variant of bovine transferrin may exhibit multiple bands that are due, in part, to differing numbers of sialic acid residues (Richardson et al., 1973; Spooner et al., 1970, 1977; Stratil and Spooner, 1971). With high resolution chromatographic and electrophoretic techniques, 12 components (6 pairs) can be visualized in the TfA homozygous variant of bovine transferrin (Stratil and Spooner, 1971). These components have been designated as 0a, 0b, 1a, 1b, 2a, 2b, 3a, 3b, 4a, 4b, 5a, and 5b (in increasing order of mobility). The numeral in each designation reflects the number of residues of sialic acid per mole of transferrin. After complete removal of sialic acid by neuraminidase treatment, all the "a" bands have the same mobility and all the "b" bands have the same mobility. However, the "b" bands have greater mobility than do the "a" bands, in spite of the fact that the "a" and "b" components of a single genetic variant have been shown to have the same molecular weight, amino acid composition, and peptide maps (Richardson et al., 1973). Maeda et al. (1980) have found cleavage in the peptide chain of the "b" component and suggested that the difference in mobility is due to scission of the "b" component peptide chain.

Several methods for isolation and purification of transferrin have been described. Most commonly, methods involve precipitation or fractionation with rivanol or ammonium sulfate, followed by ion-exchange chromatography (Letendre and Holbein, 1981; Palmour and Sutton, 1971; Sawatzki et al., 1981; Spooner et al., 1974; Van Gelder et al., 1995). Serum transferrin may be estimated directly by immunochemical methods, such as radial immunodiffusion or electrodiffusion, or indirectly by measuring the maximum amount of iron the serum can bind. This TIBC includes both bound iron and the unbound or latent iron-binding capacity; therefore, it represents the total amount of apotransferrin in the serum. The indirect method overestimates transferrin by 10%–20% because the metal attaches to proteins other than transferrin when the latter is more than half saturated (Grant and Kachmar, 1976).

18.9 TRANSTHYRETIN (PREALBUMIN)

18.9.1 PROPERTIES

TTR, formerly called PA, is a plasma protein of high negative charge when compared with other plasma proteins. Its electrophoretic mobility is greater than that of SA. The PA band is usually visible only by transmitted light on an electrophoretogram (Grant and Kachmar, 1976). The name TTR was recommended to replace PA to avoid confusion with albumin precursors and to indicate its function as a serum transport protein for both thyroxin and retinol-binding protein (RBP) (Nomenclature Committee of IUB [NC-IUB], 1981). The structure and physicochemical properties of TTR in man have been well described (Kanda et al., 1974; Morgan et al., 1971; Robbins et al., 1978). Human TTR has a molecular weight of approximately 55,000 Da and is a stable tetramer of four identical polypeptide subunits. It is high in acidic protein but contains no sialic acid or carbohydrate groups. The complete amino acid sequence has been determined.

Rat TTR is slightly smaller than human TTR and contains four identical subunits. It has a molecular weight of approximately 51,000 Da, as determined by sedimentation equilibrium analysis (Navab et al., 1977a; Peterson et al., 1973). Although rat and human TTRs are immunologically distinct, their amino acid compositions are quite similar. Analysis of the NH₂-terminal 30 amino acid residues of the rat TTR subunit showed only four substitutions from that of the human TTR subunit (Palmour and Sutton, 1971). Homologies between rat and human TTRs and rat and mouse TTRs are 93% and 97%, respectively (Fung et al., 1988). Rhesus and cynomolgus monkey TTRs

have molecular weights of approximately 65,000 and 58,000 Da, respectively, and are believed to be a tetramer similar to that of rat and man (Bernstein et al., 1970; Vahlquist and Petersone, 1972). Rabbit TTR contained the same number of amino acid residues and showed 80% homology with rat and human TTR by sequence analysis (Sundelin et al., 1985).

In man, TBPA has been shown to have two binding sites for T₄, and though the binding sites are identical, the binding of T₄ to one site inhibits the binding to the other (Robbins et al., 1978). Thus, one molecule of TBPA only binds one molecule of thyroxine.

Hepatic secretions of TTR and RBP are believed to be independently regulated processes, and the TTR-RBP complex is formed in the plasma after the independent secretion of the two proteins from liver cells (Navab et al., 1977b). The rate of PA synthesis in the rat was estimated at 3.6 mg/100 g of body weight per day, and the half-life of PA in the blood stream was 29 hours (Dickson et al., 1982). TTR also was reported to be synthesized and secreted by retinal epithelium (Dwork et al., 1990; Ong et al., 1994) and the choroid plexus in many species, including pig, rat, sheep, amphibian, and reptile (Duan et al., 1995; Dwork et al., 1990; Harms et al., 1991; Schreiber et al., 1990).

18.9.2 ROLE/FUNCTION

TTR plays an important role in the plasma transport of thyroid hormones and is also involved in the transport of vitamin A (Kanai et al., 1968; Oppenheimer et al., 1965). In contrast to human TBPA that plays a minor role in transporting thyroid hormones when compared to TBG (Cody, 1980), TBPA in the rat appears to be the major thyroid hormone transport protein (Davis et al., 1970; Peterson et al., 1973; Shutherland and Brandon, 1976). T₄ binding to TBPA has also been reported in the rabbit, rhesus monkey, horse, pigeon, and chicken (Refetoff et al., 1970; Shutherland and Brandon, 1976). T₃ binding to PA has been demonstrated in the pigeon (Reed et al., 1975).

TTR synthesis by the choroid plexus may be important in the transport of thyroxin across the blood-brain barrier (Schreiber et al., 1990). The synthesis of TTR by the liver and the choroid plexus appears to be independently regulated during the acute phase response (Dickson et al., 1985, 1986). It has been proposed that during evolution, TTR synthesis first appeared in the choroid plexus of reptiles, and TTR synthesis in the liver evolved much later (Schreiber and Richardson, 1997). In human, there are over 50 variants of TTR. Most of the mutations in TTR are not compatible with its normal metabolism and lead to its deposition as amyloid.

The electrophoretic mobility of TBPA differs considerably among animal species. In the monkey, horse, and chicken, the protein was found anodal to albumin, but in cattle, swine, dog, cat, rabbit, and frog, it was cathodal to albumin, making the term "PA" even less suitable in these species (Larsson et al., 1985).

Vitamin A normally circulates in plasma as retinol, which is bound to RBP. In turn, RBP strongly interacts with TTR and circulates together with TTR in plasma as a 1- to 1-protein-protein complex. RBP-TTR complex is thought to prevent the glomerular filtration of the low molecular size RBP in the kidney, and play a role in the secretion of RBP from hepatocytes (Wei et al., 1995). TTR knock-out mice with a null mutation of TTR locus have low serum RBP and thyroid hormone (Episkopou et al., 1993). In man, purified RBP has α_1 mobility on electrophoresis and a molecular weight of approximately 21,000–22,000 Da (Kanai et al., 1968). The RBP-TTR interactions of rat, cattle, and monkey are similar to those in man (Peterson et al., 1973; Richardson et al., 1994; Vahlquist and Petersone, 1972).

Experiments using rat liver perfusion and hepatocyte culture techniques as well as metabolic studies indicate that the liver is the main site of TTR synthesis and that TTR plays a role in the delivery of retinol to hepatocytes (Dickson et al., 1982; Felding and Fex, 1982; Navab et al., 1977b; Yamamoto et al., 1997).

18.9.3 PATHOPHYSIOLOGICAL SIGNIFICANCE

In animals, genetic polymorphism of TTR has been described for the nonhuman primate. *Macaca mulatta* (rhesus monkey) TBPA exists in three forms, and is under the control of two autosomal codominant alleles: the fast PA (designated Pt¹) and the slow PA (designated Pt²). The homozygous type Pt 1-1 migrates similarly to human TBPA. The two homozygous types Pt 1-1 and Pt 2-2 migrate as single bands on 8.5% polyacrylamide gels when submitted to electrophoresis (pH 8.9). The heterozygote Pt 1-2 is seen as three bands between the two Pt 1-1 and Pt 2-2 bands. PA polymorphism has also been observed in drills and mandrills, but no polymorphism like that seen in macaques has been found in baboons, chimpanzees, or orangutans. There is no evidence that the PA polymorphism affects thyroxine transport or RBP-PA complexing (Alper et al., 1969; Bernstein et al., 1970; Weiss et al., 1971).

TTR has been reported in the nonhuman primate, horse, cattle, rabbit, rat, mouse, chicken, pigeon, and quail (Farer et al., 1962; Heaf et al., 1980; Refetoff et al., 1970; Richardson et al., 1994; Shutherland and Brandon, 1976; Wolf, 1995). In primates, TBPA was found in catarrhini and prosimiae species, but not in platyrrhini (Callithricidae and Cebidae) (Seo et al., 1989). In pig, no clear identification of TTR was achieved in electrophoresis of serum (Larsson et al., 1985), but TTR mRNA has been found in the liver and choroid plexus (Duan et al., 1995). Reptiles have very low levels of TTR, and serum TTR has not been detected in amphibians (Harms et al., 1991).

The serum levels in selected animals are listed in Table 18.3.

Serum TTR concentrations are decreased in liver disease, hyperthyroidism, and protein calorie malnutrition, and is proposed as a nutritional marker (Ingenbleek and Young, 1994). They are unchanged in chronic renal disease (Robbins et al., 1978). Acute inflammation induced by turpentine in rats was shown to decrease the serum TTR level considerably (Dickson et al., 1982). Therefore, TTR is termed a "negative" acute-phase protein. Androgenic steroids markedly increase serum TTR concentrations, whereas estrogenic compounds have much less effect (Barbosa et al., 1970, 1971, 1973). Seasonal changes in TBPA concentrations have been described in quail, being lowest during the summer and highest during midwinter (Heaf et al., 1980).

18.9.4 ANALYTICAL METHODS

Isolation and purification of TTR is facilitated by the relative abundance of TTR and especially by its high negative charge. For bulk preparation, precipitation methods have been used; however,

TABLE 18.3
Transthyretin Serum Levels of Various Animal Species

Animal Species	Serum Levels of Transthyretin	
	µg/mL (Reference)	mg of T ₄ Bound/100 mL (Reference)
Rat	400–500 (Dickson et al., 1982)	140 (Davis et al., 1970)
	398 ± 50 (Navab et al., 1977b)	—
Rhesus monkey (<i>Macaca mulatta</i>)	291 (Robbins et al., 1978)	—
Green monkey (<i>Cercopithecus aethiops</i>)	—	203 ± 9 (Barbosa et al., 1970)
Quail		—
1-day old	220 (Heaf et al., 1980)	—
14 days old	430 (Heaf et al., 1980)	—

ion-exchange chromatography, gel filtration, and preparative electrophoresis (Robbins et al., 1978) are more commonly employed for purification. At high ionic strength, TTR complexes with RBP, which has a characteristic green fluorescence; therefore, affinity chromatography on sepharose with covalently bound RBP has also been widely used for TTR purification (Fex et al., 1977; Navab et al., 1977a).

Serum levels of TTR can be measured directly by radioimmunoassay (Benvenga et al., 1986; Navab et al., 1977b) and radial immunodiffusion (Dickson et al., 1982). TTR concentrations can also be determined indirectly and expressed in terms of thyroxine-binding capacity (Barbosa et al., 1971). Serum TTR is relatively stable under various storage conditions (Chen et al., 1986).

ACKNOWLEDGMENTS

I wish to thank Hai T. Nguyen, VMD, MS, author of this chapter in the second edition, for his vision and contributions to this chapter.

19.1 INTRODUCTION

The acute phase response encompasses a broad spectrum of pathophysiological changes that occur in an animal following numerous stimuli such as infection, tissue injury, or trauma. Among the systemic alterations are fever, leukocytosis, activation of complement and coagulation cascades, production and secretion of cytokines and glucocorticoids, and changes in the circulating levels of some plasma proteins (Watterson, 2009; Baumann and Gauldie, 1990; Dowton and Colten, 1988; Eckersall, 1995; Gruys et al., 1994; Heinrich et al., 1990; Titus et al., 1991). These liver-derived plasma proteins are collectively referred to as acute phase reactant (APR) proteins. Alterations in serum levels of individual APR proteins can occur within a few hours after exposure to an inflammatory stimulus (Kushner, 1988). Due to their value as markers of inflammation, they are being increasingly used as a diagnostic aid in both human and veterinary medicine (Watterson et al., 2008; Eckersall, 1995; Gruys et al., 1994; Kent, 1992).

The liver is the principal target of systemic inflammatory mediators; all or most hepatocytes, irrespective of their location in the lobule, are able to respond to these mediators and alter their rate of synthesis and secretion of APR proteins (Feldmann et al., 1989). These APR proteins can be broadly classified into two categories, depending on whether their circulating levels increase (positive APR proteins) or decrease (negative APR proteins) in response to an inflammatory stimulus. Interspecies variations exist in the hepatic response, which is reflected as species variations in serum levels of individual APR proteins (Table 19.1). In general, C-reactive protein (CRP), serum amyloid P (SAP), serum amyloid A (SAA), α_1 -acid glycoprotein (α_1 -AGP), haptoglobin, α_1 -proteinase inhibitor (α_1 -PI), α_2 -macroglobulin (α_2 M), ceruloplasmin (Cer), complement component C3, and fibrinogen (Fib) function as positive APR proteins, while albumin and transferrin respond as negative APRs (Watterson, 2009; Watterson et al., 2008).

TABLE 19.1
Examples of Interspecies Differences in Acute-Phase Reactant Proteins

Species	CRP	SAP	SAA	α_1 -AGP	α_1 -PI	α_2 M	CP	Fib
Human	++++	0	++++	++	++	0	++	++
Mouse	+	+++	++++ ^a	0	++ ^a	+/-	++	++
Rat	++	0	0	+++	++	++++ ^a	++	++
Dog	+++	0	++	++	+/-	+/-	++	++

CRP, C-reactive protein; SAP, serum amyloid P; SAA, serum amyloid A; α_1 AGP, α_1 -acid glycoprotein; α_1 -PI, α_1 -proteinase inhibitor; α_2 M, α_2 -macroglobulin; CP, ceruloplasmin; Fib, fibrinogen.

^a Strain-dependent acute phase responses; +/- = variable results recorded; 0 = not an acute phase reactant.

The overall importance of the positive APRs as a part of the animal's defense mechanism in the early stages of inflammation is reflected in the broad spectrum of their collective activities and the highly evolutionarily conserved nature of members of this group of proteins. These include scavenging free radicals, hemoglobin, and nuclear debris; modulating proteolytic enzyme activity; binding to bacterial components; activating complement; and regulating lipid metabolism (Watterson, 2009; Watterson et al., 2008; Downton and Colten, 1988; French, 1989; Gruys et al., 1994; Heinrich et al., 1990; Mackiewicz et al., 1988).

Despite the intraspecies and interbreed differences observed for individual proteins, there exists overall a high degree of similarity in the qualitative and quantitative patterns of APR protein responses to inflammation and trauma. The cytokine and hormone specificities of gene regulation and the genetic elements controlling the transcription of genes for specific APR proteins are quite similar for homologous genes among various species. The mediators involved in APR regulation can be divided into four main categories: interleukin-1 (IL-1) type cytokines, IL-6 type cytokines, glucocorticoids, and growth factors (Baumann and Gauldie, 1994; Murata et al., 2004). Cytokines act as primary stimulators of APR protein gene expression, while glucocorticoids and growth factors function more as modulators of cytokine function. In some species, the expression of specific APR proteins is also controlled by steroid hormones, which contributes to the altered levels observed for several of the proteins associated with age, sex, and pregnancy.

The analysis of APR proteins has been facilitated in recent years by the development of molecular biological techniques and advances in the application of immunological procedures. Initially, gross changes in the profile of plasma proteins following inflammation were evaluated by monitoring increased production in α - and β -globulins with either cellulose or agarose electrophoresis (French, 1989). Alterations in individual proteins were generally quantified with biochemical assays that did not always permit precise discrimination between different plasma proteins with related functional activity, for example, antiproteases (French, 1989). Due to the increasing commercial availability of species-specific antibody reagents to individual APR proteins, immunological assays are now generally used to quantitate the levels of individual APR proteins in animal sera (Watterson et al., 2008).

The information that has accumulated over the past decade on the mediators regulating the hepatic expression of APR proteins in laboratory animals and the extensive studies with laboratory animals on the role of these proteins in ameliorating the extent of tissue damage subsequent to inflammation and trauma have made a significant contribution to expanding the appreciation of the biological role(s) of the individual proteins in mammalian health and disease. This chapter will focus on those APR proteins listed in Table 19.1. Descriptions of the transport proteins, haptoglobin, transferrin, albumin, and complement C3 component are provided in other sections of the text.

19.2 α_1 -ACID GLYCOPROTEIN

19.2.1 PROPERTIES

α_1 -AGP, also referred to as orosomucoid or seromuroid, is a normal constituent of mammalian plasma that has been shown to respond as an APR in humans, rats, mice, and dogs. α_1 -AGP is now classified as one of the lipocalins, which are a group of proteins that bind lipophilic substances (Murata et al., 2004; Hocephied et al., 2003).

Human α_1 -AGP circulates as a single polypeptide chain consisting of 183 amino acids and two disulphide bonds (Kremer et al., 1988; Schmid, 1975; Schmid et al., 1973, 1974). The molecular weight of native human α_1 -AGP varies between 37 and 54 kDa due to (1) microheterogeneity in the carbohydrate moieties, (2) the laboratory procedures used to isolate the protein, and (3) the tissue source of the protein (reviewed in Kremer et al., 1988). The α_1 -AGPs isolated from mice, rabbits, and dogs show similar size and carbohydrate profiles as the human protein (Baumann et al., 1984; Charlwood et al., 1976; Dello et al., 1988). Rat hepatocyte cultures secrete two forms of α_1 -AGP, a

39-kDa α_1 -AGP-1 form and an α_1 -AGP-2 form, which exhibit a molecular weight range of 43–60 kDa depending on the carbohydrate content (Andus et al., 1988; Nicollet et al., 1981). Lower molecular weight forms of α_1 -AGP (with lower sialic acid content) are preferentially expressed in rats during the inflammatory response (Venembre et al., 1993). The concanavalin A binding patterns of α_1 -AGPs isolated from the sera of dogs with and without inflammation indicate that in this species, there is no preferential expression of a particular form of AGP during an inflammatory response (Dello et al., 1988).

In some strains of mice, such as BALB/c, two distinct α_1 -AGP-mRNAs are expressed, which result in the synthesis of two α_1 -AGPs of differing size and charge (Baumann et al., 1984; Yiangou and Papaconstantinou, 1993). These mouse proteins are encoded on genes *Apg-1* and *Apg-2*, which are both located on chromosome 4 (Baumann and Berger, 1985). Some inbred mouse strains, such as CE/J, express only one form of α_1 -AGP as a consequence of gene deletion (Baumann and Berger, 1985). In rats, there appears to be a single α_1 -AGP gene (Liao et al., 1985; Reinke and Feigelson, 1985). However, comparison of the complementary DNA (cDNA) sequences among rats and mice indicates significant homology between the deduced amino acid sequences of the respective α_1 -AGP proteins (Cooper and Papaconstantinou, 1986). Similarly, there is significant homology between rat and human α_1 -AGP (Fournier et al., 2000; Ricca et al., 1981).

Although secretion of α_1 -AGP by human T lymphocytes during the acute phase response has been reported (Haston et al., 2002; Fournier et al., 2000; Laurent, 1989), the synthesis of α_1 -AGP occurs primarily in the liver (Courtoy et al., 1981; Feldman et al., 1989; Jamieson and Ashton, 1973). Hepatic synthesis of α_1 -AGP is induced by a variety of inflammatory agents, including lipopolysaccharide (LPS) and turpentine (Schreiber et al., 1986), thermal injury (Gilpin et al., 1996), hypoxia (Wenger et al., 1995), exposure to heavy metals (Yiangou and Papaconstantinou, 1993; Yiangou et al., 1991), and phenobarbital administration (Chauvelot-Moachon et al., 1988; Fournier et al., 1994). The mechanism of α_1 -AGP induction associated with each inflammatory stimulus is similar but differs from the induction mechanism of phenobarbital, which does not function through an acute phase response mechanism (Fournier et al., 2000, 1994; Gilpin et al., 1996; Kremer et al., 1988; Yiangou and Papaconstantinou, 1993; Yiangou et al., 1991).

The synthesis of α_1 -AGP is influenced by both cytokines and glucocorticoids (Baumann et al., 1983, 1990, 1993; Dewey et al., 1990; Koj et al., 1984; Prowse and Baumann, 1989; Richards et al., 1992; Won and Baumann, 1990; Hochepped et al., 2003), and it is regulated at both transcriptional and posttranscriptional levels (Baumann, 1990; Ingrassia et al., 1994; Vannice et al., 1984). Maximal expression of α_1 -AGP-mRNA and protein synthesis requires the synergistic action of glucocorticoids and cytokines (Prowse and Baumann, 1989; Vannice et al., 1984). Distal regulatory elements responsive to IL-1, IL-6, tumor necrosis factor- α (TNF α), leukemia inhibitory factor (LIF), and phorbol esters have been located on the cDNA nucleotide sequence upstream from the transcription site (Dewey et al., 1990; Won and Baumann, 1990). A single glucocorticoid response element (GRE) has also been identified. However, in both rats and mice, the GRE alone is not sufficient to activate transcription, and the presence of other transcription factor(s) are required, such as α_1 -AGP/enhancer-binding protein (a member of the C/EBP transcription family), α_1 -AGP nuclear factor, and NF- κ B (Baumann et al., 1991, 1992; De Lorenzo et al., 1991; Ingrassia et al., 1994; Lee et al., 1996; Ratajczak et al., 1992).

The serum half-life of α_1 -AGP is 5.5 days in people (Weisman et al., 1961), 3.7 days in dogs (Zeineh et al., 1972), and about 24 hours in rats (Kuranda and Aronson, 1983). Studies of α_1 -AGP catabolism in rats indicate that several tissues, including kidney, liver, muscle, and skin, may be active in degrading the protein (Kuranda and Aronson, 1983).

19.2.2 ROLE/FUNCTION

Although the physiological functions of α_1 -AGP have yet to be fully defined, available evidence suggests that it may act as a nonspecific immunosuppressant (Laurent, 1989) and that it may also

serve as a transporter of cationic compounds (Kremer et al., 1988; Hochepped et al., 2003; Smith et al., 2002). For example, α_1 -AGP can suppress human T-cell activation at concentrations below those observed during the human acute phase response (Laurent, 1989). Human α_1 -AGP can also suppress the murine lymphocyte mitogenic response and inhibit neutrophil activation (Costello et al., 1984). The effectiveness of the immunosuppression is enhanced when the sialic acid content of α_1 -AGP is reduced (Bennett and Schtmidt, 1980). While there are conflicting reports on the role of sialic acid in the regulation of the inhibitory effects of α_1 -AGP on human platelet aggregation (Andersen and Eika, 1980; Costello et al., 1979), the increased reactivity of desialylated α_1 -AGP could have important implications in disease conditions, because in humans and rats, inflammation is associated with a reduction in the sialic acid content of α_1 -AGP (Serbource-Goguel Seta et al., 1986; Venembre et al., 1993; Murata et al., 2004; Fournier et al., 2000).

There have been numerous studies on the affinity of neutral and basic drugs for α_1 -AGP (Kremer et al., 1988). In people, due to the increased plasma levels of α_1 -AGP as a result of disease, drug use, and pregnancy, and due to its greater drug affinity, α_1 -AGP is considered a more important drug ligand than albumin (Kremer et al., 1988). Hormones, such as progesterone, cortisol, and testosterone, appear to become associated with human α_1 -AGP at a single binding site, while estradiol can interact at several sites (Kerkay and Westphal, 1968). Drugs such as propranolol also appear to bind to α_1 -AGP at a single site (Kremer et al., 1988). Indeed, the ability to bind propranolol is a consistent feature of α_1 -AGP in dogs, rats, rabbits, and sheep as well as people, and the protein–drug interaction results in alterations in the pharmacokinetics and pharmacodynamics of propranolol (Murata et al., 2004; Fournier et al., 2000; Hochepped et al., 2003; Belpaire et al., 1984; Evans et al., 1973; Hill et al., 1989).

A1AG is a natural anti-inflammatory agent as it inhibits mitogen-induced lymphocyte proliferation, natural killer cell activity, neutrophil activation, and increases the secretion of IL-1 receptor antagonist by macrophages (Murata et al., 2004; Fournier et al., 2000). At low concentrations, A1AG exerts an aggregating effect on neutrophils, while at higher concentrations, it inhibits aggregation. It also inhibits superoxide generation by neutrophils stimulated either by opsonized zymozan or phorbol myristate acetate. The inhibitory effect is dose dependent and inversely proportional to the concentration of the stimulus. This suggests that A1AG acts on the neutrophil membrane, rather than the stimulus itself (Hochepped et al., 2003). A1AG inhibits thrombin-induced platelet aggregation and also aggregation initiated by ADP or adrenalin in a dose-dependent manner. In all cases, inhibition of aggregation is directed against the second wave of platelet aggregation and subsequently as an inhibitor of the release reaction. This suggests that A1AG contributes to the downregulation of the further recruitment of platelets. This function is shared with polymorphonuclear leucocytes, which are in close contact with platelets and serves as an antithrombic function by inhibiting further platelet activation and recruitment. The local production of A1AG by these leucocytes may be one of the mechanisms by which the leucocytes exert their antithrombic function (Hochepped et al., 2003; Kremer et al., 1988; Fournier et al., 2000).

It has been suggested that A1AG is required to maintain capillary permeability by increasing the polyanionic charge selectively of the endothelial barrier. It has also been reported that the partially protective effect of A1AG in different rodent models of shock can be explained by enhancing the capillary barrier function and thereby maintaining the perfusion of vital organs (Fournier et al., 2000; Kremer et al., 1988). In addition, A1AG has also been found to facilitate the passage of erythrocytes through membranes. A1AG increases the bilayer thickness of liposomes and decreases the permeability for ions (Kremer et al., 1988).

19.2.3 ANALYTICAL METHODS

The various methods used to isolate human α_1 -AGP have been reviewed (Kremer et al., 1988), and the influence of different laboratory procedures on the desialylation, denaturation, and polymerization of the molecule documented. Due to poor cross-reactivity, antiserum to human α_1 -AGP cannot

be used to assess α_1 -AGP in sera from other species (Chauvelot-Moachon et al., 1988). One of the characteristics of α_1 -AGP is that unlike 98% of plasma proteins, it is nonprecipitable with 1.2 M perchloric acid. Hence, this acid treatment has been used as a means of isolating α_1 -AGP from mammalian plasma (Hill et al., 1989). Cation exchange chromatography has also been used for the purification of rat α_1 -AGP (Chauvelot-Moachon et al., 1988) as has immunoaffinity chromatography (Drechou et al., 1989).

Various methods that have been employed to evaluate α_1 -AGP in mammalian plasma have been reviewed (French, 1989). Currently, immunological methods are the most commonly used procedures in laboratory animal medicine (Chauvelot-Moachon et al., 1988; Gilpin et al., 1996; Ikawa and Shozen, 1990; Koj et al., 1984; Poüs et al., 1990). A commercial radial immunodiffusion kit method has been used for canine plasma (Rikihisa et al., 1994) that yielded a baseline α_1 -AGP value of 0.37 ± 0.04 mg/mL in healthy dogs, compared to baseline values of around 0.5 mg/mL reported with a lectin/glycoprotein precipitation method (Conner and Eckersall, 1988).

19.2.4 PATHOPHYSIOLOGICAL SIGNIFICANCE

Injection of IL-6 into male Wistar rats produced a 16-fold increase in hepatic α_1 -AGP-mRNA within 4 hours, which was considerably faster than the 16–25-hour response time following turpentine injection (Geiger et al., 1988a). Male Buffalo rats also responded to turpentine by expressing increased levels of α_1 -AGP-mRNA, but only a moderate increase was observed following administration of IL-1 (De Jong et al., 1988; Schreiber et al., 1986). In cultured rat hepatoma cells, increased expression of α_1 -AGP-mRNA could only be induced by a hepatocyte-stimulating factor when dexamethasone was also added to the culture medium (Baumann et al., 1987a). Similarly, the combined action of TNF α and IL-1 had a greater effect on α_1 -AGP synthesis in rat hepatoma cells than the individual cytokines, and the response could be further enhanced by inclusion of hepatocyte growth factor (HGF) in the culture medium (Baumann et al., 1993; Poüs et al., 1990). Likewise, in mouse hepatocytes, neither IL-1 nor IL-6 alone stimulated α_1 -AGP production above basal levels, and only a 1.5–2.0-fold increase was induced by dexamethasone alone (Prowse and Baumann, 1989). However, when the hepatocytes were exposed to a combination of each cytokine and dexamethasone, a fivefold increase in both α_1 -AGP-mRNA and α_1 -AGP protein synthesis was observed (Prowse and Baumann, 1989). In both rat and human hepatocyte cultures, insulin (unlike glucagon, growth hormone, or catecholamines) can cause a rapid, nonspecific decrease in the synthesis of α_1 -AGP induced by a combination of IL-1, IL-6, and dexamethasone (Campos and Baumann, 1992).

The human range for serum α_1 -AGP is accepted to be between 0.5 and 1.0 mg/mL, which increases two- to threefold in many disease conditions (Kremer et al., 1988). For example, in individuals with advanced rheumatoid arthritis, average serum levels of 2.2 mg/mL have been reported compared to 0.4 mg/mL in a healthy control group (Lacki et al., 1994). Using similar assay procedures, average serum α_1 -AGP values have been determined as 0.9 mg/mL in Wistar rats (Koj et al., 1984), 0.4 mg/mL in male F344 rats (Poüs et al., 1990), 0.3 mg/mL in Sprague-Dawley rats (Chauvelot-Moachon et al., 1988), and 0.3 g/L in Dark Agouti rats (Chauvelot-Moachon et al., 1988). The extent of the increase observed in serum α_1 -AGP levels in rats depends on the strain of the rat and the type of stimulus to which the animals are exposed. For example, in F344 rats that are more susceptible to thermal injury than the Buffalo strain, serum α_1 -AGP levels rose 1600-fold following burn injury compared to only 300-fold in the Buffalo strain (Gilpin et al., 1996). In comparison, only a threefold increase in serum α_1 -AGP was observed in Fisher rats following treatment with either turpentine or dexamethasone (Koj et al., 1984; Poüs et al., 1990). Phenobarbital administration caused a relatively modest increase in serum α_1 -AGP in Sprague-Dawley rats, with levels rising from 0.30 ± 0.04 mg/mL to 0.49 ± 0.05 mg/mL, while it produced a fivefold increase in serum α_1 -AGP levels in Dark Agouti rats, a strain that is susceptible to adjuvant-induced arthritis (Chauvelot-Moachon et al., 1988).

In dogs, α_1 -AGP values rise in response to endotoxin (Eckersall et al., 1985) and following surgical trauma (Conner and Eckersall, 1988). The serum α_1 -AGP values of healthy dogs have been variably reported as 0.37 ± 0.04 mg/mL and 0.47 ± 0.09 mg/mL, which rises to 2.85 ± 0.51 mg/mL during inflammatory reactions (Belpaire et al., 1987; Dello et al., 1988). However, increases as high as 17-fold above baseline have also been reported in dogs with inflammatory diseases (Ganrot, 1973a). The 1.9–8.6-fold increase in serum α_1 -AGP levels observed in dogs 4–6 days after inoculation with *Ehrlichia canis* was significantly greater than the elevation recorded for serum CRP levels (Rikihisa et al., 1994).

In most inbred strains of mice, the two forms of α_1 -AGP (AGP-1 and AGP-2) are equally inducible by acute inflammation. However, the predominant expression switches to AGP-2 in chronic inflammation (Glibetic and Baumann, 1986). This response is similar to the α_1 -AGP induction with heavy metals in BALB/c mice (Yiangou and Papaconstantinou, 1993). Prior to administration of mercury (0.5 mg HgCl₂/kg), hepatic AGP-2-mRNA levels were approximately 10-fold higher than AGP-1-mRNA levels, while at the peak of induction with Hg, AGP-2-mRNA was 80–100-fold higher than the AGP-1-mRNA (Yiangou and Papaconstantinou, 1993). Although adrenalectomy had no effect on the induction of AGP-2, the AGP-1 response was delayed in the adrenalectomized animals (Yiangou and Papaconstantinou, 1993). These studies confirm that the α_1 -AGP response is mediated by multiple factors and that the mechanism of induction has not yet been fully elucidated.

In rats, as in people, inflammatory stimuli alter the extent of glycosylation of the α_1 -AGP molecules secreted into the circulation during the acute phase of the reaction (Koj et al., 1982; Nicollet et al., 1981). In rats, the same type of response is observed in reaction to administration of either phenobarbital or pharmacological doses of estrogen (Diarra-Mehrpour et al., 1985; Monnet et al., 1986). In contrast, in dogs and mice, there is no change in the glycosylation profile of the increased amount of α_1 -AGP released into the circulation during the acute phase reaction (Dello et al., 1988; Eckersall et al., 1985; Heegaard, 1992).

Growth and development can also influence the rate of α_1 -AGP expression. Both newborn human infants and newborn rats have markedly lower serum α_1 -AGP than adult animals (Ganrot, 1972; Glibetic et al., 1992). In fetal rats, though α_1 -AGP-mRNA can be detected in the liver, inflammation in the mother does not induce an increase in the fetal hepatic transcription rate (Yiangou and Papaconstantinou, 1993). This differs from the response of fetal α_2 M and haptoglobin, which exhibit increased hepatic fetal transcription rates of their respective mRNAs in response to maternal stimulation (Yiangou and Papaconstantinou, 1993).

19.3 α_1 -PROTEINASE INHIBITOR

19.3.1 PROPERTIES

α_1 -PI, also called α_1 -antitrypsin, is the prototypical member of the family of serine proteinase inhibitors (Serpins) found in the circulation of all mammals (Goodwin et al., 1996; Potema et al., 1994; Travis and Salveson, 1983). During acute inflammation, the massive release of proteolytic enzymes from injured tissue and inflammatory cells disturbs the dynamic equilibrium between blood and tissue proteinases and their inhibitors (French, 1989; Koj et al., 1988). In laboratory animals, α_1 -PI, along with α_2 -M, has a critical role in modulating the extent of increased protease activity and hence limiting the extent of tissue damage.

There is considerable structural homology among the α_1 -PIs isolated from mammalian plasma. Human, rat, mouse, rabbit, guinea pig, gerbil, canine, and monkey α_1 -PIs are all single-chain glycoproteins consisting of 370–390 amino acids with molecular weights ranging from 51 to 60 kDa (Carrell et al., 1982; Goodwin et al., 1996; Goto et al., 1994; Koj et al., 1988; Melgarejo et al., 1996; Poller et al., 1995; Potema et al., 1994; Travis and Salveson, 1983; Verbanac and Heath, 1983). Extensive homology has been found among human, rat, guinea pig, mouse, rabbit, gerbil, and baboon α_1 -PI amino acid sequences (Goodwin et al., 1996; Melgarejo et al., 1996; Nakatani et al.,

1995; Saito and Sinohara, 1991, 1995). The arrangement of amino acids in the reactive center of the molecule is critical for recognition and binding to target proteinases and highly conserved among human, rat, rabbit, canine, hamster, and gerbil α_1 -PIs (Chao et al., 1990; Goto et al., 1994; Melgarejo et al., 1996; Nakatani et al., 1995; Saito and Sinohara, 1991). An exception is mouse α_1 -PI, which exhibits considerable structural variation, not only in comparison to human α_1 -PI but also in the amino acid sequences of the α_1 -PIs isolated from different domestic and wild-type mouse strains (Goodwin et al., 1996).

In people and rats, a single α_1 -PI gene has been identified, while in guinea pigs and rabbits, multigene families are found (Chao et al., 1990; Long et al., 1984; Ray et al., 1994, 1996; Suzuki et al., 1990). In mice, a single gene has been reported for *Mus caroli*, *Mus cooki*, *Mus cervicolor*, *Mus pahari*, and *Mus minutoides*, while three to five genes for α_1 -PI are present in *Mus domesticus*, *Mus spretus*, *Mus hortulanus*, and *Mus saxicola* (Goodwin et al., 1996; Rheaume et al., 1994). In *Mus musculus*, α_1 -PI is encoded by two multigene families located on chromosome 12 (Goodwin et al., 1996; Hill et al., 1985).

In addition to microheterogeneity of serum α_1 -PIs as a result of variations in carbohydrate content, various isoforms of α_1 -PI are also present in many species. These isoforms exhibit both different biological functions and different acute phase responses (Chao et al., 1990; Melgarejo et al., 1996; Nathoo and Finlay, 1986; Sevelius et al., 1994; Verbanac and Heath, 1983). For example, two forms of guinea pig α_1 -PI have been identified: a fast moving 61 kDa "F" form and a slower moving 55 kDa "S" form (Suzuki et al., 1990). Both forms exhibit similar substrate specificity, but only the S form, which is present in barely detectable amounts in healthy animals, acts as an acute phase protein (Suzuki et al., 1990). Four isoforms of α_1 -PI, designated as F, S-1, S-2, and E, have been identified in rabbits, and as occurs in guinea pigs, the F form is the major form of α_1 -PI present in normal serum (Koj et al., 1978; Ray et al., 1994; Saito and Sinohara, 1993, 1995). The rabbit isoforms of α_1 -PI exhibit a variety of biological activities (Koj et al., 1978; Ray et al., 1994; Saito and Sinohara, 1988, 1993, 1995). Both S-1 and S-2 can inhibit elastase but not trypsin activity, while the E form does not exhibit proteolytic inhibitory activity despite its capacity to form equimolar complexes with both elastase and trypsin (Ganrot, 1966; Saito and Sinohara, 1988, 1995). A similar pattern of α_1 -PI isoform activity has been found in *M. musculus* (Paterson and Moore, 1996). Of the five highly related α_1 -PI proteins expressed in this strain, only two are efficient inhibitors of neutrophil elastase, and there is poor correlation between substrate binding and inhibitory activities (Paterson and Moore, 1996).

The cDNA encoding rat α_1 -PI shares 70%–80% sequence identity with its human and mouse counterparts (Chao et al., 1990). Similarly, the rabbit liver cDNA coding for the F isoform of α_1 -PI exhibits 74% and 64% homology at the nucleotide and amino acid levels, respectively, with human α_1 -PI (Saito and Sinohara, 1991). The rabbit F and S isoforms share 95% homology in their complete amino acid sequences, and nine of the twenty amino acid differences that exist are located in the stretch of amino acids encompassing the reactive site region (Saito and Sinohara, 1993).

The hepatocyte is the primary source of serum α_1 -PI (Carlson et al., 1984; Hood et al., 1980; Mackiewicz and Kushner, 1989), though low levels of synthesis have also been reported in alveolar epithelial cells, submandibular glands, alveolar macrophages, neutrophils, and activated lymphocytes (Bashir et al., 1992; Carlson et al., 1988; Chao et al., 1990; Du Bois et al., 1991; Takemura et al., 1986; Venembre et al., 1994). Evaluation of human α_1 -PI expression in transgenic mice has confirmed that the presence of α_1 -PI in extrahepatic tissue is the result of de novo synthesis and not endocytosis of the protein. Studies in rabbits, rats, and mice have demonstrated that expression of α_1 -PI is regulated at the transcriptional level through *cis*-regulatory elements (Latimer et al., 1990; Montgomery et al., 1990; Ray et al., 1996; Rheaume et al., 1988). The synthesis of α_1 -PI in different tissues is regulated by different factors. For example, in *M. caroli*, which is characterized by the accumulation of α_1 -PI-mRNA in the kidneys, the expression of renal but not hepatic mRNA is regulated by testosterone (Latimer et al., 1987). Sexual dimorphism in serum α_1 -PI levels has been observed in dogs and mice, with females exhibiting higher values than males (Hughes et al., 1995;

Kueppers and Mills, 1983). In monocytes and macrophages, LPS stimulates α_1 -PI synthesis, while in human hepatocyte cultures, exposure to IL-6 alone is sufficient to increase the rate of α_1 -PI synthesis (Barbey-Morel et al., 1987; Perlmutter et al., 1989).

Serpins such as α_1 -PI are found in the circulation in three forms: (1) active or native, (2) inactive or cleaved, and (3) as stable serpin-enzyme complexes (Travis and Salveson, 1983). The cleavage of human α_1 -PI by mouse macrophage elastase, a metalloproteinase, results in the rearrangement and inactivation of the molecule (Banda et al., 1988). The native and inactive α_1 -PIs are immunologically identical, and both forms are eliminated from the circulation more slowly than the serpin-enzyme complexes (Mast et al., 1991). The rapid clearance of these α_1 -PI-enzyme complexes from the circulation is mediated by the liver through their interaction with the low-density lipoprotein receptor (LDLR) or an LDLR-related protein (LPR) (Kounnas et al., 1996; Poller et al., 1995). Macrophages and fibroblasts also express high concentrations of LPR (Moestrup et al., 1992) that contributes to the selective cellular degradation of the complexed forms of α_1 -PI (Kounnas et al., 1996). The affinity of hepatic LPR for α_1 -PI complexes is lower than that of the serpin-enzyme complexes formed with α_2 -M (Kounnas et al., 1996).

19.3.2 ROLE/FUNCTION

The primary function of α_1 -PI is thought to be its role as a modulator of the proteinases released from infiltrating neutrophils and macrophages, as well as from damaged cells, during acute inflammation. In both people and mice genetically deficient in α_1 -PI activity, spontaneous emphysematous lesions are associated with a progressive increase in elastase activity in the alveolar interstitium, resulting in the degradation of matrix proteins (De Santi et al., 1995; Martorana et al., 1993; Snider et al., 1991). Examination of pulmonary changes as a consequence of experimentally induced alveolar sepsis in Pallid, C57BL/6J, and NMRI mice, which have low, intermediate, and high levels of serum α_1 -PI activity, respectively, demonstrated that the degree of lung destruction was inversely correlated with elastase inhibitory activity levels and hence related to serum α_1 -PI activity (Cavarra et al., 1996). The increase in cellular infiltration into alveolar spaces observed in the Pallid and C57BL/6J mice (but not in NMIR mice) was considered to be related to the ability of the inactivated or cleaved form of α_1 -PI to act as a chemoattractant (Banda et al., 1988). In addition to its function as an elastase inhibitor, α_1 -PI may also have a role in the alveolar metabolism of lung surfactant, possibly through its inhibitory action on the surfactant convertase enzyme, which is a serine protease (Gross et al., 1995). Like α_1 -AGP, α_1 -PI may also have a more global role in regulating the inflammatory response because Buffalo rats, which are more resistant to thermal injury than F344 rats, exhibit higher hepatic α_1 -PI-mRNA levels both before and after burn injury than the F344 strain (Gilpin et al., 1996).

19.3.3 ANALYTICAL METHODS

The lack of cross-reactivity of α_1 -PI between species has hindered the application of immunological methods for the accurate determination of this protein in mammalian sera. For example, a monoclonal antibody against human α_1 -PI only cross-reacts with rat and baboon serum, and shows no reaction with serum from rabbits, hamsters, guinea pigs, or dogs (Silvestrini et al., 1990). The isolation procedures described for human, rat, guinea pig, gerbil, and canine α_1 -PIs employed a variety of isolation steps, including ion exchange and affinity chromatography (Goto et al., 1994; McGilligan and Thomas, 1991; Melgarejo et al., 1996; Silvestrini et al., 1990; Suzuki et al., 1990). However, dogs, mice, and humans appear to be the only species in which α_1 -PI has been quantitated by an immunological procedure such as radial immunodiffusion (Baumann et al., 1986; Hughes et al., 1995). A specific enzyme-linked immunosorbent assay (ELISA) method has been developed for the determination of α_1 -PI-bound leukocyte elastase in canine plasma and tissue fluids (Axelsson et al.,

1991). Using this procedure, it was determined that 70% of the elastase in canine plasma is bound to α_1 -PI, while the remainder is bound to α_2 -M.

Serum α_1 -PI levels have usually been quantified with functional assays using chromogenic substrates to evaluate antielastase activity (Cavarra et al., 1996; Conner et al., 1988; Goto et al., 1994; James and Cohen, 1978; Laskowski, 1986; Martorana et al., 1993; Mullins et al., 1984; Schwarzenberg et al., 1987; Suzuki et al., 1990). The use of low-molecular-weight substrates (e.g., benzoyl-arginine-*p*-nitroanilide) rather than larger proteins prevents α_2 -M from contributing to the apparent α_1 -PI antiproteolytic activity, because only the α_1 -PI-enzyme complexes remain active against the smaller synthetic compounds (French, 1989). When bovine trypsin, bovine chymotrypsin, or pancreatic elastase have been used to evaluate serum α_1 -PI activity in laboratory animals, the results of the assays have only reflected broad antiprotease inhibitory activity in the sample and not the species-specific interaction between the target enzyme and the α_1 -PI inhibitor and, hence, may have overestimated the actual α_1 -PI inhibitory activity (French, 1989).

19.3.4 PATHOPHYSIOLOGICAL SIGNIFICANCE

The plasma levels of α_1 -PI in most species are normally 1–4 mg/mL, with levels rising three- to fourfold under inflammatory conditions (French, 1989; Koj et al., 1988). In people, rats, rabbits, and guinea pigs, α_1 -PI responds as a typical APR (French, 1989; Koj and Regoeczi 1978; Nakatani et al., 1995; Suzuki et al., 1990). The response of α_1 -PI in mice is strain dependent. Although C57BL/6J mice show no increase in hepatic α_1 -PI-mRNA or serum α_1 -PI levels following turpentine or LPS administration (Baumann et al., 1986), in Swiss mice (Ha/ICR), a 35%–40% increase above baseline levels was found for both mRNA and serum α_1 -PI values 12 hours after turpentine injection (Frazer et al., 1985). This variable response is compatible with the variation in baselines serum levels of α_1 -PI found in different strains of mice. For example, in Pallid, C57BL/6J, and BALB/C strains, the serum α_1 -PI values are 0.2 ± 0.1 mg/mL, 0.6 ± 0.1 mg/mL, and 0.7 ± 0.1 mg/mL, respectively (Martorana et al., 1993). A strain-dependent acute phase response has also been observed in rats following thermal trauma (Xia et al., 1992). Subsequent to burn injury, the increase in serum α_1 -PI values was higher in the more resistant Buffalo rats than in the less resistant F344 rats (Xia et al., 1992).

In species that normally express multiple forms of α_1 -PI, there appears to be a selective increase in the circulating levels of the individual isoforms following trauma. In rabbits, turpentine injection induced a 100-fold increase in the transcription rate of α_1 -PI S-2 mRNA, while the mRNA transcription rate for the “F” and S-1 forms remains relatively constant (Ray et al., 1994). Similarly, in guinea pigs a significant increase in the circulating levels of the “S” form of α_1 -PI occurred 3 days after turpentine injection, with serum levels rising from being barely detectable to approximately 1.3 g/L, while in comparison, the “F” form of α_1 -PI only increased from 0.5 to 1.2 g/L (Suzuki et al., 1990).

The observations on the acute phase response of α_1 -PI in dogs are contradictory. Serum α_1 -PI values have been variously reported to increase (Conner et al., 1986; Lonky et al., 1980; Ohlsson, 1971), remain unchanged (Conner and Eckersall, 1988; Ganrot, 1973a), or decrease (Laurell and Rannevik, 1979; Murtaugh and Jacobs, 1985) as a result of inflammation. Whether the disparity of response is due to breed differences has yet to be determined. It is possible that serum values alone may not accurately reflect the extent of α_1 -PI synthesis because, due to its relatively small size, α_1 -PI can diffuse from the circulation into the interstitium (Andersen et al., 1994; Hughes et al., 1995). Hence, differences in the extent of extravasation of the protein during an inflammatory response can confound the observation and interpretation of alteration in serum α_1 -PI values. Further, in dogs with liver disease, though only a modest elevation was detected in serum α_1 -PI levels compared to healthy dogs, immunohistochemical staining of hepatic tissue demonstrated that α_1 -PI had accumulated in the cytoplasm as a result of protein precipitation (Sevelius et al., 1994). This type of accumulation was only observed in dogs

expressing the “S” isoform of α_1 -PI and not in animals expressing only the F isoform of the protein (Sevelius et al., 1994).

The expression of α_1 -PI can also be influenced by steroid hormones (Hughes et al., 1995; Kueppers and Mills, 1983). While the mean value for serum α_1 -PI has been determined as 2.3 ± 0.4 mg/mL in healthy dogs, the value for intact females was 2.6 ± 0.1 mg/mL compared to 2.1 ± 0.1 mg/mL in intact males (Hughes et al., 1995). In spayed females and castrated males, the serum α_1 -PI values were 2.2 ± 0.1 mg/mL and 2.1 ± 0.1 mg/mL, respectively (Hughes et al., 1995). Increased serum α_1 -PI activity has been reported in human females receiving oral contraceptive therapy (Song et al., 1970). These results suggest that in both dogs and people, α_1 -PI production may be regulated by estrogen levels. In *M. caroli*, the developmental pattern of renal α_1 -PI-mRNA but not hepatic mRNA appears to be regulated by testosterone levels, because large increases in α_1 -PI-mRNA are observed in the kidneys at puberty in male mice (Rheaume et al., 1988). In rats, the rate of α_1 -PI mRNA transcription is also regulated, at least in part, by pituitary hormones (Schwarzenberg et al., 1987). In Sprague-Dawley rats that underwent hypophysectomy, the drop in circulating levels of α_1 -PI from 14.1 ± 0.8 mg/mL to 3.9 ± 0.4 mg/mL was matched by a 50%–75% drop in hepatic α_1 -PI-mRNA levels (Schwarzenberg et al., 1987). The administration of growth hormone alone or the administration of a combination of thyroxine, corticosterone, and dihydrotestosterone failed to reverse the effects of hypophysectomy. However, when all four hormones were administered simultaneously to hypophysectomized rats, serum α_1 -PI values rose to 8.8 ± 0.1 mg/mL, and a two- to threefold increase in hepatic α_1 -PI mRNA levels was observed (Schwarzenberg et al., 1987).

19.4 α_2 -MACROGLOBULIN

19.4.1 PROPERTIES

Protease inhibitors of the α_2 M superfamily are all large glycoproteins characterized by their particular mechanism of nonspecific binding with proteinase enzymes (Gauthier and Mouray, 1976; Geiger et al., 1987; Starkey and Barrett, 1982). Amino acid sequence homology suggests that α_2 M shares a common evolutionary origin with complement components C3 and C4 (Jensen et al., 2004; Sottrup-Jensen et al., 1984, 1985). In rats, α_2 M is considered the prototype APR, though variable responses are observed in some other laboratory animals (French, 1989; Versavel et al., 1983; Weimer and Benjamin, 1965).

Rat α_2 M, like human α_2 M, consists of four identical 170 kDa subunits joined by disulfide bonds and strong noncovalent interactions (Nieuwenhuizen et al., 1979; Schaeufele and Koo, 1982). It has been estimated that there is 80% homology between the complete rat and human α_2 M cDNA and amino acid sequences, and that all 25 cysteine residues in each α_2 M subunit between rat α_2 M and human α_2 M are completely conserved (Beitel et al., 1986; Gehring et al., 1987; Northemann et al., 1985). A tetrameric form of α_2 M, homologous with rat and human α_2 M, is also found in mice (Overbergh et al., 1991; Umans et al., 1994; Van Leuven et al., 1992). Similarly, the guinea pig and hamster forms of α_2 M exhibit tetrameric structures (Godfrey et al., 1984; Miyake et al., 1993). Antibodies generated against human α_2 M yield reactions of partial identity with monkey, cat, dog, and guinea pig plasma (Baker and Valli, 1988; Pellegrini, 1994; Suzuki and Sinohara, 1986). Structurally, hamster α_2 M appears to be more loosely packed than native human α_2 M and, following activation, undergoes conformation change more slowly than its human and rat counterparts (Miyake et al., 1993).

α_2 M is unique as an antiproteinase both in terms of the broad spectrum of enzymes that it can inhibit and the nature of its inhibitory activity. In addition to binding to all types of serine proteases (serine, thiol, aspartic, and metallo), α_2 M also possesses cytokine-binding properties through a “trapping” mechanism (Jensen et al., 2004; Barrett and Starkey, 1973). The interaction between α_2 M and a protease results in the cleavage of a specific peptide bond within a small “bait” region near the center of each α_2 M subunit (Sottrup-Jensen et al., 1989). The α_2 M then undergoes

a conformational change, trapping the proteinase and forming a nondissociable complex (Jensen et al., 2004; Sottrup-Jensen, 1989). The proteinase enzyme within this complex is protected from degradation by other proteinase inhibitors, while the reactive site of the enzyme retains reactivity toward small molecules, though steric hindrance impedes the enzymatic activity directed toward larger substrates (Andres et al., 1989; Barrett and Starkey, 1973). Similarly, when IL-6 is bound to human α_2 M, it retains its biological activity and is resistant to proteolytic degradation (Matsuda et al., 1989). The α_2 M molecules isolated from hamsters, guinea pigs, and rabbits exhibit several trypsin susceptible sites, in addition to the "bait" region (Gonias and Pizzo, 1983; Miyake et al., 1993; Suzuki and Sinohara, 1986; Tamamizu et al., 1989). Further, trypsin interacts with human α_2 M at a 2:1 molar ratio (Travis and Salvesson, 1983) and with rodent α_2 Ms at a 1:1 ratio (Godfrey et al., 1984; Nieuwenhuizen et al., 1979; Suzuki and Sinohara, 1986; Van Leuven et al., 1992). In all species, the conformational change associated with the formation of an α_2 M-proteinase complex results in altered electrophoretic mobility of the α_2 M molecule on polyacrylamide gel electrophoresis. The activated, or complexed, form of α_2 M typically shows increased mobility relative to the native, or noncomplexed, form of the molecule (Barrett et al., 1979; Lamarre et al., 1991).

As a result of the activation-induced conformational change in the α_2 M molecule, a latent receptor-binding domain is exposed that facilitates the rapid removal of α_2 M-proteinase complexes from the circulation by α_2 M-specific receptor-mediated endocytosis (Gonias et al., 1983; Imber and Pizzo, 1981; Lamarre et al., 1991). For example, the half-life of radiolabeled human α_2 M-trypsin complexes in rats is only 2 minutes (Davidsen et al., 1985). There appears to be a common pathway for cellular uptake of both constitutive and acute phase macroglobulins in all mammals. Human and mouse α_2 M-proteinase complexes are eliminated by the same receptor-mediated route (Gonias et al., 1983), which is compatible with the high degree of amino acid sequence homology observed for α_2 M-receptor proteins among the species (Van Leuven et al., 1993). The human α_2 M receptor is a single-chain 440 kDa glycoprotein that is identical to the low-density lipoprotein receptor-related protein (Strickland et al., 1990) and only reacts with the activated, or complexed, form of α_2 M (Lamarre et al., 1991). Specific activated α_2 M receptors are expressed on hepatocytes (Feldman et al., 1985), fibroblasts (Hanover et al., 1983), and macrophages (Khan et al., 1995) and, at least in rabbits, on alveolar and peritoneal macrophages (Debanne et al., 1975). In healthy animals, hepatocytes are the principal cells responsible for clearing α_2 M-proteinase complexes from the circulation (Gonias et al., 1983; Lamarre et al., 1990). During an inflammatory reaction, other cell types may also become involved in the clearance of α_2 M-proteinase complexes. A comparison of the uptake and distribution of radiolabeled α_2 M in Wistar rats demonstrated that the accumulation of radiolabeled material was two to three times greater in inflamed tissue than in healthy tissue and that large amounts of both nondegraded and degraded α_2 M accumulated in inflamed renal tissue (Okubo et al., 1984).

In mice, the genes coding for α_2 M and the α_2 M-receptor have been located on chromosomes 6 and 15, respectively (Hilliker et al., 1992a, 1992b). As has been reported for other acute phase proteins, α_2 M synthesis is controlled at the transcriptional level (Baumann et al., 1991; Kurokawa et al., 1987; Pierzchalski et al., 1992). Within the nucleotide sequence, *cis*-acting hormone response elements of the α_2 M gene have been identified, which exhibit sequence homology for other APRs, such as α_1 -AGP (Baumann et al., 1991). In rat hepatoma, cells exposed to IL-1, IL-6, and dexamethasone, the transcriptional activity for α_2 M, like that of α_1 -AGP, was delayed 2–4 hours and required ongoing protein synthesis (Baumann et al., 1991; Jensen et al., 2004).

The major source of plasma α_2 M is the hepatocyte, though other cell types, such as human fibroblasts (Mosher and Wing, 1976) and human monocytes (Hovi et al., 1977), are also capable of synthesizing and secreting α_2 M. In both pregnant rats and mice, α_2 M is additionally synthesized in placental tissue (Overbergh et al., 1995; Sarcione and Bohne, 1969) along with the α_2 M receptor (Ashcom et al., 1990). In mouse embryos, mRNA for the α_2 M receptor is expressed in most organs and mRNA levels for the α_2 M protein increase progressively after day 17 of gestation (Lorent et al., 1995). As in the adult animal, the liver is the main site of α_2 M synthesis in fetal mice (Van Leuven et al., 1992).

19.4.2 ROLE/FUNCTION

In both Wistar and Buffalo rats, turpentine injection induces an increase in both hepatic α_2 M-mRNA and in plasma α_2 M levels that peak 16–24 hours after treatment (Geiger et al., 1988b; Glibetic et al., 1992). A more rapid α_2 M response is observed when IL-6 is injected into Wistar rats with peak plasma α_2 M values appearing within 4 hours of treatment (Geiger et al., 1988b). Exposure of either rat or mouse hepatocyte cultures, or human hepatoma cells, to IL-6 is also sufficient to induce an increase in α_2 M synthesis (Koj et al., 1991). In rat hepatoma cells, this effect of IL-6 can be enhanced by the addition of HGF to the culture medium (Koj et al., 1995). In the presence of dexamethasone, HGF alone can induce a selective increase in α_2 M-mRNA expression and α_2 M protein secretion in cultured rat hepatoma cells (Pierzchalski et al., 1992). When rat hepatoma cells are exposed to a combination of IL-1, IL-6, and dexamethasone, the initiation of α_2 M-mRNA transcription, like that of α_1 -AGP, is delayed 2–4 hours (Baumann et al., 1991). Other cytokines, including ciliary neurotrophic factor (CNTF), can also stimulate α_2 M synthesis in rat hepatocyte and human hepatoma cells (Kurokawa et al., 1987; Schooltink et al., 1992).

The broad spectrum of proteinases with which α_2 M interacts suggests that α_2 M has a general role in controlling inflammation, coagulation, and fibrinolysis. However, for almost all endogenous proteinases that form complexes with α_2 M, there is a more specific and a rapidly acting antiproteinase present in the circulation that confounds the elucidation of the biological function(s) of α_2 M (Jensen et al., 2004; Lamarre et al., 1991). In addition, α_2 M does not appear to be able to compensate for diseases associated with congenital deficiencies of specific proteinase inhibitors such as α_1 -PI. Consequently, it is likely that the major physiological role of α_2 M is as a vehicle for the rapid removal of proteinases from the circulation, as opposed to it serving primarily as a proteinase inhibitor. Such a role for α_2 M would be compatible with another proposed function, namely, as a binding and carrier protein for several important cytokines, such as IL-6 and TNF α (Jensen et al., 2004; James, 1990; Lamarre et al., 1991). For example, α_2 M does not inhibit the biological activity of IL-6 or the binding of IL-6 to its receptor, but it does protect IL-6 from proteolytic degradation (Matsuda et al., 1989). Cytokines, like IL-1 and TNF α , do not bind extensively with the native form of human α_2 M, but readily interact with the proteolytically active form (Borth and Luger, 1989; Wollenberg et al., 1991a). Following binding, TNF α / α_2 M complexes are removed from the circulation by the α_2 M receptor pathway (Wollenberg et al., 1991a). While α_2 Ms isolated from several species can interact with both TGF β_1 and TGF β_2 , α_2 M exhibits a 10-fold greater affinity for TGF β_2 and selectively exerts an inhibitory action only on TGF β_2 (Danielpour and Sporn, 1990; Lamarre et al., 1990). A combination of dexamethasone and human α_2 M enables normal rat hepatocytes to overcome the inhibitory effects of TGF β_1 and TGF β_2 , which indicates that α_2 M may have a role in regulating proliferative responses in hepatocytes (Wollenberg et al., 1991b).

Despite the incomplete understanding of the physiological role of α_2 M as an antiprotease, it is apparent that α_2 M has a critical role as a host defense factor in septic shock. Not only has α_2 M been shown to be the major factor in guinea pig plasma that inhibits elastase activity in vitro (Khan et al., 1994), but it can also ameliorate the development of septic shock in guinea pigs inoculated with an elastase-producing bacterial strain (Khan et al., 1995). In the inoculated guinea pigs, two-thirds of the circulating α_2 M was consumed prior to the clinical appearance of symptoms of shock, an observation that may partially explain the consistent failure to observe increases in serum levels of α_2 M in some species during inflammation. In vitro studies have demonstrated that α_2 M is able to impair cell invasion and has the capacity to enhance the phagocytic and microbicidal actions of macrophages to *Trypanosoma cruzi* (Araujo-Jorge et al., 1990). When BALB/cJ mice were infected with *T. cruzi*, only surviving animals displayed a significant increase in circulating α_2 M levels (Araujo-Jorge et al., 1992). This protective effect of α_2 M may be related to the observation that both human and rat α_2 Ms can form complexes with human fibroblast collagenase in a 1:2 stoichiometric ratio (Sottrup-Jensen and Birkedal-Hansen, 1989). Fibroblast collagenase is a proteinase that has a primary substrate specificity resembling that of the microbial proteinase thermolysin. Hence, α_2 Ms

can potentially modulate the activity of a broad spectrum of proteinases, including collagenases, of the extracellular matrix (ECM) (Sottrup-Jensen and Birkedal-Hansen, 1989).

In addition to its role as an inhibitor of mitogen-induced stimulation of lymphocytes isolated from humans (Rastogi and Clausen, 1985), rats (Miyanaga et al., 1982), and hamsters (Hart and Stein-Streilein, 1981), $\alpha_2\text{M}$ has been shown to suppress T-cell blastogenesis in several species (James, 1980; Mannhalter et al., 1986). Further, activated $\alpha_2\text{M}$ (but not native $\alpha_2\text{M}$) can inhibit the stimulation of macrophage by a T-cell dependent inflammatory lymphokine isolated from guinea pig lymph node cells (Godfrey et al., 1984). Consequently, $\alpha_2\text{M}$, like other APRs, may function as an immunosuppressive agent. $\alpha_2\text{M}$ has been isolated from both rat and human brain tissue (Dziegielewska et al., 1986; Kodelja et al., 1986), and human, mouse, and equine $\alpha_2\text{Ms}$ all exhibit nerve growth factor binding activity (Ronne et al., 1979). The ability of the activated form of $\alpha_2\text{M}$ to suppress neurite outgrowth has led to the suggestion that accumulation and activation of $\alpha_2\text{M}$ associated with inflammatory neuropathies may inhibit synaptic plasticity (Cavus et al., 1996).

19.4.3 ANALYTICAL METHODS

The majority of studies evaluating $\alpha_2\text{M}$ levels in laboratory animals have employed immunological methods in part due to the availability of species-specific antibodies, because $\alpha_2\text{M}$ has been purified from rat, mouse, guinea pig, hamster, and rabbit plasma (Watterson et al., 2008; Barrett et al., 1979; Godfrey et al., 1984; Hirschelmann et al., 1990; Miyake et al., 1993; Okubo et al., 1981; Suzuki and Sinohara, 1986; Tamamizu et al., 1989; Van Leuven et al., 1992). While single peaks are generally observed for $\alpha_2\text{M}$ determined with rocket immunoelectrophoretic procedures, multiple bands staining for $\alpha_2\text{M}$ are generally observed in polyacrylamide gel electrophoresis because native $\alpha_2\text{M}$ and $\alpha_2\text{M}$ -proteinase complexes display similar antigenic properties but have different molecular weights (Barrett et al., 1979; Lamarre et al., 1991). Spectrophotometric assays using chromogenic substrates are frequently used to assess the functional activity of $\alpha_2\text{M}$ -proteinase complexes. However, this type of assay does not discriminate between the different forms of macroglobulin-type proteinase inhibitors that are present in rat, mouse, guinea pig, rabbit, and hamster plasma (French, 1989; Ganrot, 1973b; Geiger et al., 1987; Miyake et al., 1993; Saito and Sinohara, 1985b). Inactivation of $\alpha_2\text{M}$ can occur during sample storage, which can cause disparity between estimations of $\alpha_2\text{M}$ determined by immunological and functional procedures (Ganrot, 1966; Gressner and Peltzer, 1984).

19.4.4 PATHOPHYSIOLOGICAL SIGNIFICANCE

Circulating $\alpha_2\text{M}$ levels are low in healthy rats, with values of 300 $\mu\text{g}/\text{mL}$ or less being reported (French, 1989; Geiger et al., 1987; Kurokawa et al., 1987; Okubo et al., 1981). Strain differences in the $\alpha_2\text{M}$ response in rats to turpentine as an inflammatory stimulant have been observed. For example, in Wistar rats, circulating $\alpha_2\text{M}$ levels rose from approximately 30 to 400 $\mu\text{g}/\text{mL}$ within 24 hours of turpentine injection (Okubo et al., 1981). While a ninefold increase was observed in Hans Wistar rats after 4 days of dosing with drug candidate during a preclinical toxicology study (Watterson et al., 2008). In comparison, this treatment only induced a 2.5-fold increase in serum $\alpha_2\text{M}$ in male Buffalo rats (Warwas and Osada, 1985). In Wistar:Barby rats, circulating $\alpha_2\text{M}$ levels rose from 9 ± 5 mg/mL to 157 ± 55 mg/mL within 3 days of the induction of an inflammatory response (Hirschelmann et al., 1990). Similar differences in the $\alpha_2\text{M}$ response have been documented for August and Lewis rats (French, 1989). Although no sex differences have been observed in the response of rat $\alpha_2\text{M}$ to turpentine injection, the injection of recombinant human IL-6 into Wistar rats produced an increase in circulating $\alpha_2\text{M}$ values only in male animals (Geiger et al., 1988b).

Higher blood $\alpha_2\text{M}$ levels are found in pregnant, fetal, and neonatal rats than in mature animals (French, 1989). Throughout gestation days 10–20, the level of $\alpha_2\text{M}$ -mRNA in fetal rat liver is twofold higher than that in adult liver, and the fetal liver responds to inflammation in the mother

by the transcriptional increase in α_2 M (Glibetic et al., 1992). The ability of fetal liver to synthesize large amounts of α_2 M is consistent with the observation that α_2 M is the major circulating proteinase inhibitor in human newborns (Andrew et al., 1987). During pregnancy in human females, an inducible protein, referred to as *pregnancy zone protein*, with characteristics of a macroglobulin appears in the circulation (Sand et al., 1985).

In mice, normal circulating α_2 M levels are around 1–2 mg/mL with similar values being found in pregnant and nonpregnant animals (Van Leuven et al., 1992). No increases in plasma α_2 M levels occur in mice treated with *T. cruzi* despite evidence of an inflammatory response being mounted in the animals (Araujo-Jorge et al., 1992). In Syrian hamsters, normal circulating α_2 M values are about threefold higher than human values at 6.9 mg/mL and, as was found for mice, no increase in serum α_2 M levels was observed during the acute phase reaction (Miyake et al., 1993). In contrast to the decrease in plasma α_2 M levels observed in human patients with sepsis, a dose-dependent increase in serum α_2 M levels was detected in baboons treated with *Escherichia coli* or *Staphylococcus aureus* (de Boer et al., 1993). Likewise, in rhesus monkeys, administration of IL-6 induced an increase in plasma α_2 M values from 2.2 to 4.0 mg/mL (Myers et al., 1995).

19.5 C-REACTIVE PROTEIN

19.5.1 PROPERTIES

CRP was the first APR protein to be discovered in people (Tillett and Francis, 1930), and while species variations exist, CRP is now recognized as an APR protein in most laboratory animals, including rabbits, rats, mice, dogs, and cats. Both rabbit and rat CRP have also been referred to as phosphorylcholine-binding protein (PCBP) (Murata et al., 2004; Marnell et al., 2005).

The CRPs isolated from different mammalian species share structural homology in being composed of five identical subunits, each approximately 20–23 kDa, that are arranged in a flat pentameric disk structure with cyclical symmetry (Osmand et al., 1977; Sui et al., 1996; Whitehead, 1989). In rabbit and human CRP, the subunits are noncovalently linked, while rat CRP is unique in containing a covalently linked dimer in its pentameric structure (Murata et al., 2004; Marnell et al., 2005; Nagpurkar and Mookerjea, 1981; Rassouli et al., 1992). In rat CRP, two of the five identical monomeric units are linked by interchain disulfide bonds involving the same cysteine residues that form the intrachain disulfide bonds in the other monomers (Rassouli et al., 1992). Only dog and rat CRPs are glycoproteins (Caspi et al., 1984; Nagpurkar and Mookerjea, 1981; Rassouli et al., 1992). Each mammalian CRP examined to date has been found to contain between 204 and 206 amino acid residues in the native molecule, with a hydrophobic leader consisting of 18 or 19 amino acids in the premolecule (Dowton and Holden, 1991; Rubio et al., 1993; Whitehead, 1989; Whitehead et al., 1990). There is extensive homology in the amino acid sequences among rabbit, human, rat, and mouse CRPs (Hu et al., 1986; Lei et al., 1985; Liu et al., 1987; Ohnishi et al., 1986; Rassouli et al., 1992; Taylor et al., 1984; Whitehead, 1989). For example, there is greater than 71% homology among the amino acid sequences of rabbit and human CRP, which is similar to that found between rat and human CRP (Taylor et al., 1984; Whitehead, 1989).

Both the mouse and human CRP gene are encoded as a single copy on chromosome 1 (Floyd-Smith et al., 1986; Ku and Mortensen, 1993). cDNA and genomic DNA have been cloned and sequenced for human, mouse, rat, hamster, and guinea pig CRP (Dowton and Holden, 1991; Ku and Mortensen, 1993; Rubio et al., 1993; Whitehead et al., 1990). Comparisons among species show that the major differences in the organization of the gene are in the regions that potentially determine the capacity of the CRP gene to be induced during acute inflammation (Dowton and Holden, 1991; Rubio et al., 1993; Taylor et al., 1984; Whitehead et al., 1990). Indeed, the type of response element associated with the CRP gene appears to be critical in regulating CRP synthesis (Li and Goldman, 1996; Lin and Liu, 1993; Rubio et al., 1993; Whitehead, 1989; Zhang et al., 1996). Several *cis*-elements and trans-activators are required for cytokine-induced CRP gene transcription. These include two IL-6

inducible C/EBP family members, whose binding sites are located in the proximal region of the CRP promoter (Ramji et al., 1993), and one of the signal transducer and activators of transcription (STAT) family members, STAT3 (Zhang et al., 1996). The STAT3-IL-6 response element was originally named the acute phase response element (Zhang et al., 1996; Zhong et al., 1994). In cultures of human hepatocytes, IL-6 is the primary cytokine that stimulates CRP gene expression (Marnell et al., 2005; Li et al., 1990). Although the mouse CRP gene also contains an IL-6 response element, neither recombinant human nor mouse IL-6 preparations were found to trigger CRP expression in isolated mouse hepatocytes (Ku and Mortensen, 1993). In mice, IL-1 is the primary cytokine responsible for inducing CRP synthesis. Gene transcription is induced through IL-1 interaction with both a C/EBP element and a hepatocyte nuclear factor-1 (HNF-1) element in the mouse gene (Lobetti et al., 2000; Ku and Mortensen, 1993). Since the HNF-1 element is one of the distinct promoters of liver-specific gene expression, these results may account for the tissue-specific expression of CRP as well as its limited expression as an APR protein in mice relative to other species (Ku and Mortensen, 1993).

The hepatocyte is the major site of CRP synthesis, where the rate of production is regulated at the transcriptional level (Ciliberto et al., 1987; French, 1989; Goldberger et al., 1987; Li and Goldman, 1996; Nunomura et al., 1994). In primary cultures of human hepatocytes, IL-6, in the presence of dexamethasone, stimulates the synthesis and secretion of CRP within 24 hours (Yap et al., 1991). When IL-1 is also included in the culture medium, a further increase in CRP production occurs within 48 hours. The stimulatory effect of IL-1 can be blocked by the inclusion of antibodies to IL-6 in the culture medium, indicating that the effect of IL-1 is mediated through IL-6 (Yap et al., 1991). In human hepatocyte cultures, TNF α by itself acts as an inhibitory cytokine for CRP synthesis, and it can also antagonize the actions of both IL-6 and IL-1 (Yap et al., 1991). In contrast, TNF α , like IL-1 and IL-6, induces the hepatic accumulation of CRP-mRNA in Syrian hamsters (Dowton and Holden, 1991), while in rabbits, neither IL-1 nor TNF α appear to be involved in the expression of hepatic CRP-mRNA and CRP synthesis during the inflammatory response (Mackiewicz et al., 1988).

19.5.2 ROLE/FUNCTION

Based on comparison of the structural similarities among rabbit, human, and *Limulus* CRP (which, unlike the mammalian proteins, consists of a hexameric disc of six subunits [Fernandez-Moran et al., 1986]), two functionally important regions of the molecule have been identified (Liu et al., 1987). One region confers the ability to bind calcium and is one of the most highly conserved regions of the molecule (Liu et al., 1987; Swanson et al., 1991b). The second region is a phosphorylcholine (PC)-binding region (Roux et al., 1983). Although the extent of CRP binding to PC varies between species, calcium-dependent PC binding is considered the common functional characteristic of all CRP molecules (Murata et al., 2004; Marnell et al., 2005; Nunomura, 1992; Oliveira et al., 1980; Pepys and Baltz, 1983; Schwalbe et al., 1992; Swanson and Mortensen, 1990; Swanson et al., 1991a). Interactions between CRP and a variety of ligands can also occur, indicating that CRP may be one of the proteins that serves as a connection between inflammation, immunity, lipid metabolism, and possibly atherosclerosis (Murata et al., 2004; Marnell et al., 2005; Adib-Conquy and Cavaillon, 2007). Human, rat, and rabbit CRPs have all been shown to selectively bind to plasma lipoproteins in a calcium-dependent manner (Cabana et al., 1983; Mookerjee et al., 1994; Rowe et al., 1984a, 1984b; Schwalbe et al., 1995). Further, CRP binding to immune complexes (Motie et al., 1996), basement membrane components such as fibronectin and laminin (Kolb-Bachofen, 1992; Salonen et al., 1984; Swanson et al., 1989; Tseng and Mortensen, 1988), and nuclear material (Dougherty et al., 1991; Du Clos, 1989; Nunomura, 1992) have also been demonstrated.

CRP, like other pentraxin molecules, is highly resistant to proteolytic degradation, especially in the presence of calcium (Ying et al., 1992), but human neutrophil enzymes can digest human CRP

(Shephard et al., 1992; Ying et al., 1992) and rat peritoneal macrophages can digest rat CRP with the generation and release of biologically active peptides (Nagpurkar et al., 1993). Since native CRP appears to have little biological activity unless bound to a ligand (Potempa et al., 1988), it is likely that these CRP degradation products contribute to the anti-inflammatory function of CRP (Murata et al., 2004; Marnell et al., 2005; Adib-Conquy and Cavaillon, 2007; Heuertz et al., 1996).

Based on studies in rabbits, mice, rats, and people, it has been concluded that hepatocytes are the most important site of clearance of serum CRP and that the rate of clearance is independent of plasma CRP levels (Baltz et al., 1985a; French, 1989; Hutchinson et al., 1994; Vigushin et al., 1993; Yang et al., 1992). In healthy rabbits, rats, and mice, the circulating half-life of CRP is short, ranging from 3 to 4.5 hours (Chelladurai et al., 1983; Rowe et al., 1984c). In rats undergoing an acute phase response, CRP is even more rapidly removed from the circulation, with the clearance rate increasing twofold (Rowe et al., 1984c). In transgenic mice programmed to synthesize rabbit CRP, the clearance rate of rabbit CRP from the circulation varies between 30 and 60 minutes under both normal and inflammatory conditions (Lin et al., 1995). The clearance rate of CRP is independent of ligand binding, but removal of sialic acid residues from rat CRP reduces the clearance time to approximately 5 minutes (Baltz et al., 1985a; Yang et al., 1992). The relatively rapid rate of CRP clearance may contribute to the rapid return of serum CRP to basal levels following exposure of an animal to a single inflammatory challenge.

CRP clearly plays an important role in initiating and modulating inflammatory and immune responses (French, 1989; Kushner, 1988). In the early stages of inflammation, CRP functions to stimulate the monophagocytic system through its interaction with several types of white cells. Specific and saturable high- and low-affinity binding sites for CRP have been identified on macrophages, neutrophils, and monocytes (Ballou et al., 1989; Crowell et al., 1991; Kempka et al., 1990; Kolb-Bachofen, 1991; Tebo and Mortensen, 1991; Zahedi et al., 1989) and T lymphocytes but not B lymphocytes (Mortensen et al., 1975). CRP can induce opsonin-like enhancement of phagocytosis (Murata et al., 2004; Marnell et al., 2005; Adib-Conquy and Cavaillon, 2007; Kilpatrick and Volanakis, 1985; Mold et al., 1982), which is considered a factor in the passive protection of mice against lethal challenge of *pneumocci* afforded by increased serum CRP levels (Kolb-Bachofen and Abel, 1991; Mold et al., 1981). Mouse macrophages and human monocytes respond to CRP activation by exhibiting a tumoricidal activity (Barna et al., 1984; Zahedi and Mortensen, 1986; Zahedi et al., 1989) through increased superoxide production (Foldes-Filep et al., 1992; Kolb-Bachofen and Abel, 1991; Nunomura, 1992; Zeller et al., 1986). On the other hand, both neutrophil chemotaxis and expression of adhesion molecules on the surface of activated neutrophils are inhibited by exposure to CRP (Heuertz et al., 1993, 1996; Kew et al., 1990; Webster et al., 1994), as is protein phosphorylation in CRP pretreated activated neutrophils (Buchta et al., 1988). These effects likely contribute to the protective effect that CRP exerts on lung injury in rabbit and mouse models of adult respiratory distress syndrome (Heuertz et al., 1993, 1994, 1996).

Human CRP can depress the *in vitro* aggregation response in activated mammalian platelets (Cheryk et al., 1996). When human, rabbit, or rat platelet suspensions are exposed to CRP and stimulated with the inflammatory mediator platelet activating factor (PAF), a biologically active phospholipid both the rate and extent of aggregation is depressed compared to untreated platelet suspension (Fiedel and Gewurz, 1976; Nagpurkar et al., 1988; Vigo, 1985). This response is mediated through the direct interaction of CRP with PAF, which reduces the bioavailability of the platelet agonist (Filep et al., 1991; Kilpatrick and Virella, 1985; Randell et al., 1990). The basal rate of removal of low-density lipoproteins (LDLs) from the circulation is enhanced when serum CRP levels rise, because macrophages readily endocytose the complexes formed between CRP and Apo-B and Apo-E-containing lipoproteins (Mookerjee et al., 1994). The CRP-induced increased rate of clearance of LDLs, together with the suppression of platelet aggregation, likely function to retard the activation of the hemostatic system during an inflammatory reaction, thus modulating thrombus formation at sites of tissue damage.

Another biological role for CRP in maintaining homeostasis is its function in facilitating the removal of cellular debris from areas of tissue injury. Not only can CRP bind to one or more components of damaged cells to facilitate their removal or repair (Crowell et al., 1991), but CRP is also deposited at sites of tissue damage through selective calcium-dependent binding to laminin and fibronectin (Salonen et al., 1984; Shephard et al., 1986; Swanson and Mortensen, 1990; Swanson et al., 1989; Tseng and Mortensen, 1988, 1989). At these sites, CRP may act as a scavenger of nuclear debris because human, rat, and rabbit CRPs all have the ability to bind to histones, chromatin, and small ribonuclear proteins (Burlingame et al., 1996; Dougherty et al., 1991; Du Clos, 1989; Du Clos et al., 1988; Shephard et al., 1991). The interaction of CRP with nuclear material may be a contributing factor in the role that CRP has in reducing autoantibody formation and increasing survival time in a mouse model of systemic lupus erythematosus (Du Clos et al., 1994).

19.5.3 ANALYTICAL METHODS

The majority of procedures described to isolate CRP are based on its calcium-dependent phospholipid binding and have utilized affinity chromatography with either PC or phosphatidyl ethanolamine substituted agarose beads (Burger et al., 1987; Caspi et al., 1984; Fujise et al., 1992; Macintyre, 1988; Nunomura et al., 1994; Onishi et al., 1994; Pruden et al., 1988; Yamamoto et al., 1992, 1993a). Immunoaffinity chromatography has also been used when species-specific CRP antibodies have been available (Nunomura et al., 1994; Tanaka and Robey, 1983). Numerous assay procedures, based on either immunological or functional properties, have been employed to quantitate serum CRP. Rocket immunoelectrophoresis and ELISA assays have been frequently used for measuring CRP in serum from laboratory animals (Eckersall et al., 1989; French, 1989; Nunomura et al., 1990a; Tanaka and Robey, 1983). The ELISA for canine CRP has an advantage over both the electroimmunoassay and immunodiffusion procedures in being quantitative and sensitive to levels as low as 2.5 $\mu\text{g/mL}$ serum (Yamamoto et al., 1994a); however, the assay is affected by sample hemolysis (Eckersall et al., 1991). A capillary reversed passive latex agglutination test has been developed to quantitate canine serum CRP (Wadsworth et al., 1985; Yamamoto et al., 1994a). The method is rapid and correlates well with a canine ELISA when serum CRP concentrations are $>6.9 \mu\text{g/mL}$, but it is not sufficiently sensitive to detect CRP in normal sera (Tagata et al., 1996). Other nonimmunological procedures, including an assay based on the calcium-dependent interactions of CRP and liposomes, have been developed (French, 1989; Umeda and Yasuda, 1994; Umeda et al., 1986).

19.5.4 PATHOPHYSIOLOGICAL SIGNIFICANCE

In beagle dogs, the temporal changes in serum IL-6 and TNF α , during the inflammatory response, precede the appearance of increased serum CRP levels (Yamashita et al., 1994), which explains in part the consistent and species-independent delay between an initiating stimulus and the appearance of increased circulating CRP levels (Conner and Eckersall, 1988; Myers and Fleck, 1988).

In mice, rats, and hamsters, the age and sex of the animal can influence both hepatic CRP-mRNA levels and the amount of CRP appearing in the circulation (Murata et al., 2004; Dowton et al., 1991; Nunomura, 1990; Szalai et al., 1995). In both Wistar and August strain rats, serum CRP levels are elevated at birth compared to adult values (De Beer et al., 1982; Nunomura, 1990). The constitutive levels of hepatic CRP-mRNA are significantly lower in fetal rabbits than in adult animals (Rygg et al., 1996). In the fetal Syrian hamster, hepatic CRP-mRNA exhibited an increased response following direct exposure to an inflammatory stimulant compared to the extent of the response in adult liver (Dowton et al., 1991). The role of sex hormones in controlling CRP synthesis has not been fully elucidated. Estradiol administration to male Wistar rats produced a decrease in serum CRP levels without producing any decline in hepatic CRP-mRNA levels (Nunomura, 1990; Nunomura et al., 1994). Testosterone administration to male or ovariectomized female Wistar rats resulted in an increase in serum CRP levels (Nunomura, 1990). These results correlated with the observation

that in both Wistar and Hooded strain rats serum CRP levels are significantly higher in males than in females (De Beer et al., 1991; Nunomura, 1990). Further, a direct relationship between CRP synthesis and testosterone secretion has been documented in transgenic mice genetically manipulated to express human CRP (Klein et al., 1995; Szalai et al., 1995).

In normal rabbit hepatocytes, the rate of hepatic secretion of CRP into the blood stream is inhibited due to the retention of the protein in the endoplasmic reticulum (ER) (Macintyre et al., 1994). The binding of CRP to ligands in the ER is reduced during the acute phase response, resulting in the increased secretion efficiency of CRP (Hu et al., 1988; Macintyre et al., 1985). In hepatocyte cultures derived from turpentine-stimulated rabbits, CRP represented 3.9% of the secreted protein, compared to 0.3% of the protein in control cultures (Macintyre et al., 1983).

The normal basal serum concentration of CRP varies among species, as does the acute phase response (French, 1989). Typical species variations are illustrated in Table 19.2. Healthy dogs, rabbits, and people usually exhibit low circulating levels of CRP (Table 19.1). In these species, CRP is one of the major acute phase proteins, with levels rising rapidly within 24 hours of stimulation by up to 1000-fold (Watterson et al., 2008; Caspi et al., 1987; Conner and Eckersall, 1988; French, 1989; Hunneyball et al., 1986; Nunomura, 1992). In a group of 77, clinically ill dogs in which CRP levels were markedly elevated, postmortem diagnosis established that in all the affected dogs, raised CRP values were associated with bacterial infections and pyometra and that the elevation of CRP reflected the extent of inflammatory damage (Yamamoto et al., 1993b). In this study, the extent of serum CRP levels increased from basal levels of $8.5 \pm 0.5 \mu\text{g/mL}$ in a healthy control group to up to $394 \mu\text{g/mL}$ in dogs with leptospirosis, while no increases in CRP were observed in dogs with gastrointestinal disorders or nephritis. The association between bacterial infections and elevations in serum CRP levels has also been observed in experimental studies. *Leptospira* inoculation in dogs resulted in serum CRP rising from <5 to up to $400 \mu\text{g/mL}$ 2-4 days after inoculation (Caspi et al., 1987). Inoculation of dogs with *Bordetella bronchiseptica* produced a similar response (Yamamoto et al., 1994b), while a slightly reduced response was observed following inoculation with *E. canis* with serum CRP values being increased by 3.3–6.5-fold (Rikihisa et al., 1994). It is likely that the CRP response is mediated (at least in part) by IL-6 because following turpentine injection, the increase in serum CRP from barely detectable levels up to $431.5 \pm 31.3 \mu\text{g/mL}$ was preceded by a dramatic increase in serum IL-6 levels (Yamashita et al., 1994). Elevations of CRP have also been observed in dogs postsurgery (Caspi et al., 1984, 1987; Conner and Eckersall, 1988; Yamamoto et al., 1993b), and the extent of the increases shows a weak but significant correlation with alteration in neutrophil counts (Burton et al., 1994).

In healthy New Zealand white rabbits, basal serum levels of CRP have been reported as being barely detectable to being as high as $31 \pm 9 \mu\text{g/mL}$ (Cabana et al., 1983; Heuertz et al., 1993; Noe et al., 1989). In rabbits, variations in the serum CRP response to different inflammatory stimuli, as well as the response of individual animals, have been observed. For example, the administration of

TABLE 19.2
Interspecies Differences in Basal Serum C-Reactive Protein (CRP) in Healthy Adult Animals and during the Acute Phase Response

Species	CRP $\mu\text{g/mL}$	
	Normal Sera	Acute Phase Sera
Human	<1	300–500
Rabbit	0–31	65–350
Dog	3–22	83–720
Rat	180–500	700–1300
Mouse	<2	1–2
Guinea pig	Not detected	Not detected

1% croton oil to rabbits has variously been reported as inducing a twofold increase in serum CRP to a maximum of around 64 $\mu\text{g/mL}$ 24 hours after treatment (Cabana et al., 1983) to producing an increase from barely detectable serum CRP to a peak of $350 \pm 70 \mu\text{g/mL}$ within 48 hours of treatment (Heuertz et al., 1993). When the effects of turpentine, endotoxin, and IL-1 administration in rabbits were compared, only turpentine was found to produce a marked increase in serum CRP with values rising to around 150 $\mu\text{g/mL}$ (Noe et al., 1989). In this study, the serum CRP response to endotoxin was 10-fold lower than the turpentine response, and there was no CRP response to IL-1 administration. Transient increases in serum CRP levels have been noted in rabbits with antigen-induced monoarticular arthritis (French, 1989).

Healthy rats exhibit relatively high serum CRP values, and in this species, CRP reacts only as a moderately responsive acute phase protein (Bout et al., 1986; Mookerjea and Hunt, 1995; Nunomura, 1990). A consistent observation in rats is a two- to fourfold increase in serum CRP levels following an inflammatory stimulus such as turpentine (Burger et al., 1987; Myers and Fleck, 1988; Nunomura, 1992; Nunomura et al., 1990b). However, studies carried out by Watterson et al. (2008) discovered that CRP levels in Wistar rats were variable and did not support CRP as a sensitive acute phase protein in rats. In rats, as in people, age-related changes in serum CRP levels have been found. In Wistar strain rats, serum CRP was determined to be $3.6 \pm 0.8 \mu\text{g/mL}$ at birth, and an increase to adult values did not begin until the rats were more than 15 days old (Nunomura, 1990). This is similar to the lower serum CRP values observed in human neonates compared to adults (French, 1989). In both rats and women, increased serum CRP levels are observed around the time of parturition (French, 1989; Nunomura, 1990, 1992). In pregnant rats, two additional serum CRP peaks occur at days 0 and 15 of gestation, with mean values of $770 \pm 100 \mu\text{g/mL}$ being observed for the later peak (Nunomura, 1990). The factors regulating these pregnancy-related changes are unclear. However, estradiol has been shown to exert an inhibitory activity on rat CRP expression while testosterone exerts a stimulatory effect (Nunomura, 1990, 1992).

In both the mouse and guinea pig, CRP is barely detectable (if at all) in the serum of normal animals (Table 19.2), and in neither species does CRP respond as an acute phase protein (French, 1989; Lin et al., 1995; Rubio et al., 1993; Whitehead et al., 1990). The lack of CRP response in the guinea pig has been related to a lack of the appropriate promoter region in the guinea pig CRP gene (Rubio et al., 1993).

19.6 CERULOPLASMIN

19.6.1 PROPERTIES

Ceruloplasmin (CP) is a blue multicopper oxidase that is found in all vertebrates. The circulating Cps of all species have similar molecular weights (French, 1989; Ryden, 1972). It is the major plasma copper (Cu) carrying protein in rats and people but not in dogs or mice (Montaser et al., 1992). It has been suggested that in dogs and mice transcuprein is the major Cu transport protein (Montaser et al., 1992).

Ceruloplasmin is a glycoprotein (8%–9% carbohydrate) that migrates as an α_2 -globulin and contains six to seven Cu atoms per molecule. Human CP circulates as a single polypeptide chain with a molecular weight of 132 kDa that carries 70%–90% of the circulating Cu (Gutteridge and Stocks, 1981; Harris, 1991; Kingston et al., 1977). The complete amino acid sequence of human CP and rat CP has been determined by protein sequence analysis (Takahashi et al., 1984) and by cDNA cloning (Aldred et al., 1987; Fleming and Gitlin, 1990; Kischinsky et al., 1986; Yang et al., 1986). The amino acid sequence of rat CP is 93% homologous with human CP and contains a 19 amino acid leader peptide plus a 1040 amino acid mature protein (Fleming and Gitlin, 1990). Similarly, the amino acid structure of murine CP deduced from cDNA clones indicates that close homology exists between murine and human CP (Klomp et al., 1996). Despite the similarities in structure, there are obvious physical and enzymatic differences between rat and human CPs. Rat CP is less susceptible

to proteolysis and possesses only a fraction of the ferroxidase activity found in human CP (Ryan et al., 1992).

Circulating CP is primarily derived from the liver, though studies using a variety of techniques, such as molecular cloning, gene expression, and immunohistochemical staining, have confirmed that CP can also be synthesized in many other tissues including lung (Bingle et al., 1992; Fleming and Gitlin, 1990; Klomp et al., 1996), brain (Aldred et al., 1987; Kalmovarin et al., 1991; Levin et al., 1984; Thomas et al., 1989), uterus (Thomas and Schreiber, 1988, 1989; Thomas et al., 1995), placenta (Aldred et al., 1987; Thomas and Schreiber, 1989), mammary tissue (Jaeger et al., 1991), testes (Forti et al., 1989; Skinner and Griswold, 1983), and macrophages and lymphocytes (Fleming et al., 1991; Pan et al., 1996). Investigations into the biosynthesis of CP in rat hepatocytes have been facilitated by the availability of Long-Evans Cinnamon (LEC) rats, which display a genetic defect in Cu metabolism, and by studies with rats nutritionally deficient in Cu (Gitlin et al., 1992; Yamada et al., 1993). The Cu-deficient apo-form of CP is immunologically identical to the holo-form of the enzyme and exhibits a similar glycosylation pattern, but the apo-form lacks oxidase activity (Gitlin et al., 1992; Hiyamuta and Takeichi, 1993; Terada et al., 1995; Yamada et al., 1993). The incorporation of Cu into CP occurs in the Golgi apparatus (Terada et al., 1995). Hepatic Cu content appears to have no effect on CP gene expression or the extent of CP biosynthesis, and the rates of secretion of both Cu-containing and Cu-deficient CP from hepatocytes are similar (Bingle et al., 1990; Gitlin et al., 1992; Terada et al., 1995).

The rat CP gene has been cloned, sequenced, and assigned to chromosome 2 (Fleming and Gitlin, 1992; Li et al., 1991). The CP-mRNA isolated from different rat tissues is identical in nucleotide sequence and is the product of a single transcription start site (Fleming and Gitlin, 1992). Although the tissue-specific expression of CP appears to be regulated in the rat by an exacting region 393 base pairs upstream of the transcription start site, the enhancer-binding (C/EBP) consensus elements are not involved in the selective tissue expression of CP (Klomp et al., 1996). In both guinea pigs and humans, in addition to the 3.7 kb mRNA that is expressed in rats, a second larger mRNA also encodes CP (Bingle et al., 1991). The additional CP-mRNA found in guinea pig liver is slightly larger (5.0 kb) than that found in human liver (4.2 kb) (Bingle et al., 1991). In guinea pigs, no hepatic synthesis of CP is detectable before birth, and after birth, there is no clear differential expression of the two mRNA species (Bingle et al., 1991). The expression of guinea pig CP appears to be related to the birth process rather than the gestational age of the animal (Bingle et al., 1992). This contrasts with the situation in rats and humans, where CP-mRNA is detectable in fetuses during the later stages of gestation, though the CP-mRNA levels are lower than those found in adults (Fleming and Gitlin, 1990; Gutteridge and Stocks, 1981). While CP-mRNA is found in the liver of fetal rats after day 15 of gestation, CP is not present in the circulation until later, which suggests that some posttranslational control mechanism is involved in synthesis and secretion of the protein (Bingle et al., 1991). This conclusion is also supported by kinetic studies of CP expression during the acute phase response (Gitlin, 1988).

19.6.2 ROLE/FUNCTION

One of the biological functions of CP is the delivery of Cu to tissues. Specific CP receptors have been identified in a variety of tissues, including aortic and cardiac tissue (Stevens et al., 1984), brain (Crowe and Morgan, 1996), monocytes, granulocytes, and lymphocytes (Kataoka and Tavassoli, 1985), erythrocytes (Barnes and Freiden, 1984; Stern and Freiden, 1993), and hepatic endothelial cells (Kataoka and Tavassoli, 1984, 1985; Tavassoli et al., 1986). The binding of CP to rat erythrocytes is saturable, reversible, specific, and is mediated through a 150 kDa receptor composed of 50 kDa subunits (Stern and Freiden, 1990, 1993). In contrast, the CP receptor isolated from liver endothelium is a 35 kDa protein (Omoto and Tavassoli, 1990). Whether the different molecular weights reflect the existence of different types of tissue-specific receptors has yet to be determined. It is known, however, that the receptors on erythrocytes and hepatic endothelium recognize different

parts of the CP molecule. Furthermore, a comparison of the CP receptors on hepatic Kupffer and hepatic endothelial cells indicates that the Kupffer cells can discriminate between the native, physiological conformation of CP and other forms of the protein, such as asialo-CP (Dini et al., 1990). Hepatic endothelial cells not only interact with CP but they can desialate native CP, which is then transferred to hepatocytes, where it is endocytosed via asialoglycoprotein receptors (Dini et al., 1990; Tavassoli, 1985). These galactosyl receptors are likely responsible for the rapid clearance of CP from the circulation that has been observed following removal of sialic acid residues (Gregoriadis et al., 1970; Van den Hamer et al., 1970).

Like other acute phase proteins, CP is a multifunctional protein with one of its primary physiological roles being that of an antioxidant. There are several ways in which CP can fulfill this function: (1) by donating Cu to tissues for the synthesis of Cu-containing enzymes (Campbell et al., 1981), (2) by directly scavenging superoxide anions (Goldstein et al., 1979), and (3) by inhibiting metal-catalyzed lipid peroxidation through the reincorporation of iron back into serum ferritin or transferrin (Osaki et al., 1971; Samokyszyn et al., 1989). In both rats and humans, CP is the major Cu-carrying component in blood (Gubler et al., 1953; Montaser et al., 1992; Sternlieb et al., 1961) and delivers Cu to peripheral cells and tissues, where it is absorbed by specific surface receptors (Goode et al., 1990; Percival and Harris, 1988). In both dogs and mice, CP is less important as a Cu transporter in the circulation, and both these species exhibit lower circulating levels of Cu and CP than either rats or humans (Montaser et al., 1992). It has been suggested that the high levels of gene expression in the lung during fetal development in the rat may serve as a pulmonary antioxidant defense mechanism (Fleming and Gitlin, 1990). This suggestion is compatible with the proposed role for CP during inflammation because CP can function to neutralize free radicals produced by activated leukocytes (Broadley and Hoover, 1989; Gutteridge and Stocks, 1981). Likewise, the increase in CP-mRNA in the mouse uterus at the time of implantation may occur to provide sufficient CP to serve as an effective free radical scavenger that can moderate the uterine inflammatory response and prevent overstimulation of the immune system during pregnancy (Thomas et al., 1995). It has been suggested that at least in the rat, CP may play a role in protecting the fetus and maintaining homeostasis at different stages of reproduction (Thomas and Schreiber, 1988). High levels of CP-mRNA, but not α_2 M-mRNA or α_1 -AGP-mRNAs, are present in the uterus of both pregnant and nonpregnant rats, further indicating a selective role for CP (Thomas and Schreiber, 1988).

Pulmonary CP gene expression is increased during conditions of both inflammation and hyperoxia (Fleming et al., 1991; Moak and Greenwald, 1984). The antioxidant function of CP in the airways may be related to its ferroxidase activity (Gutteridge, 1991). Relative to the oxidase activity of CP, dog and mouse CPs possess higher levels of ferroxidase activity than rat CP (Montaser et al., 1992). High-affinity iron acquisition from the environment is an essential determinant of bacterial virulence, and hence the presence of CP in alveolar epithelium may represent a host defense by limiting ferrous iron availability (Cornelissen and Sparling, 1994). The expression of CP in astrocytes within the retina and brain, as well as the epithelium of the choroid plexus may also be associated with the role of CP in iron metabolism (Klomp et al., 1996). Human aceruloplasminemia is an autosomal recessive disorder characterized by neurodegeneration of the retina and basal ganglia associated with iron accumulation (Logan et al., 1994; Miyajima et al., 1987). A further link between CP and iron metabolism is apparent in the downregulation of hepatic CP receptors that can be induced in the suckling rat as a result of iron loading (Crowe and Morgan, 1996).

In addition to its role in the inflammatory response as an antioxidant, the expression of CP in immune tissues, such as the spleen and thymus, supports a role for this protein in the activation, effector function, and cytoprotection of immune cells (Kalmovarin et al., 1991; Kojima et al., 1986; Pan et al., 1996; Saenko et al., 1994). Not only is immune system function suppressed in Cu deficiency (Bala and Failla, 1992), but in the macular mutant mouse (which is characterized by reduced CP levels), antibody production against sheep red blood cells is also reduced (Nakagawa et al., 1993). Ceruloplasmin may also influence the innate immune system in animals, because it has been

shown that the phagocytosis of *Candida albicans* by human neutrophils and monocytes is stimulated by CP (Saenko et al., 1994).

19.6.3 ANALYTICAL METHODS

Serum CP levels have been evaluated by both functional and immunological procedures, though both systems are subject to problems of accuracy in distinguishing and quantifying active CP. Ceruloplasmin oxidase in serum deteriorates on sample storage (Gutteridge et al., 1985), and while absolute protein levels are stable, laboratory procedures are frequently inadequate to discriminate between active Cu-containing CP and inactive Cu-depleted CP (Terada et al., 1995). In a denaturing polyacrylamide electrophoretic system, apo- and holo-CP cannot be distinguished, but under non-denaturing conditions, the holo-CP migrates faster than apo-CP (Terada et al., 1995). Monoclonal antibodies generated to the active site of holo-CP and to inactive CP, or apo-CP, have been used to demonstrate that only inactive CP is present in hepatic tissue in LEC rats, while both forms are present in normal rats (Hiyamuta and Takeichi, 1993). While antibodies raised in rabbits to human CP can partially cross-react with CP from dogs and rhesus monkeys (French, 1989; Ganrot, 1973a), the lack of cross-reactivity with rat CP necessitated the development of a noncompetitive ELISA assay (DiSilvestro et al., 1988). Two-dimensional electrophoresis followed by immunofixation has also been used to evaluate serum CP in dogs (Watanabe, 1995). Several methods have been used to isolate CP from serum and appear to yield similar results (Montaser et al., 1992; Ryan et al., 1992; Stern and Freiden, 1990, 1993; Terada et al., 1995). Procedures for the isolation and characterization of CP have been reviewed (Arnaud et al., 1988).

The most commonly used functional assay for serum CP is based on the enzymatic oxidation of p-phenylenediamine (pPD) (French, 1989; Ravin, 1961). If phosphate buffers are used in the assay, there can be nonenzymatic oxidation of iron, which interferes with the apparent CP oxidase activity (Ryan et al., 1992). While this problem can be overcome by the use of a sodium acetate buffering system (Ryan et al., 1992), this does not solve the difficulty of distinguishing the oxidation of the substrate by CP oxidase and the ferroxidase II activity present in some CP species (Montaser et al., 1992). When pPD is used as substrate in the absence of sodium azide, both CP oxidase and ferroxidase activity are determined; while in the presence of sodium azide, only ferroxidase activity is measured. The apparent CP oxidase activity in rat, dog, and mouse serum has been estimated to be reduced by 4.2%, 15.8%, and 46.2%, respectively, when CP ferroxidase activity is discounted (Montaser et al., 1992). Further, the net CP oxidase activity estimated as pPD oxidase $\times 10^{-2}$ nmol/min/mL was 18.6 ± 6 , 3.2 ± 0.5 , and 2.0 ± 0.4 for rat, dog, and mouse serum, compared to 90 ± 8 , 8.2 ± 1.8 , and $3.6 \pm 1.1 \times 10^{-2}$ μ mol o-dianisidine oxidised /min/mL (Montaser et al., 1992). In addition to different sensitivities toward different substrates, the optimum pH for the CP oxidase reaction also varies among species (Bingley and Dick, 1969). Consequently, when comparing published serum CP values for laboratory animals, the methodologies used by the various researchers should be considered.

19.6.4 PATHOPHYSIOLOGICAL SIGNIFICANCE

The exposure of human hepatoma cells to either IL-1 or TNF α induces a time- and dose-dependent increase in both CP-mRNA and CP-protein synthesis (Ramadori et al., 1988). The effects of IL-1 and TNF α on net CP synthesis were comparable with values increasing by 224% and 285% relative to control values, respectively, within 18 hours of treatment (Ramadori et al., 1988). The injection of IL-6 or TNF α into Wistar rats induced a twofold increase in circulating CP values within 12 hours, and this level was sustained for a further 12 hours (Sato et al., 1994). The daily injection of human recombinant IL-6 to marmosets produced a four- to fivefold increase in serum CP levels within 8–24 hours, though the dose of IL-6 that was required to induce this response was approximately 100-fold greater than that required to induce a similar increase in circulating haptoglobin values

(Ryffel et al., 1994). Although the increase in circulating CP values observed in rabbits, rat, and mice following inflammatory stimuli is likely mediated at least in part through cytokine induction, the tissue-specific nature of the response indicates that CP expression is controlled by a complex regulatory system (Fleming et al., 1991; Giclas et al., 1985; Kimura et al., 1994; Kimura-Takeuchi et al., 1992; Milland et al., 1990; Min et al., 1991). For example, in both Sprague-Dawley and Wistar rats, 8 hours after endotoxin injection, an increase in CP-mRNA was only observed in liver and lung tissue with no alterations in CP-mRNA levels being found in other tissues (Fleming et al., 1991). When the rats in this study were exposed to 95% O₂, a five- to sixfold increase in CP-mRNA was only observed in lung tissue (Fleming et al., 1991). When Lewis rats were exposed to 85% O₂ for 19 days, an increase in serum CP levels was observed, and the elevation in serum CP levels correlated with an increase in lung antioxidase activity (Moak and Greenwald, 1984). It is not clear, however, whether the hyperoxic response of serum CP levels is an acute phase reaction or is related to some other type of noninflammatory response because other APR proteins, such as plasma fibrinogen, remained unchanged in oxygen treated Lewis rats (Moak and Greenwald, 1984).

In humans, rats, rabbits, dogs, and primates, the CP responds to inflammatory stimuli as an APR, though the rapidity of the rise, as well as the extent of the increase, is generally lower than that of other acute phase proteins (Burlingame et al., 1996; Eckersall and Conner, 1988; Ganrot, 1973c; Hirschelmann et al., 1990; Solter et al., 1991). For example, following turpentine injection to rabbits, a maximum two- to threefold increase in serum CP levels is observed between 48 and 72 hours, compared to a 50-fold increase in CRP that occurs between 12 and 36 hours (Giclas et al., 1985; Mackiewicz et al., 1988). Similarly, in mice, turpentine injection induces a two- to threefold increase in serum CP oxidase activity, which is less than the alteration in either fibrinogen or metallothionein (Min et al., 1991). In a study involving 285 normal dogs, serum CP oxidase activity was determined as 17.1 ± 0.3 IU/L, which increased approximately twofold during inflammation (Solter et al., 1991). Intravenous administration of LPS (1 μ g LPS/kg) to rabbits induced a dose-related increase in serum CP with values rising from 26 ± 2 μ g/mL to 69 ± 2 μ g/mL within 24 hours of treatment (Kimura et al., 1994). In rabbits, serum CP is also responsive to viral challenge. Basal serum CP values rose from 29 ± 2 μ g/mL to 47 ± 3 μ g/mL within 24 hours of a challenge with influenza virus (Kimura-Takeuchi et al., 1992). The synthetic viral product analogue, polyriboinosinic:polyribocytidylic acid, likewise induced a twofold increase in serum CP levels in rabbits (Kimura et al., 1994). The extent of the increases in serum CP values induced by these inflammatory stimulants is similar to that induced in marmosets following daily IL-6 injections for 7 days. In the marmosets, the IL-6 treatment regime caused serum CP levels to rise from 0.3 to about 1.5 g/L (Ryffel et al., 1994). In contrast, administration of IL-1 to rats did not alter either the serum CP oxidase or serum CP protein levels (Gitlin et al., 1992). It is possible that relatively modest increases in serum CP levels following stimulation do not represent the total increase in CP synthesis during an inflammatory response. For example, in rats, endotoxin treatment can induce an increase in CP-mRNA expression in both the liver and lungs (Moak and Greenwald, 1984), and in turpentine treated rabbits, CP can be detected in the pleural fluid (Giclas et al., 1985). These increases in local tissue expression of CP are not reflected in the extent of change observed in serum CP values.

The largest variation in circulating CP activity is observed in animals with either hereditary- or dietary-induced impairment of Cu metabolism (Li et al., 1991). For example, a serum CP value of 373 ± 37 μ g/mL was found in Sprague-Dawley rats maintained on a Cu-adequate diet, compared to values of 29 ± 2 μ g/mL in animals maintained on a Cu-deficient diet (Chen et al., 1995). Nutritionally induced Cu deficiency appears to produce a greater decrease in serum CP oxidase activity than in the serum CP protein values as determined by immunological procedures (Gitlin et al., 1992). This is similar to the observation in LEC rats with inherited impairment of Cu metabolism, which exhibit approximately half the serum CP protein values compared to Sprague-Dawley rats despite the apparently identical CP-mRNA levels and the similar levels of intracellular CP synthesis in the two species (Terada et al., 1995). Further, the exposure of Cu-deficient Sprague-Dawley rats to LPS

induced an increase in serum CP levels from $110 \pm 10 \mu\text{g/mL}$ to $280 \pm 34 \mu\text{g/mL}$ without inducing a change in serum CP oxidase activity (Gitlin et al., 1992). In contrast, inflammation in normal rats induces a comparable increase in both serum CP oxidase activity and CP protein values (DiSilvestro et al., 1988).

The circulating CP levels in laboratory animals are affected by age, with newborn animals having consistently lower values than adults. In Sprague-Dawley and Wistar rats, serum CP levels are $14 \pm 8 \mu\text{g/mL}$ at birth, rising rapidly to about $200 \mu\text{g/mL}$ at day 20, with adult levels of $300\text{--}350 \mu\text{g/mL}$ being reached at about 1 year of age (Evans et al., 1970). This is similar to the age profile in guinea pigs (Bingle et al., 1992; Srai et al., 1986) and people (Cox, 1996). In guinea pigs, serum CP level is not detectable before birth, it is $3.1 \pm 2.8 \text{ ng/mL}$ at birth, and reaches $32.1 \pm 11.8 \text{ ng/mL}$ by 28 days of age (Bingle et al., 1991). Pregnancy in both rabbits and humans results in an increase in circulating CP values (Ganrot, 1972; Ungar-Waron et al., 1978), which may be related to the increased production of CP in the uterus (Thomas et al., 1995). However, although administration of estradiol increased CP levels by 75% in female rats, there is no evidence that CP-mRNA levels in the rat uterus are directly related to estrogen levels (Meier and MacPike, 1968; Thomas et al., 1995).

19.7 FIBRINOGEN

19.7.1 PROPERTIES

Fibrinogen is a large, poorly soluble β -globulin present in the plasma of all vertebrates. Due to its central role in hemostasis, fibrinogen levels in veterinary medicine are evaluated as one of the parameters included in a routine assessment of a blood coagulation profile.

An increased rate of liver fibrinogenesis represents a uniform response of the liver to hepatocyte damage induced by infectious, toxic, or metabolic agents (Neubauer et al., 1995). This response is translated into hyperfibrinogenemia, which is characteristic of a broad range of bacterial infections and other inflammatory conditions in many animal species (Hawkey and Hart, 1987).

All vertebrates have fibrinogen molecules composed of three nonidentical polypeptide chains, designated as $A\alpha$, $B\beta$, and γ , that are linked by disulfide bridges (Gentry and Downie, 1993; Lord, 1995). Among different species, the three chains share many structural features but vary in size. The human $A\alpha$, $B\beta$, and γ chains have molecular weights of 67.6, 52.3, and 48.9 kDa, respectively, resulting in a total molecular weight of 340 kDa for the complete molecule, which is similar to that of rat fibrinogen (Ichinose and Davie, 1994; VanRuijven and Nieuwenhuizen, 1978). In all species, soluble fibrinogen is cleaved by thrombin to remove short amino-terminal peptides from the $A\alpha$ and $B\beta$ chains. This allows the resulting fibrin monomers to undergo spontaneous polymerization, followed by their covalent cross-linkage under the catalytic action of a transglutaminase enzyme, Factor XIIIa (Hantgan et al., 1994; Lord, 1995). While there are differences in the molecular weight of the $A\alpha$ chains, the molecular weights of the $B\beta$ and γ chains are relatively constant among mammals (Crabtree et al., 1985; Doolittle, 1973). For example, there is 80% homology between rat and human γ chains (Frost and Weigel, 1990). The structural diversity of the $A\alpha$ chain is due to species differences in the terminal two-thirds of the chain, the αC domain (Medved et al., 1985). A comparison of this domain among rhesus monkey, pig, dog, mouse, and Syrian hamster fibrinogen indicates that the greatest variation occurs in the middle region of the αC domain and that the carboxy- and amino-terminal regions are highly conserved (Murakawa et al., 1993). There is also considerable variation among species in the amino acid sequences of the fibrinopeptides A and B released as a result of thrombin cleavage (Penny and Hendy, 1986). Based on both structural evidence and the ability of fibrinogen from various species to selectively bind hyaluronic acid, it has been estimated that the fibrinogen molecule isolated from human, baboon, rabbit, dog, and rat plasma is evolutionarily divergent from that of the fibrinogen molecule found in cow, pig, horse, goat, and sheep plasma (Frost and Weigel, 1990; Henschen et al., 1983).

While the fibrinogen stored in the α -granules of blood platelets is released during blood clot formation, the liver is both the primary site of fibrinogen synthesis and the source of circulating fibrinogen (Handagama et al., 1990; Hantgan et al., 1994). The A α , B β , and γ fibrinogen polypeptides are each encoded by distinct genes that are clustered at a 50 kbase locus on chromosome 4 in people and on chromosome 2 in rats (Ichinose and Davie, 1994; Kant et al., 1985; Lord, 1995; Marino et al., 1986). The nucleotide sequences of the cDNAs that encode for each chain of fibrinogen are quite similar, as are the cDNAs encoding for rat and human proteins (Crabtree et al., 1985; Eastman and Gilula, 1989; Morgan et al., 1987). Because the mRNAs for the A α , B β , and γ subunits of fibrinogen are transcribed by separate genes, efficient control of fibrinogen production requires coordinated expression of the three independent genes (Crabtree and Kant, 1982; Kant et al., 1985; Moshage et al., 1988). In human hepatoma cells, there is an excess of the A α and γ chains, and hence the synthesis of the B β chains is the rate limiting step (Roy et al., 1990; Yu et al., 1983), which is similar to the regulatory step for rabbit fibrinogen synthesis (Alving et al., 1982). In contrast, the formation of the A α chain is the rate limiting step in the synthesis of rat fibrinogen (Hirose et al., 1988). In all species, the assembly of the complete fibrinogen molecule occurs in the rough ER (Bouma et al., 1975; Kudryk et al., 1982).

19.7.2 ROLE/FUNCTION

Fibrinogen not only has an essential role in hemostasis, but it also contributes to inflammatory and tissue repair processes. The conversion of soluble fibrinogen to insoluble fibrin is required for the formation of the fibril mesh that adheres to damaged vascular endothelial surfaces and constitutes the matrix of the thrombus that stems the loss of blood from the circulation when the vascular endothelium is compromised (Thomas, 2000; Gentry and Downie, 1993). During the initial stage of thrombus formation, platelets are activated, and the glycoprotein IIb–IIIa complex forms on the platelet membrane, which then functions as a receptor for fibrinogen and other adhesive proteins, such as fibronectin and vonWillebrand factor (Charo et al., 1994). These interactions not only promote the adhesion of activated platelets to the damaged vasculature but also facilitate the accumulation of platelet aggregates and the localized release of mitogenic components, such as platelet-derived growth factor, from the platelets at the site of injury (Gentry, 1992). Once wound healing has been initiated, fibrinolytic components, including tissue-plasminogen activator and plasminogen that adhered to the fibrin(ogen) matrix during thrombus formation, facilitate the localized generation of plasmin, a proteolytic enzyme that selectively degrades fibrin and permits the dissolution of the thrombus with the release of proteinaceous and cellular debris, that can be removed from the circulation by phagocytic cells (Murata et al., 2004; Thomas, 2000; Gentry and Downie, 1993). Fibrin deposition can also occur in interstitial fluid because the increased vascular permeability associated with inflammation permits the extravascular accumulation of hemostatic proteins. Fibrin(ogen) can modulate the inflammatory response by enhancing fibroblast migration and proliferation and facilitating leukocyte–endothelial cell adhesion and transmigration (Brown et al., 1993; Ge et al., 1992; Languino et al., 1995; Olman et al., 1996; Senior et al., 1986; Vogels et al., 1993). A small peptide in the γ -chain of fibrinogen, representing <1% of the total molecule, is responsible for the proinflammatory activity of fibrin(ogen) (Tang et al., 1996). In a mouse model, polymerization and cross-linking of extravascular fibrin was found to be spatially and temporally related to the alveolitis and fibroproliferative areas of bleomycin-induced lung injury (Olman et al., 1996).

Induction of fibrinogen synthesis during the acute phase response is primarily transcriptional and mediated in large part by IL-6 (Birch and Schreiber, 1986; Marinkovic et al., 1989; Otto et al., 1987). Exposure of rat hepatocytes to IL-6 induced a 10-fold increase in both mRNA levels and the rates of transcription of each of the three fibrinogen subunit genes (Munck et al., 1984; Otto et al., 1987). Northern blot hybridization analysis demonstrated that IL-6 induced a coordinated increase in the mRNAs of each fibrinogen chain (Nesbitt and Fuller, 1991). An increase in mRNA levels began

immediately after the addition of IL-6 to the culture system and reached a maximum between 12 and 18 hours (Andus et al., 1988). Constant exposure of IL-6 was required to maintain the increased mRNA expression (Nesbitt and Fuller, 1991). The rapidity of the response to IL-6 is compatible with the activation of a preexisting inactive DNA binding factor, the acute phase response factor (APRF) (Wegenka et al., 1993). This APRF can bind to the CTGGGA hexanucleotide motif in the IL-6 response elements in both rat and human β fibrinogen genes (Anderson et al., 1993; Baumann et al., 1990; Huber et al., 1990; Wegenka et al., 1993). The IL-6 response element of β fibrinogen has been located close to the promoter region of the fibrinogen gene, which is similar to the organization of other IL-6 regulated rat and human genes (Baumann et al., 1987b, 1990; Marinkovic and Baumann, 1990). In rats, administration of either turpentine or human recombinant IL-6 induces an almost identical increase in hepatic β -fibrinogen-mRNA levels (De Jong et al., 1988; Gaudie et al., 1990).

Dexamethasone administration to primary cultures of *Xenopus* hepatocytes induced a dramatic increase in fibrinogen synthesis with the low basal β -mRNA levels increasing 20-fold (Bhattacharya et al., 1991). In contrast, in rat and human hepatocytes, variable increases in fibrinogen-mRNA levels and in fibrinogen secretion are observed in response to glucocorticoids in the absence of IL-6 (Huber et al., 1990; Otto et al., 1987). This variable response is also observed in intact animal studies. For example, administration of adrenocorticotrophic hormone (ACTH) consistently produces an elevation in circulating fibrinogen levels in rabbits but not in calves (Gentry et al., 1992). It is now well established that the full gene expression of fibrinogen, like that of α_1 -AGP and haptoglobin, requires the combined action of IL-6 and glucocorticoid (Baumann et al., 1989; Castell et al., 1988; Crabtree and Kant, 1982; Geiger et al., 1988a; Otto et al., 1987). The β -fibrinogen GRE functions similarly to that of α_1 -AGP (Baumann et al., 1990).

Other members of the IL-6 cytokine family, including CNTF, LIF, and cardiotrophin-1 (which all share the common signaling subunit gp 130), also induce increased β -fibrinogen-mRNA and protein expression in a dose- and time-dependent manner (Baumann and Schendel, 1991; Fuller et al., 1985; Nesbitt et al., 1993; Peters et al., 1995). Both IL-11 and LIF, in the absence of dexamethasone, induce an increase in fibrinogen synthesis equivalent to that of IL-6, but, in the presence of dexamethasone, the synergistic effect of either of these cytokines is lower than that observed for the stimulatory effect of the combination of IL-6 and dexamethasone (Baumann and Schendel, 1991; Baumann and Wong, 1989). In contrast, neither IL-1 nor TNF α , even in the presence of dexamethasone, has any effect on fibrinogen synthesis, even at concentrations that induce a 20-fold increase in α_1 -AGP (Andus et al., 1983). Furthermore, in hepatic cell cultures, IL-1 not only inhibits the basal expression of rat fibrinogen but also suppresses the stimulatory effect of IL-6, LIF, and IL-11 (Baumann and Gaudie, 1990; Baumann and Schendel, 1991). Although the injection of IL-1 into male Buffalo rats appeared to induce an increase in β -fibrinogen-mRNA expression within 24 hours of treatment, the response was indirect because heat-inactivated IL-1 also induced a similar response (De Jong et al., 1988). Further, antibodies to IL-6 but not IL-1 suppress the approximately threefold increase in fibrinogen induced by exposure of rat hepatocyte cultures to LPS (Lanser and Brown, 1989).

In human liver, the steady-state synthetic rate of fibrinogen is between 1.7 and 5.0 g/day (Hantgan et al., 1994). Hypofibrinogenemia due to decreased fibrinogen synthesis is uncommon in animals, not only due to the synthetic reserve capacity of hepatic tissue but also to fibrinogen's relatively long circulating half-life, which has been estimated as 3–5 days (Hantgan et al., 1994).

19.7.3 ANALYTICAL METHODS

Three types of laboratory procedures can be used to quantify fibrinogen: biological, physicochemical, and immunological. The biological assay based on the rate of formation of insoluble fibrin in citrated plasma in the presence of excess thrombin is the most widely used procedure for laboratory animals. Commercial reagents kits, formulated for human fibrinogen determinations, have been used successfully for laboratory animals, as have semiautomated methods (Gentry and Liptrap, 1981;

Gentry et al., 1992; Kimura et al., 1994; Riipi and Carlson, 1990). Consistent results were reported for normal canine fibrinogen levels with the thrombin-time method irrespective of the instrumentation used to detect fibrin formation (Mischke and Menzel, 1994). Physicochemical methods are based on the selective precipitation of plasma fibrinogen following mild heat treatment (Blaisdell and Dodds, 1977; Miller et al., 1971). This type of methodology is widely used in veterinary clinical pathology, particularly with the current instrumentation that permits more precise quantification of fibrinogen compared to older methodologies (Evans and Duncan, 2003; Hart, 1997).

Immunological methods that are extensively used in human medicine generally detect circulating levels of fibrin or fibrinogen degradation products or the fibrinopeptides A and B generated during fibrin formation rather than the intact fibrinogen molecule (Marder et al., 1994). The antibodies generated against components of the human fibrinogen molecule generally show only partial cross-reactivity at best toward nonhuman fibrinogen and, hence, are not useful for nonhuman fibrinogen evaluation. In human medicine, immunological methods have proved useful in characterizing the many types of dysfibrinogenemia identified in the human population (McDonagh et al., 1994). Most of the over 200 human fibrinogen variants have been identified during routine laboratory hemostatic screening because the affected individuals appear clinically and hemostatically normal (McDonagh et al., 1994). This may explain, at least in part, why dysfibrinogenemias are infrequently identified in animals.

19.7.4 PATHOPHYSIOLOGICAL SIGNIFICANCE

Basal plasma fibrinogen values can be influenced by the physiological status of an animal, particularly by pregnancy. In many species, a characteristic increase in plasma fibrinogen is observed around the time of parturition (Gentry et al., 1990). In the dog, an earlier, transient increase in fibrinogen is also observed at midgestation, which can be used as a pregnancy marker in this species (Gentry and Liptrap, 1981; Hart, 1997).

The normal range for canine plasma fibrinogen has been determined as 0.9–2.9 mg/mL (Hart, 1997; Kaneko, 1997; Mischke and Menzel, 1994). In a study of healthy dogs, circulating fibrinogen values rose from 2.0 ± 0.1 mg/mL to 3.4 ± 0.4 mg/mL following heartworm implantation, which is typical of the extent of the fibrinogen response to inflammation in dogs (Boudreaux and Dillon, 1991). In dogs, rats, and rabbits, turpentine injection induced a two- to fivefold increase in plasma fibrinogen within 48 hours of treatment (French, 1989). In rabbits, administration of ACTH alone induced an increase in fibrinogen levels from 3.2 ± 0.3 mg/mL to 8.0 ± 1.9 mg/mL within 48 hours (Gentry et al., 1992). However, in this study, there appeared to be no correlation between the increase in circulating corticosterone and fibrinogen values induced by the ACTH treatment. This finding is consistent with observations in dogs that the extent of increase in plasma fibrinogen values does not necessarily correlate with the extent of inflammation (Eckersall and Conner, 1988). Similarly, in mice, the basal fibrinogen level of 1.8 ± 0.1 mg/mL rose to 4.5 ± 0.8 mg/mL following treatment of the animals with either 1 or 5 mg LPS per kg (Rofe et al., 1996). Under certain conditions, elevated plasma fibrinogen values can persist for extended periods of time. A chronic increase, lasting up to 2 months, was reported in both endotoxin-resistant mice (C3H/HeJ) and endotoxin-sensitive mice (C3H/HeN) following a single inoculation with *C. albicans* (Riipi and Carlson, 1990). In this study, there did not appear to be a corresponding decline in albumin, a negative APR (Baumann, 1990). This result is distinct from the acute response observed in turpentine-treated Wistar rats (Ballmer et al., 1992). In rats, the increased synthesis of fibrinogen inversely follows the time course of the decline in albumin synthesis (Ballmer et al., 1992). It is likely that the persistence of elevated fibrinogen values requires the continuous presence of inflammatory cytokines. For example, administration of daily doses of IL-6 to rhesus monkeys over a 4-week period was required to induce a twofold increase in plasma fibrinogen levels (Myers et al., 1995). In the monkeys, the fibrinogen values rose from an average of 2.5–5.4 mg/mL during the study period.

19.8 HAMSTER FEMALE PROTEIN

19.8.1 PROPERTIES

Hamster female protein (FP), so named because it was first identified in serum from female Syrian hamsters, is a member of the pentraxin family and shares many structural and immunological features with CRP and SAP (Coe, 1977; Coe et al., 1981). An intriguing observation is that the FPs isolated from Syrian (*Mesocricetus auratus*), Turkish (*Mesocricetus brandti*), and Armenian (*Cricetulus migratorius*) hamsters are structurally identical but exhibit different acute phase responses (Coe, 1977; Coe and Ross, 1990a; Coe et al., 1997).

The Syrian hamster female protein (FP-S), whether isolated from serum or amyloid deposits, is a pentameric molecule composed of covalently linked glycosylated 25.6 kDa subunits containing a single intrachain disulphide bridge (Tennet et al., 1993). Under physiological conditions, FP-S may circulate as a decamer, because like SAP, isolated five unit molecules aggregate to form 10 subunit molecules in the presence of calcium (Tennet et al., 1993). Female protein isolated from the Armenian hamster (FP-A) is also a pentameric oligomer of five identical noncovalently assembled subunits (Coe and Ross, 1990a). The structural similarity between FP-S and FP-A has been demonstrated by the *in vitro* generation of a hybrid pentamer molecule consisting of both FP-S and FP-A monomer units (Coe and Ross, 1987) and by the observation that FP-S and FP-A share common antigens (Coe and Ross, 1990a). The Turkish female protein (FP-T) is also a 150 kDa pentameric molecule consisting of five identical 30 kDa subunits (Coe et al., 1997). Based on comparison of N-terminal amino acid sequences, FP-T and FP-A share 97.5% and 85.0% identity, respectively, with FP-S (Coe et al., 1997; Dowton and Waggoner, 1989). On the basis of amino acid composition, the FPs appear to be more closely related to SAP than CRP, with 77.5%, 72.5%, and 52.5% homology being found between FP-S and mouse SAP, human SAP, and human CRP, respectively (Coe et al., 1981, 1997; Dowton et al., 1985; Ishikawa et al., 1987). However, on the basis of selective binding to phosphocholine and agarose, FP-S and FP-A exhibit characteristics of CRP (Coe et al., 1990a; Dowton et al., 1985; Etlinger and Coe, 1986). There are two calcium-binding sites on the FP-S molecule, and the changes in conformation following calcium or phosphocholine binding suggest that the physiological mechanism of ligand interaction is similar to other pentraxins (Dong et al., 1992).

19.8.2 ROLE/FUNCTION

In both Armenian and Turkish hamsters, FP responds as a positive acute phase protein in both males and females, with no gender differences being found in the hepatic FP-A-mRNA response during inflammation (Coe et al., 1997; Dowton and Waggoner, 1989). Although the regulation of expression of both Syrian and Armenian hamster FP genes occurs at the pretranslation level and the FP genes from both species are capable of responding to estrogen via an estrogen receptor mechanism, structural differences have been documented between the FP genes in these species (Coe and Ross, 1983, 1987; Dowton and Waggoner, 1989). The gene encoding for FP in Syrian hamsters is structurally similar to all reported pentraxin genes from many species, particularly in the intron/extron organization (Rudnick and Dowton, 1993).

The biological function of FP is not known. Like other pentraxins, it may have a role in clearing nuclear material from damaged cells because it shares the ability of CRP to bind to histones and chromatin in a PC-inhibitable manner, and like SAP, it can bind to DNA (Saunero-Nava et al., 1992). Also, like SAP, FP is a constituent of amyloid deposits. Amyloidosis is a common feature of aging Syrian hamsters, and the disease is more prevalent in females than males (Coe and Ross, 1985). The correlation between the appearance of amyloidosis and serum FP levels has been confirmed by hormonal manipulation of FP levels in Syrian hamsters with a corresponding increase or decrease in amyloid deposits (Coe and Ross, 1985, 1990b; Snel et al., 1989). Further, amyloidosis is

a rare disease in Armenian and Turkish hamsters, which express low basal serum FP levels (Coe and Ross, 1985). In hamsters with amyloidosis, the metabolism of injected ^{125}I -FP is altered with FP rapidly entering and persisting in amyloid deposits (Coe and Ross, 1985).

19.8.3 ANALYTICAL METHODS

Due to its binding characteristics, column chromatography techniques using substituted agarose, similar to the procedures used to isolate SAP, have been employed to isolate FP from both serum and amyloid deposits (Coe and Ross, 1987; Coe et al., 1997; Skinner and Cohen, 1988; Tennet et al., 1993). Quantitative determinations of serum FP levels in all strains of hamsters have utilized immunoelectrophoretic procedures and ELISA assays (Coe and Ross, 1990a, 1997; Rudnick and Dowton, 1993).

19.8.4 PATHOPHYSIOLOGICAL SIGNIFICANCE

Like CRP and SAP, FP is synthesized in the liver, but its regulation is unique in being under the dual control of sex hormones and cytokines (Coe and Ross, 1983, 1990a; Coe et al., 1997). In both Syrian and Turkish hamsters, FP synthesis is suppressed by testosterone (Coe and Ross, 1985; Coe et al., 1997; Rudnick and Dowton, 1993), while in Armenian hamsters, estrogen is the suppressor hormone (Coe and Ross, 1990a). As a consequence, in both Syrian and Turkish hamsters, basal serum FP levels are up to 1000-fold higher in females than in males (Coe and Ross, 1985; Coe et al., 1997). Species differences are also apparent in the FP response to inflammatory stimuli. In Syrian hamsters following turpentine administration, hepatic FP-mRNA levels rapidly decline in females, reaching a nadir within 12 hours, while FP-mRNA levels rise slowly in males only reaching maximal levels after 48 hours (Rudnick and Dowton, 1993). The difference in response is unrelated to circulating testosterone levels (Rudnick and Dowton, 1993). Following injection of ^{125}I -FP, a circulating half-life of 9–16 hours was found in both males and females (Coe and Ross, 1983). Nor do the gender differences appear to be related to an alteration in the rate of hepatic FP synthesis, because the transcription rates for the FP gene are similar in male and female hamsters (Dowton and Waggoner, 1989). Consequently, it has been suggested that like CRP, the gender differences in the steady state and acute phase mRNA concentrations may be related to altered FP-specific mRNA stability (Dowton and Waggoner, 1989). The *in vivo* administration of cytokines to Syrian Hamsters produces complex responses. While IL-6 or TNF administration to females induced a decrease in hepatic FP-mRNA levels within 8 hours of treatment, a decrease in FP-mRNA was not evident until 24 hours after IL-1 administration (Rudnick and Dowton, 1993). Moreover, the expected increase in hepatic FP-mRNA in male Syrian hamsters following cytokine administration did not occur (Rudnick and Dowton, 1993).

Adult Syrian female hamsters exhibit basal levels of FP in the 1.0–2.0 mg/mL range, while the range of values for Turkish female hamsters is 0.10–0.50 mg/mL (Coe and Ross, 1983; Coe et al., 1997; Etlinger and Coe, 1986). In both strains, the males exhibit similar values in the 0.01–0.02 mg/mL range. No gender differences have been observed in Armenian hamsters, with basal values of 0.05–0.30 mg/mL being reported for both sexes (Coe and Ross, 1990a). Seasonal sex-related variations in serum FP values have also been observed. In female Turkish hamsters, average FP values decreased to 0.15 ± 0.02 mg/mL in winter months, compared to 0.40 ± 0.05 mg/mL during summer months (Coe et al., 1997). In Armenian hamsters, a three- to fourfold increase over basal levels in serum FP values was observed in females but not in males during the winter period (Coe and Ross, 1990a). No age-related changes were observed for serum FP values in Armenian hamsters. In male Syrian hamsters, peak serum FP levels occurred at 21 days of age (0.4–0.5 mg/mL), which declined to adult values by 60–90 days of age, while in the females, adult values were reached by about 35 days of age (Coe and Ross, 1983; French, 1989).

In all types of hamsters (except the female Syrian hamster), FP acts as a positive APR. In both male and female Armenian hamsters, a 3–10-fold increase in serum FP values was observed following turpentine injection, which was independent of any seasonal variations (Coe and Ross, 1990a).

In Turkish hamsters, silver nitrate administration induced a transient fourfold increase in serum FP values in females and a 100-fold increase in males, which persisted for about 48 hours (Coe et al., 1997). A divergent response to inflammatory stimuli is observed in Syrian hamsters with serum FP values increasing 5–10-fold in males and decreasing by 50% in females (Coe and Ross, 1983). Prolonged administration of exogenous corticosteroids to female Syrian hamsters produced a similar response in serum FP levels as a single turpentine injection.

Castration of male Syrian hamsters induced an increase in hepatic FP-mRNA levels, which was translated into an increase in serum FP to average values of 1.43 ± 0.31 mg/mL (Coe and Ross, 1987). Estradiol administration to the castrated males further stimulated FP production to 2.54 ± 0.28 mg/mL, while both testosterone and dexamethasone administration reduced levels to 0.07 ± 0.02 mg/mL and 0.21 ± 0.03 mg/mL, respectively (Coe and Ross, 1987). These alterations in serum FP correlated with alterations in hepatic FP-mRNA levels induced by the hormones treatments.

19.9 MURINOglobulINS

19.9.1 PROPERTIES

Murinoglobulin is a member of the α_2M family that is unique to rodents, and in some species of rodents, it is the most prominent circulating α_2M -type protein (Geiger et al., 1987; Miyake et al., 1993; Saito and Sinohara, 1985a, 1985b; Van Leuven et al., 1992).

Murinoglobulins are monomeric glycoproteins with molecular weights ranging from 180 to 210 kDa (Saito and Sinohara, 1985a, 1985b) that are constitutively expressed in mice, rats, guinea pigs, and hamsters but are not present in rabbits or other nonrodent mammals (Ganrot, 1966; Miyake et al., 1993; Saito and Sinohara, 1985a, 1985b). Murinoglobulins and α_2M show only minor differences in inhibitory activity under in vitro conditions despite exhibiting markedly different primary structures in the reactive “bait” region (Overbergh et al., 1991, 1994).

19.9.2 ROLE/FUNCTION

Murinoglobulin interferes with the proteolytic activity of trypsin, papain, and thermolysin, but not with their esterolytic activity toward low-molecular-weight substrates (Saito and Sinohara, 1985b).

19.9.3 ANALYTICAL METHODS

19.9.4 PATHOPHYSIOLOGICAL SIGNIFICANCE

In rats and mice, murinoglobulin is the major plasma constituent of the macroglobulin family with normal values ranging from 7 to 14 mg/mL in rats and around 2 mg/mL in mice (Cavus et al., 1996; Koj et al., 1995; Saito and Sinohara, 1985b; Yamamoto et al., 1985). In hamsters, the normal level of murinoglobulin is only approximately 1 μ g/mL, and the trypsin inhibiting activity is weaker than that of the rat, mouse, and guinea pig homologs (Miyake et al., 1993). In addition to murinoglobulin and α_2M , rats constitutively express an α_1 -macroglobulin, which shows a considerable degree of homology with mouse α_2M and remains unaltered during the acute phase response (Saito and Sinohara, 1985b; Van Leuven et al., 1992). Rat murinoglobulin partially cross-reacts with antibodies to mouse murinoglobulin and rat α_1 -macroglobulin but not with human α_2M or rat α_2M (Saito and Sinohara, 1985b).

Following turpentine injection, a threefold decrease in circulating levels of murinoglobulin (also known as rat α_2 -inhibitor 3) occurs in Sprague-Dawley rats, which corresponded to the decrease observed in murinoglobulin content in hepatocytes (Geiger et al., 1987). Murinoglobulin also responds as a negative APR in mice but not in guinea pigs (Miyake et al., 1993; Suzuki et al., 1990).

19.10 SERUM AMYLOID A

19.10.1 PROPERTIES

SAA proteins comprise a multigene regulated family of apolipoproteins that circulate in association with high-density lipoproteins (HDLs) (Benditt et al., 1989; French, 1989; Malle et al., 1993). In mice and people, SAA responds as a typical APR but not in rats or hamsters (Kushner and Mackiewicz, 1987). One form of circulating SAA is the precursor of secondary amyloid deposits in tissues.

In all species, the basic SAA protein is a single polypeptide chain with a molecular weight ranging from 11.4 to 16.0 kDa (Marhaug and Dowton, 1994). The prototype human and rabbit SAA proteins consist of 104 amino acid residues (Liepnieks et al., 1991; Parmelee et al., 1982), while murine and hamster SAA have 103 amino acid residues (De Beer et al., 1991, 1993; Webb et al., 1989). Dog and Abyssinian cat SAA molecules are larger due to an octapeptide insertion between the residues corresponding to 69–70 of the human sequence (Dwulet et al., 1988; Kluge-Beckerman et al., 1989; Sellar et al., 1991). The N-terminal part of the protein is hydrophobic, and confers lipid-binding properties to the molecule (Marhaug and Dowton, 1994).

Several isoforms of SAA have been identified in humans (Bausserman et al., 1980; Strachan et al., 1988), mice (Coetzee et al., 1986; Hoffman and Benditt, 1982; Lowell et al., 1986a), hamsters (Niewold and Tooten, 1990; Webb et al., 1989), rabbits (Brunn et al., 1995; Liepnieks et al., 1991; Rygg et al., 1991; Syversen et al., 1993; Tatum et al., 1990), and dogs (Sellar et al., 1991). In mice, the three distinct subfamilies of SAA proteins are produced in the liver and respond as APRs. They are classified as: (1) the isoforms, SAA₁ and SAA₂, which become major apolipoproteins in HDL in the circulation, (2) SAA₃, which is also produced in extrahepatic tissues, including macrophages, monocytes, Leydig cells of the testes and mononuclear cells of the spleen (Meek et al., 1992), and (3) SAA₅, the main isoform present in normal HDL (De Beer et al., 1996). The mouse SAA₅ isoform exhibits 48% amino acid sequence homology with the other mouse SAA proteins (De Beer et al., 1994). In Syrian hamsters, at least four distinct SAA isoforms have been identified (Niewold and Tooten, 1990; Webb et al., 1989). In rabbits, two SAA proteins characteristic of SAA₁ and SAA₂ have been identified (Brunn et al., 1995). Despite evidence that at least three SAA genes are present in the dog genome, canine SAA appears to circulate as a single homogenous 12.3 kDa protein (Sellar et al., 1991). In people, in addition to the SAA₁ and SAA₂ isoforms, there is a constitutively expressed isoform classified as SAA₄ (de Beer et al., 1995) that comprises 90% of the normal human serum SAA content and does not respond as an APR (Malle et al., 1993).

In humans, the SAA gene family is located on the short arm of chromosome 11 (Hoffman and Benditt, 1982). In mice, there are three genes and a pseudogene that are all located on the proximal arm of chromosome 7 (Butler et al., 1995; Lowell et al., 1986a; Sellar et al., 1991; Stearman et al., 1986; Stubbs et al., 1994; Taylor and Rowe, 1984). The mouse SAA₁ and SAA₂ genes show 96% nucleotide sequence homology over their entire length (Lowell et al., 1986a, 1986b; Yamamoto et al., 1987). The third gene, SAA₃, exhibits 70% homology in the translated exons but less than 25% homology in other nucleotide sequences (Huang et al., 1990; Yamamoto et al., 1987). The existence of multiple SAA gene families has also been found in the rabbit (Ray and Ray, 1991a, 1991b) and hamster genome (De Beer et al., 1993). Multiple factors are known to be involved in the induction of SAA genes. The mRNA expressed by each of the three SAA genes is elevated 200–500-fold in mice following either LPS or casein injections (Hoffman and Benditt, 1982; Lowell et al., 1986a; Meek and Benditt, 1986; Meek et al., 1989; Morrow et al., 1981). The increased SAA-mRNA expression in mice is accompanied by increased hepatocyte synthesis and secretion of both SAA₁ and SAA₂ (Benson and Kleiner, 1980; Hoffman and Benditt, 1982; Meek and Benditt, 1986; Meek et al., 1986; Selinger et al., 1980). In mice, despite evidence that SAA₁/SAA₂ is relatively uniformly distributed in all hepatocytes, it has been estimated that only 20% of hepatocytes participate in SAA synthesis (Hoffman and Benditt, 1982; Shirahama et al., 1984). In murine extrahepatic tissues, SAA₃-mRNA accumulates following LPS administration, but no increases in SAA-related

mRNA occur in response to casein administration to mice (Hoffman and Benditt, 1982; Meek and Benditt, 1986; Meek et al., 1989). In Sprague-Dawley rats, both LPS and turpentine injections induce hepatocyte expression of SAA₁- and SAA₂-mRNAs (Meek and Benditt, 1989). Similarly, it has been shown that in dogs, rabbits, and Syrian hamsters, an acute phase response induces an increase in hepatocyte SAA-mRNA levels (De Beer et al., 1993; Ray and Ray, 1991a; Sellar et al., 1991). Additionally, several isoforms have been identified in dog serum, and the demonstration of highly alkaline SAA isoforms in synovial fluid, which suggest SAA is also produced locally in inflamed joints (Kjelgaard-Hansen et al., 2007).

19.10.2 ROLE/FUNCTION

The increase in hepatic SAA-mRNA expression is regulated at the transcriptional level (Lowell et al., 1986a) and is mediated by several cytokines, including IL-1 (Boraschi et al., 1990; Huang et al., 1990; Ramadori et al., 1985a, 1985b; Weinstein and Taylor, 1987). In vitro studies with cultured mouse hepatocytes or human primary liver cell cultures indicate that the presence of a combination of IL-1, IL-6, and glucocorticoids is required to fully stimulate SAA synthesis (Ganapathl et al., 1991; Prowse and Baumann, 1989). In primary hepatocyte cultures from *M. caroli*, IL-1 and IL-6 selectively induce an increase in the acidic, but not the basic, form of the SAA protein (Prowse and Baumann, 1989). The injection of either CNTF, IL-6, IL-11, LIF, oncostatin M, or cardiotrophin-1 into CD-1 mice each produced a 25-fold increase in serum SAA levels within 18 hours (Benigni et al., 1996). The similarity in the SAA response to the various cytokines is likely related to the fact that although these cytokines differ in structure and function, they share a common receptor subunit, referred to as gp 130. Similar to the alteration in transcription rates, the action of these cytokines may also be directed toward increasing SAA-mRNA stabilization because, several studies have shown that, following cytokine stimulation, there is a greater increase in SAA-mRNA accumulation than can be accounted for solely on the basis of the increased rate of SAA-mRNA transcription (Lowell et al., 1986a; Reinhoff and Groudine, 1988). The decreased stability of SAA-mRNA in normal mouse liver has been proposed as one of the mechanisms that acts to downregulate SAA production in vivo (Brisette et al., 1989; Lowell et al., 1986a; Sellar et al., 1991; Steel et al., 1993). Clearly, the factors contributing to the regulation of SAA expression are complex because transgenic IL-1^{-/-} mice, which are incapable of expressing IL-1, exhibit a normal SAA response to LPS (Fantuzzi et al., 1996).

In extrahepatic tissues, such as macrophages and monocytes, that synthesize the SAA₃ isoform, IL-6 appears to activate a nuclear factor that binds to the promoter region of the SAA gene, resulting in increased accumulation of SAA₃-mRNA (Ray and Ray, 1993, 1996). In these cell types, glucocorticoids can further enhance the rate of SAA₃-mRNA transcription (Ishida et al., 1994; Urieli-Shoval et al., 1994). However, these effects may not be directly related to the acute phase response because there is no evidence of increased synthesis of the SAA₃ protein or its release into the circulation that accompanies the increase in tissue SAA-mRNA levels (Meek and Benditt, 1986).

In contrast to the relatively long circulating half-lives of other HDL apolipoproteins, radiolabeled SAA is rapidly cleared from the circulation in cynomolgus monkeys, vervets, rats, and mice (Bausserman et al., 1984, 1987; Gollaher and Bausserman, 1990; Hoffman and Benditt, 1983; Parks and Rudel, 1983). The circulating half-life for SAA in mice is about 3.5 hours, compared to 11 hours for apoA-1 (Hoffman and Benditt, 1983; Tape and Kisilevsky, 1990). The degradation of SAA is mediated by cell-associated enzymes and is retarded by the association of SAA with lipoproteins. The catabolism of SAA is independent of other HDL lipoproteins (Bausserman et al., 1987). Hepatic catabolism of SAA occurs primarily in Kupffer cells (Bausserman et al., 1987; Fuks and Zucker-Franklin, 1985; Meek et al., 1989), and the rate of degradation is depressed in both acute and chronic stages of inflammation (Gollaher and Bausserman, 1990).

The biological function(s) of SAA as an acute phase protein has still not been fully elucidated. It is likely, however, that SAA has a role in regulating lipid metabolism, particularly during the process of inflammation. The increased incorporation of SAA into HDL appears to accelerate the

removal of these particles from the circulation (Watterson, 2009). During inflammation, there is an increased number of binding sites for SAA-HDL on macrophages and a reduction in binding sites on hepatocytes (Kisilevsky, 1991; Kisilevsky and Subrahmanyam, 1992). These changes are associated with a three- to fourfold higher macrophage affinity for SAA-rich HDL and a twofold reduction in hepatocyte affinity for the SAA-enriched HDL, compared to SAA-poor HDL (Kisilevsky and Subrahmanyam, 1992). The increased macrophage uptake of SAA coupled with the increased expression of SAA-mRNA in these cells during inflammation suggests that these SAA-mediated events may be one mechanism by which lipid debris is cleared from the circulation (Butler et al., 1995; Malle et al., 1993; Meek et al., 1989). In people, the marked decrease in both plasma HDL and esterified cholesterol during an acute phase reaction has been related to the changes in HDL apolipoprotein content, including the SAA content (Steinmetz et al., 1989). The reduction in plasma cholesterol levels may also be associated with a reduction in the activity of lecithin cholesterol acyltransferase as a result of SAA incorporation into phospholipid vesicles (Fielding et al., 1972; Steinmetz et al., 1989).

Another biological role for SAA proteins is to enhance the recruitment of white cells into inflammatory lesions. For example, SAA can function as a chemoattractant for human monocytes, neutrophils, and T lymphocytes and can also induce the adhesion of these cells to cultured umbilical cord vein endothelial cell monolayers (Badolato et al., 1994; Xu et al., 1995). However, unlike CRP, which activates neutrophils, SAA inhibits the oxidative burst in stimulated neutrophils (Foldes-Filep et al., 1992; Nunomura et al., 1990b). There is evidence that, at least in lymphocytes, the actions of SAA may be mediated through a G-protein-coupled receptor (Xu et al., 1995). This suggestion is supported by *in vitro* studies demonstrating that SAA inhibits platelet activation initiated by thrombin but not by other agonists (Zimlichman et al., 1990). Platelet aggregation is induced by thrombin through a specific membrane thrombin receptor, a G-type protein receptor, while other platelet agonists interact with different types of platelet receptors (Coughlin, 1995). It is, however, unlikely that the SAA platelet inhibitory effect has physiological significance, because it is only observed in isolated, protein-free platelet suspensions (Zimlichman et al., 1990).

Animal model studies have established the role of one of the SAA isoforms in the pathogenesis of amyloidosis. It appears that only the SAA₂ isoform of SAA is involved in the formation of amyloid deposits. In mice, as in people, the C-terminal portion of the SAA₂ molecule is cleaved to produce a 75 amino acid, the 8.5-kDa amyloid A (AA) protein (Cohen et al., 1983; Glenner, 1980; Miura et al., 1990). A serine protease derived from monocytes and neutrophils is thought to be responsible for this degradation of apo-SAA₂ (Lavie et al., 1978; Silverman et al., 1982). Precipitation of the released AA molecules to form the amorphous amyloid fibril is facilitated by their ability to bind to basement membrane constituents, such as heparan sulphate proteoglycans and laminin (Ancsin and Kisilevsky, 1997; Inoue et al., 1996). Partial degradation of apo-SAA₂ with the subsequent formation of AA molecules is observed in amyloid-susceptible CBA/J mice, while in amyloid-resistant CE/J mice, apo-SAA₂ is completely degraded with no release of AA molecules (Elliot-Bryant et al., 1996). It has been proposed that the variation in SAA₂ degradation is a function of the different isoforms of the SAA protein expressed among different mouse strains and is related to the different degrees of SAA-gene expression (De Beer et al., 1992; Gonnerman et al., 1995; Rokita et al., 1989; Taylor and Rowe, 1984). This suggestion is supported by the observation that the SAA-like protein expressed in both normal and acute phase rats lacks the N-terminal, or AA-related region of the SAA₂ molecule (Baltz et al., 1987). Rats, like Armenian hamsters, do not develop amyloidosis, and in these species, SAA is also not an apolipoprotein of HDL (Baltz et al., 1987; De Beer et al., 1993; Meek and Benditt, 1989).

Various other effects have been reported, which include detoxification of bacterial endotoxin, inhibition of lymphocyte and endothelial cell proliferation, inhibition of platelet aggregation, and inhibition of T lymphocyte adhesion to ECM proteins. It may also play a role in downregulation of the inflammatory process by inhibiting myeloperoxidase release and directed migration of phagocytes. Intestinal epithelial cells can release SAA upon stimulation by TNF- α , IL-1, and IL-6. The protein may also be involved in the local defence mechanism of the gut to endotoxin challenge. SAA has also

been reported to bind to neutrophils and inhibit oxidative burst response suggesting it may help prevent oxidative tissue damage during inflammation. However, this effect may be concentration dependent as inhibition was restricted to lower concentrations. These results suggest that SAA may have different effects according to the local concentration, and that the anti-inflammatory effects may be selective and specific rather than systemic (Murata et al., 2004; Uhlar and Whitehead, 1999).

SAA can induce ECM-degrading enzymes such as collagenase, stromelysin, and matrix metalloproteinases 2 and 3, which are important for repair processes after tissue damage. However, prolonged expression of SAA and the long-term production of these enzymes may play a role in degenerative diseases such as rheumatoid arthritis (Uhlar and Whitehead, 1999).

19.10.3 ANALYTICAL METHODS

The majority of studies quantifying total plasma or serum SAA levels have used immunological procedures, including radioimmunoassays, ELISA, quantitative radial immunodiffusion, or solid-phase immunoradiometry (French, 1989; Hachem et al., 1991; Malle et al., 1993; Marhaug, 1983; McDonald et al., 1991; Sipe et al., 1989; Zuckerman and Surprenant, 1986). Several sandwich ELISA assays for quantifying serum SAA have been developed employing rabbit or rat antisera to human SAA (Dubois and Malmendier, 1988; McDonald et al., 1991), to AA protein (Sipe et al., 1976; Yamada et al., 1989), or to discrete SAA peptides (Saile et al., 1989). Both ELISA and micro-ELISA assays have been used to quantitate SAA in mouse serum using rat or rabbit polyclonal antibodies to mouse SAA (Vogels et al., 1993; Zuckerman and Suprenant, 1986). Despite the apparent lack of strong interspecies cross-reactivity for SAA (French, 1989), feline SAA has been detected in an ELISA assay using a rabbit anticanine SAA antibody, though the sensitivity of the antibody to the cat antigen was found to be lower than the sensitivity of the antibody to the homologous canine SAA (Kajikawa et al., 1996). A sandwich ELISA, along with Western blotting techniques, has also been used to quantitate canine serum SAA (Yamamoto et al., 1994c). Several investigators have noted that the precise quantitation of serum SAA levels is complicated due to its association in serum with HDL and that the procedures used to dissociate SAA from HDL tend to introduce increased variability to the reproducibility of the assays (Godenir et al., 1985; Malle et al., 1993; Saile et al., 1989). Isoelectrofocusing and two-dimensional electrophoresis are two techniques that have been used to visualize the isoforms of SAA in serum from various laboratory animals (Brunn et al., 1995; de Beer et al., 1991).

19.10.4 PATHOPHYSIOLOGICAL SIGNIFICANCE

Marked strain-dependent variation in serum SAA levels and in the serum SAA response to inflammatory stimuli have been reported in mice (French, 1989). In amyloid-resistant mouse strains, as in people, SAA responds as a prominent acute phase protein, with serum levels increasing 500–1000-fold following an inflammatory stimulus (Benson et al., 1977; Brandwein et al., 1985; Hoffman and Benditt, 1982; Malle et al., 1993; McAdam and Sipe, 1976; Nonogaki et al., 1996; Rokita et al., 1989). For example, in C57BL/6 mice, serum SAA levels change from being undetectable prior to treatment to 9.4 ± 1.0 $\mu\text{g/mL}$ within 16 hours of administration of nerve growth factor (Nonogaki et al., 1996). Similarly, in Golden hamsters, which also exhibit amyloid resistance, serum SAA values increased from being nondetectable to 150 ± 1 mg/mL 24 hours after LPS treatment (Hol et al., 1987). In domestic cats, which rarely develop amyloidosis, SAA appears to be a weak APR protein. The mean serum SAA values in healthy cats were estimated as 1.2 ± 0.3 $\mu\text{g/mL}$, compared to 3.7 ± 0.3 $\mu\text{g/mL}$ in animals with various inflammatory conditions (DiBartola et al., 1989). A biphasic change in serum SAA levels is frequently observed in animals with amyloidosis, with elevated values being observed in the early stages of the disease followed by a decline as amyloid deposits form (DiBartola et al., 1989; Rokita et al., 1989). Consequently, serum SAA values are not a useful indicator of amyloidosis.

A 9–20 increase in serum SAA values has been reported in beagle dogs following inoculation with *Bordetella bronchispetica* (Yamamoto et al., 1994b). Higher levels of SAA-mRNA than CRP-mRNA were detected in the liver of fetal, neonatal, and adult rabbits following LPS stimulation, suggesting that in this species (at least during the development phase), SAA rather than CRP may be the more important APR (Rygg et al., 1996).

Plasma levels of SAA can be used to predict the severity of acute pancreatitis significantly earlier than plasma CRP levels (Tape and Ksilevesky, 1990). Furthermore, SAA concentrations may be raised when CRP is not detectable in rheumatic disorders. Similarly, SAA is an early and sensitive marker for allograft organ rejection, being increased where as CRP levels are frequently within normal range or only slightly raised. The potential sensitivity of SAA has been demonstrated by its ability to predict myocardial infarction in the general population (Mayer et al., 2002). Changes of similar pattern and magnitude were observed in man and dog during an acute phase response, support this protein as a valuable diagnostic preclinical to clinical translational biomarker for toxicological studies (Watterson et al., 2008).

19.11 SERUM AMYLOID P

19.11.1 PROPERTIES

Serum amyloid P (SAP) was originally named on the basis of its identity with tissue amyloid-P component (Cathcart et al., 1965). The SAPs from different species share structural and functional similarities with both CRP and hamster FP, but among laboratory animals, only mouse SAP exhibits the characteristics of an APR.

Unlike CRP, which circulates as a single pentraxin molecule, SAP circulates as a glycoprotein composed of 10 identical, noncovalently linked subunits arranged as two stacked pentraxins bound “face-to-face” (Emsley et al., 1994; Pepys and Baltz, 1983; Siripont et al., 1988). The molecular weights of mouse, rat, and guinea pig SAP are similar, being in the range of 230–305 kDa (Baltz et al., 1982; Le et al., 1982; Nakada et al., 1986; Sarlo and Mortensen, 1987). Guinea pig SAP is composed of two types of subunits, only one of which is glycosylated (Maudsley et al., 1986). The SAP molecules from all species possess a high-affinity binding site for the 4,6-cyclic pyruvate acetal of the galactose residues present in agarose, which accounts for their preferential calcium-dependent binding to unsubstituted agarose rather than PC-substituted agarose (Baltz et al., 1982; Hind et al., 1984, 1985). Like CRP, both human and mouse SAP can bind to either phosphorylethanolamine or immobilized PC, though SAP has only one binding site per pentraxin, compared to the five per CRP molecule (Christner and Mortensen, 1994; Hawkins et al., 1991; Le et al., 1982).

Both human and mouse SAPs are coded by a single gene that is closely related to the CRP gene, located on chromosome 1 (Floyd-Smith et al., 1986; Mantzouranis et al., 1985; Whitehead et al., 1988; Yunis and Whitehead, 1990). The nucleotide sequences in the respective SAP genes from human, rabbit, mouse, hamster, guinea pig, and rat exhibit considerable homology, as do the amino acid sequences for the respective SAP proteins (Nakada et al., 1986; Rubio et al., 1993; Whitehead and Rits, 1990). The liver is the primary site of SAP synthesis, though not all hepatocytes constitutively express the SAP protein (Le and Mortensen, 1986). Like CRP, the rate of SAP synthesis is regulated at the transcription level. In mice, a single transcription initiation site on the SAP gene controls SAP-mRNA levels, regardless of the mouse strain or whether or not the animals are undergoing an inflammatory response (Itoh et al., 1992).

19.11.2 ROLE/FUNCTION

The administration of recombinant human IL-1 to C57BL/6 mice induced a dose-dependent increase in serum SAP levels (Mortensen et al., 1988). In this study, the serum SAP response to IL-1 was

greater than that observed for either fibrinogen or the C3 complement component (Mortensen et al., 1988). In the C57BL/6 mice, recombinant TNF α alone induced a modest fourfold increase in serum SAP values, but when it was administered in combination with IL-1, an additive effect was observed (Mortensen et al., 1988). Results from hepatocyte culture studies suggest that the kinetics of SAP synthesis and secretion are similar *in vivo* and *in vitro* (Zahedi and Whitehead, 1993). In hepatocyte cultures, IL-1 is one of the primary cytokines that stimulates SAP synthesis by amplifying protein production in those hepatocytes that constitutively express SAP (Le and Mortensen, 1984a, 1984b, 1986). Secretions from activated macrophages that contain multiple cytokines can both enhance protein synthesis and induce a sevenfold increase in the number of SAP producing hepatocytes (Zahedi and Whitehead, 1993). The exposure of murine hepatocyte cultures to IL-1, IL-6, or a combination of the two induced an approximately threefold increase in cellular SAP-mRNA levels within 12 hours, and the increased expression was sustained for a further 24 hours (Lin et al., 1990; Zahedi and Whitehead, 1993).

Serum SAP levels appear to be governed by the rate of protein synthesis and hepatic secretion of SAP and not by the rate of catabolism or clearance of the molecule (Baltz et al., 1985b; Shirahama et al., 1984). The circulating half-life of SAP in mice is short, having been determined as 7.0–8.25 hours, and it is similar in normal mice expressing different genetically determined basal SAP levels, in mice undergoing an acute phase response, and in mice with casein-induced amyloidosis (Baltz et al., 1985b). In mice, the liver is the main site of SAP clearance and catabolism (Hutchinson et al., 1994).

Because IL-1 can induce an increase in SAP synthesis and secretion and, in turn, SAP can enhance IL-1 secretion by mononuclear phagocytes, it has been suggested that SAP has the potential to influence inflammatory and immunological events initiated by and dependent on IL-1 (Sarlo and Mortensen, 1985). Further, inflammatory responses may be mediated, at least in part, by the selective SAP enhancement of bactericidal activity of murine macrophages through calcium-dependent binding of SAP to mannose-6-phosphate type macrophage receptors (Le and Mortensen, 1986; Siripont et al., 1988). Although the role of SAP as a modulator of the immune response is still controversial, it has been shown that in C57BL/6 mice, SAP can suppress the antibody response to a T-dependent antigen by activating a nonspecific suppressor T-cell subpopulation (Sarlo and Mortensen, 1987). This action of SAP may contribute to the lowered antibody response reported in mice undergoing an inflammatory reaction or exhibiting elevated serum SAP values and also in mice genetically manipulated to endogenously express high levels of SAP (Sarlo and Mortensen, 1987). Alternatively, the primary role of SAP in modulating the immune mechanism may be related to its ability to form a complex with C4b-binding protein (C4BP), an inhibitor of complement (Evans and Nelsestuen, 1995; Schwalbe et al., 1990). When C4BP is complexed with SAP, its inhibitory activity is reduced (de Frutos and Dahlback, 1994).

Among the recognized physiological functions of SAP are its ability to bind to both chromatin and DNA (Butler et al., 1990; Pepys and Butler, 1987; Shephard et al., 1991) and to enhance the clearance of nuclear material from dying cells (Du Clos et al., 1988; Robey et al., 1984). The rate of chromatin clearance is higher in BALB/cJ mice, which constitutively express high amounts of SAP, compared to C57BL/10J mice, which exhibit low baseline serum SAP levels (Burlingame et al., 1996). When an inflammatory response was induced in the C57BL/10J mice, not only was an increase in serum SAP observed, but the rate of chromatin clearance increased to almost equivalent levels to those occurring in the BALB/cJ mice (Burlingame et al., 1996). It was noted that higher serum SAP levels were associated with a reduction of chromatin deposits in renal tissue and a concomitant increase in hepatic chromatin deposits. This SAP-induced redistribution of chromatin may serve to reduce chromatin exposure to the immune system and to protect the kidneys from the chromatin-containing immune complexes that have been implicated in the development of immune complex glomerulonephritis (Burlingame et al., 1996; Connolly et al., 1988).

In immunodeficient mice, elevations of SAP appear to be associated with degeneration of renal function (Connolly et al., 1988). In MRL lpr/lpr, B/W, and NZB mouse strains (which all spontaneously develop autoimmune disease, though at different rates), the relative increases in serum SAP and fibronectin values observed over time correspond to the rate of onset of the disease (Connolly et al., 1988). A similar correlation between serum SAP levels and the SAP inflammatory response has been found in A/J amyloid-resistant mice and CBA/J amyloid-susceptible mice (Zahedi et al., 1991). In both mouse strains, azocasein administration induced an increase in both SAP-mRNA and serum SAP levels during the early stages of inflammation, but during the later stages, the serum SAP levels in the A/J mice dropped to half those of the CBA/J mice (Zahedi et al., 1991). It has been estimated that SAP comprises 10%–15% of the protein in the amyloid deposits that develop as a consequence of chronic inflammation (Coe and Ross, 1985; Pepys and Baltz, 1983). The incorporation of SAP into amyloid deposits may be a function of its ability to interact with basement membrane components, such as collagen, sulfated polysaccharides, and fibronectin (Hamazaki, 1987, 1989; Schwalbe et al., 1991; Zahedi, 1996). The SAP molecule is inherently proteinase resistant, and the SAP in human amyloid deposits is neither degraded nor modified, thus rendering the amyloid deposit less sensitive to proteolysis.

19.11.3 ANALYTICAL METHODS

Techniques used to quantitate serum SAP have included rocket immunoelectrophoresis (Connolly et al., 1988; Le et al., 1982), competitive binding radioimmunoassay (Sipe et al., 1982), rate nephelometry (Gertz et al., 1984), ELISA (Serban and Rordorf-Adam, 1986), and quantitative (Western) immunoblotting (Griswold et al., 1986). The rate nephelometry and Western blotting techniques are more sensitive than immunoelectrophoresis and superior to radioimmunoassay because the antigenic stability of radiolabeled SAP is lower than that of other APRs, for example, SAA (Gertz et al., 1984). The determination of serum SAP has been facilitated by the commercial availability of murine SAP protein standard and antibody preparations to murine SAP. Methods routinely used for isolating SAP from serum and tissues have been recently reviewed as have quantitative evaluation methods (Skinner and Cohen, 1988).

19.11.4 PATHOPHYSIOLOGICAL SIGNIFICANCE

There are considerable strain differences in the constitutively expressed serum SAP levels in mice (Table 19.3). Due to the structural similarities in the SAP genes from mice that are either high or low expressors of SAP, it has been speculated that trans-acting regulatory factor(s) may be involved in a suppressive manner in the transcriptional control of SAP-mRNA (Itoh et al., 1992). Peak hepatic SAP-mRNA levels were observed in female CBA/J mice 8 and 12 hours after thioglycollate and

TABLE 19.3

Serum Amyloid P-Component (SAP) in Different Mouse Strains Before and After Induction of an Inflammatory Response

Mouse Strain	SAP µg/mL	
	Normal Sera	Acute Phase Sera
C57BL/6, C57BL/10	15–37	275–403
MRL lpr/lpr, DBA1/LacJ	74–75	—
C3H/HeJ	82–126	158–170
BALB/cJ	84–138	—
DBA/2	150–180	210–230

azocasein administration, respectively (Zahedi and Whitehead, 1989), which is comparable to the time interval in which a 60-fold increase in SAP-mRNA was induced in C57BL/6 mice after LPS administration (Murakami et al., 1988). The SAP-mRNA response to LPS is approximately 10-fold greater than the CRP-mRNA response in the C57BL/6 mice, though it takes almost four times as long for the SAP-mRNA to reach maximum levels (Murakami et al., 1988). These results are compatible with the observation that the rate of SAP synthesis is generally fivefold higher in mice undergoing an acute phase response than in healthy mice (Le and Mortensen, 1984a). An increase in hepatic SAP-mRNA expression in rats has also been reported following LPS stimulation (Dowton and McGrew, 1990).

As shown in Table 19.3, baseline serum SAP values in mice show marked strain differences (Burlingame et al., 1996; French, 1989; Griswold et al., 1986; Le et al., 1982; Mortensen et al., 1983). The absolute serum SAP values determined for the same mouse strain can vary, depending on the methodology used for the determination. With Western blotting, the relative serum SAP values for BALB/c, DBA1/LacJ, MRL lpr/lpr, and C3H/HeJ strains were 33.7 ± 7.7 $\mu\text{g/mL}$, 35.4 ± 7.6 $\mu\text{g/mL}$, 45.6 ± 3.7 $\mu\text{g/mL}$, and 56.2 ± 4.2 $\mu\text{g/mL}$, respectively (Griswold et al., 1986). The higher values obtained with other laboratory methods are illustrated in Table 19.3. There appears to be only a modest correlation between basal hepatic SAP-mRNA levels and serum SAP levels in different mouse strains (Itoh et al., 1992). For example, in several strains of mice, LPS treatment induces a ninefold increase in SAP-mRNA that does not always correspond to the extent of the observed elevations in serum SAP values. In DBA/2J mice, only a 1.4-fold elevation in serum SAP occurred following LPS administration, while a ninefold increase was observed in C57BL/6 mice (Mortensen et al., 1983).

A similar lack of correlation between SAP-mRNA and serum SAP levels has been observed in rats. In Sprague-Dawley rats, turpentine treatment induced a 46-fold increase in hepatic SAP-mRNA levels while producing only a twofold increase in serum SAP (Nakada et al., 1986). In CBA/J mice, peak SAP-mRNA levels were recorded 8 and 12 hours after thioglycollate or azocasein injections, respectively, and the alterations in SAP-mRNA correlated with changes in other inflammatory parameters (Zahedi and Whitehead, 1989). In the CBA/J mice, SAP-mRNA levels had returned to near normal by 36 hours, at which time a 20-fold increase in serum SAP levels was detected (Zahedi and Whitehead, 1989). A lag phase between SAP-mRNA induction and increased serum SAP levels has also been noted in TO mice following endotoxin injection (Myers and Fleck, 1988). In both C57BL/6 and C57BL/10 mice, a single intraperitoneal injection of thioglycollate resulted in an 8- to 10-fold increase in serum SAP values within 24 hours (Burlingame et al., 1996; Sarlo and Mortensen, 1987). Similarly, casein administration to C57BL/10 mice caused serum SAP levels to rise to 340 ± 64 $\mu\text{g/mL}$ from a baseline of 26 ± 11 $\mu\text{g/mL}$ (Burlingame et al., 1996). Elevations in mouse serum SAP values also occur in response to parasitic and bacterial infections (French, 1989). Strain differences are also apparent in this type of response. Endotoxin administration to Parkes strain mice elevated serum SAP values from 89 ± 1 $\mu\text{g/mL}$ to 248 ± 19 $\mu\text{g/mL}$, while the same treatment to C3H/HeJ mice had essentially no effect on serum SAP levels (Poole et al., 1984). In the C3H/HeJ mice, average serum SAP values only change from 109 ± 17 $\mu\text{g/mL}$ to 164 ± 6 $\mu\text{g/mL}$ following endotoxin treatment (Poole et al., 1984).

The baseline values of serum SAP in Dunkin–Hartley guinea pigs have been reported as 16 ± 4 $\mu\text{g/mL}$, which is similar to the basal values found for SAP in rat and human serum (Maudsley et al., 1986; Pepys et al., 1978). Subcutaneous administration of a 4% solution of silver nitrate to guinea pigs caused serum SAP to rise to only 25 ± 4 $\mu\text{g/mL}$ within 24 hours, but lower doses were ineffective in raising serum SAP values (Maudsley et al., 1986). Hence, SAP is not considered to be a major APR protein in guinea pigs.

Human neonates have low serum SAP that rises to the adult range within a few weeks after birth (Pepys et al., 1982), while neonatal and adult mice exhibit similar serum SAP values (Waites et al., 1983). In female Wistar rats, age differences have been noted, with serum SAP levels rising from 29 $\mu\text{g/mL}$ at 11 weeks of age to 107 $\mu\text{g/mL}$ at 58 weeks (Hashimoto et al., 1995). Human

males have been reported to have higher basal serum SAP levels than females (Pepys et al., 1978). In mice, no sex-related alterations in serum SAP levels have been found (Rordorf-Adam et al., 1985). In rats, variable results have been found with no gender-related differences being reported in one study (Nakada et al., 1986), while in another study, higher serum SAP values of $63 \pm 18 \mu\text{g/mL}$ were reported for old females Wistar rats compared to values of $39 \pm 10 \mu\text{g/mL}$ for age-matched males (Hashimoto and Migita, 1990). The gender- and age-related differences in serum SAP levels in Wistar rats have been attributed to the influence of estrogen, because estradiol administration to young males increased serum SAP levels from $26 \pm 2 \mu\text{g/mL}$ to $49 \pm 7 \mu\text{g/mL}$ while testosterone administration had no effect (Hashimoto and Migita, 1990; Hashimoto et al., 1995).

Syngenic pregnancy in C57BL/10 mice produces a transient increase in serum SAP levels in the 3 days before parturition (Waites et al., 1983). In contrast, allogeneic pregnancy (CBA/Ca males) produced triphasic serum SAP response in the C57BL/10 females with a transient twofold increase being observed at day 4 of pregnancy, a sustained threefold increase between days 8 and 12, and a maximum increase of five- to sixfold on day 18 of gestation (Waites et al., 1983). In both types of pregnancy, serum SAP returned to basal levels by day 8 postpartum.

ACKNOWLEDGMENT

I wish to thank Patricia A. Gentry, author of this chapter in the 2nd edition, for her vision and contributions to this chapter.

20.1 INTRODUCTION

Defects in carbohydrate metabolism are the major focus of research because of the extremely high incidence of diabetes mellitus (DM) and obesity in the United States population. Based on the National Centers for Disease Diabetes Fact Sheet (www.cdc.gov/diabetes/library) ~11.3% of the adult (>20 years old) population in the United States has diabetes (25.6 million people). The two most common forms of diabetes mellitus (DM) are referred to as type 1 and type 2, ~90% have type 2 DM. In type 1 (previously called insulin-dependent diabetes mellitus [IDDM]), there is an absolute deficiency of insulin, generally due to an autoimmune destruction of the pancreatic β cells.

Type 2 (previously called non-insulin-dependent diabetes mellitus, NIDDM) is characterized by insulin resistance and inadequate compensatory increase in the secretion of insulin. Almost 90% of individuals with type 2 DM are overweight or obese. The rise in obesity and diabetes risk is also mirrored in companion animals (dogs and cats) although the relative contribution of type 1 versus type 2 DM varies depending on the species (German et al., 2010; German, 2006; Catchpole et al., 2008; Prahl et al., 2007). In cats, the most common form of DM is type 2 and is associated with islet amyloidosis (O'Brien, 2002). In canines, the primary cause is type 1 DM (Catchpole et al., 2008).

Other less common causes of defects in glucose homeostasis either target endocrine systems that modulate carbohydrate metabolism or directly affect organs that metabolize carbohydrates (primarily liver and muscle). Congenital defects in β -cell function can cause hypo- or hyperglycemia secondary to inappropriate insulin secretion (Hussain, 2010). An excess in thyroid hormone, growth hormone, or glucocorticoids can cause hyperglycemia and a deficiency on one or another can cause hypoglycemia. Glycogen storage diseases (GSD) can either limit the ability of the liver to release carbohydrate or store carbohydrate. This can have profound effects on glucose homeostasis. GSD can affect skeletal muscle function, which commonly manifests as exercise intolerance. Defects in the metabolism of fructose or galactose can dramatically affect liver function (Mayatepek et al., 2010).

Animal models are very powerful tools with which to understand the physiology and pathophysiology of metabolic disease. Rodents, canines, and nonhuman primates have been used extensively to understand how carbohydrate is metabolized and glucose homeostasis is maintained. Each species of laboratory animal has one or more particular area of strength most amenable for the study of carbohydrate metabolism. Research using canines was critical in the discovery of insulin in 1922, and dogs have been used extensively to study the regulation of hepatic and muscle glucose metabolism. Nonhuman primates, because of their evolutionary proximity to humans, and canines have been used extensively to test new therapeutics and to determine if observations made in other mammalian systems translate to other species (Cruzen and Colman, 2009; Saisho et al., 2010). For rodents and mice, in particular, the ability to genetically manipulate (spontaneous or genetically induced gene deletion or overexpression) has afforded development of many models of human disease that are not as easily generated in other animal models. In addition, rodent models have served as tools to evaluate potential therapeutic agents.

20.2 REGULATION OF GLUCOSE HOMEOSTASIS

Plasma glucose concentration is a tightly controlled physiologic variable. The mechanisms in place to prevent hypoglycemia are particularly critical, as hypoglycemia can cause metabolic dysfunction, neuroglycopenia, seizures, and even death. In our present Western society, carbohydrate and nutrient availability is high and predispose us to develop obesity and DM. The control systems to prevent hyperglycemia are less robust; therefore, hyperglycemia is more common. Chronic hyperglycemia can lead to end-organ damage (e.g., retinopathy, nephropathy, and neuropathy).

The three major sources of plasma glucose are dietary carbohydrate (glucose, galactose, and fructose), glycogenolysis (breakdown of glycogen, which is a polymerized storage form of glucose), and gluconeogenesis (formation of glucose from gluconeogenic precursors including lactate, gluconeogenic amino acids, and glycerol). Dietary carbohydrates, after being digested into monosaccharides in the lumen of the intestine, are readily absorbed and enter the portal circulation. Common carbohydrates in the diet are starch (amylose or amylopectin), sucrose, and lactose. The three monosaccharides that make up these carbohydrates are glucose, fructose, and galactose. Starch is a polymer of glucose. Sucrose (table sugar) is a disaccharide (glucose and fructose). Lactose is a disaccharide (glucose and galactose). All monosaccharides are not treated equally when metabolized. Fructose and to a lesser extent, galactose are preferentially metabolized by the liver (McGuinness and Cherrington, 2003; Tappy and Le, 2010; Leslie, 2003). Approximately one-third of dietary glucose is taken up by the liver. The remainder is metabolized by peripheral tissues (e.g., brain, muscle, and fat).

To maintain glucose homeostasis, physiologic mechanisms allow tight coupling between the rates of glucose entry into the circulation and the rates of glucose disposal. In the fasted state, the liver is the main source of glucose. The liver releases glucose from one of two pathways (glycogenolysis and gluconeogenesis) into the plasma at rates equal to the uptake of plasma glucose by peripheral (e.g., brain, muscle, and fat) tissues. Although the kidney produces glucose, it is a minor source compared with the liver. The brain and formed elements of the blood (e.g., erythrocytes) consume ~60% of the plasma glucose used in the sedentary, fasted person and their absolute rate of utilization is relatively constant. In contrast, glucose utilization in muscle, fat, and liver can change markedly depending on the physiologic setting.

The absolute rates of glucose production and the contribution of the brain to basal glucose uptake vary between species. The basal rate of glucose production is ~2 mg·kg⁻¹ min⁻¹ in humans, dogs, and nonhuman primates, ~7 mg·kg⁻¹ min⁻¹ in rats, and 15–20 mg·kg⁻¹ min⁻¹ in mice (Wasserman, 2009; Reivich et al., 1979; Nagle et al., 2007). The contribution of the brain to basal glucose uptake is substantially lower in rodents than in humans and nonhuman primates (Moore et al., 1999; Reivich et al., 1979). In the mouse and rat, the brain consumes only about 15% and 10%, respectively, of the basal rate of glucose utilization (Grunstein et al., 1985).

The endocrine pancreas plays an essential role in the minute regulation of glucose homeostasis. Insulin release by the β cell is very sensitive to changes in plasma glucose concentration. Insulin has effects on multiple tissues including the liver, muscle, and adipose tissue. It also has effects on specific brain regions that regulate feeding behavior and energy expenditure. Its release can be further amplified by incretins (e.g., glucagon-like peptides) released by endocrine cells in the intestine when nutrients are ingested. Insulin's primary effect is to lower plasma glucose concentration by promoting cellular uptake of insulin. The hormone opposing insulin is glucagon, which is released by the α -cells of the endocrine pancreas. Glucagon's primary site of action is the liver where it is a potent stimulator of liver glucose production; it is also a modest regulator of lipolysis.

The robustness of this glucose control system is readily demonstrated with the glucose response to ingestion of a meal or to exercise (Wasserman, 2009; Moore et al., 2003). Ingestion of a meal high in carbohydrates increases β -cell insulin secretion. Insulin suppresses the rate of liver glucose production and augments glucose uptake by muscle, liver, and fat. The result is that excursions in plasma glucose concentration are dampened. Exercise augments glucose uptake in the working muscle despite a fall in plasma insulin. The fall in insulin and rise in glucagon allow the liver to exactly match the increase in muscle glucose requirements, thus minimizing deviations in plasma glucose.

As animals do not eat continuously, a substantial portion of dietary carbohydrate must be stored and subsequently released during the postabsorptive state. While multiple tissues contribute to the disposal of dietary carbohydrate, the metabolic fate varies. In the liver, the primary metabolic fate is storage as glycogen. In response to the accompanying increase in insulin, arterial glucose, and delivery of glucose into the portal vein, the liver switches from a glucose producer to a glucose consumer and removes approximately one-third of the dietary glucose (Pagliassotti and Cherrington, 1992). The liver expresses hexokinase IV (i.e., glucokinase). In contrast to the other hexokinases found in muscle and fat, glucokinase has a low affinity for glucose ($K_m = 7$ mM vs. <1 mM) and is associated with glucokinase-associated regulatory protein (GKRP). When bound to GKRP, glucokinase is inactive and is located in the nucleus. Metabolic intermediates (glucose-6-phosphate and fructose-1-phosphate) can compete with the binding of glucokinase to GKRP and thus activate glucokinase. This allows glucokinase and thus the liver to be very responsive to changes in glucose concentration (McGuinness and Cherrington, 2003; Van Schaftingen et al., 1994). The rapid entry of glucose facilitated by activation of glucokinase combined with the rise in insulin act to suppress hepatic glycogenolysis and augment glycogen synthesis. About 50% of the glycogen synthesized in the liver is from dietary glucose that is directly taken up by the liver in a process referred to as direct glycogen synthesis. The remaining 50% is from gluconeogenic precursors (e.g., lactate, alanine, and glycerol) taken up by the liver, which instead of being released as glucose, are diverted to glycogen storage (Pagliassotti and Cherrington, 1992; Moore et al., 1991; Giaccari and Rossetti,

1992; Chueh et al., 2006). Thus, the gluconeogenic pathway is continuously active during both the fed and fasted setting. What differs is the fate of the glucose that is synthesized. Less than 25% of the glucose taken up by the liver is completely oxidized. While the liver has the capacity to convert glucose carbon to lipid (i.e., *de novo* lipogenesis), which will then subsequently be assembled into very low-density lipoprotein (VLDL) particles and released; this is a relatively minor metabolic pathway, except with carbohydrate over feeding (Lewis, 1997; Chong et al., 2007). The addition of fructose to the diet may amplify *de novo* lipogenesis, as the majority of dietary fructose is removed by the liver. The majority of the VLDL released by the liver is derived from free fatty acids taken up and reesterified by the liver. The glycerol used in the synthesis of the glycerol backbone of triglycerides can be derived from carbohydrates (glucose, galactose, and fructose) or gluconeogenic precursors taken up by the liver.

Muscle glucose uptake is very low in the fasted state and increases markedly following a carbohydrate-rich meal (Moore et al., 2003). The increase in muscle glucose uptake is driven by the increase in the prevailing glucose and insulin concentration and the decrease in circulating nonesterified fatty acids secondary to the suppression of adipose tissue lipolysis and enhancement of reesterification. The majority of the glucose taken up by the muscle is deposited as glycogen (Mandarino et al., 2001). The remaining is oxidized or released as lactate or alanine. The augmentation of muscle glucose uptake is facilitated by the increase in glucose delivery to the muscle and the direct effects of insulin on the muscle to augment fractional extraction of glucose from the plasma by the muscle. The increase in glucose delivery is due to the combined increase in glucose concentration and the insulin-mediated increase in muscle blood flow. The increase in fractional glucose extraction is due to the direct effect of insulin to stimulate muscle glucose transport (glucose transporter type 4 [GLUT4] translocation) and augment glucose phosphorylation and glycogen synthetic capacity (Wasserman, 2009).

In adipose tissue, glucose uptake in response to a meal increases markedly due to the ability of insulin to facilitate glucose entry by translocation of GLUT4 (a facilitated glucose transporter) to the plasma membrane. While adipose tissue is very sensitive to insulin, relative to skeletal muscle, adipose tissue plays less of a role on whole body glucose disposal. The majority of the glucose carbon taken up by the adipose tissue is used either to provide glycerol to esterify circulating lipid or for *de novo* lipogenesis (Bederman et al., 2009). As the carbohydrate content of the diet increases, the contribution of the *de novo* pathway for lipid synthesis in both the liver and, to a lesser extent adipose tissue, increases (Chong et al., 2007; Brown et al., 2005; Postic and Girard, 2008).

As individuals transition from the fed state into a fast, plasma glucose and insulin gradually diminish and the liver switches from a glucose consumer to a glucose producer. The hepatic glycogen stores are mobilized, and gluconeogenic carbon that was being diverted to glycogen during the absorptive period is released by the liver. Hepatic glycogen stores are limiting (~100 g in the human in the postabsorptive state) and would be depleted in 10 hours, if gluconeogenesis did not provide a significant portion of the glucose carbon. As the fast progresses beyond 12 hours, the absolute rate of glucose production gradually decreases and the contribution of gluconeogenesis to plasma glucose increases. The carbon used to support gluconeogenesis comes from lactate-derived hydrolysis of muscle glycogen (~400 g), glycerol from adipose tissue lipolysis, and amino acids derived from muscle protein breakdown. The rates of glucose uptake by fat and muscle diminish, while brain glucose uptake remains relatively constant after a brief fast in humans (24–48 hours). The equivalent fast to an overnight fast in humans is much shorter in rodents. Thus, because glucose uptake by peripheral tissues decreases as one progresses into a fast, the absolute rate of gluconeogenesis does not increase even after hepatic glycogen stores are depleted (Bjorkman and Eriksson, 1985). Adipose tissue breakdown gradually increases, allowing nonesterified fatty acids to become the major oxidative fuel of both the muscle and the liver. As the net rate of lipolysis exceeds, the immediate oxidative needs of the liver and muscle, the liver reesterifies the lipid and releases VLDL and ketones. Ketones are rapidly oxidized by metabolically oxidative tissues such as heart and muscle, and after a long-term fast, by brain. If the metabolic demands of peripheral tissues increase

in the postabsorptive state, as is seen during exercise, glucose uptake, and oxidation increase in the working muscle. This is matched with an increase in hepatic glucose production derived from a combined increase in glycogenolysis and gluconeogenesis (Wasserman, 2009).

Problems in these homeostatic mechanisms can result in metabolic dysfunction. If glucose production does not increase during exercise or is not maintained during a fast, as sometimes happens in diabetics treated with too much insulin or drugs that augment insulin secretion or action, hypoglycemia ensues. As individuals gain adipose tissue mass, they generally become insulin resistant. Interestingly, the preferential accumulation of adipose in the visceral, as opposed to the subcutaneous, compartment confers a greater risk in developing insulin resistance, diabetes, and cardiovascular disease (Lam et al., 2011). In most individuals, insulin secretion increases to compensate for the insulin resistance and near-normal glucose homeostasis is maintained. Those individuals who cannot sustain this increase in β -cell insulin secretion develop DM. The medical management of the accompanying hyperglycemia either with pharmaceuticals or insulin will commonly result in iatrogenic hypoglycemia (Cryer, 2010; Banarer and Cryer, 2004).

The mechanism to protect against hypoglycemia (whether iatrogenic or pathophysiologic) requires responses to work in concert to augment hepatic glucose production, augment lipolysis, and impair glucose removal by peripheral tissues. These responses are suppression of endogenous insulin secretion, stimulation of glucagon secretion, and activation of the autonomic nervous system (epinephrine and neural drive) (Cryer, 2010; Banarer and Cryer, 2004). Other factors such as increases in growth hormone and cortisol (or corticosterone in rodents) play a relatively minor role in the acute (minutes to a few hours) protection against hypoglycemia, but play a more important role in prolonged periods of hypoglycemia, and when deficient, can predispose one to develop hypoglycemia. Humans and animals exposed to repeated bouts of hypoglycemia can develop autonomic failure that will predispose them to very severe and life threatening hypoglycemia. This is a major hurdle in the medical management of DM. Activation of these same stress-activated pathways explains the robust increase in glucose that occurs when an animal is under stress (e.g., physical restraint, novel environment, an infection, or toxin). Thus, understanding how to monitor and manage glucose homeostasis requires an understanding of the normal regulation of carbohydrate metabolism and how defects in carbohydrate metabolism, insulin action and β cell, and neuroendocrine function can impact glucose homeostasis.

20.3 LABORATORY ANIMAL MODELS OF CARBOHYDRATE METABOLIC DYSFUNCTION

Diabetes and obesity are the most common causes of defects in carbohydrate metabolism in humans; therefore, several animal models have been developed to mimic these conditions. Multiple animal models have been used to study endocrine disorders (cortisol and growth hormone excess or deficiency) or genetic disorders (GSD, defects in fatty acid oxidation) that can also cause either hypoglycemia or hyperglycemia. We focus on animal models of diabetes and obesity, but we have included a discussion of models that affect glycogen storage and fructose and galactose metabolism.

20.3.1 TYPE 1 DIABETES MELLITUS

Type 1 DM is characterized by a specific destruction of pancreatic β cells and is, in many cases, associated with immune-mediated damage.

20.3.1.1 Spontaneous or Genetically Derived Type 1 DM Models

Spontaneous type 1 DM models have been developed by either identifying one or several genetic mutations or by selective outbreeding of nondiabetic animals for hyperglycemia (Rees and Alcolado, 2005). Typically, the animals present with basal insulin deficiency and a defect in the insulin response to glucose load (see Table 20.1).

TABLE 20.1
Animal Models of Type I Diabetes

- Nonobese diabetic (NOD) mouse (Thayer et al., 2010)
 - Bio breeding (BB) rat (Parfrey et al., 1989)
 - Long Evans Tokushima lean (LETL) rat (Shima et al., 1999)
 - New Zealand white rabbit (Wang et al., 2010a)
 - Keeshond dog (Kramer et al., 1980)
 - Chinese hamster (Chang, 1981)
 - Celebes black ape (*Macacca nigra*) (Stanhope and Havel, 2008)
-

The nonobese diabetic (NOD) mouse and bio breeding (BB) rat are the two most commonly used animals that spontaneously develop type 1 diabetes. These animals have been inbred in laboratories for many generations by selecting for hyperglycemia. In NOD mice, overt diabetes typically presents between 12 and 30 weeks of age. Ketoacidosis is relatively mild; affected animals can survive for weeks without the administration of insulin. In BB rats, weight loss, polyuria, polydipsia, hyperglycemia, and insulinopenia develop at around 12 weeks of age, often at the time of puberty. Ketoacidosis is severe and fatal unless exogenous insulin is administered. In both the NOD mouse and BB rat, the pancreatic islets are subjected to an immune attack, as T cells, B cells, macrophages, and natural killer cells are recruited to the islets. Diabetes in the Chinese hamster is inherited as a homozygous recessive trait. It exhibits no lymphocytic infiltration into the pancreatic islets and no evidence of autoimmunity.

20.3.1.2 Chemical-Induced Type 1 DM Models

Alloxan (ALX) and streptozotocin (STZ) are most commonly used to induce type 1 DM in experimental animals. Both cause selective loss of pancreatic β cells, while leaving pancreatic α and δ cells intact. The cytotoxic action of both these diabetogenic agents is mediated by reactive oxygen species; however, the source of their generation is different (Szkudelski, 2001). ALX is a uric acid derivative. ALX and the product of its reduction, dialuric acid, establish a redox cycle with the formation of superoxide radicals, which undergo dismutation to hydrogen peroxide. Highly reactive hydroxyl radicals are formed by Fenton reaction. The action of reactive oxygen species with a simultaneous massive increase in cytosolic calcium concentration causes rapid destruction of β cells. STZ is a nitrosourea derivative and a powerful alkylating agent that has been shown to interfere with the glucose transporter (GLUT2) and glucokinase. STZ may cause alkylation or breakage of DNA strands and a consequent increase in the activity of poly-ADP-ribose synthase, an enzyme that depletes NAD, leading to energy deprivation and death of β cells. The intravenous route of administration is preferred for ALX, because of its low stability and very short half-life (less than 1 minute). ALX is disadvantageous because the extent of β cell death and the severity of hyperglycemia and ketosis are quite variable and are not proportional to the dose of ALX that is used. In part, this is because the β cell damage can be reversible. Therefore, STZ has now replaced ALX for the induction of diabetes in most laboratory animal models. There is one exception. ALX is used in rabbits because STZ is ineffective for induction of diabetes in this species and has a well-characterized multiorgan (liver and kidney) toxicity (Rerup, 1970). Dogs exhibit a high mortality following the administration of diabetogenic doses of either ALX or STZ likely secondary to severe liver and kidney damage including necrosis and fatty infiltration (Rerup, 1970). Mortality can be avoided if diabetes is induced by a combination of the two compounds (Issekutz et al., 1974). The dosages when both drugs are used together are considerably below the diabetogenic doses required to induce diabetes and off target organ toxicity, if either drug is to be used individually. The combined drug approach has shown no evidence of any significant organ toxicity other than the intended toxicity to β cells in the pancreas (see Table 20.2).

TABLE 20.2**The Doses of Alloxan (ALX) and Streptozotocin (STZ) in Different Species Used to Induce Type 1 Diabetes**

Species	Dose	Route	Reference
Dog	35 mg STZ/kg + 40 mg ALX/kg	IV	Issekutz et al. (1974), Black et al. (1980), and Anderson et al. (1993)
Rat	60 ~ 70 mg STZ/kg	IV	Beech et al. (1989), Gibson et al. (1993), Koopmans et al. (1996), Burcelin et al. (1995), Hough et al. (1982), and Dardevet et al. (1991)
	65 ~ 85 mg STZ/kg	IP	Napoli et al. (1995), Youn et al. (1994), and Webster et al. (1986)
Mouse	200 mg STZ/kg	IP	Kim et al. (2009), Kim et al. (2008), and Gronbaek et al. (2002)
	50 mg STZ/kg	IP 4–5 × daily injections	Amirshahrokhi et al. (2008), Kim et al. (2009), Yuan et al. (2008), and Karabatas et al. (2005)
Rabbit	65–100 mg STZ/kg	IV	Jablecka et al. (2009), Marrachelli et al. (2010), Shukla et al. (2008), and Kohli et al. (2004)
Pig (Göttingen minipig)	100 ~ 125 mg STZ/kg	IV	Larsen et al. (2002)

20.3.2 TYPE 2 DIABETES MELLITUS

Type 2 DM models exhibit hyperglycemia with near normal or increased concentration of plasma insulin. The development of hyperglycemia is generally associated with insulin resistance in various tissues/organs, which can lead to impaired glucose disposal and inappropriate endogenous glucose production. In general, males have a more severe diabetic phenotype in most animal models of type 2 DM than do females.

20.3.2.1 Spontaneous or Genetically Derived Type 2 DM Models

Many spontaneous type 2 diabetic models exhibit hyperphagia and obesity. The most widely used mouse (an inbred C57BL/6J or a C57BLKS/J background) models carry a single mutation in either the leptin (*Lep*) or the leptin receptor (*Lepr*) genes. In a C57BL/6J background, hyperglycemia is transient, but plasma insulin concentration increase steadily with age. The time course and symptoms on a C57BLKS/J background are more severe; this is not related to the presence of a mutation in the NAD nucleotide transhydrogenase (*Nnt*) gene on the C57BL/6J background (Nicholson et al., 2010). Mice become diabetic by 6 weeks of age. They develop pancreatic islet degeneration and renal complications. This results in lethality as early as 16–20 weeks of age. KK mice (KK/HIJ) are an inbred mouse strain that become diabetic when they are maintained on a high-calorie diet. Obesity and hyperinsulinemia are not as prominent as in *Lep^{ob}/Lepr^{ob}* (often referred to as ob/ob) mice, but hyperglycemia is generally higher. Insulin resistance and body weight increase considerably at 2–3 months of age, peak at about 5 months, and return to normal at 9–12 months. T-KK hybrid or KKBL mice were developed by crossing the KK mice with C57BL/6J. Yellow KK or KKA^y mice were developed by inserting the yellow agouti (*A^y*) gene from the yellow obese mice into the Japanese KK. T-KK and Yellow KK become diabetic when they are obese. In NZO (NZO/HILtJ) mice, an inbred mouse strain, body weight rises considerably during the first 10 weeks of life and peaks at 12–14 months, together with the parallel manifestation of hyperglycemia and hyperinsulinemia.

The most widely used diabetic rat models include the Zucker Fatty rat (outbred ZUC-*Lepr^{fa}*) or the inbred Zucker diabetic fatty (ZDF-*Lepr^{fa}*) rat. In the Zucker Fatty rat, obesity is accompanied by mild hyperglycemia and significant hyperinsulinemia detectable as early as 2–3 weeks of age.

Profound insulin resistance persists throughout their life span. Ketosis is absent. The Zucker diabetic fatty rat is an inbred substrain of markedly hyperglycemic Zucker fatty rats (Friedman et al., 1991). Compared with Zucker fatty rats, this model is more hyperglycemic and less hyperinsulinemic. Fasting hyperglycemia increases gradually with a progressive decrease in plasma insulin concentration beginning approximately at 8 weeks of age. The Otsuka Long-Evans Tokushima fatty (OLETF) rat originates from an outbred colony of Long-Evans rats selectively bred for glucose intolerance and possesses a spontaneous mutation in the gene encoding the receptor for the brain–gut peptide cholecystokinin (gene symbol *Cckar*; Takiguchi et al., 1997). The rats are mildly obese and develop diabetes in adult life (Shafrir, 1992; Rees and Alcolado, 2005; Srinivasan and Ramarao, 2007).

Some rodent models are available with nonobese type 2 DM. The Akita mouse (C57BL/6-*Ins2^{Akita}*) is the nonobese mutant mouse derived from the colony of C57BL/6 (Shafrir, 1992; Rees and Alcolado, 2005; Srinivasan and Ramarao, 2007). The Akita (*Ins2^{Akita}*) spontaneous mutation is an autosomal dominant mutation in the insulin II gene (*Ins2*), which is the mouse homologue of human preproinsulin gene. This mutation disrupts normal insulin processing and causes a failure in secretion of mature insulin, which results in early development of hyperglycemia. The Goto-Kakizaki (GK/KyoSwe) rat was developed by the selective breeding of Wistar rats with abnormal glucose tolerance repeated up to 35 generations. The rats are nonobese and develop stable hyperglycemia in adult life. The fasting hyperglycemia is mild but rises further on challenge with glucose. Their impaired glucose tolerance neither improves with age nor deteriorates with further breeding, and it does not proceed to a ketotic stage. The Cohen diabetic rat expresses genetic susceptibility to a carbohydrate-rich diet. The Torii rat was derived from a Sprague-Dawley rat strain.

Three distinctive quantitative trait loci (QTLs) were identified for glucose intolerance and were highly associated with the development of diabetes. The Nagoya-Shibata-Yasuda (NSY) inbred mouse was developed by selective inbreeding using a laboratory strain of mouse termed Jc1:ICR. NSY mice develop diabetes in an age-dependent manner (see Table 20.3).

20.3.2.2 Chemical-Induced Type 2 DM Models

Gold thioglucose (150–350 or 200 mg/kg, intraperitoneal [IP]) injection into mice can induce type 2 DM associated with obesity. The gold thioglucose is transported to the cells of ventromedial hypothalamus and causes necrotic lesions, which subsequently is responsible for the development of hyperphagia and obesity. Mice gradually develop obesity, hyperinsulinemia, hyperglycemia, and insulin resistance over a period of 16–20 weeks after gold thioglucose injection (Le Marchand et al., 1978).

Chemically induced type 2 DM can be induced in the absence of obesity by the neonatal injection of STZ into rats. A single injection of STZ (80–100 mg/kg; intravenously [IV] or IP or

subcutaneously [SC]) into 1- or 2- or 5-day old pups induces type 2 diabetes in outbred Wistar (WI) or Sprague-Dawley (SD) rats (Takada et al., 2007; Portha et al., 1989). The neonatal type 2 diabetic models can also be developed by injecting ALX (200 mg/kg, IP) to male neonatal rats at 2, 4, or 6 days after birth (Kodama et al., 1993). These models develop hyperglycemia, abnormal glucose tolerance, and mild hypoinsulinemia that does not manifest until the animals are adults. Adult male rats are more severely affected than female rats, while β cell susceptibility to STZ in vivo or in vitro during the neonatal period is not influenced by gender (Ostenson et al., 1989). Type 2 diabetic models have also been developed by injecting STZ (35 mg/kg) into animals that are genetically insulin resistant (e.g., Spontaneously Hypertensive Rat [SHR] and ZUC) (Reaven and Ho, 1991). These models develop mild hyperglycemia without altered plasma insulin concentration.

20.3.2.3 Diet/Nutrition-Induced Type 2 DM Models

Several nondiabetic animal species may acquire type 2 DM associated with obesity when they are exposed to energy-abundant diets (Shafir, 1992; Rees and Alcolado, 2005; Srinivasan and Ramarao, 2007; Islam and Loots du, 2009). Although they do not appear to carry an overt genetic defect, they may be considered as carriers of a genetic trait, which limits the capacity of their metabolic system to adjust to the high nutrient intake. C57BL/6J mice, in contrast to other strains, develop hyperglycemia and hyperinsulinemia when they are exposed to high-fat diet (45%–60% of calories from fat). Since this mouse strain is shown to be mildly insulin resistant with a weak first phase of insulin release, latent genetic factors may become expressed in this mouse strain on high-fat diet. Sand rats remain normal in their natural habitat (e.g., fed their usual low-energy density vegetable diet). When placed on standard (e.g., higher energy density) laboratory chow, however, sand rats develop hyperphagia, obesity, hyperinsulinemia, and glucose intolerance. Over time, they exhibit β -cell degeneration and necrosis, resulting in profound insulin deficiency, overt diabetes and ketosis. Spiny mice (*Acomys* spp.) also develop obesity and marked pancreatic β -cell hyperplasia, hypertrophy, and increased pancreatic insulin content followed by an impaired insulin release mechanism when they are fed with rodent lab chow. Over time they develop overt hyperglycemia and fatal ketosis.

Type 2 DM can be induced by combining diet (high-fat or high-fructose diet) and STZ treatment in outbred rats (see Table 20.4). The diets induce hyperinsulinemia and insulin resistance. When treated with STZ to cause β -cell damage, hyperglycemia develops in the presence of almost normal insulin concentrations. The combination method has been used to induce obese-type 2 diabetes in canines (Bevilacqua et al., 1985; Ionut et al., 2009).

Golden hamsters fed a high-fat diet do not overeat, but they become obese because of decreases in energy expenditure (Wade, 1982, 1983). This decrease in energy expenditure is accompanied

TABLE 20.4

Diet-Induced Type 2 Diabetic Obese Models

High Energy Diet-Induced Type 2 Diabetic Obese Models (Srinivasan and Ramarao, 2007; Shafir, 1992)

- Male C57BL/6J mouse by high-fat diet (40%–65% calorie as fat)
- Spiny mouse (*Acomys calirinus*): by standard laboratory chow
- Sand rat (*Psammomys obesus*): by standard laboratory chow

Type 2 Diabetic Models Induced by a Combination of Diet and Chemicals

- Injected with STZ (50 mg/kg IV) after high-fat diet (40% calories as fat) for 2 weeks (Reed et al., 2000)
 - Injected with STZ (35 mg/kg, IV) after high-fat diet (33% calories as fat) for 2 weeks (Wang et al., 2011)
 - Injected with STZ (45 mg/kg, IV) after high-fat diet (22% calories as fat) for 4 weeks (Zhang et al., 2003)
 - Injected with STZ (15 mg/kg, IV) after high-fat diet (30% calories as fat) for two months (Zhang et al., 2003)
 - Injected with STZ (25 mg/kg, IV) after high-fat (25.7 wt%) plus high fructose (46.5 wt%) for 6 weeks (Menard et al., 2010)
-

by increases in thermogenic capacity and brown adipose tissue mass, protein, and DNA content. They are hyperinsulinemic, hyperleptinemic, hypercholesterolemic, and hypertriglyceridemic (van Heek et al., 2001). The lipid and lipoprotein aspects of this model have been found to closely parallel lipid metabolism in humans (Spady et al., 1993; Dietschy, 1997; Kris-Etherton and Dietschy, 1997).

20.3.3 SURGICALLY INDUCED DM MODELS

The entire pancreas or a portion of the pancreas can be removed to induce diabetes. The advantage of a total pancreatectomy is that it avoids the cytotoxic effects of chemical diabetogens on other body organs. The disadvantage of this technique is that it causes severe digestive problems, because the exocrine portion of the pancreas is also removed. To avoid malabsorption, the animals must receive pancreatic enzymes (Pancrease MT; Viokase®) with their diet. In addition, this technique removes α cells (glucagon-secreting cells) as well as β cells, leading to problems in the counter-regulatory response to hypoglycemia. Partial pancreatectomy (remove 70% or 90%) has been performed in dogs, pigs, rabbit, rats, and mice (Islam and Loots du, 2009; Srinivasan and Ramarao, 2007; Leahy et al., 1993). It is characterized by moderate hyperglycemia with neither a reduction in body weight nor in basal levels of plasma insulin.

A combined partial pancreatectomy with chemical treatment (e.g., ALX and STZ) is another model. The advantage of this technique is that it minimizes the adverse effect of chemicals on the body. In addition, it leads to a more stable form of chronic DM in the dog, pig, monkey, and other species. Another stable form of type 2 DM has been produced by combination of 50% partial pancreatectomy, NAD (350 mg/kg), and STZ (200 mg/kg) treatment in BALB/c mice (Kurup and Bhonde, 2000).

20.3.4 OTHER DISORDERS AFFECTING CARBOHYDRATE METABOLISM

Glycogen storage diseases (GSD) include a clinically heterogeneous group of disorders that are associated with inherited abnormalities of the carbohydrate metabolism. These abnormalities are caused by enzyme deficiencies, which give rise to the intracellular accumulation of structurally normal or abnormal glycogen or the decrease in normal glycogen in one or multiple tissues. As shown in Table 20.5, the GSD have been classified into 10 groups based on deficient genes. GSD have been verified in animals and mouse models of some types of GSD have been generated.

In most organisms, the utilization of galactose requires the Leloir pathway (Lai et al., 2009). The pathway converts galactose to UDP-glucose by a series of enzymatic reactions. In humans, deficiencies or mutations in one or more of these enzymes in the Leloir pathway will result in significant toxicity (e.g., cataracts, liver complications, hypotonia, and sepsis). In humans, newborn screening programs test for defects in this pathway. Defects in this pathway in other species have not been reported. In the rodent, targeted defects in this pathway have been generated (Leslie et al., 1996); however, the toxicity is not as severe as in humans, suggesting that alternative pathways may be active in rodents.

Fructose is a very popular addition to the Western diet (Mayes, 1993) and likely contributes to the prevalence of obesity, insulin resistance, and dyslipidemia. High-fructose diets are used to induce insulin resistance in a number of animal models (Coate et al., 2010; Wei et al., 2007; Zhang et al., 2009). In many cases, the insulin resistance is in the absence of accompanying obesity. In humans, hereditary fructose intolerance can occur; it is caused by the deficiency of either aldolase B or fructokinase (Mayatepek et al., 2010). While the absence of fructokinase has relatively silent phenotype, the absence of aldolase B causes hypoglycemia because of the enzymes central role on the metabolism and synthesis of glucose. Animal models of these defects have not been reported.

TABLE 20.5
Glycogen Storage Disease

Type	Subtype	Gene	Protein	Human Metabolic Symptoms	Animal Models	Reference
GSD-0		<i>GYS2</i>	Hepatic isoform of glycogen synthase (glycogen synthase2)	Reduced glycogen storage in the liver, ketotic hypoglycemia, low lactatemia after prolong fasting. Hyperglycemia, hyperlactatemia and hyperlipidemia in the postprandial period		Orho et al. (1998), Wolfsdorf and Weinstein (2003), Weinstein et al. (2006), and Bachrach et al. (2002)
GSD-I	GSD-Ia	<i>G6PC</i>	Glucose-6-phosphatase- α	Hypoglycemia, hepatomegaly, nephromegaly, hyperlipidemia, hyperuricemia, lactic acidemia, growth retardation	Mouse (autosomal recessive) <i>G6pc</i> ^{-/-} mice (Kim et al., 2008; Lei et al., 1996) A naturally occurring dog model	Walvoort (1983), Wolfsdorf and Weinstein (2003), and Walvoort (1983)

20.4 MEASURING METABOLIC AND ENDOCRINE STATUS

20.4.1 ANIMAL HUSBANDRY AND EXPERIMENTAL DESIGN

Evaluation of the metabolic and endocrine status of an animal requires the collection of blood samples that are reflective of the physiology of the animal in its normal environment. The most important presampling procedure is to develop a standard protocol specific for the particular species of interest. The investigator should pay careful attention to a number of parameters when designing the protocol. These include the presampling status of the animal (i.e., fasting status, the environment, acclimation of the animal to the environment), the sampling procedure, the skill of the investigator/phlebotomist, blood sample handling, and reliability of the assays employed. To obtain reproducible baseline data, the animal should be fasted. For large species (e.g., nonhuman primates, dog), an overnight fast is appropriate (i.e., fasting glucose concentration), as these animals tend to eat during the day and are fed at predictable times. For example, canines are generally fed once a day and are slow absorbers, taking ~14–16 hours to absorb a chow meat meal (Davis et al., 1984). They should be trained to eat all of their meal in a defined period of time, so as to better control the duration of the fast prior to sample collection. Thus, feeding canines the afternoon prior to a study and assessing glucose metabolism after 18 hours is appropriate. Assessing glucose kinetics in the canine after fasting of much shorter duration (<16 hours) may not reflect basal metabolism as they will likely be still absorbing nutrients. For rodents (especially mice), an overnight fast is a major metabolic stress (Ayala et al., 2006). Mice have a very high metabolic rate, are typically housed in facilities well below their thermoneutral zone and are primarily nocturnal feeders. After an overnight fast, mice can lose a significant amount of lean body mass and, if individually housed during the fast, can go into a torpor state (McGuinness et al., 2009; Swoap et al., 2006; Geiser, 2004). A shorter 5–6-hour fast is often more appropriate for mice. For the rat, the current practice is to fast the animals overnight. While rats are not at risk of developing torpor, they, like mice, are nocturnal feeders. Thus, an overnight fast in rodents is metabolically similar to a 24–48 hours fast in primates or canines; the liver will be essentially glycogen depleted. In contrast, a 5–6 hours fasted mouse has a similar glycogen content as an overnight-fasted human and an 18 hours fasted dog (~30–40 mg/g liver). Once these variables are controlled, the plasma glucose sample is most likely to reflect the basal metabolic status of the animal. As will be discussed later, if the animal is metabolically stable, whole body insulin sensitivity (S_I) can be estimated from concurrent insulin and glucose concentrations.

Some investigators wish to assess endocrine status by collecting random and/or individual measures of glucose and/or insulin. The difficulty with this approach is that endocrine and metabolic parameters exhibit a high degree of diurnal variability. To assess endocrine status in the nonfasted state, the investigator should control for the time of day and the feeding patterns of the animal model, so as to minimize day-to-day variations in metabolic and endocrine status (Hut et al., 2011; Clifton, 2000). For rodents fed ad libitum, changes in diet composition can alter feeding patterns (e.g., rodents on a high-fat diet [40%–50% fat] tend to eat throughout the day and night, while rodents on a standard diet [e.g., 5%–7% fat] eat predominantly during the night). Unless accounted for when randomly assessing metabolic and endocrine parameters, data interpretation can be complicated. Alternatively, a 24-hour glucose profile can ameliorate the impact of diurnal variability on data interpretation.

The animal needs to be acclimated to the laboratory environment and sampling procedure (Ellacott et al., 2010). Frequently handled and trained animals will have fewer variations caused by the excitement and apprehension induced by unaccustomed handling and sampling. The phlebotomist must be experienced and able to obtain a sample with minimal disturbance. Individual housing, novel environments, restraint, and bright lights are all stressors for rodents that require acclimation to obtain reliable data.

Ideally, all samples should be taken from an artery as it reflects the blood that perfuses the major organs. Moreover, depending on the substrate (e.g., glucose, lactate, amino acids)

venous plasma concentration may not be reflective of what is in arterial plasma (Sonnenberg and Keller, 1982; Jensen and Heiling, 1991). However, arterial access is difficult without surgical intervention, and common practice in a laboratory setting is to use venous blood. In general, the location from which blood is obtained (vein or artery) will not alter most metabolic or endocrine parameters, if animals are metabolically stable and the sample can be taken with minimal stress. Ideally, if blood is taken from a vein, the vein should drain tissues that are not very metabolically active (i.e., saphenous or cephalic, submandibular or tail vein in rodents) and are well perfused (Aasland et al., 2010; Christensen et al., 2009). As red blood cells are metabolically active, it is best that blood samples are immediately centrifuged and the plasma or serum should be quickly separated from the cells (see Section 20.4.2.1 for additional information on sampling handling for specific analytes).

20.4.2 LABORATORY ANALYTES/TESTS OF CARBOHYDRATE METABOLISM

20.4.2.1 Glucose

While plasma glucose concentration is a tightly controlled parameter, it still changes throughout the day and is rapidly increased by stressful conditions. Once a sample is obtained, it is also important that glucose utilization by red blood cells be minimized. Therefore, the plasma or serum must be separated from the red cells as soon as possible, and if immediate separation is not feasible, the glucose in the blood sample must be protected from glycolysis by the red blood cells. This is best done by placing the blood sample in an ice bath followed by refrigeration and the addition of sodium fluoride (10 mg/mL of blood). Standard sodium fluoride-containing evacuated tubes are ideal for this purpose. Samples can be collected in serum separator tubes. In one study, human glucose concentration was stable for up to 24 hours after centrifugation (Landt et al., 1986). While it was unchanged, the authors recommend separating the plasma from the cells as soon as possible. Do not rely on fluoride or cold to completely inhibit glycolysis.

Of the many methods for glucose determination in plasma or serum, the enzymatic methods used in clinical analyzers are the most accurate (Johnson et al., 2009). However, despite the level of accuracy of enzymatic methods, many investigators rely upon handheld blood glucose meters to assess plasma glucose concentrations. Their ease of use, portability, and the very low blood volume requirements allows serial sampling for rodents, which have a very limited blood volume. While handheld glucometers are convenient to use, these instruments have significant drawbacks (D'Orazio et al., 2006). The majority of handheld glucose meters are standardized for human blood. The handheld glucose meters measure blood, not plasma, glucose concentration. This is important as the difference between blood and plasma glucose is substantial in some species because of the differences in erythrocyte glucose permeability (Rendell et al., 1985; Higgins et al., 1982). The order of erythrocyte glucose permeability across species occurs in the following descending order: primate>rodent>canine>pig. In primates, blood and plasma glucose are very similar, because their erythrocytes are relatively permeable to glucose. In canines, the red blood cell is relatively impermeable to glucose, such that blood glucose is ~70% of plasma glucose. This is important as the physiologically regulated variable is plasma glucose. In addition, blood glucose meters from different manufacturers can give different readings for the same blood sample (Cohn et al., 2000; Johnson et al., 2009). An additional confounding issue is that these meters as stated on the package insert are sensitive to the hematocrit and some pharmaceuticals (Mann et al., 2009; Boren and Clarke, 2010; Heinemann, 2010). For the dog, nonhuman primates and rat, blood volume is not a limitation, and plasma glucose concentration should be measured with a chemistry analyzer. For mice, if multiple samples need to be taken, such as during a glucose tolerance test (GTT), a blood glucose meter may be more practical. However, if blood glucose is monitored, the same meter should be used for a given experiment, and hematocrit should be checked to verify that it is not a variable in the study. In addition, the meter should be calibrated against a chemistry analyzer over the range of glucose concentration obtained in the study.

A plasma glucose concentration of 90 ± 12 mg/dL (SD) or 5 ± 1 mmol/L (SD) is a general reference value for the dog, cat, or nonhuman primate and is comparable to that of the adult human (Kaneko, 1997). For mice, glucose concentrations tend to be higher than in larger species and are strain and gender dependent. A database of typical glucose values in commonly used mice strains is available in the Jax phenome database (<http://phenome.jax.org>) (note the data use human and not rodent standardized meters). Mice with mixed backgrounds may have a higher variability in glucose concentration depending upon the relative contribution of the two strains in any given animal. Given the number of parameters that can influence glucose concentration it is best when making comparisons between groups that control and experimental groups be assayed together. Animals should be matched for genetic background, gender, and age. It is best to use littermates as controls; if it is possible.

20.4.2.2 Glycated Hemoglobins

Glycated hemoglobin or HbA1c is now widely used as an index of long-term average plasma glucose. The hemoglobins in the erythrocyte, when first formed, are not linked to glucose. If the red cell is permeable to glucose (note: permeability varies between species), a fraction of the hemoglobin, the HbA1, is glycosylated by a slow, nonenzymatic, and relatively irreversible mechanism. Multiple HbA1 fractions (HbA1a, HbA1b, and HbA1c) are slowly and irreversibly glycosylated. Of the fractions, HbA1c is the one that binds glucose in direct proportion to the plasma glucose concentration. Because the binding is irreversible, glucose remains bound to Hb over the life span of the red cell. Thus, HbA1c can be used as an index of the average plasma glucose concentration over a previous time period approximating half the life span of the red blood cell (Kaneko, 1997). The average red blood cell life span can range from 100 days in the dog and macaque, 70 days in the cat, and 40 days in the mouse (Bennett, 2002; Wang et al., 2010b). Therefore, HbA1c is used as an index of the average plasma glucose over the previous 30–60 days in most laboratory animals. The species-dependent differences in the permeability of the erythrocyte to glucose will markedly alter the rate of glycosylation (Higgins et al., 1982). For species whose erythrocytes are relatively impermeable to glucose, the basal rate of glycosylation is very low.

In veterinary clinical practice, HbA1c is used to monitor a patient's average plasma glucose control by sampling as infrequently as once every month or two, rather than having to measure blood glucose daily, which was common practice for animals with DM prior to the use of HbA1c. HbA1c is, however, insensitive to brief bouts of hypoglycemia and should not replace periodic plasma glucose monitoring.

In humans, an immunochemistry-based approach that detects HbA1c using a monoclonal antibody against human HbA1c has been widely used (e.g., DCA 2000 analyzer). The reference range for HbA1c in humans is ~3%–6% of the total Hb, and it is very closely correlated with reference plasma glucose concentration (Elliott et al., 1997; Wood and Smith, 1980). Significantly higher levels of HbA1c are associated with persistent hyperglycemia during the preceding months. This indirect method of monitoring plasma glucose is a valuable means to monitor glucose control (Nathan et al., 2008), and has been used in humans, nonhuman primates, rats, mice (Han et al., 2008), cats, and dogs (Marca and Loste, 2000; Bennett, 2002; Kaneko, 1997). However, the period that a given HbA1c reflects is dependent on the half-life of the red blood cell, which varies between species. Measurement of HbA1c is now the glycated protein of choice in humans and is used in animal models of DM to test the efficacy of new therapeutics. Controlling plasma glucose within narrow limits is highly beneficial to the well-being and survival of the patient, and measuring HbA1c is a valuable adjunct to maintaining this tight control therapeutically (Cohen and Smith, 2008). The applicability of this to mice has been examined (Han et al., 2008). HbA1c most closely correlates with 5–6 hours fasting glucose concentration in this species; however, the absolute value for HbA1c for any glucose level is mouse strain dependent. The mechanism for this difference is unclear.

20.4.2.3 Fructosamine

Fructosamine is a glycated serum protein that reflects glycemic control over the previous 1–3 weeks (Koga and Kasayama, 2010) in primates, dogs, and cats reflecting the higher rate of albumin

turnover relative to red blood cells (Armbruster, 1987; Reusch et al., 1993). Glucose molecules are joined to protein molecules to form stable fructosamines, through glycation by a nonenzymatic mechanism (Armbruster, 1987). The assay assesses the formation of ketoamines in plasma proteins (Young et al., 1975; Schnedl et al., 2005). If a plasma sample is contaminated with hemoglobin or very lipemic, the data will not be accurate. Since albumin is the major plasma protein, alterations in albumin concentration or turnover will alter data interpretation.

20.4.2.4 Insulin

Insulin is secreted by the β cells of the endocrine pancreas and is released in a 1:1 molar ratio with C-peptide into the portal vein. Approximately 50% of the insulin is cleared on the first pass by the liver. Insulin half-life in primates is 3–5 minutes (Duckworth et al., 1998). Insulin is stable in plasma collected with EDTA or in serum if it is stored frozen (-70°C) until analyzed (Öberg et al., 2011). Because insulin's structure varies between species, investigators must use species-specific assays for analysis (Smith, 1966). Although the structure of insulin does differ across species, these structural differences do not affect insulin's biological activity. Occasionally, C-peptide is assayed, and, as with insulin, species-specific antibodies must be used. Basal insulin concentrations vary between species but are typically between 5 and 40 $\mu\text{U}/\text{mL}$ in nonobese animals on a normal low-fat diet. Canines tend to have lower insulin concentrations than nonhuman primates and rodents. As insulin concentration is very sensitive to plasma (or serum) glucose concentration, both parameters should be measured and interpreted at the same time, and same procedures to control for fasting status and animal handling also apply.

20.4.2.5 C-peptide

C-peptide is secreted from the pancreatic β cell in equimolar concentration with insulin, but is not extracted by the liver. In contrast to insulin, C-peptide is primarily metabolized by the kidney and has a longer half-life (Castillo et al., 1994; Valera Mora et al., 2003). Thus, the absence of C-peptide is a more sensitive marker of residual insulin secretion in animal models of type 1 diabetes (Polonsky and Rubenstein, 1984). Moreover, peripheral C-peptide concentrations can be used as a marker of β cell secretory activity in a variety of clinical situations (Bonser et al., 1984; Polonsky and Rubenstein, 1984). The mouse and rat have two insulin genes (Shiao et al., 2008). The C-peptide released by the genes is not identical. C-peptide can be measured in the urine to obtain an index of daily C-peptide excretion, if renal function is normal and daily urine is accurately and quantitatively collected. This can be done by housing the animal in a metabolic cage that collects all of the urine, a second option is to measure urine creatinine and calculate the ratio of C-peptide to creatinine. As with insulin, the plasma should be stored (-70°C) frozen prior to being analyzed.

20.4.2.6 Glucagon

Glucagon is secreted primarily by the α cells of the endocrine pancreas. However, cells within the gastrointestinal tract can secrete glucagon in animals that are insulin deficient. This is most apparent in dogs (Vranic et al., 1974; Vranic et al., 1976). Normal plasma glucagon concentrations are ~ 50 – 100 pg/mL in mammalian species. The liver is exquisitely sensitive to both increases and decreases in glucagon. Like insulin, glucagon is secreted into the portal vein, resulting in an elevated glucagon concentration in the hepatic portal circulation. As such, changes in arterial or systemic plasma glucagon concentration will underestimate the accompanying changes in the portal vein (Wasserman and Cherrington, 1991; Cherrington, 1999). Stress can rapidly increase glucagon secretion into the blood; appropriate animal handling techniques are required to obtain accurate basal glucagon concentrations. In DM, plasma glucagon concentration can be normal or elevated in the basal state but are inappropriately elevated following a meal and inappropriately low during hypoglycemia (Cryer, 2012). Thus, inappropriate glucagon secretion contributes to the glucose dys-homeostasis in DM. The fact that basal plasma glucagon concentration is very low and glucagon is readily degraded requires that special care be taken following plasma collection. After separation of plasma from blood (preferably

collected in EDTA-containing tubes), the plasma should be treated with aprotinin (500 Kallikrein Inhibitory Units/mL) to prevent proteolytic degradation and kept frozen (-70°C) until it is analyzed.

20.4.2.7 Catecholamines

The primary catecholamines in plasma are epinephrine and norepinephrine. Epinephrine is released by the adrenal medulla. Norepinephrine is released from both the adrenal medulla (although much less than the quantity of epinephrine released) and from spillover from noradrenergic nerve terminals. Epinephrine is a potent stimulator of hepatic glucose production and a potent stimulator of muscle glycogen breakdown with subsequent release of lactate. In individuals with longstanding diabetes, the adrenergic response to hypoglycemia is blunted (Cryer et al., 1989). In unstressed animals, plasma epinephrine concentration is less than 100 pg/mL, but it can increase to over 2000 pg/mL in stressful settings. Plasma norepinephrine concentration is higher than epinephrine (~ 300 pg/mL) and can increase to over 2000 pg/mL during stress (Wasserman and Cherrington, 1991; Stevenson et al., 1991; Cherrington, 1999). Baseline catecholamines are very sensitive to stress from handling. As such, it is very difficult to obtain reliable values when catecholamine concentrations are low, especially in mice. When handling stress is minimized, rodents, dogs, and nonhuman primates have very similar basal catecholamine concentrations (Ayala et al., 2006; Grouzmann et al., 2003). In general, measuring basal catecholamines are not very informative in ascribing changes in glucose metabolism to changes in adrenergic tone. Generally, they are measured in studies where a controlled stress (e.g., hypoglycemia) is induced to determine if the adrenergic response is altered (Jacobson et al., 2006; Davis et al., 1994, 1992). Because catecholamines are light sensitive, blood must be immediately treated with an antioxidant such as glutathione (1.0 mg/mL blood) with ethylene glycol tetraacetic acid (EGTA—1.8 mg/mL blood). The plasma should be separated from the blood cells and stored at -70°C until analyzed either via HPLC or enzymatic analysis (Macdonald and Lake, 1985).

20.4.2.8 Insulin-Like Growth Factor

Insulin-like growth factor (IGF) has two isoforms (IGF I and IGF II) (Annunziata et al., 2011). In plasma, the IGFs are associated with binding proteins (IGFBP I-VI), which dramatically increase their half-life (Clemmons, 1997). The affinity of IGF for their binding protein exceeds that of their affinity for their receptor. Thus, both IGF and the major binding partners should be measured (Quarmby et al., 1998). IGF-I (70 amino acids) is identical in human and porcine with three residues different in rodents (Humbel, 1990). IGFII (67 amino acids) is less homologous between species. Because of the binding proteins, standardization of IGF assays and assessing “Free” IGF has been challenging (Frystyk, 2007).

20.4.2.9 Glucagon-Like Peptide

Glucagon-like peptides are synthesized and secreted in response to nutrient ingestion (Drucker, 2007). GLP-1 is secreted from intestinal endocrine L-cells, which are located mainly in the distal ileum and colon (Baggio and Drucker, 2007). GLP-1 exists in multiple forms in vivo. GLP-1(1–37) and GLP-1(1–36) NH_2 are thought to be inactive. GLP-1(7–37) and GLP-1(7–36) NH_2 are biologically active. The active GLP-1 is rapidly cleared from circulation ($T_{1/2} < 2$ minutes). It is rapidly inactivated by dipeptidyl peptidase-4 (DPP-4). Since DPP-4 is present in blood, when collecting blood, a DPP-4 or protease (aprotinin) inhibitor has to be directly added to the blood prior to centrifugation (Di Marino et al., 2011). Plasma should be frozen immediately and thawed on ice when the assay is performed.

20.4.3 FUNCTIONAL EVALUATION OF INSULIN ACTION AND SECRETION

Insulin resistance is a characteristic of obesity, metabolic syndrome, and cardiovascular disease. When combined with defects in pancreatic insulin secretion, animals will progress from normal glucose tolerance to glucose intolerance and overt diabetes. Glucose tolerance is not a measure of insulin resistance. Obese individuals can have a normal GTT, but are typically insulin resistant.

Normal glucose tolerance is maintained because they hypersecrete insulin. If they are unable to do this, they become glucose intolerant. To quantify S_I /resistance and whole body glucose handling in animal models is of great importance. In humans, a number of approaches have been developed to assess insulin action from the most difficult (hyperinsulinemic-euglycemic clamp) to the simplest (calculation of basal insulin action) (Muniyappa et al., 2008). The hyperinsulinemic-euglycemic clamp is considered the “gold” standard to assess insulin action. However, it is not very practical for screening large populations for insulin resistance. Other tests were developed that were easier to perform and compared to the gold standard in humans. These approaches have been adapted to evaluate insulin action in other species with little or no critical analysis. No attempt was made to systematically compare the modified protocols to the “gold standard” (see Table 20.6).

20.4.3.1 Basal Insulin Action

In the fasting state, insulin serves to inhibit hepatic glucose production, limit mobilization of fat from adipose tissue and maintain basal glucose uptake in insulin-responsive tissues. In so doing, the liver can meet the glucose demands of tissues such as the brain. In insulin-resistant states, glucose requirements do not change, but pancreatic insulin secretion must increase to maintain the same rate of hepatic glucose production as basal glucose requirements by the brain and other tissues including muscle are not markedly altered. If it does not increase, the glucose concentration will rise. Thus, in insulin-resistant states, fasting hyperinsulinemia is commonly seen.

A commonly used approach to quantify insulin action is to measure fasting insulin and glucose concentration, and calculate an index of insulin action from those data (Table 20.6). In the human, a homeostasis model assessment (HOMA) is calculated from fasting plasma insulin (FPI) and fasting plasma glucose (FPG) data obtained from an overnight fasted individual. It can be used to predict β -cell function ($\text{HOMA—\%B} = [20 \times \text{FPI}]/[\text{FPG} - 3.5]$) and insulin action ($\text{HOMA-IR} = [\text{FPI} \times \text{FPG}]/22.5$) (Wallace et al., 2004). A more improved HOMA (HOMA2) can be calculated using a computer model. This has been used in nonhuman primates with good success (Zhang et al., 2011). Other calculations can be made, such as quantitative S_I check index (QUICKI). This has been less commonly used in canines. The extent of the fasting hyperinsulinemia after a high-caloric diet is less consistent despite the presence of overt insulin resistance when a more sensitive and provocative test (intravenous or oral GTT or hyperinsulinemic-euglycemic clamp; see Section 20.4.3.4 for more details in these tests) can detect insulin resistance (Coate et al., 2010; Stefanovski et al., 2011). Recently, investigators have begun calculating HOMA-IR for mouse and rat studies (Muniyappa et al., 2009). However, this calculation assumes that the model parameters for mice are the same as for humans. One study found that the correlation between HOMA-IR and clamp estimates of insulin action was rather poor in mice and rats (Lee et al., 2008). The correlation could be improved,

TABLE 20.6
Measures of Insulin Sensitivity in Animal^a Models

Direct Measure of Insulin Action

Hyperinsulinemic-euglycemic clamp	$M = \text{steady state glucose infusion rate}$ $SI_{\text{clamp}} = M/(G \times DI)$ where, G is the glucose concentration and DI is the difference in the insulin concentration between the clamp and basal insulin
Frequently sampled IVGTT	S_I calculated from MINMOD model

Basal Insulin Action

G/I ratio	ratio of fasting plasma glucose (mg/dL) and insulin ($\mu\text{U}/\text{mL}$)
HOMA	$\text{HOMA-IR} = \text{fasting plasma insulin } (\mu\text{U}/\text{mL}) \times \text{fasting plasma glucose (mM)}/22.5$
QUICKI	$1/[\text{Log (fasting plasma insulin, } \mu\text{U}/\text{mL}) + \text{Log (fasting plasma glucose, mg/dL)}]$

^a The use of these calculations for mammals other than humans has not been critically evaluated.

if the data were normalized to body weight and log transformed. This approach is similar to the approach used in humans (Wallace et al., 2004). As mentioned in Section 20.4.1, in larger species, overnight fasting is appropriate. However, insulin and glucose concentration are markedly decreased in overnight-fasted mice resulting in an apparent marked improvement (decrease in HOMA-IR) in insulin action (Andrikopoulos et al., 2008). This improvement may or may not correlate with clamp assessment of insulin action (Lee et al., 2008; Ayala et al., 2006). A 6-hour fast allows for good discrimination of insulin action between chow and high-fat-fed mice, especially when HOMA-IR is calculated. Others have calculated the ratio of glucose to insulin (Dokmanovic-Chouinard et al., 2008) as a marker of insulin action. These surrogate indices of insulin action (many of which have not been validated for rodents) reflect basal insulin action. Since in large species (human, nonhuman primate, dog) the major fraction of the glucose is taken up by insulin-independent tissues (i.e., brain), basal estimates of insulin action are likely weighted to reflect hepatic as opposed to peripheral insulin action. In smaller species, such as the mouse, the brain is a relatively minor contributor to basal glucose utilization. A change in HOMA-IR in mice likely reflects the combined effects of insulin action in hepatic and peripheral tissues.

20.4.3.2 Glucose Tolerance Test

The term *glucose tolerance* describes the shape of the plasma glucose curve in the oral (OGTT) or intraperitoneal (IPGTT) glucose tolerance test or the shape and rate of disappearance of glucose in the intravenous glucose tolerance test (IVGTT). In comparison to a normal tolerance curve, the curve expressing glucose intolerance describes one with a very high peak and a slow return to fasting concentrations. The test was originally developed to identify individuals who have diabetes or have increased risk of developing diabetes (impaired glucose tolerance). Many investigators tried to quantify glucose tolerance so as to compare groups. However, it is important that investigators realize glucose tolerance and S_I are not synonymous. Glucose tolerance is influenced by the combined effects of three parameters:

- β -cell function
- Insulin action
- Glucose-mediated glucose disposal

As such, glucose tolerance is not a measure of insulin action. In the case of oral glucose delivery, the glucose excursion tends to be more variable, as it is also influenced by the rate of gastric emptying, glucose absorption, and any effects of incretins.

The GTT is commonly used to evaluate whether the animal can efficiently dispose of a defined glucose load. Many variations exist in GTTs conducted for diagnostic purposes in clinical medicine. They are generally not used to quantify glucose tolerance, but rather to detect glucose intolerance and diabetes. For the purpose of evaluating the laboratory animal, the need exists for establishing and defining a more narrowly reproducible result than is normally required so investigators can quantify glucose tolerance to assess whether their experimental manipulation improves or exacerbates glucose tolerance. Generally, one of two forms of the GTT is used: the oral (OGTT) or intravenous (IVGTT) test (in rodents; IPGTT).

Glucose tolerance can be assessed by administering glucose (IV, IP, or oral) and taking a limited number of blood samples in appropriately fasted animals. The IVGTT is widely used in the larger of the laboratory animals, particularly the dog, cat, and nonhuman primate, and it is also useful in the rabbit (Vicini and Cobelli, 2001; O'Brien et al., 1985; Leow, 1997; Beard et al., 1986; Finegood et al., 1984). For the IVGTT, a standard load of glucose is infused intravenously after a conditioning regimen similar to that for the OGTT. The standard glucose load of 0.5 g/kg body weight is sufficient to provoke a maximal insulin response and to permit reliable evaluations of glucose clearance in dogs, nonhuman primates and humans (Rottiers et al., 1981). Glucose loads greater than 0.5 g/kg are rapidly excreted in the urine and do not directly reflect the glucometabolic status of the

dog (Kaneko, 1997). In the standard IVGTT, a preinfusion blood sample is taken, and the glucose load of 0.5 g/kg bw is infused as a sterile 50% solution in 30 seconds. Timing for the test is begun at the midpoint of the infusion period. Subsequent blood samples are taken at 5, 15, 25, 35, 45, and 60 minutes for glucose and insulin. The glucose concentrations are plotted on semilogarithmic coordinates versus time. The half-life ($T_{1/2}$) is calculated or can be graphically estimated from a linear segment of the disappearance curve (Rottiers et al., 1981). The time interval must be established for each species because the rate of glucose disappearance is truly a curve and is only quasilinear at certain time intervals. The half time is calculated or read from the linear portion of the curve, and the fractional turnover rate or K value can be calculated from the relationship:

$$\text{Fractional turnover rate (K)} = 0.693 / T_{1/2} \times 100 = \%/\text{m}$$

The fractional turnover rate has been described as the glucose turnover rate, glucose disappearance rate, glucose clearance rate, glucose disappearance coefficient, or simply the K value. In fact glucose clearance rate, turnover rate, and glucose disappearance rate are not the same as K or fractional turnover rate. Glucose clearance rate (mL/min or mL · kg⁻¹ min⁻¹) is equal to the product of K and the volume of distribution of glucose divided by 100. Glucose turnover rate and disappearance rate (= glucose clearance rate × plasma glucose concentration; mg/min or mg·kg⁻¹ min⁻¹) represent absolute fluxes of glucose and should not be used as a steady state is not present. In fact, their rate changes as the glucose concentration changes during the GTT. Using this standardized method, the reference range for $T_{1/2}$ in the dog is 15–45 minutes (25 ± 8 minutes) and a K value greater than 1.5%/min. The diabetic curve with its slower rate of glucose disappearance results in a half-time longer than 45 minutes, which calculates into a K value of less than 1.5%/min (Kaneko, 1997). In rats glucose (0.5–1 g/kg) can be injected via the tail vein and samples can be taken (5, 10, 15, 30, 60, 90, and 120 minutes) from the tail vein artery (Holemans et al., 2004; Lim et al., 2011). In mice, the dose of glucose is higher (1–2 g/kg; IP or per os [po]) and for practical reasons, it is only given by intraperitoneal injection or oral gavage. The glucose concentrations are monitored every 30 minutes between 0 and 120 minutes (Ayala et al., 2010). The glucose excursions are much higher in mice, but the renal glucose threshold is also higher (~400 mg/dL) (Noonan and Banks, 2000). As it is difficult to accurately calculate K from the limited time points using the rodent protocol, the area under the curve after subtracting the baseline glucose concentration can be used as an index of glucose tolerance. However, the kinetics of glucose disposal are rather fast after intravenous glucose delivery, and detecting impairments in glucose tolerance in insulin-resistant rat models is less reliable without accompanying insulin data (Varcoe et al., 2011). This helps to reinforce the fact that the GTT is not a measure of insulin action as compensatory increases in β -cell function can minimize any overt glucose intolerance. Generally, the glucose excursion is attenuated when glucose is given orally due to the combined effect of delayed gastric emptying, greater first pass hepatic glucose extraction and the effects of incretins (Andrikopoulos et al., 2008). In mice, higher doses of glucose may be better at allowing detection of impaired GTT in a high-fat–fed model (Morino et al., 2008). Interestingly, in cats, glucose tolerance is prolonged compared with other species. This is likely due in part to the fact the cat is an exclusive carnivore. Moreover, the feline liver has very little glucokinase or its binding partner glucokinase regulatory protein, which are essential for the liver to dispose of significant amounts of glucose (Ballard, 1965; Kienzle, 1994; Hiskett et al., 2009).

A number of factors should be considered when using the GTT. Glucose tolerance will be affected by the route of glucose delivery. Ideally, samples should be taken to define the rate of rise and fall in glucose until it returns to baseline values. Depending on the species and its metabolic state, the dose of glucose will have to be adjusted. It is important that the glucose concentration during the GTT not exceed the renal threshold, which is ~180 mg/dL in large species (canine and primate), ~270 mg/dL in rats and ~400 mg/dL in mice (López-Novoa et al., 1996; Noonan and Banks, 2000). Two groups could have differing baseline glucose values; baseline glucose values should be subtracted before calculating area under the curve. While area under the curve is informative in a manuscript, it

is best to report the actual glucose values as well. The actual glucose values can give additional information as to the rate of rise and fall of glucose. This could give hints as to possible defects in pancreatic function or in the case of oral glucose delivery, changes in rate of glucose absorption.

The majority of exogenous glucose is disposed of by lean body tissues. If the dose of glucose is given on a per body weight basis, obese animals will be biased to have impaired glucose tolerance. If one is comparing animals with differing body composition, a fixed dose of glucose as is used in humans (e.g., 75 g) in mice could be used. In mice, a dose of 40 mg may suffice. Or ideally if lean body mass could be assessed, the dose could be normalized per lean body weight. In humans and primates, the dose can be normalized to body surface area.

To obtain more information from a GTT, the frequently sampled intravenous GTT (FSIGTT) can be used to assess β -cell function and insulin action. It requires rapid sampling of blood for both glucose and insulin following an intravenous glucose challenge. The data are then analyzed using the minimal model of Bergman and Cobelli, which was originally developed for the dog. It has since been adapted for humans and nonhuman primates (Bergman et al., 1985; Casu et al., 2008). After an overnight fast, an intravenous bolus of glucose (0.3–0.5 g/kg body wt) is infused over 2 minutes starting at time zero. Blood samples are taken for plasma glucose and insulin measurements at –10, –1, 1, 2, 3, 4, 5, 6, 7, 8, 10, 12, 14, 16, 20, 22, 23, 24, 25, 27, 30, 40, 50, 60, 70, 80, 90, 100, 120, 160, and 180 minutes. The approach requires a lot of blood samples and vascular access for injection and sampling. In addition, these data have to be analyzed using the computer program MINMOD to generate an index of S_I . The model, while robust, does oversimplify glucose homeostasis and lumps together hepatic and peripheral insulin action. Moreover, the accuracy of estimating S_I decreases in models where β -cell function or insulin action is low. The protocol was modified in humans with impaired β -cell function; exogenous insulin (4 mU·kg⁻¹ min⁻¹) is infused over 5 minutes beginning 20 minutes after the intravenous glucose bolus (Quon et al., 1994; Ionut et al., 2009). In some studies, a bolus of insulin or a sulfonylurea is given to augment insulin availability, so a better estimate of S_I can be obtained. The FSIGTT was adapted for mice, pigs, and rats (Di Nardo et al., 2009; Christoffersen et al., 2009). However, the amount of blood required is substantial and will deplete total blood volume, if applied to mice (Ahren and Pacini, 2006).

20.4.3.3 Insulin Tolerance Test

In human studies, a quick test was developed to assess insulin action. This was termed the short insulin tolerance test (ITT). The basis of the test is to give overnight fasted humans an intravenous bolus of insulin (0.1–0.5 U/kg) and assess the rate of fall of plasma glucose. Glucose concentration is assessed every 2 minutes over a 15-minute period (Wallace and Matthews, 2002). Insulin action is calculated as the rate of fall of the log transformed glucose concentration. An important aspect of the design is to focus on the early rate of fall in glucose so as not to have the complicating effects of glucose counter-regulation and hypoglycemia. The ITT that is used in humans is relatively reliable and can be, but is rarely, used in nonrodent (e.g., canine) species.

The ITT has been adapted to the mouse, but the protocol has been substantially modified with no consistent approach (Cederroth et al., 2008; Dallaire et al., 2008; Duncan et al., 2008; Feral et al., 2008; Gomez-Valades et al., 2008; Jiang et al., 2008; Kebede et al., 2008; Li et al., 2008; Nieto-Vazquez et al., 2008; Oriente et al., 2008). Generally, mice are either not fasted or are fasted for a very brief period (0–3 hours). The dose of insulin is given intraperitoneally (0.5–2 U/kg), and the glucose is monitored over a longer duration (glucose assessed at 0, 20, 40, 60, and 120 minutes). Unfortunately, the modified design has major problems (McGuinness et al., 2009). Investigators did not consider that by 60 minutes most of the insulin injected has been metabolized and the higher doses of insulin increases the risk of hypoglycemia. Moreover, the abbreviated fast increases the risk of an unstable glucose baseline as food absorption abates, and the animal progresses into the fast. Thus, based on our experience, we do not recommend the modified ITT for mice. For larger species (rat, pig, dog, and primate) where limitations in blood volume is less of a concern and vascular access can be easily achieved, a short (<30 minutes) ITT can be used (Christoffersen et al.,

2009; Ropelle et al., 2009). A technical note is that insulin will stick to plastic further increasing the variability of the data. If insulin has to be diluted prior to injection, either obtain the insulin diluent from the company that provides the insulin (usually the pharmacy can obtain it) or dilute it with saline containing 0.3% serum from the species you are testing.

20.4.3.4 Hyperinsulinemic-Euglycemic Clamp

The hyperinsulinemic-euglycemic clamp is referred to as the gold standard upon which all other indices of insulin action are evaluated (DeFronzo et al., 1979). Investigators recognized that the reliability and accuracy of the method depended upon standardization of procedures and the ability of the investigator to clamp glucose concentrations to obtain a metabolic steady state. The principle of the clamp is that a defined insulin infusion is given at a constant rate into a peripheral vein that will increase arterial insulin concentration. To prevent glucose concentration from decreasing, glucose is infused at a variable rate to maintain euglycemia. Typically, the clamp is ~120 minutes in duration and glucose is measured at least every 10 minutes. Usually, after 90 minutes into the clamp method, a steady state for the glucose infusion rate is reached, and the glucose infusion rate (GIR; $\text{mg}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$) is reflective of insulin action, if the insulin concentration during the clamp is measured and is comparable between groups. While there are algorithms available for clamping, an experienced investigator can empirically obtain a good clamp (Furler et al., 1986).

There are a number of important assumptions and considerations when designing and interpreting clamp data. At a given insulin concentration, GIR is a measure of insulin action, if endogenous (i.e., hepatic glucose production) is completely suppressed. Since a steady state is assumed to have been reached at the end of the clamp, whole body glucose utilization ($= \text{GIR} + \text{endogenous glucose production}$) will be underestimated by the amount of glucose still being released by the liver. Thus, enough insulin needs to be infused to be confident that endogenous glucose production is completely suppressed. However, if a very large insulin dose is used, it is difficult to see differences between models that are only moderately insulin resistant and the maximal rates of insulin-stimulated glucose disposal are very similar (i.e., shift in K_m but no change in V_{max}). If two groups are being compared, the glucose and insulin concentrations during the clamp should be matched. The insulin dose is typically given on a per body surface area in humans. In many rodent studies, the insulin dose is based on body weight. Increased adiposity can increase the insulin concentrations obtained during the clamp, if the dose is administered on a per body weight basis. Thus, it is critical that insulin concentration is measured in both in the basal and clamp periods. For animal models with severe insulin resistance, a much higher insulin concentration will have to be attained during the clamp to augment whole body glucose disposal so as to detect a change in insulin action. For individuals who wish to assess hepatic insulin action, lower doses of insulin and a glucose tracer will have to be infused. The tracer will allow the investigator to assess the extent of suppression of endogenous glucose production and the total rate of whole body glucose disposal.

In clamp studies, the ideal sites for glucose and insulin infusion are into a peripheral vein, and blood samples should be taken from an artery. If a vein is used for sampling, it should drain tissues that are not metabolically active. If the vein drains metabolically active tissues, the difference between arterial and venous glucose concentration during the clamp will be greatest in the most insulin-responsive animals. This will bias one to overestimate how insulin-responsive the most sensitive animals are, as they will be clamped at higher arterial glucose concentrations, even though the venous glucose concentrations will be equivalent. In humans, a heated hand vein is commonly used, as the glucose concentration in the vein reflects the arterial glucose concentration. In large animals, an artery is commonly used. In rodents, a tail vein can be used, if surgical implantation of an artery is not practical for the laboratory. Collecting blood from the tail is stressful in mice, if a significant volume of blood ($>10 \mu\text{L}$) has to be obtained at each time point.

Some specific comments should be made about clamp studies in mice. Performing clamp studies is not easy in mice, especially in conscious, unstressed mice. Their small size and limited blood volume severely limits the number of investigators who can successfully perform a clamp in mice

(McGuinness et al., 2009; Wasserman et al., 2009). Moreover, the genetic background can have a marked effect on insulin action and pancreatic function (Berglund et al., 2008). This can confound interpretation of studies using mice on mixed backgrounds. Ideally, litter mates of the same gender are the best controls.

20.4.3.5 Assessing β -Cell Function

As mentioned in Section 20.4.3.2, abnormal glucose tolerance could be due to defects in β cell function. There are three basic approaches to assess β -cell function. The first is to measure basal glucose and insulin concentrations and calculate HOMA%B using the HOMA model an estimate of β -cell function (Wallace et al., 2004). The appropriateness of this approach for species other than humans is unclear. Essentially, what the model allows one to do is determine if the insulin concentration is appropriate for the prevailing glucose concentration. If the insulin concentration is less than one might predict, a defect in β -cell function would be suspected. This calculation is very model dependent. In addition, in the basal state, β cells are not being challenged, thus this approach is very insensitive to small alterations in β -cell function. The two other approaches use provocative tests to evaluate the ability of the β cell to respond to a hyperglycemic stimulus. These are the hyperglycemic clamp and the FSIGTT; the latter was discussed in Section 20.4.3.2. In the FSIGTT, the time course of both insulin and glucose are assessed after an intravenous bolus of glucose. The data are put into a model (note using human parameters) and an estimate of β -cell function can be obtained. It has been used in mice to assess β -cell function (Alonso et al., 2012). Because of the large number of samples and the large amount of blood that will have to be taken, we do not recommend it for mice; unless blood is reinfused at each time point to minimize changes in blood volume and the hematocrit. The hyperglycemic clamp can be used to assess β -cell function. The study must be done in animals with direct vascular access. In large animals, a saphenous or cephalic vein can be cannulated. In rodents, a jugular cannula inserted 3–5 days in advance using sterile techniques will be required. This site will be used for the continuous infusion of glucose. A separate site for blood samples will be needed as well (e.g., artery). Typically, glucose is infused to approximately double the plasma glucose concentration. The glucose concentration is held at the target glucose concentration for ~90 minutes, and the insulin concentration is assessed at baseline and during the clamp. This approach allows one to assess both the first phase and second phase insulin secretion (Mager et al., 2004; Postic et al., 1999). In humans, it is the first-phase insulin secretion that is lost early in the progression of the type 2 DM (DeFronzo and Abdul-Ghani, 2011). Depending on whether one wants to assess first and/or second phase insulin secretion will determine the frequency of measurement of glucose and insulin concentrations.

20.5 SUMMARY

The basic control systems used by mammals to regulate carbohydrate metabolism are shared among species, and there are many different animal models available to study carbohydrate metabolism in normal and disease states. Each species and model has its advantages and disadvantages. If an investigator's goal is to translate observations made in a particular species to humans, appreciating the differences between species will be very helpful in optimizing experimental design. Thus, knowledge of the differences in species and appropriate research tools actually aids in understanding how these control systems regulate metabolism in all mammals.

21.1 OVERVIEW OF LIPID FUNCTION

The physiologic importance of tissue lipids and lipid transport in the body is undeniably critical to life for all multicellular organisms. Lipids serve structural, functional, and metabolic roles within cells. Moreover, they provide insulation, protection (e.g., as waxes), and surfactant properties for various tissues. Structurally, the most generalized role of lipids is as the primary component of cell membranes. Notably, within membranes of different cell and organelle types, the specific lipid composition is highly diverse and dynamic. Some membrane lipids have further functional roles in organizing the cytoskeleton (Kwik et al., 2003) or as signaling or signal transduction molecules. Membrane lipids organized into heterogenous rafts can regulate major cellular events, including intracellular enzyme activity, electrolyte trafficking, exocytotic and endocytotic pathways, receptor presentation, ligand recruitment, cellular mobility, cell proliferation, membrane fusion, and even apoptosis (Gajate et al., 2009; Rosa and Fratangeli, 2010; Abbal et al., 2006; Knorr et al., 2009; Eum et al., 2009; Li et al., 2010). Extra-membrane lipids serve a tremendous range of other functional roles such as vitamins, hormones, local regulatory molecules (e.g., eicosanoids, sphingolipids [SLs]), specific ligands for the immune and nervous systems, and transcriptional factors. With inflammation, blood lipids act as acute phase reactants with purported direct bacteriostatic activity and as transporters for inflammatory mediators (e.g., C-reactive protein, serum amyloid A; Jahangiri, 2010; Taskinen et al., 2002). Lipids are the most concentrated source of energy for organisms, with β -oxidation of free fatty acids (FAs) to acetyl-CoA that then may enter the Krebs cycle for generating high-energy phosphates. Alternatively, acetyl-CoA can be recycled back for the synthesis of structurally new lipids.

Considering these broad functional roles, and variability in constitutive and inducible forms of lipids with physiologic needs, it is not surprising that tissue and blood lipid homeostasis is commonly altered in response to disease or toxicity. Accordingly, changes in serum/plasma lipid concentrations are most often attributable to a combination of influences, rather than a single cause. Importantly, circulating lipid values are also dependent upon metabolic rate, hormonal state, and relative age of the animal. Diet and nutritional state can have significant but often aleatoric and not fully predictable effects on circulating lipids. Species differences in baseline blood lipid concentrations and effects of pathologic states relative to such can be particularly prominent often due to phylogenetic differences in the predominant lipoprotein (LP) types and composition, and their associated channeling, regulation, and turnover. Hence, major species, sex, and age differences in blood lipid concentrations should be expected in both health and in response to pathologic states.

Useful interpretation of lipid data in laboratory animal species requires understanding of the differences in baseline states and factors influencing lipid transport and metabolism for the animals of interest and—as models of human disease—in comparison with human. A major reason for differences in circulating lipids between laboratory species and humans is due to dissimilar LP metabolism. In many laboratory species, blood cholesterol is predominantly carried by high-density lipoprotein (HDL) instead of low-density lipoprotein (LDL)—the major carrier of cholesterol in humans (Table 21.1). This is partly attributable to species differences in enzymes presence or activity (e.g., cholesterol ester transferase protein [CETP]) and LP synthesis and catabolism. The structure of most apolipoproteins (apos) also differs between nonhuman species and humans. In addition, the regulation of genes encoding proteins involved in lipid and LP metabolism is not identical between humans and studied laboratory species (e.g., peroxisome proliferator-activated receptors [PPARs]). Thus, the data obtained in nonhuman animals are often not directly relevant to humans.

TABLE 21.1
General Lipid Profiles across Species

Species	Detectable CETP	Inducible CYP7A1 ^b	TG:TC Ratio ^c	Relative Absolute Serum Values for These Major Lipoproteins ^d			Predominant Cholesterol LP Carrier in Blood	Potential to Develop Atherosclerosis Spontaneously
				VLDL ^e	LDL-c	HDL-c		
Mouse (C57BL/6, CD1, BALB/c)	No	Yes (though inhibition with very chronic cholesterol feeding in other strain[s])	1:1 to 1:3	Very low	Low	High	HDL	No (except in a few strains [e.g., C57BL/6J] on chronic very high cholesterol, high-fat diet + cholic acid)
Rat (Sprague-Dawley, F344, Wistar)	No	Yes	1:1 to 1.5	Low	Low	Low-moderate	HDL	No
Hamster (Syrian Golden)	Yes	No	1:2 to 2:1	Very low	Low	High	HDL	Yes (inconsistently in males on high cholesterol diet)
Rabbit(New Zealand White - NZW)	Yes (high)	No	1:1 to 2:1	Very low	Very low	Low	HDL	No
Guinea Pig	Yes	No	1:1 to 1:2	Very low	Low	Low	HDL to 1:1, LDL:HDL (LDL for some rabbit strains)	Yes (especially with high cholesterol diet in susceptible lines)
Dog (Beagle)	No	Yes	1:2 to 1:6	Very low	Low	Very high	HDL	No
Yucatan Miniature Pig	No	No	1:3 to 1:7	Very low	Low-moderate	Low-moderate	LDL	Yes (some vessels [e.g., abdominal aorta], especially with chronic high cholesterol diet)
Marmoset	Yes	No	1:1 to 1:2 (Crook et al., 1990)	Low	Moderate	Low-moderate	HDL (Crook et al., 1990)	Yes (on high cholesterol diet)
Cynomolgus monkey	Yes	No	1:2 to 1:6	Very low	Moderate	Moderate	1:1, LDL:HDL	Yes
African Green monkey	Yes	No (inhibition with chronic high cholesterol feeding)	1:2 to 1:2.5	Very low	Moderate	Low-moderate	LDL to 1:1, LDL:HDL	Yes
Rhesus monkey	Yes	No	1:3 to 1:7	Very low	Low-moderate	Low-moderate	1:1, LDL:HDL to LDL	Yes

(Continued)

TABLE 21.1 (Continued)
General Lipid Profiles across Species

Species	Detectable CETP	Inducible CYP7A1 ^b	Relative Absolute Serum Values for These Major Lipoproteins ^d				Predominant Cholesterol LP Carrier in Blood	Potential to Develop Atherosclerosis Spontaneously
			VLDL ^e	LDL-c	HDL-c	HDL-c		
Normal human ^a	Yes	No	1:1.1 to 1:3	Moderate to low	Low–moderate	LDL	Yes	
db/db mouse	No	Yes	2:1 ^d	Very low	Very high	HDL	Yes	
ApoE ^{-/-} mouse	No	Yes	1:4	Very high	Very low	LDL	Yes	
LDLr ^{-/-} mouse	No	Yes	1:2	Very low	Moderate	LDL	Yes	
ZDF/+ rat	No	Yes	1:1 to 1:1.5	Very low	Low–moderate	HDL	No	
Hamster (high fat diet)	Yes	No	2 to 3:1	Low	High	HDL	Yes	
Rabbit (cholesterol fed NZW)	Yes	No	1:>10	Very high	Low–moderate	HDL to LDL	(<i>lesion occurrence may be inconsistent and unrepeatable</i>) Yes	
Rhesus (diabetic)	Yes	No	1:1	Low	Low–moderate	LDL	Yes	

Table values adapted from reference ranges and other data of a variety of private corporation animal clinical laboratories and from published resources (Loeb and Quimby, 2012). CETP, cholesterol ester transfer protein; TG, triglyceride; CE, cholesterol ester; VLDL, very low-density lipoprotein; LDL, low-density lipoprotein; HDL, high-density lipoprotein; LP, lipoprotein.

^b CYP7A1 inducibility with high cholesterol diet toward enhanced cholesterol catabolism to bile. (CYP7A1 inhibition/downregulation with high cholesterol feeding is also noted in Table 1 when known [Henkel et al., 2011; Rudel et al., 1994; Shang et al., 2006].)

^c Ratio data based on SI units and primarily encompasses that from fed states in young adult laboratory animals on normal commercial chow/pellet diet.

^d “very low” = <+; “low” = +; “low–moderate” = ++; “moderate” = +++; “high” = ++++; “very high” = > to >>>>>>.

^e Based on total lipid associated with apoB100-lipoprotein migration in fasted state.

^a Human estimates including ranges for ratio of triglycerides: total cholesterol at least 20 years of age, multiple published commercial laboratory ranges and limited to general recommended ranges for health of fasting serum triglycerides 1.1–1.7 mmol/L and total cholesterol 3.2–5.2 mmol/L.

The lack of directly relevant animal models is one reason that the understanding of blood lipids and factors influencing their concentrations has been historically slower paced compared with that of other routinely measured circulating metabolites. This slower pace is also due to the many secondary variables influencing blood lipids and lipid changes, the cloudy definition of what constitutes a lipid, and the inconsistent and noncomparable methods to measure (and accordingly, classify) lipids. Indeed, there are still many aspects of lipid metabolism that are incompletely understood. The goal of this chapter is to aid the reader in understanding and interpreting measurable lipid concentrations in common laboratory species to the extent possible based on accumulated scientific knowledge. The focus is particularly on commonly evaluated lipids in serum/plasma, and factors that influence their concentrations. Circulating lipids that are not routinely evaluated and have primary functions in signaling, hormonal, enzyme/coenzyme or antioxidant activity (e.g., adrenocortical and sex steroids, and terpenes or isoprenols such as vitamin A, E, and K), or other complex roles (e.g., bile acids, oxidized lipids) or are absorbed plant-source lipids (phytosterols) will not be addressed in detail. Tissue lipids distinct from those in circulation greatly expand the complexity of physiologic and species differences in total lipid profile, and will not be addressed in detail in this chapter.

21.2 LIPID STRUCTURES

There are multiple ways for classifying mammalian blood lipids including blood transport form, function, or analytical properties. However, the most fundamental method is to consider physiologic lipids as subtypes of “simple” or “complex” lipids based on their structural components. This section provides a brief overview of lipid structure; more extensive and detailed information regarding lipid structures and anatomic and functional associations is readily available on several convenient websites including that on exogenous, and plant lipids at The LIPID Metabolites And Pathways Strategy (LIPID MAPS, <http://www.lipidmaps.org>), and on structures, sources, and analytical methods at Lipid Library (<http://lipidlibrary.co.uk>). Additional and complementary information on lipid structures, including steroids, waxes, vitamins, and those in bile are readily found at Lipid Bank (<http://lipidbank.jp/>). Moreover, particularly didactic websites of lipid structures and analysis are found at Cyberlipids (<http://www.cyberlipid.org>) and <http://lipidlibrary.aocs.org>. A literature search site for lipid physical and analytical information is available at LIPIDAT (<http://www.lipidat.tcd.ie/SearchStart.htm>).

21.2.1 SIMPLE LIPIDS

Simple lipids (also called “neutral lipids”) are composed exclusively of carbon chains, covalently bonded hydrogen, and a few oxygen atoms. These include lipids, which are predominantly linear carbon chains, including nonesterified fatty acid (NEFAs) and acylglycerols. Simple lipids also include those based upon a four-fused carbon ring structure, cholesterol, cholesterol esters (CEs, also known as cholesteryl esters), and other sterols, and variably straight-to-ringed five-carbon terpene (isoprene) polymers. (Representative simple lipid structures are presented in Figure 21.1a through f.)

21.2.2 COMPLEX LIPIDS

Complex lipids (also called “polar” lipids) yield three or more products with hydrolysis: FA(s), an alcohol, and an additional polar/hydrophilic component that incorporates an inorganic phosphate or sphingosine group. Complex lipids in mammals are limited to phospholipids (PLs) or SLs, which are particularly concentrated (with PLs predominating overall) in cell membranes. PLs and SLs also show prominent differential tissue and organelle distribution. (Representative complex lipid structures are presented in Figure 21.2a through e.)

21.2.2.1 Fatty Acids

FAs consist of a single linear nonpolar carbon chain with a polar carboxyl terminus. FAs occur in blood and tissues predominantly in the esterified form as part of larger lipid molecules and thus, are commonly classified as *precursors* of simple lipids. NEFAs occur in much lower concentration in the blood and tissues. Because they are relatively, although variably, hydrophobic, NEFAs are bound to fatty acid-binding proteins (FABPs) within cells, and to FA transport proteins or albumin in the extracellular environment. In blood, these bound NEFAs are a particularly dynamic lipid constituent.

All mammalian-produced FAs consist of an even number of carbon atoms (reflecting the synthetic steps involved) up to 28 methyl groups, although most are less than 22 carbon atoms in length (Brockerhoff et al., 1966; Christie and Moore, 1970). FAs of 14–18 carbons are widely distributed in tissues, and the predominant FA lengths in blood, liver, and adipose tissue (Christie and Moore, 1972). Longer-chain esterified FAs have selective distribution in mammals, with the longest chains (≥ 22 carbon atoms) primarily restricted to specialized tissues such as brain, retina, and spermatozoa. Medium-chain esterified FAs (8–12 carbon atoms; 6–10 carbons in some references) have broader distribution but occur in far more limited proportion in mammalian tissues. Short-chain FAs (≤ 6 carbon atoms) in mammals are primarily limited to milk fats of some species, have greater solubility in water, and are more rapidly digested and absorbed in the intestinal tract compared to longer-chain fats. Eicosanoids are a special class of FAs hydrolyzed primarily from 20-carbon arachidonic acid in mammalian membrane PLs and modified by downstream enzymes to generate a five- or six-carbon ring within the chain; this imparts the lipid with inter- and/or intracellular signaling activity (e.g., as prostaglandins, prostacyclins, thromboxanes, leukotrienes, or lipoxins).

FAs are subclassified based on their length and degree of unsaturated carbon bonds. Unsaturated, naturally occurring FA bonds are generally *cis* configuration and separated by at least one unsaturated methyl group resulting in a 120° bend in the chain. There are multiple FA naming systems, most based on chain length and number, and/or location of unsaturated bonds. The delta (Δ) and omega (ω) systems are common and recognize double bonds based on position relative to the carboxyl or methyl terminal, respectively. Thus, $C_{20:4}$ in the Δ system indicates a 20-carbon chain with double bond between C-5-6, 8-9, 11-12, and 14-15 with the carboxyl carbon representing C-1. This FA (arachidonic acid) with the omega system would be designated $C_{20:4n-6}$ with only the first double bond from the carboxyl terminal designated by location. Notably, each of these FA variables contributes to an expansive number of FA forms (length and degree of saturation) and exponential number of larger lipids synthesized from them, contributing to the heterogeneity of lipids associated with different organelles and cell types, species, and so on (Christie and Moore, 1970, 1972; Sheppard and Herzberg, 1992). Dietary lipid intake can further influence tissue lipid content; the popularity of dietary omega 3n FAs (with three or more double bonds) is partly because these forms are readily synthesized in the body into anti-inflammatory mediators, such as resolvin E1 (RvE1) and oxylipins (Abbott et al., 2012; Arita et al., 2005; Shearer et al., 2010).

21.2.2.2 Acylglycerols

The “simple lipid” classification is especially used to refer to lipids that yield two product types with hydrolysis: FAs and alcohols. This includes the acylglycerols with one to three FAs covalently linked to a glycerol backbone (hence, also referred to as acylglycerides or glycerolipids). Within this group, triglycerides (TGs) are the most common form in blood and tissues, whereas monoglycerides (MGs) and diacylglycerides (DGs) are traditionally regarded as endogenous intermediates in the synthesis or degradation of other lipids. Both MGs and DGs are also end products of dietary fat digestion that are directly absorbed by intestinal epithelial cells. Transiently generated DG within cell membranes serves further complex functions in directly contributing to cell membrane fluid changes, membrane channel current activation, and secondary intracellular signaling (Carrasco and Mérida, 2007; Large, 2002). Particularly well recognized is the role that phospholipase C-generated DG serves as an activator of protein kinase C (Cai et al., 1997).

TGs serve as the primary intracellular lipid and are stored in specialized intracellular lipid droplet organelles. TG-containing lipid droplets are most abundant in adipose tissue, with much lower proportions in liver and striated muscle in most mammalian species. The constituent FAs of TGs in droplets vary, and the TG turnover within these intracellular stores is highly regulated. Intracellular TGs serve primarily as a source of components for other lipids and metabolizable energy. In contrast with most other major lipid types, TGs are not found in, and cannot cross through, cell membranes. In serum/plasma, TGs are second in concentration only to PLs of the major circulating lipids by class.

Structurally, the three different glycerol carbons of acylglycerols available for covalent linking with an FA are stereochemically identified by the (*-sn-*) numbering system (*sn*-1, -2, or -3), or α , β , or α' . The *sn*-1, and *sn*-1 and *sn*-2 positions are typically acylated in MGs and DGs, respectively. These different carbons are also differentially recognized by endogenous enzymes of lipolysis and lipogenesis.

21.2.2.3 Sterols

A distinct category of simple lipids that also yield FAs and alcohols with hydrolysis are those composed of a four-fused carbon ring structure. This includes free cholesterol, CEs, and other sterols and sterol esters (e.g., steroid hormones: estrogens, androgens, glucocorticoids, and mineralocorticoids; bile acids and absorbed plant sterols) and five-carbon terpene (isoprene) polymers. Of all of these members, free cholesterol and CEs strongly predominate in mass in mammalian tissues, including blood.

Free cholesterol is abundant in cell membranes and has an important structural role in adding rigidity, and lateral organization by intercalating between other membrane lipids and proteins. The rings of cholesterol, as with most sterols are joined by *trans* junctions and give the molecule a planar conformation, with outside groups lying at the same angle away from the plane. The greatest relative proportion of cholesterol is in plasma membranes, while the less rigid membranes of mitochondria, endoplasmic reticulum (ER), and Golgi have much lower content. Free cholesterol content of membranes also varies between tissues, with the brain containing the greatest proportion by weight compared to all other organs. The distribution of the sterol in membranes also has functional, as well as structural purposes. The rigidity and planar nature enables free cholesterol to partition into membrane microdomains or “lipid rafts” variably organized with other lipids and proteins. Lipid rafts are essential for numerous membrane activities, including endocytosis, exocytosis, protein trafficking, signaling, and apoptosis. Conversely, free cholesterol in blood is the minor component; CEs are the major transport form of cholesterol in the circulation (Quehenberger et al., 2010).

CEs are covalently linked with long-chain FAs and are less polar than free cholesterol and thus, have a more limited role in cell membranes (Forrest and Cushley, 1977). Rather, intracellular CEs predominate within cytoplasmic lipid droplet organelles, and they are hydrolyzed in lysosomes and endosomes for component transfer to membranes, or metabolism/degradation (Wang et al., 2005). As with TGs, lipid droplet regulation of CE turnover is highly regulated. In adipocytes, CEs in lipid droplets are relatively low in concentration, likely due to their very active turnover in these cells (Radeau et al., 1995). Conversely, CE-containing droplets are particularly abundant in cells of the adrenal cortex (serving as precursor source for adrenal steroids) with some differences between species and sexes (Kraemer et al., 2002). With certain pathologic conditions (e.g., atherosclerotic plaques, xanthoma), CEs build up within (e.g., macrophage) lysosomes (Jerome, 2010).

21.2.2.4 Terpenes

Terpenes comprise a relatively miniscule proportion of blood lipids (Quehenberger et al., 2010). Polymers of five-carbon isoprene synthesized in mammals are generally limited to triterpenes and include lanosterol and squalene waxes and polyprenols (which mostly exist in cell membranes). Most, but not all of terpene structures contain carbon rings; in particular, squalene is a linear chain.

Notably, exogenous terpenes with other than three unit numbers are common in plants and bacterium, and include important essential nutrients such as vitamins A, E, and K. The carotenoids (α -carotene, lycopene, lutein, and zeaxanthin) taxol, limonene, and menthol are also among the plant terpenes with medicinal use.

21.2.2.5 Phospholipids

PLs are the major lipid components in blood, by concentration, comprising around 40% of total circulating lipids (Quehenberger et al., 2010; Quehenberger and Dennis, 2011). These complex lipids have a glycerol backbone linked to long-chain FAs on carbon (C)1 and C2, plus a phosphate group on C3, and may also be referred to as glycerophospholipids or phosphoglycerides (Goldfine, 2010). The most fundamental PL, phosphatidic acid has a simple, small, highly charged phosphate head and is relatively short-lived. Phosphatidic acid is a common precursor to other lipids within cells, including eicosanoids, DGs, and more extended PLs. Some PLs have their phosphate group further acetylated to an amino alcohol, such as choline, inositol, cephalin, or serine (i.e., phosphatidylcholine, phosphatidyl-inositol, phosphatidylethanolamine, or phosphatidylserine, respectively). Phosphatidylcholine (PL-C) is the most abundant PL in blood, cell membranes, and alveolar surfactant, and is termed “lecithin.” Lysolecithin and other “lyso” PLs are phosphoglycerols esterified to only a single FA, and mostly serve as intermediates in interconversion of charged PLs with other structures. In lipid membranes, the combination and conversion of PLs with polar heads of different charge contribute to vesicle formation, fusion, and other aspects of membrane shape (Kooijman et al., 2003; Roelofsen et al., 1987; Weigert et al., 1999). In addition, PLs with cationic amino acids such as phosphatidic acid and PL-C tend to be in the outer bilayer leaflet, whereas anionic amino acid-containing PLs, such as phosphatidylethanolamine and phosphatidylserine tend to reside in the inner leaflet of resting membranes. Flip-flop of these charged PLs between leaflets has been linked to signaling events such as initiation of coagulation, apoptosis and specific binding, and phagocytosis by mononuclear phagocytes (Sapay et al., 2010).

Plasmalogens are a particularly unique PL found in high concentration in membranes of cardiac myocytes, adult nervous tissue, testes (especially spermatozoal acrosomes), and eye lenses (Goldfine, 2010; Lessig and Fuchs, 2009). Plasmalogens resemble phosphatidylethanolamine except that the *sn*-1 FA is linked by an ether bond with *cis* double bond on the adjacent alkyl chain. This difference allows plasmalogens to pack more closely in membranes making them less permeable and cleaved only by specific enzymes, which may account for their concentration in these specific tissues. Plasmalogens also facilitate membrane fusion and are a major reservoir of arachidonic acid for synthesis of lipid second messengers; functions that may also help explain their distinct tissue distribution (Lessig and Fuchs, 2009; Nagan and Zoeller, 2001).

21.2.2.6 Sphingolipids

SLs are also a major lipid component in blood. SLs consist of a sphingosine backbone linked by amide bond to a FA. The sphingosine molecule has a long (mainly 18 carbons in length) unsaturated hydrocarbon chain with C17 polar amino; thus, like the PLs, SLs consist of a polar group bound to two nonpolar tails (and are sometimes considered a form of PL, although lacking glycerol). Ceramide is the simplest SL, and a precursor to more complex SLs that are also referred to as glucosylceramides and galactosylceramides. For example, ceramide can react with phosphatidylcholine to form sphingomyelin (ceramide phosphorylcholine), which is the most abundant SL in blood, and cell membranes overall (primarily in the outer bilayer leaflet) (Quehenberger et al., 2010; Merrill, 2011). Sphingomyelin is particularly concentrated in membranes of the central nervous system (CNS), and uniquely in erythrocytes of ruminants (Wood and Quiroz-Rocha, 2010). Other complex SLs are more selectively found in mammalian tissue-type membranes, and include cerebroside, sulfatides, globosides, and gangliosides. Membrane SL content also varies within cells; plasma membranes generally have greater SL content compared with major organelles.

SLs in cell membranes have been shown to have bioactive roles in signal transduction, cell adhesion, intracellular and transcellular protein trafficking (e.g., transferrin endocytosis), modulating hormone responses, and/or antigen recognition (Merrill, 2011; Taniguchi and Okazaki, 2014). Some of these functions are mediated by SLs in combination with cholesterol as lipid membrane microdomains or rafts. A particularly well-studied signaling SL and downstream product of ceramide is sphingosine 1-phosphate (S1P). S1P is an example of a signaling lipid that retains this role within, and outside of cell membranes, including in circulating blood (Argraves and Argraves, 2007). This SL has a growing list of signaling roles including modulation of cellular immunity and cell growth, survival, differentiation, and migration (Rosen and Goetzl, 2005; Taha et al., 2006). SLs and their signaling role or metabolism have additionally been functionally associated in different contexts with a wide variety of human diseases including diabetes, and select neurodegenerative, cardiovascular, respiratory, neoplastic, and infectious diseases (Deevska and Nikolava-Karakasian, 2011; Haughey, 2010; Goldkorn and Filosto, 2010; Berenson et al., 2010; Xu et al., 2010).

21.3 LIPID SOURCES

21.3.1 DIETARY LIPIDS

In the normal fed state, the primary source of tissue lipids of humans and most laboratory animals are derived from the diet. Dietary lipids require digestion to NEFAs, MGs, DGs, and free cholesterol for intestinal absorption. Ingested fats are first exposed to lipases in the oral cavity and stomach, and then to pancreatic acylglycerol lipases, phospholipases, carboxyl (cholesterol) ester lipases, and conjugated bile acids in the proximal small intestine (Hamosh et al., 1998; Hui and Howles, 2002; Kirby et al., 2002; Vaganay et al., 1998). Oral (lingual) lipase is a significant contributor to lipid digestion in adult mice and rats but appears to be less important in other tested species (rabbit, guinea pig, baboon, and humans) (DeNigris et al., 1988; Hamosh, 1978; Voigt et al., 2014); therefore, ingestion and gavage of lipid meals in most animals show limited difference in the products absorbed. Oral and gastric lipases vary in their efficiency with dietary long medium-chain versus medium-chain TGs and collectively enable some fat absorption even in the absence of pancreatic lipase. Pancreatic/small intestinal emulsification of the lipids with micelle formation is enabled by mixing with bile acids and is an essential process, as critical enzymes are generally active only at the oil–water interface. In addition, the quantity of each individual lipid type that can be absorbed depends upon the amount emulsified into, and size and content of the mixed micelles. In this way, although each lipid type is absorbed separately from the micelle, the amount of digestible TGs has an important positive influence on the amount of absorbed cholesterol. Conversely, the amount of select PLs in micelles may have a negative impact on cholesterol absorption (Rampone and Long, 1977). Importantly, absorbed lipid is also derived from enterocyte cell turnover and bile acids; these perpetual cholesterol-rich sources help explain why blood cholesterol concentration is far less affected than circulating TGs with fasting/anorexia, or loss of pancreatic enzyme activity (Tso et al., 2004).

Dietary FAs less than 12 carbons in length can be at least partly absorbed in the small and large intestine without micelle incorporation (Jørgensen et al., 2001; Ruppin and Middleton, 1980; You et al., 2008). These short- and medium-chain FAs are transported in portal circulation as albumin-bound NEFAs and are largely fated for hepatic β -oxidation in mitochondria (Section 21.7). Correspondingly, a diet rich in medium-chain FAs has been used to treat various human and animal malabsorption syndromes, and has reported benefit in upregulating metabolic oxidative processes (Beermann et al., 2003; Kuwahata et al., 2011; Pan et al., 2010; Wein et al., 2009).

Additional components of intestinal micelles are plant sterols, which are usually poorly absorbed and not utilized by mammalian cells; however, they displace cholesterol in micelles, inhibiting non-esterified cholesterol enterocyte uptake (Batta et al., 2006; Lu et al., 2001). Animals and patients with mutations in adenosine triphosphate (ATP)-binding cassette (ABC) transporter protein genes

(*ABCG5* and *ABCG8*) that encode for sterolin-1 and sterolin-2 enterocyte brush border transporter proteins lack the ability to restrict the amount or type of sterols absorbed, or to excrete sterols into bile, and have hypercholesterolemia as well as increased circulating plant sterols (Izar et al., 2011). Findings in these individuals provided early confirmation of the presence of enterocyte transporter proteins for specific lipid species.

Other specific enterocyte membrane transporter proteins for NEFAs, 2-MGs, and cholesterol have also now been reported (Murota and Storch, 2005; Nassir et al., 2007). These include the jejunal enterocyte brush border cholesterol transporter known as Nieman-Pick C1-like 1 (NPC1L1) protein (inhibited by the serum cholesterol-lowering drug ezetimibe), and cluster of differentiation 36 (CD36) and fatty acid transport protein 4 (FATP4), which have both shown measurable activity only under conditions of fasting and thus, may represent a redundant mechanism to ensure uptake of essential FAs when supply is limited (Garcia-Calvo et al., 2005; Tso et al., 2004). Enterocyte absorption of micellar lipids additionally occurs by passive diffusion facilitated by a low-pH microclimate lining the small intestinal villus surface that protonates NEFAs, reducing their solubility within micelles (Shia et al., 1985). Collectively, these findings indicate multiple mechanisms for intestinal lipid uptake with redundancy and supply-dependent mechanisms ensuring maintenance of essential nutrient absorption.

21.3.2 DE NOVO LIPID SYNTHESIS

Both FAs and cholesterol (and a spectrum of simple and complex lipids derived from these products) are synthesized in mammalian tissues. Synthesis is particularly promoted in states of high insulin activity or excess dietary carbohydrates (with corresponding high mitochondrial Krebs cycle citrate and ATP production). Synthesis begins with the transport of citrate out of mitochondrion into the cytosol, where it is cleaved to form acetyl-CoA. These synthetic processes for both FAs and cholesterol are particularly active in hepatocytes. FA synthesis is also generally active in adipocytes (white and brown fat), lactating mammary gland and, to much a lesser extent, in striated muscle and skin (Harvey et al., 2005). However, cholesterol synthesis occurs in essentially all tissue cells, with prominent activity in intestine, adrenal gland, and reproductive tissues (e.g., ovaries, testes, placenta) in addition to liver (Tso et al., 2004; Turley et al., 1995).

21.3.2.1 Fatty Acid Synthesis

FA synthesis from acetyl-CoA occurs in two carbons at a time from the carboxyl end toward the carboxylic acid end via condensation with malonyl-CoA, and release of CO₂. This reaction is initiated by the rate-limiting enzyme, acetyl-CoA carboxylase (ACC), which is highly regulated by nutritional status and hormones (e.g., insulin, epinephrine, and glucagon) (Brownsey et al., 2006; Tso et al., 2004). Nearly all subsequent cytosolic FA-synthesizing enzyme reactions in mammals are catalyzed by a single, long peptide with multiple functional domains (“fatty acid synthase”). The product of these reactions is a saturated FA up to 16 carbons long (i.e., palmitic acid).

Further FA chain elongation and/or desaturation can occur through transport, and additional enzymes in mitochondria or ER. Regulation of these elongases and desaturases, and the role of specific FA chain length and saturation in physiological processes of cells are still poorly defined. However, a general role for nuclear hormone receptors in FA synthetic process has been reported for peroxisome proliferator-activated receptor α (PPAR α), liver X receptor (LXR), sterol-regulatory element-binding protein-1 (SREBP-1), and others (Wang et al., 2006, 2008). These factors are, in turn, regulated by local levels of glucose, insulin, thyroid hormones, and leptin. Products of the FA synthesis pathway also bridge with FA catabolic pathways in regulating key enzymes (Section 21.7).

21.3.2.2 Cholesterol Synthesis

Cholesterol synthesis is initiated by condensation of acetyl-CoA with four-carbon-chain acetoacetyl-CoA to form the branched 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA), catalyzed by

cytosolic HMG-CoA synthase (an enzyme distinct from mitochondrial HMG-CoA synthase; Section 21.7). This six-carbon product is then reduced to mevalonate with release of coenzyme A (CoA) in a two-step reaction by the critical, rate-limiting enzyme, HMG-CoA reductase. HMG-CoA reductase is localized to the ER membrane, but with the catalytic domain exposed to the cytosol. HMG-CoA reductase is also highly regulated by certain hormones and end-product negative feedback. Stimulation of this enzyme's activity and ultimately, cholesterol synthesis is mediated by insulin, and inhibited by glucagon and epinephrine. Regulation by these hormones is rapid as it involves reversible protein phosphorylation of HMG-CoA reductase through a chain of upstream protein kinases. However, more long-term effects on the enzyme's activity by intracellular cholesterol levels involves the transcription factor SREBP and is mediated by complex multivalent regulation of HMG-CoA reductase gene transcription and translation, and mRNA degradation (Clarke and Hardie, 1990). Because of its pivotal role in cholesterol synthesis, HMG-CoA reductase is a major pharmaceutical target for blood cholesterol reduction (e.g., statins).

21.4 BLOOD LIPID TRANSPORT

Considering blood lipids based on their transport in circulation has particular relevance for understanding and interpreting serum/plasma lipid changes. The majority of blood lipids are transported in LPs. Structurally, LPs are disk shaped to spherical with a single outer layer of amphipathic lipids (PLs, SLs, and free cholesterol) surrounding a core of more hydrophobic TG, CEs, and sometimes terpenes (e.g., carotenes, vitamin D, E, K). Lipoproteins are classified based on their relative concentrations of each of these lipid structural types and surface-expressed apos. Laboratory classification of LPs is also by measurable particle size and density; however, the methods and cut-off values for these endpoints varies between methods, studies, and species. Importantly, the concentration of these LPs generally determines concentrations of plasma/serum simple and complex lipids, with the exception of NEFAs, which are transported, bound to other circulating components.

21.4.1 APOLIPOPROTEINS

Apos largely consist of amphipathic peptide helices that have one face of hydrophobic amino acids associated with the particle surface lipids, and the other face of polar/hydrophilic amino acids variably exposed to interact with the environment. Apos in these particles serve as enzyme cofactors, activators, or inhibitors, and/or as ligands to facilitate membrane interactions, tissue secretion, or uptake. In this way, the proteins are the primary determinant of the fate of the circulating LP lipids. Notably, except for the larger apoB proteins, apos are only weakly associated with the outer layer lipids via hydrogen bonding and van der Waals forces enabling variable exchange of apos between particles. Similar weak bonding also enables considerable exchange of outer layer lipids between circulating LP types.

Among common laboratory species and humans, major apo classes and functions are generally comparable (Table 21.2). However, they have (often phylogenetically based) differences in amino acid sequence, thus requiring species-specific assays for accurate and optimal quantitation in collected samples (Luo et al., 1989). Also important for interpreting nonclinical lipid data and translating findings to humans is recognition of major species differences in (1) organ/tissue sources of some apos (e.g., apoB48), (2) lipid-metabolizing enzymes that interact with these proteins (e.g., CETP), and (3) common regulatory mechanisms of lipid metabolism (e.g., catecholamines).

21.5 LIPOPROTEIN SYNTHESIS AND METABOLISM

Lipoproteins are typically distinguished in the laboratory based on analytical properties (density, diameter, electrophoretic migration, and proportional lipid content). However, they are interdependent with each other and with regulators of lipid metabolism overall so that physiologic or pathologic

TABLE 21.2
Apoproteins of Animals and Humans

Apoprotein	Lipoproteins Associated	Tissue Source of Plasma Levels	Major/General Function	Associated Enzyme and Transporter Interactions	Disease Relationship(s)
A-I	HDL > chylomicron (<i>readily transferred to HDL in circulation</i>)	Enterocytes; hepatocytes	Promotes cholesterol efflux from tissue cells to HDL, and HDL uptake of free cholesterol from VLDL and LD in exchange for TG via LCAT	LCAT cofactor; additionally, interacts with cell transporters (<i>ABCA1</i> and <i>ABCG1</i>) and SR-B1 enabling selective cholesterol uptake from tissues	Human mutations have been associated with low blood HDL, Tangier-like disease, or variant of systemic amyloidosis. ApoA-I blood levels have also been negatively correlated with hepatic fibrosis (Bedossa et al., 1989; Vigushin et al., 1994)
A-II	HDL >> chylomicron > VLDL	Hepatocyte; enterocytes	Role in HDL particle size and composition	Conflicting findings that ApoA-II inhibits or enhances hepatic lipase activity. (Bedossa et al., 1989; Vigushin et al., 1994)	Broad species differences in ApoA-II structure. ApoA-II is absent or only in very low concentrations in plasma of dogs, rabbits, pigs, and chickens. (Zhong et al., 1994)
A-IV	Chylomicron (<i>nascent</i>), HDL (<i>especially larger particles</i>)	Enterocytes, and in mice, rats, and rabbits, also hepatocytes	Modulates enterocyte and hepatocyte transcellular lipid transport and has role in appetite and satiety via CNS (inhibits food intake in rodent models). Synthesis upregulated by intestinal fat absorption and PYY hormone (Mowri et al., 1996)	Activates LCAT; inhibits LPL activation (Blanco-Vaca et al., 2001)	ApoA-II deficiency or over-expression in mice is associated with altered HDL size distribution, with no overt abnormalities. (Tso et al., 1999)
A-V	VLDL, chylomicron, HDL	Hepatocytes	Regulation of plasma TG levels	LPL activation	Humans with select ApoA-IV polymorphisms show delayed chylomicron clearance. Mice lacking apoA-V have 4X increased blood TG; some human variants are associated with higher plasma TG (Tso et al., 1999)

TABLE 21.2 (Continued)
Apoproteins of Animals and Humans

Apoprotein	Lipoproteins Associated	Tissue Source of Plasma Levels	Major/General Function	Associated Enzyme and Transporter Interactions	Disease Relationship(s)
B-48	Chylomicrons, chylomicron remnants > and (in mice, rats, and dogs) VLDL	Enterocyte; and (in mice rats, dogs) hepatocytes	Enables synthesis and secretion of TG-rich LPs; truncated version of apoB-100 (and lacks the LDL receptor-binding domain)	Interacts intracellularly with the ER lipid transfer protein (MTP)	Genetic deficiency of both ApoB-48 and B-100 (abetalipoproteinemia) may be attributed to mutations in MTP gene. Clinical signs are due to impaired intestinal absorption of fat and fat-soluble vitamins. Blood levels of ApoB-48 have been purported to be a marker of metabolic syndrome risk
B-100	VLDL, IDL, LDL	Hepatocyte >> enterocyte	Aids synthesis and secretion of TG-rich LPs, and their uptake in tissues by the LDL receptor	Interacts intracellularly with the ER lipid transfer protein "MTP"; binds tissue LDL receptor	In addition to abetalipoproteinemia (above), mutations of the LDL receptor interfere with ApoB-100 function, generally impairing VLDL, IDL and especially LDL uptake (e.g., "familial hypercholesterolemia"). Selective deficiency of ApoB-100 has also been reported (Hockey et al., 2001)
C-I	HDL, chylomicrons, chylomicron remnants, VLDL, and IDL (<i>readily transferred between particles</i>)	Hepatocytes >>skin, testes, spleen, lung	Regulatory role in tissue lipid uptake from, and clearance of lipoproteins	Role in activating LCAT; and to a lesser degree, inhibiting LPL, HL, phospholipase A 2, CETP and ApoE-mediated binding to LRP, LDR, and VLDLR (may be due to ApoC-I ability to displace, mask or alter conformation of ApoE).	Familial chylomicronemia with deficiency in man (Kluger et al., 2008); Mice with deficiency show mildly impaired VLDL clearance. Knockout mice develop hypercholesterolemia with high cholesterol diet.
C-II	Chylomicron remnants, VLDL, IDL, HDL		Regulatory role in tissue lipid uptake from, and clearance of lipoproteins	Activator of LPL > Role in inhibiting ApoE- and ApoB-mediated receptor binding, HL, and LCAT activity	ApoC-I overexpression in mice results in hypertriglyceridemia and hypercholesterolemia (Herbert et al., 1985) Human deficiency: hyperlipoproteinemia type IB

Apoproteins of Animals and Humans

Apoprotein	Lipoproteins Associated	Tissue Source of Plasma Levels	Major/General Function	Associated Enzyme and Transporter Interactions	Disease Relationship(s)
J (<i>aka: clusterin</i>)	HDL (<i>primarily smaller, more dense particles</i>)	Many tissues, including (human) smooth muscle cells associated with atherosclerotic lesions (Chamley et al., 1997)	May have a beneficial role in reverse cholesterol transport, and inactivation of complement C5b-9 complexes; however, has also been linked with amyloid β plaque formation (De Groot and Meijers, 2011; Schwarz et al., 2008)		Blood levels have been proposed as a negative risk factor for vascular disease
(a)	Covalently attached to ApoB100 in man and some nonhuman primate species	Hepatocytes	May have adverse role in inhibiting fibrinolysis, and promoting oxidation of PL and LDL within atherosclerotic lesions		Biomarker for cerebro-and cardio-vascular atherothrombosis risk (Gelissen et al., 1998)

Anglés-Cano et al. (2001).

changes are generally not isolated to a single LP. Lipid content within LPs is also generally comparable between common laboratory species and humans for the dominant lipid types (Table 21.3). However, the specific lipid and protein composition and proportions vary between species. These differences, as well as those in regulating enzymes, neurohormonal, nutritional, and other physiologic signals that affect LP metabolism account for many of the species differences in routine blood lipid data.

TABLE 21.3
Composition of Lipoproteins of Animals

Lipoprotein	Major Organ/Cell Synthesizing	Core Lipids (Approximate %)		Surface Components (Approximate %)			MW ^a / Diameter ^b	Major Associated Apolipoproteins (apo)
		TG	CE	PL	FC	Protein		
Chylomicron	Small intestine enterocyte	≥85	<10	6–12	1–3	1–2	1000/ 100–1000	Major: B-48; E; Minor: A-I; A-II; A-IV; A-V; C-I; C-II; C-III
VLDL	Hepatocyte; enterocyte; cardiac myocyte	60	8	15	7	10	7500/ 30–80	B-100; E; C-I; C-II; C-III; A-II; A-V (B-48 in mice, rats and dogs)
IDL	VLDL degradation product	20	30	20	10	20	4000/ 25–35	B-100; E, C-I, C-II, C-III
LDL	VLDL degradation product	30	20	15	15	20	2000/ 15–25	B-100

NEFAs	Adipose; skeletal muscle	–	–	–	–	–	–	Primarily bound to albumin

Lipid composition values adapted (rounded) from unpublished studies of rats and dogs, and published data for rat (Cartwright et al., 1982).

TG, triglyceride; CE, cholesterol ester; PL, phospholipid; FC, free cholesterol; MW, molecular weight; VLDL, very low-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; Lp(a), lipoprotein A; NEFA, nonesterified fatty acid.

^a MW, molecular weight (kilodaltons).

^b Diameter in nanometers (nm); d: Lp(a) composition in nonhuman primates was not available, but expected to be similar to that of LDL in the respective species.

21.5.1 CHYLOMICRON ASSEMBLY AND SECRETION

Chylomicron synthesis begins with enterocyte absorption of long-chain FAs that are bound to intestinal FABPs (Mansbach and Siddiqi, 2010). These are transported into the ER for reassembly into TGs. De novo TG synthesis through uptake of blood FAs and the α -glycerophosphate pathway is also utilized for chylomicron synthesis by enterocytes, especially when intracellular FA supply is inadequate (Gangl and Ockner, 1975; Guo et al., 2005; Shiau et al., 1985). The generated TGs are packaged via microsomal triglyceride transfer protein (MTP) with much smaller proportions of cholesterol, PLs, and LPs of apoB48, A-I, and A-IV within the ER to produce chylomicrons (Table 21.3) (Berriot-Varoqueaux et al., 2000). Mutations in MTP constitute the genetic basis for abetalipoproteinemia in humans and animal models (partly characterized by severe steatorrhea and reduced circulating lipids). Inhibitors of MTP have also been investigated as therapeutics to lower circulating blood lipid, especially TG concentrations (Aggarwal et al., 2005).

The nascent intracellular chylomicrons are transported by ER carrier proteins into the Golgi. Rare defects in these ER chylomicron transporter proteins have been demonstrated in human (e.g., Sar1b) resulting in chylomicron retention diseases characterized by severe fat malabsorption (Shoulders et al., 2004). Notably, these proteins are also being evaluated as drug targets for metabolic diseases. Chylomicrons reaching the Golgi complex are transferred to exocytotic vesicles, which are transported to the basolateral membrane, and their contents are secreted extracellularly. Secreted chylomicrons, aided by interstitial hydration, enter into mucosal lymphatics and ultimately into the bloodstream (Tso and Balint, 1986).

21.5.2 CHYLOMICRON CATABOLISM

Of all the circulating LPs, nascent chylomicrons are the largest and least dense due to their predominance ($\geq 85\%$) of unsaturated FA containing TGs (Table 21.3) (Kalogeris and Story, 1992). The wide range in size and density for chylomicrons is similarly linked to a wide range in TG content. The primary protein associated with chylomicrons, apoB48, is so called as it represents the N-terminal $\sim 48\%$ of apoB100 in humans. ApoB48 in laboratory species is similarly derived from the homologous apoB100 gene mRNA as a co- or posttranslationally modified protein (although variable amino acid sequences for these apos between species generally require distinct assays for detection/measurement) (Corsini et al., 1992; Greeve et al., 1993; Kendrick et al., 2001). The expression of apoB48 enables efficient synthesis and secretion of chylomicrons by small intestinal enterocytes. Importantly, mice lacking the capacity to produce apoB48 from apoB100 (due to knockout of the splicing gene, apobec-1) show little difference in lipid absorption and export in the fed state, but reduced capacity for particle production in the fasted state (Kalogeris and Story, 1992). Thus, the evolutionary change toward apoB48 in chylomicrons may have resulted from greater efficiency of TG utilization with this smaller apo in starvation conditions.

ApoB48 is exclusively produced by enterocytes in humans, rabbits, and hamsters in health (Liu et al., 1991; Greeve et al., 1993). However, apoB48-containing TG-rich particles are produced by the liver in dogs, rats, and mice (i.e., apoB48 very low density LPs or VLDLs). This difference has been purported to explain the prominent species differences in concentrations of circulating LDL cholesterol. ApoB48 particles (chylomicrons and some VLDLs in species with liver apoB48 production) are not metabolized to LDL (unlike apoB100-containing VLDLs). Therefore, apoB48 particles yield lower total downstream cholesterol-rich LDLs in the blood than comparable levels of apoB100 VLDLs (Greeve et al., 1993; Van't Hooft et al., 1982).

Nascent chylomicrons travel from intestinal lacteals to blood via the thoracic duct, bypassing the liver. In the process, they acquire apoCs (I, II, and III) and apoE transferred from HDL particles, while apoA-IV is displaced from the chylomicron surface. This exchange, which yields a "mature chylomicron," is critical for activation of enzymes essential for chylomicron metabolism and clearance. In tissue capillaries, particularly those of skeletal muscle and adipose, chylomicrons

interact with the serine esterase lipoprotein lipase (LPL), which is secreted by endothelial cells and attached to their surfaces by heparan sulfate. Activity of LPL is enabled by cofactor apoC-II, and chylomicrons are the preferred enzyme substrate among all blood lipid transport vehicles (Bickerton et al., 2007). Interaction with LPL liberates NEFAs from the glycerol backbones of chylomicron core TGs. These NEFAs are partly absorbed by the endothelial cell and partly released into the surrounding blood (contributing to postprandial surge or “spillover” of NEFAs in blood). Deficiency of apoC-II, as the critical LPL cofactor, occurs as a rare autosomal hereditary disorder, and accordingly, is associated with hypertriglyceridemia and elevated chylomicron serum levels. Insulin is also important in enabling endothelial cell uptake of NEFAs from chylomicrons (Section 21.9). Water-soluble glycerol released with TG hydrolysis diffuses into blood and is readily absorbed by blood and tissue cells.

Among the other apos carried by chylomicrons, apoA-I is a cofactor, and apoA-IV and apoC-I are activators of lecithin:cholesterol acyltransferase (LCAT, also called phosphatidylcholine-sterol O-acyltransferase). This enzyme converts free cholesterol into more hydrophobic CE via transfer of FA to it from phosphatidylcholine (converting the latter into lysolecithin). Cholesterol can be retained in the core of a LP particle in the esterified form in greater proportion than as free cholesterol in the outer ring of amphipathic lipids encasing the particle. Thus, this enzyme enables enhanced cholesterol containment by chylomicrons, which acquire some CEs from other particles in transit. However, LCAT has an even greater role in formation and metabolism of cholesterol-containing HDL particles, which acquire the enzyme cofactors and activator apos from chylomicrons during chylomicrons lipolysis (see below) (Vigne and Havel, 1981). In humans, these transferred apos from chylomicrons include apoA-I and C-I; however, in contrast to rats and other laboratory species, the majority of human apoA-IV is released free into blood. This distinction for apoA-IV, as well as the highly variable LCAT activity in plasma among species have been proposed as additional factors accounting for some of the species differences in LP profiles and cholesterol metabolism (Lefevre et al., 1986; Ouguerram et al., 2004).

Another apoC carried by chylomicrons that undergoes exchange with HDL is apoC-III. This protein inhibits apoC-II activation of tissue LPL, as well as hepatic lipase, thereby slowing chylomicron degradation and premature hepatic uptake. Accordingly, increased circulating apoC-III concentrations have been linked with prolonged postprandial lipemia, metabolic syndrome, and other dyslipidemic conditions in human (Clemente-Postigo et al., 2010). Notably, the transfer of apoC and apoA proteins between chylomicrons and HDL particles is continuous and recycling; however, retention of these proteins by chylomicrons dwindles as the particles progressively shrink in size with lipid loss. The decreasing proportion of LPL-activating apoC-II in chylomicrons with degradation is likely particularly critical in initiating termination of chylomicron TG hydrolysis.

Additional functional roles for apoC-III, apoC-I, apoA-I, and apoA-IV that are important in other LP types are discussed below and listed in Table 21.2.

21.5.3 CHYLOMICRON REMNANTS—FORMATION AND CLEARANCE

As chylomicrons lose TGs as FAs to peripheral tissues, and apoA and C to HDL, they also transfer a substantial portion of PLs to HDL. The proportional loss of apoA and apoC proteins renders the particles less capable of binding and activating LPL in capillaries, while the loss of PLs and the relative enrichment in apoB48 and apoE and CEs enhances hepatocyte uptake (Cooper, 1997). These chylomicron remnants are thus, distinct from their parent particle in both protein phenotype and lipid content. In particular, compared with parent chylomicrons, remnants are TG depleted and cholesterol- and lipid-soluble vitamin (terpene) enriched.

Hepatic uptake of these remnants is the final step in chylomicron clearance. This uptake occurs by multiple mechanisms. Most remnants reach a sufficiently small size to enter into the space of Dissé through the endothelial fenestre (Havel, 1998). These PL-depleted particles then interact with the microvillous hepatocyte surface LDL receptor via apoE and can undergo receptor-mediated endocytosis. A secondary slower apoE-dependent pathway (which takes precedence in conditions

of defective LDL receptor-mediated uptake; e.g., familial hypercholesterolemia) is via the LDL receptor-related protein (LRP), a multifunctional receptor also known as $\alpha 2$ macroglobulin and found in many tissues in addition to liver (Hussain et al., 1991; Martins et al., 2000). Notably, the remnant particles may also be enriched with apoE secreted free into the space of Dissé or bound by heparan sulfate to the hepatocyte microvillar surface, both of which increase remnant affinity for LRP (Mahley and Ji, 1999; Willnow, 1997). Some chylomicron remnants in the space of Dissé may instead interact via their outer polar lipids with proteoglycan-bound sinusoidal endothelial-surface hepatic lipase and undergo nonreceptor-mediated (TG and PL) hydrolysis and hepatocyte absorption of their lipid content. A distinct chylomicron remnant clearance mechanism by hepatic Kupffer cells has been purported to take precedence with larger, oxidized, or overload remnant particles that do not enter the space of Dissé (Havel, 1998; Umeda et al., 1995). Notably, while apoB48 on chylomicrons is critical for particle assembly and secretion, it lacks the LDL-receptor binding domain that is present in the larger apoB100 protein, and thus lacks a functional role in remnant clearance (Hui et al., 1984).

Chylomicron clearance is generally rapid in health, occurring within ~30 minutes in a rodent, and a few hours in humans following a meal. Other relative species and strain differences in the capacity to generate and clear chylomicrons have been reported (Jeffery and Redgrave, 1982). Chylomicrons rich in polyunsaturated FAs are more rapidly cleared than those high in saturated FAs. A wide variety of pathologic conditions have also been associated with prolonged postprandial triglyceridemia due to delayed chylomicron clearance.

21.5.4 OTHER LIPOPROTEIN PRODUCTS OF ENTEROCYTES

In addition to chylomicrons, small intestinal enterocytes have been shown to produce small amounts of particles that correlate in size and lipid constituents with VLDLs. These are derived from scavenged products of intestinal cell turnover and bile acids during fasting/starvation, and under some hormonal influences (e.g., with late pregnancy in rats) (Lioi et al., 2010). This overlap in secretion of two distinct TG-rich particles from enterocytes likely ameliorates flux in circulating TG and cholesterol concentrations during fasting/starvation. However, the hallmark of VLDL particles and their metabolic successors (intermediate-density lipoprotein [IDL] and LDL) is the presence of apoB100. In human and most laboratory species, the reported capacity of apoB100 secretion by enterocytes is relatively low (Risser et al., 1978; Van't Hooft et al., 1982). Thus, the liver, with significantly greater capacity to generate apoB100, is still considered the primary organ capable of generating VLDL. Variable amounts of HDL particles have also been reported to be produced by enterocytes (Brunham et al., 2006). These functional overlaps in LP particle output between intestine and other tissues is primarily of consideration in analyzing samples and interpreting results from animals in the starved or physiologically stressed states.

21.5.5 VLDL—ASSEMBLY AND SECRETION

The other major TG-transporting LPs in blood are VLDLs, which are smaller and contain a lower proportion of TG, and greater total cholesterol by particle weight compared with chylomicrons. Accordingly, except for the postprandial state, a change in serum/plasma TGs can generally be attributed, in large part, to an alteration in VLDL metabolism (i.e., production, degradation, and/or clearance).

VLDLs are synthesized and secreted almost exclusively by the liver. Synthesis is highly dependent upon the available pool of metabolically active lipid constituents (especially FAs) with only a portion of hepatocellular lipid content contributing to this active pool (Gross et al., 1967). The assembly of lipids into VLDLs also depends upon the availability of apoB100; however, in mice, rats, dogs, and some other species, apoB48 (typically associated with chylomicrons) may be alternatively associated with VLDL-like particles produced by the liver (Greeve et al., 1993). A single nonexchangeable

apoB100 (or apoB48) occurs with each VLDL particle. As with TG-rich chylomicrons, particle assembly is facilitated by the lipid transfer protein, MTP within the ER (Salter et al., 1998; Swift et al., 2003). Deficiency of MTP as a familial condition (abetalipoproteinemia) results in symptoms described above (associated with impaired chylomicron assembly), and also persistently and profoundly low blood TGs, and to a lesser magnitude, low circulating cholesterol attributed to impaired generation of VLDLs. Inability to transport lipid-soluble vitamins via these particles to peripheral tissues also contributes to clinical symptoms of the condition. The role of MTP further contributes to stepwise lipid loading of VLDL particles, with VLDL₁ and VLDL₂ representing TG-rich and TG-poor particles, respectively, secreted from the liver (Olofsson and Borèn, 2005).

Circulating VLDL concentrations also depend upon translational and posttranslational control of apoB100 synthesis and posttranslational degradation within hepatocytes. Altered degradation of apoB100 is a particularly common regulatory mechanism linked with hormonal, metabolic, and inflammation-related signaling. Increased ApoB intracellular degradation has been associated with insulin and choline deficiency, whereas reduced degradation has been linked with insulin resistance, endogenous glucocorticoids, dexamethasone administration, and activation of the inflammatory I κ B kinase (IKK)–nuclear factor (NF)– κ B signaling cascade (Wang et al., 1995; Tsai et al., 2009). These mechanisms are consistent with observed decreased or increased VLDL secretion associated with these conditions or treatments, accordingly.

Other apos that associate with VLDL particles include apoC-I, C-II, C-III, and E. These proteins are rapidly transferred from plasma and/or HDL to the nascent VLDL in the space of Dissé (Bébé et al., 2005; Cohn et al., 2002; Dolphin et al., 1986). This immediate transfer to VLDL within the peri-hepatocellular space is critical for blocking hepatic premature recapture or hydrolysis of VLDL via apoB100 (or apoE) binding to the LDL (or LRP) receptors (Jong et al., 1999). These apos further serve similar functions in VLDL as in chylomicrons. ApoC-I, as with apoC-III, has also been shown to delay VLDL catabolism via inhibiting LPL activity (Jong et al., 1999).

Notably, while VLDL is the predominant TG-carrying particle in blood in the postprandial state, the proportion of TG and cholesterol in VLDL is also species-, and diet-variable (Havel and Kane, 1995; Madani et al., 2003; Ramaswamy et al., 1999).

21.5.6 VLDL CATABOLISM

Catabolism of VLDL lipid content is similar to that of chylomicrons. As with chylomicrons, apoC-II serves as required cofactor for LPL on capillary endothelial surfaces (especially within adipose and skeletal muscle tissue). ApoE also has a critical role in VLDL lipid catabolism in peripheral tissue in aiding LP interaction with LPL though associating with endothelial cell-surface proteoglycans and slowing particle movement (Kowal et al., 1990). Loss of this function or deficiency of apoE in humans is associated with accumulation of an abnormal form of VLDL particles (Schaefer et al., 1986). Most apoC-I proteins are exchangeable with HDL, and readily transfer as VLDL particles circulate and shrink in diameter.

Notably, another peripheral tissue lipase, endothelial lipase (EL), which is putatively associated with endothelial surfaces via heparan sulfate binding similar to LPL, is a relatively newly identified lipase that facilitates catabolism of VLDL (as well as IDL, LDL, and HDL). Unlike LPL, this enzyme also has activity against PLs; its phospholipase activity is considered at least as potent as that against TGs (McCoy et al., 2002). PLs and free cholesterol in the outer shell of VLDLs are also lost during the process of lipolysis to other LPs, particularly HDLs through the activity of plasma phospholipid transfer protein (PLTP) (van Tol, 2002). Plasma PLTP activity has been reported to be significantly greater in mice, dogs, and pigs compared with humans (among tested species), a factor that has been proposed to contribute to differences in serum lipid concentrations, and atherogenesis between these species (Guyard-Dangremont et al., 1998; van Haperen et al., 2009).

As VLDLs lose lipids, apoE proteins gain exposure enabling them to undergo some TG hydrolysis by hepatic lipase and engage with apoE receptors, LRP or LDL receptors for hepatic uptake,

or continue to be remodeled into IDLs. Notably, although apoB100 is also able to engage with the hepatic LDL receptor for particle uptake, the efficiency of this interaction is many times less than that of the apoE-LDL receptor, or -LRP, interactions; in addition, each LP carries only a single apoB100 protein, in contrast with multiple apoE proteins/particle.

21.5.7 INTERMEDIATE DENSITY LIPOPROTEINS

In general, IDLs are about half the diameter and contain about half as much TG, and twice as much cholesterol relative to particle weight as VLDLs. More simply, IDLs consist of roughly similar TG and cholesterol content by weight. These transient catabolic remnants are either ultimately taken up by the liver via similar hepatic receptor interactions as for VLDL, or undergo further hydrolysis with loss of apoE, and conversion to LDLs. In human, much of the IDL particles are converted to LDL. However, in rats and dogs, the majority of IDLs are cleared by the liver, a difference putatively attributable to lower apoB100 to apoB48 ratio in these species (Dupras et al., 1991; Gross et al., 1967).

21.5.8 LOW-DENSITY LIPOPROTEINS

Unlike IDL, VLDL, or chylomicron particles described above, LDLs consist largely of cholesterol, and lack associated apoE. Hepatic uptake of LDL is therefore dependent upon interactions of a single apoB100 per particle with the LDL receptor. Accordingly, LDLs show relatively slow clearance from circulation among the Apo-B containing LPs.

In circulation, and once formed from IDL, LDL are remodeled via exchange of lipids with other LPs. As with VLDL particles, PLs and free cholesterol in the outer shell of LDLs undergo transfer to HDL via PLTP activity (an effect thought to ultimately stimulate hepatic uptake of HDL cholesterol) (van Haperen et al., 2009). In some species, LDLs also lose residual TGs via shuttling these to HDL in exchange for CEs via the actions of CETP. Plasma CETP among tested species has been found to be inversely correlated with HDL cholesterol concentration, and with the ratio of HDL, relative to total serum cholesterol (Tsutsumi et al., 2001). Accordingly, this difference in plasma CETP activity significantly contributes to species differences in serum cholesterol profile, and associated susceptibility to atherogenic conditions. It is noteworthy that mice and rats appear to lack a functional CETP gene altogether (Hogarth et al., 2003).

Final clearance of LDL particles requires interaction between apoB100 and hepatocellular LDL receptors. Dependency on the LDL receptor for clearance is exemplified in human and animal models that have deficiency or dysfunction of the LDL receptor. Both conditions are characterized by very high serum LDL cholesterol and excess cholesterol deposition in tissues. In humans, the condition (familial hypercholesterolemia) has been found to be caused by a mutation in the genes encoding the low-density lipoprotein receptor (LDLR), apolipoprotein B (APOB), a protein required for clathrin-mediated hepatic LDL receptor internalization, or recently, a member of the proprotein convertase family, (i.e., PCSK9 [proprotein convertase subtilisin/kexin type 9]) that has a role in mediating LDL-receptor protein degradation (Maxwell and Breslow, 2005), and is currently considered a novel target of cholesterol-lowering therapeutics.

21.5.9 HIGH-DENSITY LIPOPROTEINS

HDLs are the smallest, most protein dense of the major LPs. These particles are 10–200-fold smaller than the diameter of chylomicrons, and particularly heterogenous among the LP types. Further classification of HDL is somewhat complex, with categories based on specific particle density, electrophoretic migration (single- or two-dimensional), size and/or apo content. There are animal species differences in HDL lipid and protein profiles, so that the relevance of more narrowly defined HDL properties/subclasses across species is not explicit or direct. However, the two major human HDL

classes, HDL₃ and HDL₂, show good correlation with HDL particles in laboratory species based on density and protein: lipid content (Edelstein et al., 1976; Haug and Høstmark, 1987). HDL₃ are nascent smaller, and more dense (and may be discoidal) particles that convert to larger, less dense, more spherical HDL₂ with LCAT-driven accumulation of CEs. Accordingly, HDL₃ consists of higher protein and less esterified cholesterol than the more spherical HDL₂. Both HDL₃ and HDL₂ contain predominantly apoA-1 as the apo component and lack detectable apoE.

A much more minor subtype, HDL₁, occurs in laboratory species with relative CETP deficiency in health (especially dog and pig), and humans with mutations resulting in CETP deficiency (Mori et al., 2011; Zak et al., 2002). A high cholesterol diet in these subjects can result increased circulating HDL₁ levels. HDL₁ are particularly rich in CE (as an outcome of reduced CETP-promoted CE exchange with other LPs), and also endowed with apoE, which can facilitate hepatic LP clearance. Another minor subtype, HDLc (cholesterol-enriched HDL-like particles), contains even greater concentrations of CEs than HDL₁, and almost exclusively apoE as the apo. HDLc LPs most often are found in human and animals with relative CETP deficiency and very high circulating cholesterol (e.g., >700 mg/dL or 18 mmol/L), such as dogs with hypothyroid conditions or high cholesterol feeding (Sloop et al., 1983; Wilson et al., 1986). Being highly enriched in CEs, these high apoE HDL₁ and HDLc particles are larger and lower in density than HDL₂ or HDL₃. Consistent with the reverse cholesterol transport function of apoE in facilitation of cholesterol efflux from macrophage foam cells and LP hepatic uptake (Table 21.2), formation of high apoE HDL₁ or HDLc may aid in limiting the relative risk of atherogenesis in these animals/subjects (Tietjen et al., 2012).

The majority of HDL particles originate with secretion by the liver or intestine of the major structural protein, apoA-I, as a proprotein (pro-apoA-I) in a lipid-poor particle (Gordon et al., 1982). These gradually acquire free cholesterol from cell membranes and apoB particles, and convert it to CEs via LCAT. With acquisition of CEs, pro-apoA-I is converted to the mature apoA-I, and lipid-poor pre- β HDL (based on surface charge with nondenaturing gel electrophoresis) becomes α HDL (HDL₃). These maturing HDL particles further acquire apoA-II and/or apoE in circulation. A minority of HDL particles also can form via intravascular metabolism of chylomicrons and hepatic VLDL; these begin as lipid-poor particles containing apoA-I or apoE, before acquiring sufficient CEs to be classified as α HDL (Zannis et al., 2008). All of these HDL particles lack apoB and generally contain a mixture of core CEs with outer shell of PLs, sphingomyelin, and free cholesterol.

ApoA-I is the major LP of HDL and serves as a cofactor for LCAT, enabling increased particle cholesterol-carrying capacity (as for chylomicrons discussed above). In lipid-poor HDL, apoA-I has the additional role of binding to the ABC subfamily A, member 1 (encoded by *ABCA1* gene) transporter of cells, including macrophages, to enable uptake of excess tissue cell cholesterol (Wróblewska, 2011). With this uptake, the lipid-poor HDL is converted to Pre- β -HDL, and with the action of LCAT, from thin discoid to spherical α -HDL. Pre- β -HDL and more mature α -HDL particles are capable of additional cholesterol uptake from cholesterol-laden peripheral tissue cells through facilitated diffusion mediated by the ABC subfamily G, member 1 (*ABCG1*) transporter, and the scavenger receptor class B type 1 (SR-B1) (Wang et al., 2004; Wróblewska, 2011). Discovery of these cellular HDL receptors/cholesterol transporters was an outcome of research in understanding the genetic basis for Tangier disease (TD). Patients with TD have a mutation of the *ABCA1* transporter gene and consequently, very low levels of circulating HDL and prominent cholesterol accumulation in cells (especially macrophages) with enlargement or discoloration of various organs (e.g., liver, spleen, lymph nodes) (Dechelotte et al., 1985; Kolovou et al., 2006).

The tissue distribution of these HDL receptors is broad, with redundant regulation of expression driven principally by intracellular cholesterol content. For *ABCA1* and *ABCG1* encoded transporters and possibly SR-B1, increased expression with increased cellular cholesterol is mediated by the LXR transcription pathway (Hu et al., 2010; Venkateswaran et al., 2000). For SR-B1, the receptor is distinct in being distributed especially in steroid hormone-producing tissues (e.g., adrenal gland, ovaries, testes, endometrium) with expression further regulated by systemic and tropic hormones,

and being functionally unique in directing cholesterol transport both out of and into cells, and binding with LDL and VLDL proteins (Landschulz et al., 1996; Li et al., 1998; Rigotti et al., 1996, 1997). Collectively, these findings suggest that apoA-I binding to SR-B1 is part of a mechanism ensuring appropriate cholesterol supply to steroidogenic cells for hormone synthesis, as well as regulating cholesterol metabolism overall.

The role of apoA-II, the second most common apo of HDL, has been less clearly defined. This is partly due to prominent species differences (without apparent phylogenetic basis) in occurrence, and the activity of the protein and the enzymes and regulators with which it interacts (Blanco-Vaca et al., 2001; Fournier et al., 2002; Hime et al., 2006; Wróblewska et al., 2010). For example, apoA-II is readily detected in the plasma of humans, nonhuman primates, rats, mice, and fish, whereas it is expressed at either very low levels or absent in dogs, pigs, rabbits, and chickens. In humans, rats, and mice, the protein is produced by the liver and to a minor extent by the intestine; however, the amino acid sequence and protein structure is profoundly different, and the expression in response to the same regulatory transcription factors (e.g., PPAR α) is contradictory between humans and these rodent species. Upregulating the murine apoA-II in mice is also associated with blood lipid findings distinct from those in transgenic mice expressing the human protein. Some of these functional species differences may also be due to dissimilar downstream enzymes that are regulated by apoA-II. Currently, the most scientifically supported proposals for the role of apoA-II is that it modifies interaction between apoA-I and LCAT, HDL and PLs (e.g., in cell membranes), and/or lipase-mediated degradation of HDLs. Collectively, the results of numerous studies suggest apoA-II does not facilitate, and may inhibit HDL-mediated cholesterol clearance from peripheral tissues. The multifaceted species differences in this apoA protein highlight the importance of considering such in interpreting blood lipid changes in general.

Several other apos that occur in human HDL, including apoE, apoC-I, C-II, and C-III, and apoA-IV and A-V are variably found in HDL of other species (Hollanders et al., 1986). The first five of these proteins are also associated, as described above, with chylomicrons and/or VLDLs; although, their expression and function(s) may have more or less of a prominent role with HDLs. The last of these, apoA-V is a recently discovered apo also found in chylomicrons and VLDLs, and purported to serve as regulator of LPL (affecting TG turnover in these LPs) (Ebara et al., 2010; Vaessen et al., 2009).

21.5.10 HDLs AND REVERSE CHOLESTEROL TRANSPORT

HDL particles have a pivotal role in cholesterol metabolism by facilitating efflux of the lipid from peripheral tissue cells and ultimate delivery to the liver and biliary excretion. This process is credited with preventing accumulation of intracellular cholesterol from tissue cells, which can be cytotoxic and atherogenic. The process is termed reverse cholesterol transport (RCT) as it is considered a reversal of the effects cholesterol delivery to peripheral tissues via apoB LPs, especially LDL and VLDL. Much of the current research in RCT is focused on (1) the interaction of HDL apoA-I with peripheral tissue *ABCA1* and *ABCG1* encoded transporters, and the SR-B1 receptor enabling selective CE uptake; (2) HDL (and LDL) interactions with liver receptors important in whole particle clearance; (3) LCAT activity on HDL that enables increased quantity of cholesterol to be retrieved and transported per particle; and (4) HDL transfer of CEs to LDL and other particles through CETP.

Selective hepatocyte uptake of cholesterol from mature (cholesterol- and PL-rich) α HDL is considered the predominant means of RCT. This selective uptake is achieved primarily via interaction of apoA-I with specific receptors (e.g., SR-B1) (Trigatti et al., 2003). Notably, dogs have shown particularly prominent selective hepatic uptake of cholesterol from HDL (about twofold greater than even rats and mice) attributed to high activities of SR-B1 and LCAT and leading to very efficient RCT (Ouguerram et al., 2004). The remodeling of the HDL particle by this selective cholesterol uptake, as well as by hepatic and endothelial lipase and PLTP, results in a regeneration of lipid-poor HDL particles being returned to circulation.

Removal of cholesterol-rich whole HDL particles by the liver is another mechanism of RCT that can occur with HDL subtypes rich in apoE (HDL1 and especially HDLc). Clearance of these particles is mediated through interaction of apoE, as ligand for the LDL receptor or LRP on hepatocytes.

Transfer of cholesterol from HDL to LDL and other apoB particles, with subsequent clearance or degradation of the recipient particle by the liver is a third mechanism of RCT. As noted above, transfer of cholesterol (as CEs) to apoB particles is primarily catalyzed by CETP in exchange for TGs. The cholesterol in these recipient particles may then be delivered to the liver. However, the more common fate of the transferred cholesterol is delivery back to tissue cells, consistent with the dominant role of apoB particles in delivering lipids to peripheral tissue cells, and the converse of RCT. This reinforces the important difference in CETP activity between humans and common laboratory species (e.g., mice, rats, or dogs) (Groot et al., 2005). In the latter, the absence of significant plasma CETP activity results in HDL cholesterol captured from peripheral tissue to be delivered to the liver more consistently by the same particle, whereas in humans, CETP enables ready transfer of HDL CEs to other LPs. The influence of CETP on RCT has made it a target for antiatherogenic pharmaceutical development (De Grooth et al., 2004).

21.5.11 LIPOPROTEIN(A)

Lipoprotein(a) [Lp(a)] is a particle that resembles LDL with an added apo(a) protein, synthesized by the liver and covalently attached to apoB100 via a single disulfide bond. The particle occurs in human and Old World monkeys (including macaques) and has also been detected in marmosets (Guo et al., 1991; Makino et al., 1989; Lawn, 1996), and has been associated a wide variety of human atherosclerotic conditions through epidemiological studies. Studies with evaluation of Lp(a) in transgenic mice and rabbits have also been reported; however, interpretation of results is confounded by the fact that the particle is not found in the wild-type animals. The hedgehog has an apo(a)-like protein that has evolved independently and is genetically distinct, with a distinct “Kringle” domain structure, characterized by large folded loops stabilized by three disulfide linkages (Lawn et al., 1995).

Numerous isoforms of Lp(a) are found in the plasma of human and Old world monkeys and their presence and concentration appear to be largely genetically determined (Boerwinkle et al., 1990; Taddei-Peters et al., 1993; Koschinsky, 2004). Isoforms differ in the number of repeated molecular “Kringle” units, which have also been shown to variably bind to biological substrates, including plasminogen and fibrinogen/fibrin and fibronectin. These binding properties contribute to proposals that Lp(a) is linked with vascular disease via inhibition of fibrinolysis, aortic smooth muscle cell proliferation, and oxidation of PL and LDL within atherosclerotic lesions. The absolute and relative concentration of different isoforms in plasma have shown better correlation with common human vascular diseases than nonspecific total Lp(a). Notably, commercial assays are nonstandardized and may vary in cross-reactivity to the nonhuman primate antigen.

21.5.12 NON-ESTERIFIED FATTY ACIDS (NEFAs) IN BLOOD—TRANSPORT AND CLEARANCE

In contrast with LPs, NEFAs are transported in blood as single hydrophobic carbon chains bound to a carrier molecule, primarily albumin. The plasma/serum concentration of NEFA is often a reflection of the extent of peripheral hydrolysis of TG-rich LPs (chylomicrons or VLDL). During hydrolysis, a portion of the resulting NEFAs are refluxed into surrounding capillary blood. This accounts for the rise in circulating NEFAs in the early postprandial state, and pathologic and physiologic states of hypertriglyceridemia. The other source of circulating NEFAs is attributable to intracellular TG lipolysis of regional depots of white adipose (and to a much lesser extent, intracellular lipids of muscle and glandular tissue). Prominent increases in circulating NEFAs from tissue lipolysis can occur with food restriction/anorexia, insulin deficiency or resistance, or excess β -adrenergic or thyroid hormone activity (Section 21.9) (Haude and Völcker, 1991; Horowitz, 2003).

Blood transport of NEFAs by albumin is efficient; a single albumin molecule can bind multiple NEFAs, with affinity and clearance correlated with chain length and saturation (Choi et al., 2002). However, NEFAs comprise only a minor fraction of total circulating lipids even in states of amplified lipolysis. There is little evidence that physiologic ranges of circulating NEFAs can significantly displace other albumin-bound (endogenous or exogenously administered) components, or that albumin-binding sites can reach saturation (Monks and Richens, 1979). The circulating half-life of individual NEFAs is generally very brief due to rapid tissue uptake, and accordingly, total blood NEFA concentration tends to be highly dynamic (Dole and Rizack, 1961).

21.6 PERIPHERAL TISSUE LIPID UPTAKE

Peripheral tissue uptake of circulating long-chain NEFAs from albumin, and TG-rich LPs (generated via endothelial LPL lipolysis) is considered to occur primarily through facilitated transport by specific membrane-associated, and cytoplasmic fatty acid transport proteins (FATPs), FABPs and fatty acid translocases (e.g., CD36/FATs) (Berk et al., 1994; Pownall and Hamilton, 2003). These proteins vary in type and distribution among tissues, depending partly on energy and hormonal state and circulating NEFA supply (Berk and Stump, 1999; Nickerson et al., 2009). Some FATPs and FATs may be regulated by physiologic factors to channel FAs toward esterification or oxidation (Consitt et al., 2009; Pohl et al., 2004). Despite such regulation, NEFA transport into tissue cells does not appear to be particularly rate limiting for clearance from blood; downstream metabolism is more likely limiting in tissue turnover of NEFA. Some NEFA uptake is also believed to occur by diffusive pathways.

Peripheral tissue cell uptake of cholesterol from circulating LPs has been most completely studied with steroid producing cells and adipocytes. Notably, pathways of such by these cells are likely more robust, with some differential aspects compared to other tissue cells. Cells of the adrenal, ovary, and other steroid-producing tissues have been shown to acquire cholesterol via the LDL receptor with endocytosis of ligand (apoB or apoE)-presenting LPs; albeit preferential uptake of LDL, over the other apoB LPs has been shown (Hu et al., 2010; Tsibulsky and Yakushkin, 1997). LDL receptor expression, and its regulation by fasting, has also been demonstrated on adipocytes (Kraemer et al., 1994). Conversely, uptake of HDL cholesterol by peripheral tissues occurs via the scavenger receptor class B type 1 (SR-B1) receptor (as noted above for hepatocytes) with selective removal of cholesterol and recycling of lipid-poor apoA-I HDL back into circulation (Reaven et al., 2004). The extent of reliance of steroid-producing cells on either LDL or HDL cholesterol for steroidogenesis appears to be species-dependent; that is, in rodents, steroid-producing cells preferentially utilize the SR-B1 pathway, while in humans, pigs, and cattle, these cells primarily utilize the LDL-receptor endocytic pathway for exogenous cholesterol supply. In adipocytes, there is also evidence of an SR-B1-independent mechanism that involves interaction of HDL apoE and the LRP receptor (Fazio and Linton, 2004).

Peripheral tissue uptake of PLs occurs by phospholipase hydrolysis to NEFAs and limited direct uptake of intact anionic (e.g., inner cell membrane) PLs via the SR-B1 and CD36 receptors (Rigotti et al., 1995; Ryeom et al., 1996).

21.7 INTRACELLULAR LIPID METABOLISM

Within tissue cells, FAs and cholesterol are generally esterified and may be (1) utilized for synthesis of more complex lipids, (2) released back into the blood, or (3) catabolized. Catabolism of FAs for energy occurs via oxidation in most cells of the body with metabolites entering into the Krebs cycle. Alternatively, FAs may be catabolized via ketogenesis to ketone bodies; a process essentially limited to hepatocytes. Catabolism of cholesterol is usually considered to involve the steps toward excretion into bile. These metabolic pathways are briefly described below.

21.7.1 FATTY ACID OXIDATION

Fatty-acid degradation in the cell can occur by α -, β -, and ω -oxidation pathways, which take place in mitochondria, peroxisomes, and the ER. The major catabolic pathway is via β -oxidation in mitochondria, with α -, and ω -oxidation being far more minor routes. These processes rely on a multitude of enzymes and specific transport proteins. Deficiencies and impairment of these proteins can occur with familial disorders, chemical/drug toxicity, infectious diseases, and the cytokines of inflammation. Clinical deficiencies or impairment of some of the proteins shows a wide variety of symptoms that tend to be individualistic in their pattern (Moczulski et al., 2009). Because striated muscle and liver have especially high capacity for FA oxidation, these tissues tend to be particularly affected with such conditions. Some classic symptoms of impaired FA oxidation include skeletal muscle hypotonia, rhabdomyolysis, cardiomyopathy, cardiac arrhythmia, hypoketotic or ketotic hypoglycemia, metabolic acidosis, hyperammonemia, hepatic steatosis, and/or liver failure. Some marketed drugs (including aspirin, valproate, amiodarone, perhexiline, and tetracyclines) have been directly linked with impaired FA oxidation and associated clinical symptoms (Fréneaux et al., 1988; Fromenty and Pessayre, 1995; Silva et al., 2008; Spaniol et al., 2001; Vázquez et al., 2014; Ashrafian et al., 2007). Accordingly, understanding of lipid oxidative processes is important in interpretation of the collective laboratory data associated with such conditions.

21.7.1.1 β -Oxidation in Mitochondria

FAs undergo β -oxidation in mitochondria of most of the cells of the body (with known exceptions being erythrocytes and cells of the brain and adrenal medulla). The process enables straight chain FAs to be incorporated into the citric acid cycle for energy.

To enter the β -oxidation pathway, the carboxyl terminus of FAs must first be esterified to CoA in an ATP-dependent process. The acyl-CoA synthetases that catalyze this reaction are found in the cytosol, and within mitochondria, ER, and peroxisomes or their membranes, with most of these enzymes having specificity as to FA chain length (Watkins et al., 2007). Short- and medium-chain FA-CoAs may then diffuse into the mitochondria, while long-chain FAs (>16 carbons) require the acyl-CoA terminus to be esterified with carnitine for translocation (as acylcarnitine) across outer and inner mitochondrial membranes. This esterification occurs via a critical rate-limiting outer mitochondrial membrane enzyme, carnitine palmitoyltransferase (CPT) 1, and is followed by regeneration of the fatty acyl-CoA and free carnitine via the inner mitochondrial membrane enzyme, CPT 2 (also known as carnitine acyltransferase II) (Bonfont et al., 2004). At the mitochondrial inner membrane or within the matrix (depending on chain length), the first step in β -oxidation of transferring electrons from the α - and β -carbon to the flavin cofactor occurs with generation of a C–C double bond. The electrons are, in turn, transferred to the electron transport chain with the production of ATP, and the double bond is hydrated with subsequent cleavage of a two-carbon molecule from the fatty acyl-CoA. The electron transfer is catalyzed by various dehydrogenases that are, again, specific for the FA chain length. Sequential cleavage of the FA chain then occurs with each two-carbon moiety combining with oxaloacetate in the Krebs cycle to form citrate. For those uncommon (diet-derived) odd-numbered FAs, the final three-carbon propionyl-CoA is reduced to succinyl-CoA, for entrance into a different step in the Krebs cycle. Unsaturated FAs require an additional step or two for isomerization at the double bond.

Lipid disorders attributed to deficiency of CPT 1, CPT 2, and mitochondrial medium-chain, long-chain, and very-long-chain acyl-CoA dehydrogenases are recognized in human. Several mouse models have been produced to study various defects in the FA oxidation pathway (Spiekerkoetter and Wood, 2010). Affected proteins (e.g., CPT 1) may have tissue-specific isoforms with differential regulation that help explain some of the varied clinical conditions associated with deficiency or inhibition (Eaton et al., 1996). Specific chemical/drug toxicity that results in impairment of β -oxidation are usually attributed to uncoupling of the electron transport system, mimicry of FA substrates, or inhibition of pathway enzymes or transporters, or their mitochondrial DNA transcription.

21.7.1.2 β -Oxidation in Peroxisomes

While mitochondria are the organelle responsible for the majority of FA oxidation within cells, peroxisomes are also capable of β -oxidation of long-chain and very-long-chain FAs. Fatty-acyl CoAs can diffuse across the peroxisomal membrane without involvement of carnitine, and where acyl-CoA oxidase transfers the electrons to oxygen, yielding hydrogen peroxide rather than ATP. Cleavage of the carbon chain in two-carbon sections is otherwise largely analogous to that described earlier, with production of a shortened fatty acyl (typically C9–C11) that is then exported to mitochondria for further β -oxidation. Peroxisomal β -oxidation also occurs for some unsaturated, branched, and ether FAs, eicosanoids, and bile acid intermediates.

Of note, these β -oxidation pathways, particularly those for long-chain FA oxidation in peroxisomes can be transcriptionally regulated and inducible by PPAR α , and in rodents by the liver X receptor α (LXR α) (Van Veldhoven and Mannaerts, 1999; Braissant et al., 1996; Winegar et al., 2001; Hu et al., 2005) (see Section 21.12).

21.7.1.3 α -Oxidation

Alpha-oxidation is a minor process of FA catabolism by which certain dietary FAs branched at a β -carbon (e.g., phytanic acid in dairy products) cannot initially undergo β -oxidation in mitochondria, and are first catabolized in peroxisomes. Alpha-oxidation involves removal of the branched terminus of formyl-CoA, converting the new terminal carbon to an aldehyde, and then a carboxyl group for esterification with CoA and subsequent β -oxidation (Wierzbicki, 2007). The regulation of this process in peroxisomes is tissue and species variable (Singh et al., 1993).

21.7.1.4 ω -Oxidation

Omega oxidation is another minor pathway of FA oxidization. This pathway occurs almost exclusively in smooth ER, and involves (ω -1)-hydroxylation of medium- and long-chain FAs catalyzed by selected members of the cytochrome P450 (CYP) 4A enzyme family (Norlin and Wikvall, 2007). Hydroxylation is uniquely initiated at the carbon end opposite to the carboxyl group (Reddy and Hashimoto, 2001). The ω -hydroxy FA produced is ultimately converted into a substrate for β -oxidation. This becomes an alternative pathway of clinical significance in inherited mitochondrial FA β -oxidation deficiencies because of the generation of potentially toxic dicarboxylic acids.

21.7.1.5 Ketogenesis

FA ketogenesis occurs in hepatocyte mitochondria as a consequence of impaired cellular glucose utilization (e.g., hypoglycemia, insulin resistance), excessive energy demand (e.g., with illness, pregnancy), or excessive peripheral FA mobilization with delivery to the liver. Ketogenesis also occurs at a low rate under normal physiological conditions, and increases as an appropriate adaptive physiological response to glucose shortages (e.g., starvation, prolonged fasting).

In conditions of excessive FA delivery to the liver, the acetyl-CoA produced by mitochondrial β -oxidation may not readily enter the Krebs cycle due to substrate competition (for oxaloacetate). Instead, acetyl-CoA undergoes condensation to ketone bodies, which can serve as oxidizable fuels for extrahepatic tissues. In conditions of poor cellular glucose utilization, the decreased Krebs cycle flux limits the supply of oxaloacetate as substrate. With all of these conditions, ketone production provides an alternate energy source to carbohydrates primarily for the brain, heart, renal cortex, and skeletal muscle as an adaptive response for the survival of the organism (Laffel, 1999).

Three major ketone bodies are produced in liver mitochondria: acetoacetate, acetone, and 3- β -hydroxybutyrate (β -OHB). Their formation is initiated essentially as a reversal of the chain cleavage of β -oxidation, with condensation of two acetyl-CoAs to generate acetoacetyl-CoA. Addition of a third acetyl-CoA generates 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) via action of mitochondrial HMG-CoA synthase (an isozyme encoded by a distinct gene from that of cytosolic HMG-CoA synthase, Section 21.3). This product is then enzymatically degraded to acetoacetate

and acetyl-CoA. Acetoacetate, if not oxidized to usable energy, is converted to β -OHB in another catalyzed reaction, or it degrades spontaneously to acetone. Acetoacetate and especially β -OHB released by the liver can be converted in peripheral tissues back to acetoacetyl-CoA for incorporation into the β -oxidation pathway. (The liver lacks the enzyme necessary to generate acetoacetyl-CoA, thus facilitating ketone body export to other tissues.) Hence, the ratio of circulating β -OHB to acetoacetate increases with progression of ketosis and shifts back with resolving severity of the condition. Accordingly, β -OHB is the predominant blood ketone with significant ketosis in mammals (Dedkova and Blatter, 2014). Ketoacidosis occurs if these ketone acids (H^+) exceed the buffering capacity of bicarbonate.

The shift toward utilization of ketones as energy is somewhat tissue-dependent, and there are also age and species differences in tendency toward upregulation of ketogenic pathways (Hegardt, 1999; Spiekerkoetter and Wood, 2010; Thumelin et al., 1993). Ketogenesis is further subjected to hormonal influences (e.g., insulin, glucagon) and more long-term to nuclear-receptor-responsive elements of ketogenic enzymes. For example, expression of the rate-limiting enzyme, mitochondrial HMG-CoA synthase has been found to be regulated by PPAR α , and the enzyme protein has been shown to translocate to the nucleus and potentiate PPAR α -dependent activation of its own synthase gene promoter (Meertens et al., 1998). Ketone body production has additionally been reported to occur at low level in the neonatal kidney, intestine, and brain, and a few adult nonhepatic tissues (Hegardt, 1999; Thumelin et al., 1993).

21.8 CHOLESTEROL EXCRETION

Unlike FAs, mammals are not capable of catabolizing cholesterol intracellularly; rather, hepatic excretion into bile is the primary route of cholesterol elimination. Biliary excretion of cholesterol is in the form of bile acids and to a minor extent as free cholesterol. Bile acids are formed through modifying cholesterol to a more planar amphipathic molecule with distinct hydrophobic and hydrophilic surfaces that enable mixed-lipid micelle formation when secreted in the intestinal tract. Hence, bile acid formation serves to both protect against excess systemic cholesterol accumulation, as well as enable dietary lipid absorption, and other established functions (e.g., aid intestinal motility and limit bacterial growth in the small intestine and biliary tract). Bile acids further serve as ligands that signal through nuclear receptors and other transcription factors to regulate bile acid synthesis and transport, and other aspects of hepatic lipid metabolism.

Synthesis *de novo* of bile acids from cholesterol occurs predominantly in pericentral hepatocytes in health (Twisk et al., 1995) and involves multiple intracellular compartments, namely cytosol, ER, mitochondria, and peroxisomes, and numerous enzymatic steps with several alternative pathways. A review of these steps, and major species differences can be found in Chiang (2013), Lundell and Wikvall (2008), Norlin and Wikvall (2007), and Russell (2003). In all pathways, cholesterol requires three main modifications: (1) hydroxylation, (2) ring modification to eliminate the double bond, and (3) oxidation and shortening of the side chain. These steps vary in order among the different pathways. The two main pathways are the classical or “neutral,” and “acidic,” with the major primary bile acids synthesized via these pathways being cholic acid and chenodeoxycholic acid, respectively (Russell, 2003). Cholic acid is trihydroxylated and the more hydrophilic (and pH neutral), whereas chenodeoxycholic is dihydroxylated (i.e., “deoxy” terminology is relative to cholic acid) and the more hydrophobic (and acidic, with greater detergent properties). These primary bile acids can undergo further reactions to alter their properties; however, the ultimate ratio of hydrophilic to hydrophobic bile acids secreted in bile is critical to regulation of their synthesis and transport, as well as other aspects of systemic cholesterol metabolism.

Bile acid synthesis from cholesterol through the classical pathway initiates in the ER by the rate-limiting P450 cytochrome, cholesterol 7 α -hydroxylase (CYP7A1), which drives the first required cholesterol modification, hydroxylation of cholesterol. Subsequent ring modification occurs via

the microsomal enzyme required for synthesis of all bile acids: 3β -hydroxy-27-steroid dehydrogenase/isomerase (HSD3B7 or 3β -HSD). The intermediate formed by this latter enzyme in the classical pathway is “C4” (7α -hydroxy-4-cholestern-3-one), which also serves as a blood biomarker of CYP7A1 activity in human and animals (Chiang, 2013; Gälman et al., 2003). Another important downstream enzyme is sterol 12- α -hydroxylase (CYP8B1), the activity of which directs synthesis to cholic acid and essentially determines the ratio between cholic and chenodeoxycholic acid via the classical pathway. The alternative “acidic” pathway for bile acid synthesis is minor in humans, but significant in rats and mice (and human neonates) (Norlin and Wikvall, 2007; Repa et al., 2000; Vlahcevic et al., 1997). This pathway initiates with side-chain hydroxylation by the mitochondrial enzyme, sterol 27-hydroxylase or CYP27A1 resulting in an oxysterol that can then be hydroxylated by oxysterol 7α -hydroxylase (CYP7B1) with subsequent steps forming chenodeoxycholic acid. Chenodeoxycholic acid synthesized through either pathway can be further converted to more hydrophilic trihydroxylated muricholic acids and to additional dihydroxylated acids (e.g., hyocholic acid in pig). This further conversion of chenodeoxycholic acid is rapid and efficient in the mouse and rat (to muricholic acids) and occurs in some types of hepatobiliary disease but is otherwise negligible in humans and most other laboratory species (García-Cañaveras et al., 2012; Ellis et al., 1998; Hagey et al., 1998; Lundell and Wikvall, 2008; Russell, 2003). Additional alternative synthesis pathways that result in the conversion of cholesterol to an oxysterol intermediate can initiate extrahepatically (including in macrophages and cholangiocytes, brain, and lung). However, only the liver possesses the full enzyme complement to complete all molecular modifications of cholesterol for bile acid synthesis (Chiang, 2009, 2013; Xia et al., 2012; Russell, 2003).

Prior to secretion into hepatic canaliculi, the majority of bile acids are conjugated to taurine or glycine in peroxisomes. Conjugation converts bile acids to bile salts, decreasing cytotoxicity, and increasing their amphipathicity and solubility. As with bile acid constituents, there are species differences in conjugation. For example, conjugation is to taurine only in the dog and cat, predominantly taurine in rat, mouse, macaque, and squirrel monkey, predominantly glycine in rabbit and pig, and a variable mixture of glycine and taurine (diet-influenced) in human (García-Cañaveras et al., 2012; Lehman-McKeeman, 2013; Li and Chiang, 2013; Schwenk et al., 1978). Particularly, hydrophobic bile acids may also be conjugated to sulfate or glucuronidated by uridine diphosphate (UDP)-glucuronosyl N-transferases (with some species differences). Differences in whether taurine or glycine is the conjugated amino acid can affect the rate of active transport of a bile salt into canaliculi and enterocyte and hepatocyte uptake, as well as micelle structure (Hofmann and Mysels, 1992). However, these distinctions have less regulatory consequences on lipid metabolism than the overall ratio of conjugated to unconjugated bile acids (Ballatori et al., 2005; Carey et al., 1981; Parks et al., 1999; Russell, 2003; Van Der Meer and De Vries, 1985; Chiang, 2009; Solaas et al., 2004).

Conjugated bile salts are exported across the canalicular membrane by active transport (e.g., particularly by the bile salt export pump [BSEP]). Free cholesterol and other neutral sterols are transported out of hepatocytes into the canaliculi via liver ABC transporters, subfamily G, members 5 and 8 (encoded by *ABCG5* and *ABCG8* genes, the same sterolin-1 and sterolin-2 transporters that limit intestinal sterol absorption [Section 21.3, 21.4]). Free cholesterol transport into bile also depends upon an ABC transporter, multidrug resistance protein 3 (MDR3) in human (*Mdr2* in mice, or PL flipase) for the transport of PLs into bile. As with bile acid constituents, there are some significant species differences in the role and/or regulation of bile acid and free cholesterol transporters in bile secretion. For example, human BSEP shows bile acid substrate differences compared with the rat homolog (*Bsep*), and functional differences between human and mouse are indicated by the finding that human BSEP deficiency results in severe liver disease with intrahepatic cholestasis, whereas *Bsep*-knockout mice develop only a mild form of cholestasis (reviewed in Stieger, 2009). Function and regulation of these transporters is still under concerted investigation.

Cholesterol excretion in bile is dependent not only on formation and ratio of bile salts and bile acids with PLs but also on the rate of bile flow. Bile flow is dependent upon the constituency and

concentration of bile salts and acids (and their individual choleric properties), as well as proportion of cholangiocyte secreted water and bicarbonate and osmotically active substances such as glutathione and glutathione conjugates (Kubegov and Karpen, 2008). Cholangiocyte stimulation and choleresis is also influenced by gastrointestinal-associated hormones, such as cholecystokinin, secretin, bombesin, vasoactive intestinal polypeptide, and gastrin. In addition, bile concentration with water resorption occurs in the gall bladder in species that possess such. These collective factors contribute to the broad species differences in bile flow, including the significantly greater water content and relative bile flow in rat compared with other common laboratory species and human (Boyer, 2013). Bile that reaches the duodenum facilitates dietary lipid absorption throughout the small intestine. Unresorbed bile salts that reach anaerobic and facultative bacteria (mainly in the large intestine) can be deconjugated and oxidized converting them to secondary bile acids such as deoxycholic, lithocholic, and ursodeoxycholic acid (and murideoxycholic, hyodeoxycholic, and/or 7-oxolithocholic acid with some laboratory species) (Kasbo et al., 2002; Penno et al., 2013). Review of the factors involved in bile flow and enterohepatic circulation can be found in a number of current references (e.g., Chiang, 2013; Kubegov and Karpen, 2008; Steiger, 2011).

Excretion of cholesterol in bile is tightly regulated to support systemic cholesterol homeostasis and adequate intestinal lipid emulsification, as well as preclude bile acid-linked toxicity. This regulation is largely mediated by bile acid signaling through receptors that control the enzymes and transporters in the synthesis pathways. Distinctions in bile acid composition reaching enterocytes and returning to hepatocytes provide important feedback for regulation. Among the most well-established aspects of this signaling is that bile acids (particularly, the unconjugated hydrophobic bile acids, chenodeoxycholic, and lithocholic acids) are natural activating ligands for the nuclear receptor farnesoid X receptor α (FXR α). Expression of FXR α isoforms are found particularly in high concentration in the small intestine and liver (Zhang et al., 2003; Zhu et al., 2011). Accordingly, activation of small intestinal FXR α induces enterocyte release of fibroblast growth factor (FGF)19 (or FGF15 ortholog in mouse and rat) into portal blood, and upon reaching hepatocyte sinusoidal membrane receptors, signals downregulation of gene expression for key enzymes in bile acid synthesis, particularly CYP7A1 (reviewed in Chiang, 2013; Jones et al., 2012). Concomitantly, activation of liver FXR α independently induces the transcription factor, SHP ("small heterodimer partner"), which interacts with other proteins to repress transcription of CYP8B1, the key enzyme in regulating bile acid hydrophobicity (and to a lesser extent—at least in murine models, of CYP7A1) (Kong et al., 2012; Gardès et al., 2013). Intestinal and liver FXR α activation also induces transcription of genes that promotes bile acid conjugation and efflux from hepatocytes and enterocytes through transporter proteins, including upregulation of BSEP and MDR3 (for cholesterol) and terminal ileal organic solute transporter alpha and beta (OST α and OST β , active in transporting bile acids from enterocytes into portal blood) (Ballatori et al., 2005; reviewed in Chiang, 2013; Zhu et al., 2011). Hepatic FXR α activation further downregulates hepatocellular uptake of recirculated conjugated bile acids. Collectively, these effects mediated through intestinal FXR α enable negative feedback for regulation of bile acid synthesis and resorption, and those mediated by hepatocellular FXR α activation are critical for protection of the liver from excessive exposure to cytotoxic hydrophobic bile acids such as with intrahepatic cholestasis. In support of these differential intestinal- and liver-specific FXR α functions, administration bile acids (taurocholate) into the duodenum of rats is more effective in suppressing hepatic CYP7A1 than with intravenous bile acid administration (Nagano et al., 2004). In contrast, intrahepatic cholestasis is associated with greater susceptibility to hepatotoxicity in FXR-null compared with wild-type mice (Cui et al., 2009; Shi et al., 2010). (Conversely, animals with extrahepatic cholestasis may be more susceptible to hepatotoxicity, in association with the increased FXR α activity due to the induced increased bile acid efflux (Stedman et al., 2006). Of added consideration pertaining to FXR α regulation, the hydrophilic muricholic acids that form a major portion of bile in mice (and a significant component in rat) inhibit FXR α activation in opposition of the effects of hydrophobic bile acids on the nuclear receptor (Botham and Boyd, 1983; Hu et al., 2014); a finding that may

explain some of the prominent *in vivo* species differences in lipid profile response to bile acid feeding and cholestasis.

Bile acids have additional important regulatory roles on systemic lipid metabolism and blood lipid profiles that are both dependent and independent of FXR α activation. Well established is that hydrophobic bile acid feeding decreases blood TG and liver VLDL, whereas reduction in recirculating bile acids through oral administration of bile acid-binding resins conversely increases circulating TG. These effects are considered at least partly FXR α -mediated, as FXR $^{-/-}$ mice have increased concentration of blood and liver TG, and FXR agonists decrease blood TG in mice. Studies have supported the mechanism for these findings to be linked with FXR/SHP inhibited transcription of the SREBP-1c, which promotes hepatic lipogenesis, and MTP, which enables hepatic VLDL efflux from the liver (Watanabe et al., 2004; Hirokane et al., 2004). In addition, FXR activation induces apoCII and inhibits apoCIII expression, which collectively promotes LPL activity and hence, tissue catabolism of circulating TG-rich LPs such as VLDL (Kast et al., 2001; Pineda Torra et al., 2003). FXR-mediated inhibition of apolipoprotein A-I (apoAI) and induction CETP expression are further associated with decreased blood HDL cholesterol levels (Gautier et al., 2013). Other reported effects of FXR that impact blood cholesterol include positive regulation of gene expression for PLTP, which facilitates transfer of PLs and cholesterol from other LPs to HDL, and negative regulation of hepatic lipase (HL), thereby decreasing hepatocyte TG and PL uptake from LDL and HDL (Urizar et al., 2000; Sirvent et al., 2004). These enzyme alterations collectively support increased LDL and HDL lipid accumulation and particle size. Conversely, studies have also shown that an increased bile acid pool promotes HDL lipid loss through upregulation of the scavenger lipid receptors SR-B1 and CD36, which enhance hepatic and adrenal uptake of cholesterol and PL from the LP (Gardès et al., 2013 and associated references; Li et al., 2012; Malerød et al., 2005; reviewed in Stanimirov et al., 2012). Overall, the effects of FXR activation and/or an increased bile acid pool on blood cholesterol have tended to result in decreased HDL and increased LDL cholesterol, although these changes seem dissociated from atherogenic effects (reviewed in Mazuy et al., 2015; Mudaliar et al., 2013; Hartman et al., 2009). Highly hydrophobic bile acids (e.g., lithocholic acid) can additionally affect blood lipid metabolism through activation of other important nuclear hormone transcription factors: pregnane X receptor (PXR) and vitamin D receptor (VDR) (Adachi et al., 2005; Wistuba et al., 2007; Khan et al., 2011).

One of the most remarkable differences between species in biliary cholesterol excretion associated with nuclear hormone receptor activation is that between both rats and mice and other common laboratory species (and humans) in response to a cholesterol-rich diet. In human and most other laboratory species, a high cholesterol diet expands the total pool of hydrophobic bile acids, which are natural ligands for activating FXR, triggering downregulation of CYP7A1 (and bile acid synthesis through the classical pathway). FXR activation in these species can also lead to increased liver and blood cholesterol concentration (Horton et al., 1995; Nguyen et al., 1999; Rudel et al., 1994; Xu et al., 2004) through some of the mechanisms mentioned previously. In contrast, mice and especially rats are resistant to increased hepatic synthesis of cholesterol-rich LPs and blood cholesterol due in part to high baseline and responsive induction of CYP7A1 through LXR activation (see Section 21.12.4) and lack of induction of FXR with cholesterol feeding (Xu et al., 2004). The activation of LXR is linked with increased formation of natural ligands, oxysterols that are formed through the alternative cholesterol metabolism pathways, while the lack of FXR activation in rats and mice is attributed to the significant formation of hydrophilic muricholic bile acids from cholesterol through the alternative pathways and which do not serve as FXR ligands. Hence, this important species difference is largely due to the distinctions in dominant bile acid synthesis pathways.

Other well-established factors that can affect cholesterol excretion through effects on key regulatory enzymes in bile acid synthesis include fasting/fed state, circadian cycles, hormones (e.g., estrogen, androgens, glucocorticoids, thyroid hormones, insulin, and glucagon) as well as inflammatory cytokines and disease pathology. These effects are generally described in other sections of this chapter.

21.9 PHYSIOLOGICAL ALTERATIONS IN BLOOD LIPIDS

21.9.1 CIRCADIAN RHYTHM

Circadian rhythms of serum lipids and apos have been long-studied in humans and some animal species, both with and without fasting. Diurnal rhythms in rats have been reported for total serum TGs and cholesterol, as well as VLDL, IDL/LDL, and HDL lipid concentrations (Ahlers et al., 1980; Cayen et al., 1972; de Gasquet et al., 1977; Kalopissis et al., 1979; Marrino et al., 1987; Mondola et al., 1995). The lipid changes in these studies follow circadian rhythms of endogenous neurohormonal factors, especially insulin (Benavides et al., 1998; reviewed in Gnocchi et al., 2015). The pattern in fed rats typically shows a nadir in circulating NEFA, TG, and TG-rich LPs in the very early dark phase (corresponding with the early post prandial period) followed by increasing blood concentrations of these lipids during the later dark and early light phase (de Gasquet et al., 1977; Marrino et al., 1987). These early postprandial lipid decreases (which may be missed with less frequent evaluations) are linked with a rise in glucose and insulin with feeding and consequential inhibition of adipose secretion on NEFA and hepatic release of VLDL. Late in the postprandial phase, insulin-stimulated adipose LPL activity and increasing chylomicron catabolism lead to the increasing blood NEFA and TG (largely associated with increasing VLDL) levels. Total cholesterol changes tend to be less pronounced and more variable in this timeframe, with the upswing in HDL cholesterol from a nadir occurring at similar or slightly earlier intervals than for LDL cholesterol in the postprandial period, and with ApoB LPs also being a significant source of total cholesterol (Deshaies et al., 1990; Mondola et al., 1995; Miettinen, 1982; Rivera-Coll et al., 1994). This sequential pattern of changes in blood NEFA, TG, cholesterol, and associated LPs linked with postprandial periods are generally similar across species with adjustment of the diurnal periods and meal timing, that is, TG and NEFA nadir in the early light period, and peak values in the very late light to early dark phase in human and other diurnal species (Bertolucci et al., 2008; Miettinen, 1982; Karpe et al., 1998; Ishioka et al., 2005; van Oostrom et al., 2000).

However, the diurnal rhythms of blood lipids are not only substrate-driven but also more broadly regulated by complex molecular organization surrounding an organism's central circadian clock. Indeed, alterations in these normal lipid cycles are generally in magnitude and only incremental in time with short-term fasting or dietary changes (Kalopissis et al., 1979; Cayen et al., 1972; Mirani-Oostdijk et al., 1981; Mondola et al., 1995; Schlierf and Dorow, 1973). The central circadian clock controlling lipid metabolism is often described as beginning with the anterior hypothalamus (the suprachiasmatic nuclei or SCN) and its connection to the eye as part of a "retinohypothalamic tract" leading to both behavior and neuroendocrine patterned responses (reviewed in Gnocchi et al., 2015). Hence, master mediators of lipid metabolism throughout the body, including tissue-specific transcription factors (e.g., PPARs), bile acid and LP synthesis and uptake, and neurohormones are regulated by the SCN, in combination with environmental and physiologic cues (reviewed in Adamovich et al., 2014; Gooley and Chua, 2014; Hussain and Pan, 2012). The central circadian clock is also the source of some otherwise-unexplained diurnal differences in response to environmental (e.g., food, temperature) and physiologic factors (e.g., stress hormones). For example, the decline in insulin sensitivity in the evening relative to the light period in human has been proposed to be due to core clock genes regulating oscillating patterns of FA metabolism in adipose relative to skeletal muscle tissue (Yoshino et al., 2014). Similarly, differences in intestinal lipid absorption between the dark and light period may be partly due to SCN-mediated downstream variation in enterocyte capacity to absorb FAs and synthesize LPs (Hussain and Pan, 2012).

Hence, circadian rhythms in combination with diurnal patterns of nutrient intake and skeletal muscle activity explain both the relatively stable patterning of blood lipids over the course of a 24-hour day, as well as the differences between species and between daylight and nocturnal periods in these patterns. It is important to consider that these blood lipid cycles reflect cyclic fluctuations in the mediators of lipid metabolism, including expressed genes, enzyme activity, and circulating

hormone levels—related endpoints that may be the specific focus of a study or target of a therapeutic. Evaluation of these specific mediators may also require consideration their circadian rhythm within the species evaluated.

21.9.2 DEVELOPMENT AND AGING

Aging has been positively associated with increasing levels of serum cholesterol and TGs in rats. In a study by Reaven and Reaven (1981), substantial increases in both cholesterol and TGs occurred in rats as early as 3–4 months of age compared with young adult rats at 1.5 months of age. In this same study, additional increases in these serum lipids were evident at 6–8 months, while concentrations leveled off by 10–12 months. Boudet et al. (1988) similarly reported significant age-related higher concentrations of serum cholesterol, TGs and PLs when comparing adult (15–17 weeks of age) to aged (59 and 122 weeks of age) Wistar rats. Yet, Van Liew et al. (1993) reported an age-related increase in F344 rats in cholesterol in both sexes but with an increase in TG only in females. Overall, the majority of pertinent published data have indicated that age-related increases occur in both cholesterol and TGs in rats (Carlson et al., 1968; Ghezzi et al., 2012; Hubert et al., 2000; Matsuzawa et al., 1993; Nestic et al., 2013). Studies that do not show this pattern have usually involved animals on a restricted diet or of a distinct strain (Aguila et al., 2002; Hubert et al., 2000; Moriyama et al., 2006; Story et al., 1976).

While the mechanism(s) of increasing serum cholesterol and TGs with age in rats have not been clearly identified, some age-related lipid metabolism enzyme and hormone alterations may offer insight. Both Choi et al. (1988a) and Ståhlberg et al. (1991) observed a decline in HMG-CoA reductase (the rate-limiting enzyme for hepatic cholesterol biosynthesis) and more progressive and persistent decrease in CYP7A1 (the rate-limiting enzyme for bile acid synthesis via the classical pathway) in rats from early postweaning to middle-aged or geriatric stages. Nestic et al. (2013) further reported an increase in responsiveness of aged rats to selective effects of exogenous ghrelin, including an increase in white adipose mass, and circulating TGs, LDL cholesterol, and corticosterone levels compared with similarly treated younger rats. Age-related decreased insulin sensitivity and decrease in the hepatic expression of LDL receptor and LRP (resulting in relative delayed clearance of chylomicron remnants) has also been demonstrated in some rat studies (Field and Gibbons, 2000; Kazumi et al., 1989). Collectively, these enzyme, receptor, and hormonal findings suggest that multifactorial alterations in lipid metabolism homeostasis contribute to the age-related blood lipid changes in rats. Notably, cholesterol and/or TG increases in the aging rat have been prevented through dietary restriction or exercise training (Van Liew et al., 1993; Takeuchi et al., 2009; Reaven and Reaven, 1981; Hubert et al., 2000).

In Rhesus and African Green monkeys, mild increases in serum cholesterol have been associated with increasing age relatively consistently, whereas serum TGs have been found to increase (Mattison et al., 2012; Szymanski and Kritchevsky, 1980; Wolfe et al., 1991) or decrease (Kessler and Rawlins, 1983) in association with age. In cynomolgus monkeys on standard chow diets, no consistent age-related pattern of change in blood lipids across studies or reference databases have been reported. However, a slight positive correlation between age and calculated plasma LDL cholesterol concentration in adult male cynomolgus monkeys fed a low cholesterol (0.04 mg/kcal) relatively high saturated fat diet for more than 2 years has been described (Colvin et al., 1994); the increase in LDL cholesterol was high in animals with the greatest body weight, which was also age-related. Hence, the authors suggested the interaction of age and bodyweight were most correlated with plasma LDL cholesterol.

In adult dogs, no consistent age-related pattern in total serum TGs and cholesterol concentrations was evident in a number of comparative studies with either beagles, or dogs of variable, including mixed breeds (Levine, 2009; Piccione et al., 2004; Uchiyama et al., 1985; Wolford et al., 1986). While in miniature swine (including Sinclair, Göttingen, and Hormel-Hanford variants), serum TGs

and cholesterol were unchanged or decreased with age in one or both sexes (Berlin et al., 1985; Pond et al., 1968; Tumbleson et al., 1976; Zöllner and Tacconi, 1968).

The transition from immature to adult animal can show converse changes in serum lipids compared with aging. Indeed, serum lipids (TGs \pm cholesterol and associated LPs) in very immature (suckling) animals of some species tend to be greater than those in the adult animals. In studies of juvenile Wistar or Sprague-Dawley (SD) rats (approximately 1–3 weeks postnatal), total serum cholesterol and TG, as well as circulating VLDL and LDL cholesterol (determined in one or both studies chemically or by ultracentrifugation) showed values notably greater than those in the adult animals (McMullin et al., 2008). Circulating levels of these lipids were reported to subsequently decline by around the end of the third or fourth week of age, presumably associated with weaning. Similarly, in mixed breed canine puppies, total plasma TGs, cholesterol, and β -lipoprotein cholesterol were considerably greater than the levels in the postpartum dams, especially up to about 3 weeks of age (Wright-Rodgers et al., 2005). Increases in TGs and cholesterol in preweaning piglets relative to adults has also been reported (Chen et al., 1982; Hollanders et al., 1985). Total TGs are generally more consistently or prominently affected than the other parameters evaluated in these juvenile animals. These greater lipid values in very young, rapidly growing animals partly reflect their overall high dietary lipid intake and downstream metabolism.

Serum TGs and correspondingly, β -lipoproteins are also higher in pregnant rat dams, dogs, and humans in the last half to third of pregnancy (Hachey, 1994; Kontinen et al., 1964; Liberati et al., 2004; McMullin et al., 2008; Wright-Rodgers et al., 2005; Sitadevi et al., 1981; Teichmann et al., 1988; Williams et al., 2009; Knopp et al., 1986). Higher β -lipoproteins in pregnancy are particularly attributed to hormonally mediated increased hepatic VLDL synthesis and decreased adipose LPL (Knopp et al., 1986; Wasfi et al., 1980; Herrera and Ortega, 2008; Martín-Hidalgo et al., 1994). Significantly increased cholesterol during late or the majority of gestation has also been reported for dogs (Wright-Rodgers et al., 2005), Sinclair miniature swine (Tumbleson et al., 1970), human (Sitadevi et al., 1981; Teichmann et al., 1988), and Wistar (but not CD) rats (McMullin et al., 2008). Conversely, lower cholesterol and TGs in cynomolgus monkeys, and lower cholesterol without significant difference in TGs in Rhesus macaques during pregnancy (stage inconsistently defined) compared with nonpregnant females have been reported (Gilbert and Rice, 1991; Kessler and Rawlins, 1983; Yoshida et al., 1988). Notably, maternal lipid profiles during late gestation do not correlate with fetal lipid values, as LPs do not freely cross the placenta (Herrera et al., 1988; Knopp et al., 1986). Rather, maternal circulating TGs are metabolized via LPL of the placental endothelium with release of NEFAs into the fetal circulation. The placenta also presents select receptors for regulated transfer of maternal cholesterol to the fetus, including the LDL receptor and scavenger receptor, SR-B1 (particularly important for HDL cholesterol uptake) (Wyne and Woollett, 1998; Ethier-Chiasson et al., 2007).

21.9.3 GENDER

Gender differences in common laboratory species in mean fasting baseline total circulating TGs and/or cholesterol and corresponding LPs are common, but generally small in magnitude and not particularly consistent between reported studies. The limited differences in serum lipid profiles, despite overt differences in body mass, adipose distribution, energy metabolism, and hormonal influences between the sexes, partly reflects the inherently wide biological variability of blood LP concentrations and lipid content within and across individuals (including across age groups), along with the low “n” and timepoints commonly evaluated. Gender-related differences in blood lipids may also be more or less apparent with certain epidemiologic populations, strains, variants, and age categories within species but of limited relevance to other groups.

While gender differences in lipid profiles lack a universal pattern among species, a common reported finding among healthy fasted adult rats and mice is greater serum TGs in reproductively intact males compared with age-matched intact females (Matsuzawa et al., 1993; Moriyama et al., 2006; Wolford

et al., 1986). Conversely, in other routinely studied species including human, nonhuman primates, and dogs, differences in serum TG values between the genders have not been consistent in either occurrence or pattern among published studies reference databases.

Sex-related differences in blood cholesterol concentrations in several laboratory species are suggested based on consistency of patterns across reported relevant studies. In particular, these studies suggest lower total and/or HDL cholesterol concentrations in adult males relative to females in Rhesus monkeys (Eggen et al., 1982; Mattison et al., 2012; Fless and Scanu, 1986), African Green monkeys (Wolfe et al., 1991), dogs (Pasquini et al., 2008; Barrie et al., 1993) rabbits (Hromadová and Hácik, 1984) guinea pigs (Roy et al., 2000), and miniature pigs (Tumbleson et al., 1976; Zamami et al., 1981). In a study of Hormel-Hanford miniature pigs (Berlin et al., 1985), serum TG, total cholesterol, and all cholesterol fractions (HDL, LDL, and VLDL) from puberty until old age were significantly lower in males than females. Consistent with these findings between sexes for HDL cholesterol, lower range for HDL cholesterol in men compared with women has been attributed to higher androgenic hormones. Concordantly in cynomolgus monkeys, increased HDL cholesterol in castrated males, and decreased HDL cholesterol in males administered exogenous testosterone or ovariectomized females administered 5 α -dihydrotestosterone (DHT) have been observed (Greger et al., 1990; Leblanc et al., 2004; Nantermet et al., 2008; Weyrich et al., 1992). Two of these studies also showed a reduction in HDL particle size as reported in humans with increased androgen exposure (Weyrich et al., 1992; Nantermet et al., 2008). However, the induction of HL with increased androgen exposure seen in men (and associated with the HDL cholesterol change) was not detected in cynomolgus monkeys (Nantermet et al., 2008). Collectively, these studies suggest broadly similar sex-related hormonal influences on HDL cholesterol in cynomolgus monkeys as in human.

In association with estrogen flux and the menstrual cycle in females, several studies in women have shown aligned alterations in blood lipid profiles. However, no consistent cyclical changes in total cholesterol, or in HDL, LDL, or Lp(a) (analyzed by density-gradient ultracentrifugation, electrophoresis, and/or fast protein liquid chromatography) were seen in a large study of female Rhesus monkeys (Fless and Scanu, 1986) or in cynomolgus monkeys (Lehmann et al., 1993). Whether hormonal changes with the female reproductive cycle in other laboratory species impacts blood lipids is unclear, although published and other available information suggests that the effects are minor or not apparent.

Sex-related differences in lipid profile have additionally been reported in response to modified diets, aging, and disease states (Choi et al., 1988b; Galan et al., 1994; Rudel and Pitts, 1978; Priego et al., 2008; Thomàs-Moyà et al., 2006; Valle et al., 2007) and may be hormone-mediated, or secondary to gender-related differences in body composition and/or energy metabolism. These differences between males and females in responsive blood lipid profiles are commonly incremental in magnitude, timecourse, and/or balance of serum lipids/LP changes but still demonstrate the general utility of evaluating both sexes when investigating blood lipid effects. However, even in laboratory species susceptible to atherogenic diets (e.g., cynomolgus monkeys, baboons, pigs, New Zealand white rabbits, hamsters, guinea pigs), the gender-related changes in serum lipids with dietary manipulations or disease can, but often do not, clearly mimic the lipid profile differences observed between women and men with corresponding condition. Yet, understanding the gender differences in lipid profile within a species can enable translation of the findings from nonhuman species to human.

The outcome of functional gonadectomy or exogenously altered hormonal state in female or male animals can also result in hormone-related shifts in blood lipid. These are further addressed below in Section 21.9.12.

21.9.4 FASTING AND CALORIE/NUTRIENT DEFICIENT DIETS

Fasting for more than a few hours can measurably affect serum lipids and lipid metabolic pathways in small mammals with relatively high metabolic rates. Similar, albeit usually less prominent changes can be seen in larger laboratory species with short-term (e.g., overnight) fasting. In contrast,

more prolonged calorie restriction results in progressive and adaptive changes in lipid turnover that orchestrate with the organism's metabolic needs. Accordingly, serum lipid patterns with prolonged calorie deficiency are distinct from both fed and acute fasting states, with, the extent of differences understandably variable with the level of macro- and micronutrient deficiencies as well as starting nutritional state, gender, hormonal state, age, species, and strain.

With acute fasting of monogastric species, the most consistent and prominent serum lipid change is a decrease serum TGs in association with decreased intestinally derived apoB chylomicrons and inhibition of hepatic VLDL secretion (Bertolucci et al., 2008; Ockner et al., 1969; Boudet et al., 1988). This decrease in TG is only partly ameliorated by a decrease in tissue uptake of TG-rich particles with the drop in adipose LPL activity (Bergö et al., 2002). Increase in NEFAs with peripheral tissue lipolysis and circulating ketones may also be seen, with the magnitude depending on the extent of fasting relative to metabolic rate and the animal's baseline nutritional level. However, changes in serum total cholesterol and cholesterol-rich particles are more minor or nondetectable mainly due to the continued efflux of cholesterol-rich LPs from the liver as well as intestinal cells (Section 21.5), and little to no change in the clearance of circulating LDL (Kraemer et al., 1994; Lane et al., 2000; Matsuzawa et al., 1993; Sokolović et al., 2010).

In contrast, more prolonged fasting/acute starvation may lead to increases in circulating TGs and/or cholesterol in association with more profound peripheral tissue lipolysis to meet energy needs, with resultant upregulation of hepatic VLDL synthesis (Iacono and Ammerman, 1966; Kalderon et al., 2000; Cahill et al., 1966; Parilla, 1978). The lipolysis-induced increased flux of NEFAs from peripheral (adipose, skeletal muscle) tissues is mediated primarily by a decrease in insulin activity and increase in circulating catecholamines, especially epinephrine (Jensen et al., 1987). Tissue NEFAs that are released into circulation in an animal that has undergone prolonged fasting/acute starvation are mostly consumed via oxidation for energy by a broad spectrum of peripheral tissues. However, those NEFAs that escape this process are absorbed by the liver and channeled (in individuals with adequate liver lipid stores) into VLDL correlating with the increased serum TG and cholesterol (Gibbons and Burnham, 1991; Kalderon et al., 2000; Lata et al., 2002). Prolonged fasting is also associated with insulin resistance, which further contributes to increased circulating TG through reduced inhibition of hepatic VLDL synthesis, reduced VLDL and LDL (receptor-mediated) uptake, and impaired peripheral tissue mitochondrial lipid oxidation (Chen et al., 2010; Hoeks et al., 2010; Markel et al., 1985; van der Crabben et al., 2008). These changes result in a relative increase in production and decrease in the clearance of VLDL and LDL. In some species (e.g., those with relatively high CETP; Sections 21.5 and 21.6, and Table 21.4), HDLs may be conversely decreased; a finding purported to reflect their increased clearance in association with insulin-resistance-triggered upregulated CETP activity (leading to loss of cholesterol from HDL) and increased TG transfer to HDL (due to increased circulating TG-rich VLDL) leading to increased hepatic HDL uptake (Borggreve et al., 2003; Lacombe et al., 1983; Markel et al., 1985; Rashid et al., 2002). Decreased peripheral lipid loading of HDL may also contribute to their decreases (Magun et al., 1988). Collectively, these insulin-resistant effects significantly contribute to the increases in TGs and cholesterol (and more variable LDL/HDL ratio) that can occur with prolonged fasting/acute starvation. However, some differences in extent and timecourse of these serum lipid and LP effects with differences in species, gender, nutritional state, NEFA re-esterification and oxidation, and hepatic LP synthesis rates should be expected (Lafontan, 1981; Lafontan et al., 1985; Levine, 2009; Piccione et al., 2004). As a general example of species differences, the overall NEFA flux in adipose tissue with comparable fasting is 5- to 15-fold higher in rats than in humans, while the extent of re-esterification of these NEFAs and the role of insulin resistance in hepatic VLDL synthesis appear to be greater in human.

More chronic calorie deficit leads to further adaptive changes in lipid metabolism, with a general shift toward enhanced peripheral tissue efficiency in lipid utilization. This shift is marked by enhanced LPL activity, NEFA uptake, and FA oxidation in nonadipose (i.e., energy consuming) peripheral tissues (e.g., skeletal muscle) (Bruss et al., 2010; Taskinen and

TABLE 21.4
Selective Enzymes and Proteins Important in Blood Lipid Transport

Enzyme	Abbreviation	Tissue Source/Site	Major/General Function	Species/Comments
Lipoprotein lipase	LPL	Capillary endothelial cells (particularly of adipose, skeletal, and cardiac muscle); Heparin bound to luminal surface	Hydrolyzes TGs in circulating large lipoproteins; chylomicrons are a preferred substrate	Activity is enabled by apoC-II and enhanced by A-V
Lecithin:cholesterol acyltransferase	LCAT	Hepatocytes	Catalyzes the transfer of long-chain FAs from PLs (mostly lecithin) to free cholesterol to form cholesterol esters (CEs); The FAs are mostly transferred from TG-rich LPs (chylomicrons, VLDL) and cells to HDLs. The CEs can then be stored and transported in the HDL core	ApoA-I is a cofactor, and apoA-IV and apoC-I are activators
Phospholipid transfer protein	PLTP	Synthesized by many tissues including lung, adipose, testis, brain, skeletal and heart muscle, liver, macrophages	Promotes transfer of PLs and free cholesterol between LPs Activity is particularly important during peripheral VLDL lipolysis to capture lipids released from the VLDL outer shell and transfer to HDLs (Schwarz et al., 2008)	Plasma PLTP activity is significantly greater in mice, dogs, and pigs compared with humans (among tested species), a factor that likely contributes to differences in serum lipid concentrations, and risk of atherogenesis between these species
Hepatic lipase	HL	Hepatocytes; heparin bound to sinusoidal endothelial surfaces in space of Disse; also synthesized by macrophages; other tissues in some species (e.g., adrenal in rat)	Hydrolyzes both TGs and PLs from LPs, particularly LDL and HDL, generating small LDL and small HDL via nonreceptor-mediated catabolism with hepatocyte (macrophage) absorption of their lipid content	Species variability in HL expression level and tissue distribution; HL (mRNA) is particularly low in liver of rabbits
Endothelial lipase	EL	Synthesized by capillary endothelial and smooth muscle cells; heparin bound to luminal surfaces similar to LPL	Peripheral tissue lipase that hydrolyzes TGs and PLs of VLDL (as well as IDL, LDL, and HDL); has distincte sn-1 phospholipase activity	Increased expression in endothelial cells induced by inflammatory stimuli (e.g., TNF α , IL-1 β , LPS); and in macrophages and vascular smooth muscle cells with hypertension, angiotensin II

(Continued)

TABLE 21.4(Continued)
Selective Enzymes and Proteins Important in Blood Lipid Transport

Enzyme	Abbreviation	Tissue Source/Site	Major/General Function	Species/Comments
Cholesterol ester transfer protein	CETP	Expressed in various tissues: adipose, skeletal and heart muscle, hepatocytes, stomach, testis spleen (some species variability in distribution)	Mediates transfer of CEs from HDL to TG-rich lipoproteins, and shuttling of their TGs to HDL in exchange	Laboratory species widely vary in CETP activity (Section 21.5, Table 3). Plasma CETP among tested species has been found to be inversely correlated with HDL cholesterol concentration, and the ratio of HDL ₂ to total serum cholesterol
Cholesterol 7 α hydroxylase	CYP7A1	Hepatocytes (located in ER and mitochondria)	Rate-limiting enzyme in the conversion of cholesterol to bile acids via the classic pathway. Highly regulated by various circulating hormones and nuclear hormone receptors	Large species differences in baseline rate, and regulation of this classic enzyme pathway, and in occurrence of additional, alternative bile acid synthetic pathways
Hormone-sensitive lipase	HSL	Steroidogenic tissues (e.g., gonads, adrenal) where CEs are hydrolyzed for hormone synthesis. A truncated form is expressed in other tissues for intracellular hydrolysis of acylglycerides (e.g., adipose, skeletal and heart muscle, lung, pancreatic β cells, macrophages)	Hydrolyzes esters of TGs, DGs, MGs, and cholesterol. With TGs, only the initial esterase step is rate-limiting and regulated by the enzyme (and hormone signaling). The most important hormones in regulating this step are catecholamines, ACTH, and insulin	Some differences in tissue isoforms are associated with variable regulation between species and individuals

Nikkilä, 1979, 1987). These adaptations, together with decreases in hepatic lipid stores with prolonged calorie deficit eventually lead to decreased NEFA, TG, and VLDL serum levels. In contrast, decreases in peripheral tissue LDL receptor expression helps to maintain serum cholesterol levels for longer calorie-restricted periods, especially in species in which LDL is a prominent serum cholesterol-carrying LP. Greater efficiency of lipolysis within adipocytes has also been reported with chronic calorie restriction in rats, with increased white adipose capacity for basal and catecholamine-stimulated lipolysis (Lafontan et al., 1985). This adaptive effect in rats is attributed to increased response to β -adrenergic and hormonal lipase signaling, decreased inhibition of intracellular lipid droplet modulators, and decreased local LPL activity (and thus decreased adipose circulating lipid uptake) (Bertile et al., 2003; Taskinen and Nikkilä, 1987; Zechner, 1997). Incremental increases in lipolytic hormones such as circulating norepinephrine, growth hormone (GH), glucagon, and selective catecholamines also contribute to more efficient adipose lipolysis with chronic calorie restriction.

Effects of chronic calorie restriction can show additional sex-related differences in lipid metabolism and adaptive responses. For example, female rats and pigs have been reported to metabolize adipose stores and preserve lean body mass better than age-matched males during chronic undernutrition (Hill et al., 1986; Serrano et al., 2009; Smyers et al., 2015). Female Rhesus monkeys have also been shown to have lower energy expenditure than age-matched males with adaptation to long-term calorie restriction (Raman et al., 2007). These gender differences may explain some serum lipid distinctions between the sexes in caloric restriction studies, particularly the often more prominent TG changes in females of these species with food restriction (Cortright and Koves, 2000; Thomàs-Moyà et al., 2006; Hoyenga and Hoyenga, 1982; Hill et al., 1986). Dietary alterations (e.g., in carbohydrate and protein content) with chronic calorie restriction can further alter these common adaptive patterns of lipid metabolism. Effects of sustainable chronic food restriction have additionally been shown to interrupt typical age-related increases in serum TG and cholesterol levels in rodents and primates (Hubert et al., 2000; Roth et al., 2001).

Notably, short-term fasting (e.g., 12–24 hours in humans and large animal species; 6–12 hours in rodents) is commonly employed in evaluation of study animals. However, even short-term fasting can affect the magnitudes of normal diurnal changes in blood lipids and LP content (Ahlers et al., 1980; Mondola et al., 1995; Benavides et al., 1998). Hence, as in humans, fasting serum samples alone may not fully reflect, or can even mask effects of a treatment on blood lipids (Mora et al., 2008). Fasting also alters neurohormonal signaling in association with the changes in lipid metabolism; in particular, even short-term calorie deficiency is associated with increases in circulating GH, and catabolic hormones (e.g., glucagon, epinephrine, and cortisol) and decreases in insulin and insulin-like growth factor-1 (IGF-I) levels. More prolonged calorie restriction (or anorexia) can also impair functional activity of metabolic enzymes important for lipid, as well as xenobiotic metabolism (Zhang et al., 1999). Some specific nutrient deficiencies can lead to alterations in blood lipid profiles even with adequate caloric intake. One of the more classic changes is an increase in blood TG, and cholesterol in guinea pigs fed a diet deficient in ascorbic acid (Roomi, 1997). Deficiencies of zinc, copper, vitamin A, magnesium, or protein have also been associated with consistent alterations in blood lipid profiles in various laboratory species (Bouziane et al., 1994; Gatica et al., 2006; Hing and Lei, 1991; Lefevre et al., 1985; Rayssiguier et al., 1981; Schoenemann et al., 1990).

Refeeding after fasting or starvation also transiently alters serum lipid profile relative to that in health. As with the effects of fasting and starvation, these refeeding effects are mediated by neurohormonal and other variables, and can be especially species-variable in extent and timecourse. For example, the increase in serum TGs after refeeding is distinct in rats and mice (and to a lesser extent in dogs) compared with humans and nonhuman primates, in part, due to the capacity for hepatic apoB48 synthesis in the former (Baum et al., 1990; Greeve et al., 1993; Leighton et al., 1990).

21.9.5 NEUROHORMONAL SIGNALING

Several neurohormones have a major regulatory role in lipid metabolism. The most potent and direct acting are catecholamines and insulin. Catecholamines primarily enhance TG hydrolysis and NEFA release into circulation by adipocytes, and can overcome the inhibitory effect on adipocyte lipolysis by insulin. Conversely, insulin is a potent antilipolytic hormone, inhibiting the activation of enzymes responsible for adipose lipolysis and promoting adipocyte uptake of glucose and NEFAs and de novo lipogenesis in hepatocytes. Other commonly measured circulating hormones have lesser but still significant impact on lipid metabolism and serum lipid levels. Most notably these include GH, glucocorticoids, thyroid hormone, estrogen, and testosterone—all of which partly to largely act through effects on catecholamine or insulin signaling. For example, thyroid hormone and testosterone (in rats) enhance adipocyte lipolysis largely by regulating cell sensitivity to β -adrenergic catecholamines (Fain and Garc a-S ainz, 1983; Arner, 2005). Estrogens also affect the signaling pathway of stimulatory catecholamine receptors (Lafontan and Berlan, 1993). Both corticosteroids and GH can promote NEFA generation partly through inhibition of insulin-mediated responses (Yang et al., 2004; Yip and Goodman, 1999; Bur en et al., 2008).

A common mechanism of many of these neurohormones for stimulating lipid hydrolysis in adipocytes is upregulation of adenylyl cyclase through G-protein-coupled receptors, with generation of cyclic adenosine monophosphate (cAMP) and protein kinase A (PKA) (reviewed in Carmen and V ctor, 2006; Fain and Garc a-S ainz, 1983; Str alfors and Honnor, 1989; Wang et al., 2008; Zechner et al., 2009). PKA-mediated phosphorylation of hormone-sensitive lipase (HSL) and coactivation of regulatory proteins surrounding intracellular TG-storing lipid droplets (e.g., perilipin-1) is associated with translocation (or enhanced docking) of HSL to the lipid droplet. HSL is found predominantly in (white and brown) adipocytes, with lower expression of HSL isoforms in other cell types, particularly muscle, steroidogenic cells, pancreatic β -cells, and macrophages (Yeaman, 2004). Hormones that directly stimulate HSL activity through intracellular cAMP/PKA generation include catecholamines (via β -adrenergic receptors), corticosteroids (e.g., dexamethasone) and (especially or exclusively in rodents) glucagon, adrenocorticotrophic hormone (ACTH), parathyroid hormone, thyrotropin and α -melanocyte-stimulating hormone, and (in primates) atrial natriuretic protein (Carmen and V ctor, 2006; Marcus et al., 1988; Sengen s et al., 2002; Xu et al., 2009; reviewed in Zechner et al., 2009, and in Wang et al., 2008). On the other hand, insulin suppresses lipolysis by activating an intracellular phosphodiesterase that degrades cAMP (reviewed in Kolditz and Langin, 2010).

While HSL serves a critical role in hormone-activated lipolysis, two other intracellular lipases coordinate to complete the process of adipocyte TG hydrolysis. Adipose triglyceride lipase (ATGL; also known as desnutrin) initiates the first step through cleavage of *sn*-2 FA from the glycerol backbone generating *sn*-1,3 diacylglycerol (preferred substrate for HSL) and a free FA (Eichmann et al., 2012; Ryd en et al., 2007; Villena et al., 2004; Zechner et al., 2009). A less specific MG lipase completes the final hydrolytic step to cleave the remaining FA from glycerol (Kolditz and Langin, 2010; Nielsen et al., 2014). As with HSL, ATGL shows the highest expression and activity in adipose tissue and can be activated or repressed by similar neurohormonal signals. However, regulation and some responses of ATGL are distinct from that for HSL, including being increased with long-term calorie deficiency, upregulated by PPAR γ agonists, and purportedly altered by obesity (Zechner et al., 2009; reviewed in Nielsen et al., 2014). Conversely, MG lipase has not been found to be directly under hormonal control. Notably, while these lipases are active in multiple cell types, only adipocytes are capable of releasing the generated NEFAs extracellularly (Kolditz and Langin, 2010).

Species differences in the extent of neurohormone responses of these intracellular lipases and lipid droplet docking sites (perilipins) have been reported and can be prominent (Arner, 2005; Castan et al., 1994; Lafontan et al., 1985; Bousquet-M elou et al., 1995). An animal's age, fed/fasted state, energy expenditure, and activity of other lipomodulating hormones are also important variables affecting these molecular responses (Arner et al., 1990; Bertile and Raclot, 2011; Lafontan,

1981; Villena et al., 2004). The impact of some of these variables is noted below for specific neurohormones; however, all of these potential variables should be considered when designing studies and evaluating specific blood lipid data.

21.9.6 CATECHOLAMINES

Catecholamines are the primary activators of both fasting- and exercise-induced peripheral lipolysis, which is promoted through stimulation of adipocyte β -adrenergic receptors. Norepinephrine and epinephrine, as well as chemically synthesized catecholamimetics (e.g., isoproterenol, phenylephrine, theophylline), induce this adipose lipolytic effect, with norepinephrine and isoproterenol having a greater overall potency than epinephrine (Fain and García-Sáinz, 1983; Frisk-Holmberg and Ostman, 1977; Lafontan and Berlan, 1993). Stimulation of adipocyte β -adrenoceptors results in HSL activation (i.e., phosphorylation), intracellular lipolysis, and facilitated long-chain NEFA transport across the plasma membrane of white fat cells (Lafontan and Berlan, 1993). There are at least three functionally distinct β -adrenoceptor subtypes; all promote white and brown fat cell lipolysis with stimulation, but the distribution, participation, and functional importance of each receptor subtype in lipolysis varies with fat type, body region, gender, age, nutritional level (e.g., leanness vs. obesity), and species (Bousquet-Mélou et al., 1994; Carpéné et al., 1994a, 1994b, 1998; D'Allaire et al., 1995; Langin et al., 1991; Meyers et al., 1997).

Adrenoceptors β 1 and β 2 are the predominant β -adrenoceptor types in white adipose and induce lipolysis co-regulated by proteins surrounding intracellular lipid droplets. However, the β 3-adrenoceptors predominate in brown fat where they promote thermogenesis, and have distinct regulation (Carpéné et al., 1998; D'Allaire et al., 1995). Accordingly, β 3-adrenoceptors have prominent expression and functional importance in brown fat, as well demonstrated in certain rodents (rats, mice) and hibernating species (e.g., hamsters) (Carpéné et al., 1994a; Lafontan and Berlan, 1993; Carmen and Victor, 2006). In white fat, functional β 3-adrenoceptors are lipolytic but, in some species, have lesser catecholamine responsiveness than the other β -adrenoceptors. The lipolytic responsiveness of white fat β 3-receptors is relatively high in rats and hamsters; moderate in rabbits, dogs, and marmosets; and essentially absent in human, guinea pig, macaques, and baboons (Bousquet-Mélou et al., 1994; Sengenès et al., 2002; Langin et al., 1991; Meyers et al., 1997). These species distinctions in functional β -adrenoceptors, as well as those in α -receptors (described below), explain species differences in lipolytic response for a plethora of conditions that alter catecholamine activity.

White and brown fat cells also express α 1- and α 2-adrenoceptors that have distinct characteristics. Alpha1-receptors are predominantly found in brown fat and, as with β 3-adrenoceptors, have a role in thermogenesis (thus, less direct effect on blood lipid content), but a different signaling pathway involving protein kinase C (rather than PKA). In even greater contrast, α 2-adrenoceptors have an inhibitory role on lipolysis through attenuation of adenylate cyclase generation. Thus, the lipolytic outcome of catecholamine stimulation of fat cells is a result of the interplay between the stimulatory and inhibitory effects of β - and α -adrenoceptors, respectively. The functional importance of α 2-adrenoceptors in adipocytes is particularly dissimilar between species. In rats, there is a minor adrenoceptor with minimal to no functional activity in adipose. Moreover, in guinea pigs, hamsters, dormouse, and rabbits, the adrenoceptors do not appear to be involved in physiological control of lipolysis by catecholamines (Carpéné et al., 1994b; Pecquery et al., 1983; Castan et al., 1994). However, in humans and nonhuman primates, α 2-adrenoceptors occur in relatively high density in fat cells—exceeding that of β -adrenoceptors in major adipose depots—and are functionally efficient and important in moderating lipolysis (Castan et al., 1994; Berlan and Lafontan, 1985; reviewed in Kolditz and Langin, 2010.). Not only do catecholamines (especially epinephrine), but also 3- β -OHB, the final product of ketogenesis stimulates this receptor in human (Wang et al., 2008). Thus, catecholamine stimulation and other mediators associated with fasting exert essentially an exclusively lipolytic effect in the rat, and a partly inhibitory effect on lipolysis in humans

and nonhuman primates (Bousquet-Mélou et al., 1994). This moderating role of $\alpha 2$ -adrenoceptors on lipolysis in humans has also been shown to be most prominent at rest (Arner et al., 1990).

Importantly, enhanced NEFA mobilization via catecholamine-mediated activation of adipocyte HSL is generally rapid in onset. However, increased adipose lipolysis via ATGL (which also occurs in rodents with fasting) appears to be triggered by a distinct signaling mechanism and follows a time-course uncorrelated with blood NEFAs (Bertile and Raclot, 2011; Zechner et al., 2009). Thus, ATGL activation has been proposed to be driven by glucocorticoids rather than to be stimulated by catecholamine and, accordingly, plays a particularly prominent role in severe starvation in rodents (Bertile and Raclot, 2011; Villena et al., 2004). In humans, ATGL has been reported to function in basal lipolysis but may have a less significant role in stimulated lipolysis than in rodents (Rydén et al., 2007).

21.9.7 INSULIN

Insulin is the most potent inhibitory hormone on lipolysis. Acting primarily via the insulin receptor on adipocytes, insulin not only prevents HSL activation but also causes dephosphorylation of activated HSL (Strålfors and Honnor, 1982). Physiologic increases in insulin also upregulate peripheral lipid uptake through increased adipose LPL activity and intracellular NEFA re-esterification (Sadur and Eckel, 1982). Accordingly, blood NEFAs rapidly decrease postprandially due to the suppression of adipocyte NEFA secretion with increased plasma insulin (Karpe et al., 1998) (Figure 21.3a). However, in the late postprandial/postabsorptive phase (e.g., a few to several hours after a meal in primates [Figure 21.3b], and usually 1–2 hours postprandial in rats), NEFAs increase from this nadir

FIGURE 21.3 Pattern of serum NEFA (a) and TG (b) in cynomolgous monkeys (pre- and postprandial on standard chow). *Note:* Associated relationship with expected normal insulin response across the same timecourse.

mainly due to insulin-mediated late increases in adipose LPL activity (through both transcriptional and posttranscriptional mechanisms) with resultant increased TG-rich LP catabolism and spillover of NEFAs into plasma (Chen et al., 2010; Fielding, 2011; Jelic et al., 2009; Karpe et al., 1998; Picard et al., 1999; Sadur and Eckel, 1982). This insulin-stimulated increase in adipose LPL is in contrast with skeletal muscle LPL activity, which is high during the fasting states. Blood NEFAs also peak during the fasting state predominantly due to low fasting insulin levels, which lift the inhibition on adipose NEFA secretion.

Physiologic increases in insulin are also associated with decrease in both tissue FA oxidation, and circulating VLDL (purportedly through inhibition of hepatic VLDL apoB secretion and increase in hepatic lipogenesis-related genes) (Chirieac et al., 2002; Malmström et al., 1997; reviewed in Kersten, 2001). Collectively, these changes contribute to the anabolic effect of insulin in promoting lipid uptake/retention and suppressing lipid degradation in adipose tissue and liver. In insulin-resistant states, the converse effects on apoB secretion and hepatic lipogenesis contribute to the hypertriglyceridemia commonly seen with this condition. Insulin resistance is also associated with a hampered upregulation of adipose tissue LPL activity; hence, peripheral tissue uptake of lipid from TG-rich VLDL and chylomicrons is slowed, augmenting the tendency toward hypertriglyceridemia.

The impact of insulin on serum lipids and lipid metabolism can be confounded by the concomitant influence of other hormones especially those that are responsive to, and/or directly influence insulin actions (e.g., glucagon, GH, IGF-1). Thus, the relative ratio of circulating insulin and these other hormones (and/or their receptors at the tissue level), rather than that of the individual hormones independently, is most relevant to the serum lipid profile (Frick et al., 2002; reviewed in Møller and Jørgensen, 2009).

21.9.8 GROWTH HORMONE

GH is well established to have significant effects on lipid metabolism, with the expression of the GH receptor demonstrated on rodent and human adipocytes as well as hepatocytes (Vikman et al., 1991; Wei et al., 2006). However, the effects of the hormone on blood lipids and LPs are particularly complex in that they differ over time, as well as with gender, species, and age (Edén, 1979; Gabriel et al., 1992; Lado-Abeal et al., 2005). Lipid changes in response to endogenous GH alterations can also be challenging to directly link, because anterior pituitary release of the hormone occurs in oscillatory pulses of variable amplitude through the day so that frequent, serial time-point evaluations are required to measure functional circulating levels (Edén, 1979; Gabriel et al., 1992; Gobello et al., 2002; Lado-Abeal et al., 2005). The frequency and overall amplitude of these GH pulses, and some blood lipid responses are also strongly sexually dimorphic in many species (Edén, 1979; Edén et al., 2000; Oscarsson et al., 1991; Gabriel et al., 1992; Engström et al., 1998; Lado-Abeal et al., 2005). An added complexity in assessing GH effects on lipid metabolism is that the effects are often present in combination with other hormone abnormalities, which contribute especially to the chronic alterations in blood lipids.

Acute or short-term GH effects on lipid metabolism can be insulin-like in promoting adipose lipogenesis and have been shown to increase DNA synthesis and proliferation of islet β -cells and insulin secretion *in vitro*, and decrease glucose oxidation *in vivo* (Davidson, 1987; Frick et al., 2002; Møller et al., 1990; Nielsen, 1982). However, the long-term effects of GH are insulin-antagonistic, attributed to GH-upregulated adipose lipolysis, increased hepatic VLDL secretion, and increased nonadipose (skeletal muscle and heart) lipid uptake and oxidation (Frick et al., 2002; Oscarsson et al., 1999; reviewed in Nam and Marcus, 2000; Møller et al., 1993; Rathgeb et al., 1970). Adipose tissue lipolysis is partly mediated through enhanced HSL and β -adrenergic activity, which leads to increased circulating NEFA with downstream increased hepatic VLDL secretion and serum TG. Accordingly, increased blood NEFA and TG changes are common with acromegaly and reported as an effect of GH-treatment of growth hormone deficiency (GHD) in humans (reviewed in Frick et al., 2002). Increased blood NEFAs have also been reported in dogs and pigs with non-acute GH administration

(Rathgeb et al., 1970; Schneider et al., 2002) and hypophysectomized GH-administered rats after a two-day delay (McKee and Russell, 1968). Increased blood TGs have been further considered to be promoted through direct GH-enhanced hepatic secretion of ApoB (Apo48 in rats and ApoB100 in human) (Christ et al., 1999; Lindén et al., 2000). Increased circulating NEFAs and TGs may contribute to GH-associated insulin resistance through the same mechanisms as seen with obesity, particularly in inhibiting tissue glucose uptake and reducing hepatic insulin clearance.

Both chronic GH excess (acromegaly) and GHD in humans are additionally linked with increased risk for atherosclerosis, but only inconsistently with alterations in blood cholesterol typically associated with this condition. Untreated or active acromegaly has been most associated across studies with increased plasma concentration of LP(a), small dense LDL, and decreased HDL/LDL cholesterol ratio (Boero et al., 2012; Beentjes et al., 2000; Kostoglou-Athanassiou et al., 2013; Maldonado Castro et al., 2000; Oscarsson et al., 1999). Acromegalic patients have also been shown in some studies to have reduced plasma LCAT and PLTP, and decreased or increased CETP activity levels relative to a control population, which may collectively contribute to LDL cholesterol increases (Boero et al., 2012; Beentjes et al., 2000). While these findings are linked with GH excess, patients with untreated GHD have also been found to have an atherosclerotic lipid profile; most commonly, increased total and LDL and/or VLDL cholesterol levels (de Boer et al., 1994; Christ et al., 1999). One mechanism proposed for these findings in GHD patients is that, in addition to the role in ApoB secretion, the hormone has been found to upregulate LDL receptor expression in hypophysectomized rats and human liver tissue *in vitro* (Rudling et al., 1992). Hence, recovery of the expression of the hepatic LDL receptor following long-term GH replacement therapy may explain normalization of blood LDL cholesterol and HDL/LDL cholesterol ratio in treated GHD patients (Christ et al., 2006; de Boer et al., 1994).

These effects of GH on blood lipids are consistent with the hormone's role during prolonged fasting, significant physiologic (e.g., inflammatory) stress, or prolonged exercise. In such catabolic states, GH is anabolic for skeletal muscle tissue supporting protein preservation through increased availability and oxidation of FAs, and shifting energy generation away from glucose oxidation. In this role, GH directly and indirectly antagonizes the effects of insulin as a defense especially against hypoglycemia during these system challenges. While this role is similar across individuals and species, some differences in the effects of GH on blood lipids relative to age, gender, and diet and in animal models compared with acromegaly and GHD in humans deserve comment. The absolute secretion of GH in health is maximal (as with circulating IGF-1) at midpuberty. Circulating levels and the combined effects between GH and IGF-I gradually decline in adulthood and further with senescence. Hence, studies in very young animals may not duplicate effects seen in fully mature adult or aged animals (including human patient populations). Differences between genders in the baseline pulsatile pattern and the absolute amount of GH secreted, as well as sex-hormone influences on GH, and blood lipids are substantial in both humans and common laboratory animals (Edén, 1979; Edén et al., 2000; Ciresi et al., 2013); hence, GH-mediated blood lipid responses are generally not directly comparable between genders. Moreover, in rodent models, the differences in the GH effect on tissue LPL are considered as the potential cause of the differences in blood lipid responses with alterations of the hormone. In particular, GH robustly promotes increased LPL activity in skeletal muscle (including heart) in mice and rats, whereas GH-mediated decrease in adipose LPL activity with less distinct effect on muscles LPL has been reported in humans (Oscarsson et al., 1999; Frick et al., 2002; Richelsen et al., 2000; Khalfallah et al., 2001). These difference between species may explain the lack of increased blood NEFA, TG, and VLDL in a nonfasted GH transgenic mouse model and GH-mediated decreased LDL (with increased VLDL turnover) in a hypophysectomized female rat model in contrast with general GH-mediated blood lipid effects in humans (Frick et al., 2002). Moreover, short-term fasting alone has been associated with decreased GH in mice, in converse of the well-established findings in human (Steyn et al., 2012). These findings, as well as specific blood lipid responses to GH with altered diet in rodents, are complex in

translation to human and in need of continued study. Some GH effects on blood lipids are also partly indirect in being secondary to insulin resistance or GH-stimulated IGF-1 synthesis and release.

21.9.9 INSULIN-LIKE GROWTH FACTOR-1

Hepatic synthesis and secretion of IGF-1 are stimulated by GH. Indeed, the actions of IGF-1 are necessary for promoting the protein anabolic effects of GH, including for adipose tissue (promoting preadipocyte proliferation and differentiation). IGF-1 release is also dependent upon sufficient nutrient intake and availability, and portal insulin levels, with blood concentrations rapidly decreasing during fasting. In turn, IGF-1 negatively regulates the secretion of GH and insulin. Hence, there is a complex balance between the effects of GH, IGF-1, and insulin in the regulation of blood lipid and LP metabolism. Yet, the effects of IGF-1 on serum lipids in health are generally only indirect, and primarily mediated through stimulation of the insulin receptor. Administration of recombinant IGF-1, or chemical mimetics, to healthy or diabetic animals increases insulin sensitivity and can result in decreases in circulating TGs and VLDL as well as LDL cholesterol through mechanisms that are primarily the same as for insulin (Yuen and Dunger, 2006; Turkalj et al., 1992; Binoux, 1995). Exogenous IGF-1 can also result in (rapid, but temporary) hypoglycemia, and inhibition of insulin and GH secretion (with corresponding downstream impact on lipid metabolism). These, and relatively high incidence of other side effects of IGF-1 (e.g., arthralgia, edema), have limited the benefits of pharmaceutically enhanced IGF-1 activity in diabetic or dyslipoproteinemic conditions (Froesch and Hussain, 1994).

21.9.10 GLUCOCORTICOIDS

Glucocorticoids (GCs), whether released endogenously in response to physiologic stress (e.g., starvation) or exogenously administered, have complex effects on lipid metabolism that are attributed to alterations primarily at the level of the adipocyte and hepatocyte.

In adipocytes, GCs have both lipolytic and anabolic effects. Lipolytic actions are principally indirect through a permissive effect on catecholamine-induced lipolysis and antagonism of insulin lipogenic response. Glucocorticoid response elements occur in regions of β -adrenergic receptor genes, and response to GCs have been shown to include increased adipocyte β receptor expression. Additionally, GCs appear to increase transcription of other elements of the β -adrenergic signaling cascade in the cells. The requisite protein synthesis explains the delayed onset and prolongation following withdrawal of exogenous steroids in adipocyte lipolytic effects (Vance and Vance, 2008; Campbell et al., 2011). This permissive effect of GCs on adrenergic activity, and the distinctions between species in adrenergic receptor expression, and brown and white fat content (see above on *Catecholamines*) may also explain the greater sensitivity of some species (e.g., rats and mice) to GC-mediated lipolysis compared with human.

Antagonism of insulin-induced adipocyte lipogenesis also contributes to lipolysis with long-term GC administration. A glucocorticoid receptor-dependent (transcription-independent) mechanism that attenuates insulin receptor (IRS-1) signaling for cell glucose uptake has been identified as one mechanism for this effect (Sakoda et al., 2000). GC-mediated upregulation of HSL and variable downregulation of LPL in adipose tissue also are considered to contribute to the insulin resistance (Slavin et al., 1994; Bagdade et al., 1976). Collectively, these lipolytic effects of GCs result in persistent increases in blood NEFA as well as impaired chylomicron and VLDL clearance.

Within hepatocytes, GCs promote uptake of the mobilized NEFA, and stimulation of VLDL synthesis and secretion (in animals with positive caloric balance) (Reaven et al., 1974; Mangiapanè and Brindley, 1986). Thus, increases in blood VLDL and hypertriglyceridemia with GC excess is mediated by both decreased clearance and increased secretion of the LPs. Increase in LDL cholesterol is also common with GC excess, and likely represents an outcome of the impaired VLDL clearance

(Bagdade et al., 1976; Campbell et al., 2011). Consistent with these multiple contributing factors, the magnitude of circulating TG increase can be prominent. In a study of rats maintained for 5 days on a low dose of triamcinolone, serum TG concentration was doubled with a parallel rise in VLDL (Krausz et al., 1981). Of note, a much higher dose of triamcinolone for similar time period in this study produced a fall in serum TG and VLDL with increase in serum HDL cholesterol; a finding likely reflective of profound lipolytic effect and hyperinsulinism with concomitant negative caloric state as induced by high dose GCs in rats (You et al., 2009).

Glucocorticoids can also have an anabolic effect on adipose tissue in certain body regions, and in general, occurs through differentiation of preadipocytes in visceral fat. Thus, this effect likely has only muted impact on analyzed blood lipid content.

21.9.11 THYROID HORMONE (TRIODOTHYRONINE)

Triiodothyronine (T3) regulates, and predominantly promotes, adipose tissue lipolysis by both direct and indirect mechanisms. The effects of T3 on lipid metabolism have become particularly important to consider when evaluating blood chemistry data from animal studies where the administered drug or chemical toxicant inadvertently affects the hormone's function in the tested species (e.g., through upregulated T4 metabolism or impaired conversion to the active hormone). T3 directly influences the activity of critical enzymes in lipolytic pathways by acting on thyroid hormone-specific nuclear receptor isoforms. These receptor isoforms, and their corepressors/activators, are tissue specific and show age/development stage-dependent patterns in expression (reviewed in Zhu and Cheng, 2010). The hormone also promotes lipolysis indirectly through augmentation of local adrenergic, and (to a lesser extent) other hormone (e.g., GH) signaling in adipose tissue. Collectively, these T3-promoted processes enhance intracellular HSL-catalyzed lipolysis and β -oxidation. In animals with hyperthyroid conditions, increased FA uptake and β -oxidation in peripheral tissues are largely the reasons for the lack of prominent increase in circulating VLDL-TG despite the increased blood NEFA (Heimberg et al., 1985; Vance and Vance, 2008). Hyperthyroidism is also associated with the reduced hepatocyte esterification of FAs into TG, and the increased rate of clearance of circulating VLDL and chylomicron by peripheral tissues (Abrams et al., 1981; Erem et al., 1999; Jokinen et al., 1994; Wilcox and Heimberg, 1991). Thus, blood TG concentrations tend to be decreased to minimally increased with hyperthyroid conditions (Abrams et al., 1981; De Bruin et al., 1993; Erem et al., 1999; Heimberg et al., 1985). The slightly increased blood TG common in some species (typical with rats and mice) with hyperthyroidism may be partly due to an associated increased synthesis and release of intestinal apoB48 LPs (Davidson et al., 1988).

With conditions of low T3 (hypothyroidism), the change in blood TG shows a more species-distinct pattern. Hypothyroidism in humans and dogs is generally accompanied by increases in circulating TG with corresponding increases in VLDL (Dixon et al., 1999; Nikkilä and Kekki, 1972; Rogers et al., 1975; Schenck et al., 2004). However, in rats and mice (and most studied in the former), hypothyroidism results in rapid-onset, prominently and persistently decreased blood TG and VLDL (Dory et al., 1981; Patel et al., 2013; Meyer, et al., 1989; Davidson et al., 1988; Raheja et al., 1982). The reason for this species divergence, and the effect in other common laboratory species of hypothyroidism on TG have not been fully explored, although differences in α -adrenoceptor types in adipose tissue between these species is likely an important factor (see above on *Catecholamines*). In miniature pigs with experimental hypothyroidism, a response similar to rats (decreased serum TG), and in horses with spontaneous hypothyroidism, a pattern similar to human and dogs have been reported (Müller et al., 1983; Frank et al., 1999). In all evaluated species, hypothyroidism has generally been associated with slightly decreased to unchanged liver VLDL-TG secretion, and significantly decreased peripheral clearance of circulating VLDL (Dolphin and Forsyth, 1983; Fabbrini et al., 2012). In one study of hypothyroid rats, the rate of VLDL clearance from the plasma was about a third of that of pair-fed euthyroid controls (Dory et al., 1981). These factors are considered primary contributing factors to the increased serum TG in humans and dogs. However, in

rats (and species with similar blood TG response), concomitant decreased intestinal synthesis of TG-rich apoB48 particles may be the most significant cause of the distinctly decreased VLDL-TG with low thyroid activity (Davidson et al., 1988).

One of the hallmark laboratory findings of thyroid hormone dysregulation in human and common laboratory species is altered serum cholesterol. Total blood cholesterol is typically decreased or increased inversely with change in thyroid hormone activity. These changes in total cholesterol predominantly reflect those in LDL cholesterol and are partly attributed to T3 augmentation of hepatocyte LDL receptor expression and function, and biliary excretion of cholesterol (Angelin and Rudling, 2010; Ness and Zhao, 1994; Staels et al., 1990; Salter et al., 1991; Thompson et al., 1981). A reduction in enterohepatic bile acid circulation is also reported with high T3 conditions. Thus, LDL cholesterol clearance is either enhanced or impaired with hyper- or hypo-thyroidism, respectively. These changes in blood LDL cholesterol occur despite counteracting thyroid hormone effects on cholesterol synthesis; that is, hyperthyroid conditions result in enhanced, and hypothyroidism exhibits reduced de novo cholesterol synthesis. These changes in blood LDL also occur in rats, despite the decrease in blood VLDL concentrations in this species with hypothyroidism (Dory et al., 1981).

Alterations in circulating HDL cholesterol concentration with thyroid dysfunction are less consistent or prominent than those in VLDL-TG or LDL cholesterol. Most commonly reported in human, dogs, and rats is a small increase in circulating HDL with hypothyroidism (Gross et al., 1987; Friis and Pedersen, 1987; Kung et al., 1995; Tan et al., 1998). The increase has been proposed to be due, in part, to greater apoA-I expression and decreased activity of HL and/or CETP (in species that express this enzyme; e.g., humans, rabbits, and guinea pigs) (Dory et al., 1981; Tan et al., 1998; Boone et al., 2011). Decreased HL can impair hepatic clearance of the LPs. While low CETP activity impairs net transfer of neutral lipids including CEs from HDL particles to the less dense apolipoprotein B (apoB)-containing LPs; hence decreased activity will prolong circulation time of some HDL forms (and may thus impair RCT in species that express the enzyme). Notably, these changes in HDL with thyroid dysfunction are generally small and not entirely consistent across published studies, especially in human in which HDL has also been reported to be decreased with hypothyroid conditions, and atypically increased with hyperthyroid conditions or unchanged in either endocrinopathy (Abrams et al., 1981; reviewed in Heimberg et al., 1985).

Although still under some debate, hypothyroidism has also been associated with increased blood Lp(a) in humans (De Bruin et al., 1993; Erem et al., 1999); whether this change is also seen in non-human (Old World) primates is unclear.

21.9.12 TESTOSTERONE AND ESTROGENS

One of the most prominent effects of testosterone and estradiol in laboratory rodents is the effect of these hormones on adipose lipolysis. Castration or ovariectomy in adult rats is associated with a blunted lipolytic and corresponding blood lipid response to catecholamines (see section above on *Catecholamines*) (De Pergola et al., 1990; Xu et al., 1991). Conversely, testosterone and, to a lesser extent, estradiol administration to rats or mice of either sex enhances the lipolytic action on catecholamines with corresponding increase in blood NEFA and VLDL-TG (Uryszek et al., 1989; Tvorogova and Titov, 1986; Hansson et al., 1991). The predominance of these effects is species-specific in that, unlike primates and most other studied laboratory species, adipocytes of rats and mice express adrenoceptors that strongly promote lipolysis with catecholamine stimulation (see section on *Catecholamines*). In primates (and variably between adipose depots in all studied species), the lipolytic potential of testosterone varies with the regional balance of α - or β -adrenoceptors (Arner, 2005; Dicker et al., 2004; Hansson et al., 1991). Testosterone has also been shown in some species (e.g., hamsters) to alter tissue adrenoceptor balance over time (Arner, 2005). Administration of estradiol or testosterone to healthy rats has less pronounced impact and more select effects on lipolytic pathways in comparison with surgical castration and does not fully reverse effects of the latter on blood and tissue lipids.

In other species, both estrogens and testosterone at physiologic and supraphysiologic levels have mixed lipogenic and lipolytic effects with gender, age, and/or hormonal state and fat depot site as important variables. Accordingly, administration of exogenous estrogen or testosterone and/or gonadectomy in common non-rodent laboratory species (e.g., rabbit, dog, pig, and nonhuman primates (NHP), as in human, has not been associated with consistent pattern(s) in circulating NEFA, TG, or VLDL (Aydilek and Aksakal, 2005; Tvarijonaviciute et al., 2013; Hussein et al., 1999; Hromadová and Hácik, 1988a, 1988b; Pynadath and Chanapai, 1981).

In humans, the most well-established effect of testosterone and estrogens on blood lipids has been altered cholesterol levels, with correspondingly altered HDL and/or LDL cholesterol or LPs. More specifically, higher functional estrogen levels are linked with decreased (and testosterone levels with increased) total cholesterol, and/or LDL/HDL and/or HDL/total cholesterol ratio in humans. This hormonal influence has been long-studied, and variably supported by widely diverse animal models (some of which are discussed in Section 21.9.3). A very important consideration in the interpretation of the data from these animal models is that the effects of exogenous testosterone or estrogen on lipid metabolism (and blood lipids) partly depend upon whether the circulating hormone is in the physiologic or pharmacologic range. For example, Parini et al. (2000) described this as “biphasic” when presenting results in intact female rats, given 17β -estradiol (E2) for 1 week. At physiological doses in these animals, blood HDL cholesterol and apoA-I, and key liver enzymes activities for bile acid and cholesterol synthesis (HMG-CoA reductase and CYP7A1) were increased, whereas at higher (pharmacological) E2 doses, these hepatic enzyme activities were not increased, but hepatic LDL receptor protein and mRNA were increased and plasma total, HDL, and LDL cholesterol were decreased. Thus, the effects and mechanisms for estradiol-induced blood lipid changes in animal models can vary and even show contrasts depending upon the dose, although findings at all doses in this model (as commonly with animal models of estrogen effects on lipid metabolism) showed some consistencies with at least some effects of E2 in humans.

In animals, pharmacologic doses of estrogens and testosterone can also affect food consumption; and, as mentioned previously, in rodents, the doses can also be associated with adipose lipolysis and weight loss. These clinical effects affect the blood lipid profile and can confound assessment of the studied hormonal influence. In addition, and especially in rats, high-dose estrogens can also induce reduction of bile flow that can lead to intrahepatic cholestasis. The mechanisms for this are multifold and may overlap with those inducing cholestasis of pregnancy in women (Krell et al., 1987; Stieger et al., 2000). Blood lipid changes with the induced cholestasis in rats are also a consideration.

In summary, sex hormones can significantly affect blood lipid profiles in humans and animals, but the overall outcome is influenced by many factors, with species differences being one of the most important. Thus, while blood lipid changes with sex hormone administration can occur, the changes have not shown a consistent pattern.

21.9.13 ACUTE PHASE RESPONSE

The acute phase response (APR) can have a profound effect on circulation lipids in all species. The APR is induced by a variety of pathologic stimuli, including infection, inflammation, necrosis, and some malignancies. The blood lipid changes with the response are rapid, occurring within 2 hours after administration of lipopolysaccharide (LPS) and are associated with the same cytokines that produce fever and anorexia (Feingold et al., 1992).

The most prominent, sensitive, and consistent APR blood lipid change is an increase in circulating TG (Nonogaki et al., 1995; Khovichunkit et al., 2004). Hypertriglyceridemia has been shown to be induced by *in vivo* injection of bacterial cell wall components (e.g., LPS and lipoteichoic acid) and a broad range of proinflammatory cytokines (e.g., tumor necrosis factor (TNF) α , interleukin-1 [IL-1], IL-6) (reviewed in Khovichunkit et al., 2004; Feingold et al., 1992; Nonogaki et al., 1995). The increase in TG is predominantly due to acute stimulated lipolysis with increased delivery of NEFA to the liver, and concomitant increased hepatic FA synthesis and VLDL secretion. However,

with prominent APR, the increase in blood TG reflects TG enrichment of all circulating LP classes that is also associated with altered (generally reduced) FA oxidation and ketogenesis, and decreased clearance of TG-rich LPs attributed to reduced LPL and ApoE levels (Cabana et al., 1989, 1996; Khovidhunkit et al., 2004). Decreased clearance of TG-rich LPs is additionally a presumed cause of the significant APR-linked increase in blood IDL-TG and LDL-TG.

The effect of APR on increasing blood TG is similar in all species, with onset that is not only rapid but can be profound in magnitude. In rabbits injected intramuscularly with croton oil, serum TG increased 8- to 15-fold within 2–3 days (Cabana et al., 1983, 1989). African green monkeys given a subcutaneous injection of LPS showed increases in serum TG that reached sevenfold by 48 hours, and showed full resolution after 6 days (Auerbach and Parks, 1989). In rabbits given common water-in-oil adjuvants, one of the authors (DW) has observed that serum TG increased consistently between 5- and 12-fold within 24 hours and that fully resolved within 48–72 hours.

Importantly, the increases in TG-rich LPs are considered physiologically appropriate as part of the innate immune response offering some immediate protection against infection. As reviewed in Khovidhunkit et al. (2004), TG-rich VLDL, LDL, and chylomicrons have been shown to bind and neutralize LPS, lipoteichoic acid (LTA), certain bacterial toxicants, and a variety of DNA and RNA viruses. Lipoprotein bound to these bacterial components can also beneficially modify the inflammatory response by decreasing monocyte/macrophage activation, and accelerating the hepatocyte uptake and biliary excretion of these bacterial constituents (Feingold et al., 1998). Some apoB and C-reactive protein (CRP) that are carried by TG-rich apoB-containing particles appear to have added beneficial roles for the host against infections.

In contrast to the overt change in blood TG, changes in serum cholesterol with inflammation are more subtle. In both primates and rodents, circulating HDL and HDL cholesterol have been shown to decrease, and the particles show APR-induced composition changes (Auerbach and Parks, 1989; Cabana et al., 1989, 1996; Fon Tacer et al., 2007; Khovidhunkit et al., 2004; Jahangiri et al., 2009). These composition changes include not only HDL enrichment with TG (noted above) but also with serum amyloid A (SAA; which binds to some bacterial toxins) and apoE (in contrast with decreased tissue and total circulating apoE). The increase in apoE and SAA likely contributes to lower HDL levels by enhancing uptake by hepatocytes (e.g., via apoE-LDL receptor binding) and scavenging by macrophages (via apoE-LDL-receptor and SAA-mediated mechanisms) (Artl et al., 2000; Auerbach and Parks, 1989; Cabana et al., 1996). With an APR, HDL is also typically depleted of cholesterol and apoA-I, II, and apoCs (negative APR proteins) (Auerbach and Parks, 1989). The decrease in HDL apoA-I content contributes to decreased cholesterol efflux from peripheral tissue to HDL, and, as enzyme cofactor, to decreased LCAT activity. Hence, there is decreased CE formation and capacity to absorb cholesterol from cells/other LPs. Directly decreased LCAT synthesis and activity with an APR have also been reported (Kitagawa et al., 1992). Collectively, these changes contribute to impaired RCT, a well-established APR effect.

Although these HDL alterations are generally consistent across species, APR effects on total serum cholesterol differ between several common laboratory species and primates, including humans (Artl et al., 2000; Cabana et al., 1996; Feingold et al., 1993; Kitagawa et al., 1992). In rodents and rabbits (nonstarved), serum total cholesterol concentration modestly increases, whereas in primates, total serum cholesterol shows no change to slight decreases with the APR. This converse effect appears to predominantly reflect species differences in baseline serum cholesterol concentration and metabolism. That is, the increase in total cholesterol in rodents and rabbits appears to largely represent the increase in VLDL particle number and VLDL cholesterol (that occurs with the APR in general) relative to the normally low baseline total cholesterol of the animals.

Additional reasons for the subtle, opposite change in total serum cholesterol between laboratory animal species (especially rodents) and primates can be attributed to species differences in the direction of change in LDL cholesterol content with the APR. Major proinflammatory cytokines (IL-1 and/or TNF α) have been shown to increase cholesterol content of LDL in rodents, and decrease cholesterol in LDL of primates (although decreases in blood LDL protein concentration

are reported in both species with administration of the cytokines) (Cabana et al., 1996; Ettinger et al., 1992; Fon Tacer et al., 2007; Feingold et al., 1993). Changes in LDL cholesterol in all studied species are at least partly attributed to inflammation-induced increases in HMG-CoA reductase (the rate-limiting enzyme in hepatic cholesterol synthesis, Section 21.3), and decreases in CYP7A1 and CYP27A1 (the rate-limiting enzymes in the classic and alternative pathways for bile acid synthesis from cholesterol; Section 21.7) activity (reviewed in Khovidhunkit et al., 2004). The effects on these enzymes—in light of the known differences of the species in their enzyme regulation and cholesterol metabolism and catabolism—significantly explains the differences between rats and primates in blood LDL cholesterol content with the APR. Notably, the inhibition of these key enzymes, as well as transporters, for excretion of bile is believed to contribute to the intrahepatic cholestasis sometimes associated with inflammation (reviewed in Khovidhunkit et al., 2004).

An additional noteworthy mechanism for the differences of the species in the direction of the change in LDL cholesterol is the effect of inflammation on CETP. The concentration of CETP in plasma has been shown to significantly decrease with inflammation in humans (or following LPS injection in human CETP-transgenic mice) (Jahangiri et al., 2009; Masucci-Magoulas et al., 1995). Because CETP catalyzes the transfer of cholesterol from HDL to LDL (Section 21.5), the decreased enzyme protein is considered to contribute to decreased LDL cholesterol uptake. However, because CETP activity is virtually absent in the rat and several other laboratory animal species, this is not an important component of their altered blood lipids with the APR.

Additional mechanisms for changes in blood lipids and LPs with the APR have been described in the literature, although most are less well studied and/or consistent. These proposed mechanisms, collectively with known effects, indicate highly complex species-adaptive effects on lipid metabolism. It is therefore important to recognize the impact of inflammation/infection or proinflammatory cytokine administration when evaluating blood lipids in animals.

21.9.14 HEPATIC MICROSOMAL ENZYME INDUCTION

There are relatively few published studies specifically addressing the potential for a link between general hepatic enzyme induction and blood lipid changes. Among them, small changes in blood TG and/or cholesterol have been reported with classic enzyme inducers, but the occurrence and direction of the changes has been inconsistent between studies and species (Elcombe et al., 2012; Ennulat et al., 2010; Goldberg et al., 1981; Heller et al., 1988; LaPorte et al., 1981; Luoma et al., 1982; Nousiainen and Ryhänen, 1984; Romaschin and Goldberg, 1987). Results of some studies on hepatic enzyme induction are also confounded by other factors affecting blood lipids independent of the induction (e.g., hepatic cirrhosis, inflammation, and/or altered food consumption or diet). Conversely, increased lipid content and/or synthesis in the liver has been fairly consistently reported in studies with various laboratory animals (mostly nonprimate) given phenobarbital or other inducers (de Haan et al., 2009; Ennulat et al., 2010; Je et al., 2015; Moreau et al., 2008). The increase in hepatic lipid content and blood lipid changes—when seen and directly associated—has been largely attributed to the inducing agents that activate certain hepatic nuclear receptors (e.g., PXR, FXR, and/or constitutive androstane receptor [CAR]), which have broad effects on metabolic pathways, including those of lipid metabolism. As an example, PXR induction with CYP3A-inducing agents (e.g., phenobarbital or rifampin) in rats has been closely associated with increased hepatic lipid content and also serum apoA-I and correspondingly, serum HDL cholesterol (Bachmann et al., 2004). This model has been considered representative of the increase in blood HDL cholesterol and apoA-I reported in humans administered antiepileptic CYP3A inducers (Luoma et al., 1988). However, the specific nuclear receptors targeted by hepatic enzyme inducers (or inhibitors) vary considerably between specific agents and animal species, and the associated downstream effects can be different even between individuals with the same signalment (see also Section 21.11). These differences, along with the role of other hepatic and nonhepatic factors in metabolism on blood lipid levels offers explanation for the lack of consistent or prominent changes in serum TG and cholesterol with hepatic microsomal enzyme induction.

Induction or inhibition of hepatic metabolizing enzymes can also affect enzymes critical to endogenous mediators, especially hormones. If this effect is adequate in severity and selectivity, blood lipid changes secondary to the altered mediator can result. A common example is induction of hepatic enzymes that catabolize circulating thyroxine (T₄), or inhibit enzymes that convert T₄ to T₃ in rodents. Prominent effects on these enzymes in rats or mice are associated with a hypothyroid state and corresponding blood lipid alterations (Bookstaff et al., 1996; Gieger et al., 2000). Induction of a hypothyroid state in rats secondary to phenobarbital hepatic enzyme induction is well established. Alterations in testosterone or estrogen with enzyme induction have also been reported and could plausibly have some influence on blood lipid profile (Peakall, 1976).

21.10 PATHOPHYSIOLOGICAL ALTERATIONS IN BLOOD LIPIDS

21.10.1 SECONDARY HYPERLIPIDEMIA

Conditions that cause secondary hyperlipidemia are numerous. Some of the most common and/or well-established conditions, with particularly consistent lipid changes, are attributed to pathology that exacerbates physiologic influences on lipid metabolism (Section 21.8), for example, hypothyroidism, hyperadrenocorticism, diabetes mellitus, and inflammation. Other well-established causes include protein-losing nephropathy, acute pancreatitis, and cholestasis; these conditions are described in other chapters of this text pertaining to the major injured organ. However, due to the overlap in the pattern of altered blood lipids between pathologic conditions and confounding physiologic or pathologic factors (e.g., pregnancy, anorexia), only occasionally are the lipid changes specifically useful for a diagnosis. More often, the known condition can be helpful in explaining the pattern of blood lipid profile seen.

21.10.2 PRIMARY HYPERLIPIDEMIA

Primary hyperlipidemia refers to a congenital, inherited, or idiopathic increase in fasting blood lipids that cannot be explained by other, including downstream or indirect, causes. The mechanism for primary conditions is usually due to deficiency or abnormality of an apo or its receptor, an LP transporter or a rate-limiting enzyme in lipid metabolism. Several of these conditions, especially those that are more common or scientifically significant in humans or animal models are described above (Section 21.5). Classically, these conditions are associated with persistent serum/plasma lactescence due to high serum concentration of TG (generally over 200 mg/dL to contribute to plasma turbidity) (Bauer, 1995). However, some primary hyperlipidemias are associated with more significant increases in blood cholesterol (e.g., some defects involving the LDL receptor or *CYP7A1* gene), or hypercholesterolemia without an abnormal TG concentration (e.g., HDL-associated primary hypercholesterolemia in Briard Dogs) (Watson et al., 1993). Not surprisingly, due to the many species differences in lipid metabolism and LP size and content, defects in a correlative apo, receptor, transporter, or enzyme is generally not associated with entirely identical lipid profile changes between species.

Compared with the number of established, spontaneously occurring, primary hyperlipidemias in human, those investigated in animals are relatively few. For most of these primary hyperlipidemias in nonhumans, the specific defect is still unclear; yet, they exhibit some consistent characteristics: occurrence at even a young age, persistence over time while consuming a normal diet, and absence of underlying hormonal or other contributing condition(s). Essentially, all recognized spontaneous primary hyperlipidemias in animals have also been reported only in purebred lines, with similar changes in litter mate(s) or others of the same breed or strain. It should be noted, due to species and analytical differences in measured baseline blood lipid levels, there are no universal cut-off values as to what classifies a significant increase in TGs or cholesterol in these animals. Depending on the lipid moieties affected, the condition can also be asymptomatic, or associated with a wide

variety of clinical signs such as cutaneous and other tissue xanthomas (primarily seen in cats with hyperchylomicronemia), eye disorders (e.g., corneal lipid deposition, lipemia retinalis, lipid accumulation in aqueous humor), vomiting, diarrhea, pancreatitis, diabetes mellitus, peripheral neuropathies, seizures, vacuolar hepatopathy, and/or atherosclerosis (Johnstone et al., 1990; Crispin, 1993; Kluger et al., 2010; Watanabe, 1980; Whitney, 1992; Center, 1996; Williams, 2005). Recommended laboratory analysis for the investigation of potential primary lipidemic disorders has been reported (Whitney, 1992).

21.11 IMPORTANT NUCLEAR HORMONE RECEPTORS

21.11.1 PEROXISOME PROLIFERATOR-ACTIVATED RECEPTOR

Peroxisome proliferator-activated receptors are a group of nuclear hormone receptors that regulate lipid metabolism, and other cellular metabolic processes. Of the three PPAR subtypes, alpha (α), gamma (γ), and beta/delta (β/δ), the α subtype is the most relevant to lipid metabolism. PPAR α is predominantly expressed in tissues that have a high level of FA catabolism, such as liver, heart, and skeletal muscle (Fruchart, 2009; Reddy and Hashimoto, 2001; Yoon, 2009). During a state of fasting, there is an increased release of NEFAs (the endogenous ligand of PPAR α) from adipose tissue; consequently, PPAR α induces expression of FA transport/translocase proteins, and increases mitochondrial and peroxisomal β -oxidation of the NEFAs delivered to these tissues (Fruchart, 2009; Reddy and Hashimoto, 2001). Influx of NEFA to the liver is accompanied by their complete catabolism and hepatic gluconeogenesis in response to the lower caloric intake (Reddy and Hashimoto, 2001). Thus, agonism of PPAR α promotes lipolysis, lipid catabolism, and decreased hepatic synthesis of lipids and proteins for release to circulation. Accordingly, the agonism of PPAR α is generally considered a therapy for dyslipidemia and atherosclerosis, and has been shown to lower blood TG, VLDL, and LDL, and increase circulating HDL.

Lower serum TGs with PPAR α agonism is partly through upregulated expression of LPL (hydrolyzing circulating TGs at the tissue level), decreased apoC-III (which delays hepatic TG uptake; Section 21.5), and inhibition of hepatic VLDL synthesis (Yoon, 2009). Decreased serum TGs have been demonstrated in rodents and obese dogs, but only inconsistently in nonhuman primates administered PPAR α agonists (Konig et al., 2009; Chen et al., 2008; Pugh et al., 2000).

PPAR α agonism also can decrease circulating levels of small, dense LDL (which have lower affinity to the LDL receptor), and increased large, buoyant LDL (which display higher LDL receptor affinity; Sections 21.5 and 21.6) resulting in increased LDL clearance rate overall. PPAR α agonists have also been shown to modestly increase HDL cholesterol through stimulating hepatic apoA-I and apoA-II expression (the two most abundant proteins in HDL particles; Section 21.5; Table 21.2) and promoting HDL-mediated cholesterol efflux from macrophages partly via enhanced expression of SR-B1 (Sections 21.5 and 21.6). Notably, PPAR α agonism has also been associated with inhibition of CYP7A1 (Section 21.8; Table 21.4), and hence, decreased catabolism of cholesterol in bile and increased risk of gallstone formation in humans (Li and Chiang, 2009).

Species differences in tissue distribution and response to PPAR α are significant (Braissant et al., 1996; Mukherjee et al., 1994; Van Veldhoven and Mannaerts, 1999). A number of responses to PPARs in regulated lipid metabolism moieties have been shown to be distinct or even converse between rodents and primates. Most notably, the receptor in rats is especially rich in hepatocytes, where agonism readily induces peroxisome proliferation. However, the primate PPAR α expression is the greatest in the skeletal muscle followed by liver, kidney, and adrenal, and pharmacologic agonism shows far less potential for peroxisome proliferation (reviewed in Winegar et al., 2001; Mukherjee et al., 1994). Accordingly, several studies have shown that PPAR α inducing agents elicit hepatic peroxisome proliferation, hepatocyte proliferation, hepatomegaly, and liver cancer in rats, while primates are considered resistant to these effects (Chopra et al., 2008; Holden and Tugwood, 1999; Mukherjee et al., 1994).

21.11.2 LIVER X RECEPTOR

LXR is a nuclear hormone receptor that is closely related to (and induced by some isoforms of) PPARs and similarly regulates multiple genes involved in lipid metabolism. In particular, LXR plays a pivotal role in controlling excess free cholesterol in the cells by enhancing cholesterol efflux and bile acid synthesis. As such, pharmacologic LXR agonists have been developed as a strategy in the treatment of atherosclerosis, to promote RCT and increase blood HDL cholesterol.

The nuclear hormone receptor has two isoforms, alpha (α) and beta (β), both of which regulate the expression of genes of cholesterol absorption, excretion, catabolism, and cellular efflux. The tissue distribution of these two isoforms differs: LXR α is expressed especially in liver, and predominantly in adipose tissue, intestine, macrophages, spleen, lung, and kidney, whereas LXR β is an expression, which is essentially ubiquitous among tissues (reviewed in Wójcicka et al., 2007). Endogenous agonists for both isoforms consist of intracellular oxidized cholesterol (oxysterols; e.g., intermediates in cholesterol metabolism and steroid hormone synthesis); oxysterols can accumulate with increasing concentrations of cellular cholesterol (reviewed in Baranowski, 2008; Zhao and Dahlman-Wright, 2010). LXR α has a more significant regulatory role in cholesterol metabolism and RCT than LXR β (reviewed in Steffensen and Gustafsson, 2004). Some of the genes regulated with LXR α activation include those involved in cholesterol absorption from the intestine, cholesterol biosynthesis, and incorporation of cholesterol in HDL (e.g., apoE) (Zhao and Dahlman-Wright, 2010; Steffensen and Gustafsson, 2004).

In addition to the beneficial role in maintaining cholesterol homeostasis, the agonism of LXR also activates hepatic FA synthesis and a liver-specific secretory protein that inactivates LPL. Thus, LXR activation tends to lead to increased liver and blood (VLDL) TG and PL (Groot et al., 2005). These deleterious effects of LXR α -mediated FA synthesis lead to hepatic steatosis and increased circulating LDL cholesterol. The effect on LDL cholesterol is especially seen in species that express CETP (including primates; Section 21.5) (Groot et al., 2005). An additional important species difference is in LXR α -mediated stimulation of CYP7A1. In rats and mice, LXR α stimulates transcription of CYP7A1, the rate-limiting enzyme in the classic bile acid biosynthetic pathway (Goodwin et al., 2003); thus, LXR α activation enhances the efficiency of cholesterol excretion via conversion to bile acids in these rodents. Conversely, the expression of the human hepatocyte CYP7A1 gene has been shown to be inhibited by LXR α (Goodwin et al., 2003). Further, LXR agonism has also been shown to regulate inflammatory processes through suppressing proinflammatory chemokine gene, and enhancing anti-inflammatory mediator gene induction. This LXR function may be a contributing factor in the link between inflammation and lipid metabolism pathways (Section 21.9).

21.12 NOVEL HORMONES OF LIPID METABOLISM

21.12.1 LEPTIN

Leptin is a cytokine-like hormone that is linked with lipid metabolism, as well as general energy homeostasis, neuroendocrine function, and immunity. The hormone is released into circulation in proportion to the amount of stored tissue lipid, and acts on the leptin receptors in the brain (principally, the hypothalamus) to regulate food intake and energy expenditure. In animals with normal body weight, leptin is readily transported into the CNS where it inhibits feeding and enhances thermogenesis. However, in obese animals, altered blood/brain concentration of leptin has been associated with the disruption of the feedback loop between hyperleptinemia and appetite, and with hyperglycemia, arterial hypertension, and diabetes mellitus type 1 and type 2. Thus, the replenishment of leptin specifically in the hypothalamus has been proposed as the target therapy for the metabolic syndrome (Kalra, 2011).

Leptin is produced predominantly in white adipose tissue, and to a lesser extent in other organs including the pituitary gland (reviewed in Sone and Osamura, 2001). Leptin activation of receptors

in white adipose tissue mediates increased HSL activity resulting in lipolysis in lean (but not obese) animals, and induces adipocyte apoptosis. Leptin appears to have a role in regulating thermogenesis in brown fat as well, although the pathways are still not well defined (Baile et al., 2000; Richard et al., 2010). In the brain, leptin impacts central nervous system regulators that control food intake and energy balance such as neuropeptide Y (NPY), corticotropin-releasing hormone (CRH), proopiomelanocortin (POMC), melanin-concentrating hormone (MCH), and somatostatin (Baile et al., 2000). Overall, leptin appears to play a key role in the maintenance of serum TG. Several prominent animal models of hypertriglyceridemia are due to the defects in leptin signaling including the leptin deficient (*ob*) and leptin-receptor mutant (*db*) mouse, and the leptin receptor mutant Zucker rat.

Leptin concentrations in blood have diurnal variability that is impacted by body weight and gender (Baile et al., 2000). Circulating leptin levels are also affected by food intake with increases in postprandial levels of leptin that gradually decline hours after a meal. Fasting causes a proportionately greater decline in leptin levels in lean, compared with obese animals (Baile et al., 2000; Radin et al., 2009). Importantly, blood leptin concentrations do not directly reflect (and can be inversely) correlated with the hypothalamic concentrations, with the latter being the more significant regulator of food intake and energy homeostasis.

21.12.2 GHRELIN

Ghrelin is a signaling peptide that has a role in feeding behavior, energy expenditure, and obesity. Ghrelin blood levels have been shown to increase before meals and decrease after meals and is accordingly, believed to stimulate hunger. Ghrelin actions are also similar to (and may have evolved from the same peptide precursor as) motilin in inducing gastric acid secretion and gastric motility (reviewed in Asakawa et al., 2001; reviewed in Yin et al., 2009). Ghrelin effects in decreasing energy expenditure may be linked with an influence on GH and insulin secretion, adipocyte response to insulin and thermogenesis (Kojima et al., 1999; St-Pierre et al., 2004).

Ghrelin is primarily secreted by specialized cells in the gastric fundic mucosa and pancreas in response to a reduction in gastrointestinal contents, and its receptor is GH secretagogue receptor found in a variety of tissues including hypothalamus, pancreas, intestine, and adipose tissue (Kojima et al., 1999; reviewed in Yin et al., 2009). The transcriptional, translational, and post-translational modifications of the ghrelin gene are complex, with dissociated gene and protein expression, and with related hormones (including acyl ghrelin, des-acyl ghrelin, and obestatin) of differing activity also being released into the circulation (Ghelardoni et al., 2006; Yin et al., 2009). The amino acid sequence of ghrelin is well conserved across species, but the sequence and the number of these related hormones and secreting cell morphology is more variable among animals (Kojima et al., 1999; reviewed in Yin et al., 2009). In general, ghrelin and/or acyl ghrelin levels increase in blood with long-term fasting and insulin-induced hypoglycemia, and at night versus daylight hours. In humans and mice, levels of ghrelin (and/or acyl ghrelin) are higher in females compared with males, and decrease with age in both sexes (reviewed in Yin et al., 2009). In mice, the decrease with age is specific to acyl ghrelin and occurs after weaning is initiated. In humans, there is an inverse correlation between circulating ghrelin and body mass index (reviewed in Yin et al., 2009).

Ghrelin decreases have been proposed to be linked with increases in glycogen synthesis and tissue carbohydrate stores, and may result in decreased appetite stimulation. Blood glucose levels can impact ghrelin, with glucose infusions acutely decreasing circulating forms of ghrelin concentration in humans and rats (McCowen et al., 2002; Hotta et al., 2004). Less pronounced ghrelin decreases are also seen with increases in circulating long-chain NEFA (reviewed in Yin et al., 2009). Ghrelin also decreases with exercise training that may be linked with increased muscle glycogen stores; after 6 weeks of treadmill training in rats, there were decreases in ghrelin levels in plasma (Ghanbari-Niaki et al., 2009). In obesity, leptin and ghrelin have a negative correlation, with leptin generally accepted as an inhibitor of ghrelin synthesis, possibly through the ghrelin receptor in the stomach

(reviewed in Yin et al., 2009). Notably, the physiology of ghrelin is not fully understood within, and across animal species at this time, complicating interpretation of blood levels.

21.12.3 ADIPONECTIN

Adiponectin is a hormone produced by mature adipocytes, and its gene has been reported to be one of the most highly expressed in white adipose tissue (reviewed in Radin et al., 2009). It was discovered in mice and human adipose tissue in the same year by several laboratories and hence initially given various monikers (apM1, Acrp30, GBP28 and AdipoQ) (Scherer et al., 1995). Adiponectin is now considered an important mediator of lipid metabolism, involved in regulating both glucose levels and lipolysis and linking insulin resistance with obesity.

Adiponectin is induced by insulin and promotes insulin sensitivity and adipocyte differentiation. In humans, with insulin resistance, adiponectin plasma concentration shows a negative relationship with serum TGs and obesity and inverse relationship with fasting (Merl et al., 2005; Scherer et al., 1995; Vendrell et al., 2004; Weyer et al., 2001). In horses, dogs, cats, and rats, there is a similar inverse correlation between adiponectin levels and obesity, adiposity, and/or fat mass (Radin et al., 2009). However, the level of circulating adiponectin appears to be most closely related to the extent of insulin resistance rather than of adiposity or glucose intolerance (Weyer et al., 2001). Unlike ghrelin and leptin, adiponectin appears to have a random secretion pattern, unaltered by time of day or feeding (Yildiz et al., 2004).

Exercise may also have an effect on adiponectin levels; intermittent, repeated moderate aerobic exercise resulted in a rapid two- to threefold increase in circulating adiponectin in rats and men (Kriketos et al., 2004; Zeng et al., 2007). In one study of overweight men, multiple sessions of moderately intense aerobic exercise resulted in a 260% increase in circulating adiponectin levels within a week of baseline that remained elevated after 10 weeks of exercise (Kriketos et al., 2004). Authors of this study proposed that it may take repeated exercise to induce exercise-related changes in plasma adiponectin. However, while repeated intense exercise increased tissue mRNA adiponectin, no change in serum adiponectin was detected in rats (Zeng et al., 2007). Similarly, no change in the blood levels of adiponectin were detected in horses following repeated intense exercise (Gordon et al., 2007). Thus, the interpretation of blood adiponectin levels should be approached with understanding of these complexities and potential species distinctions.

21.12.4 NEUROPEPTIDE Y

Neuropeptide Y (NPY) is a neuromodulator produced in the hypothalamic arcuate nucleus (Malva et al., 2012). This neurotransmitter is considered to be one of the most orexigenic (appetite stimulating) peptides to play a role in the control of food intake and regulation of energy balance (Higuchi, 2012; Edelsbrunner et al., 2009). It signals through several NPY receptors, such as Y1 and Y5 in the paraventricular nucleus. A role in energy balance has been demonstrated in NPY^{-/-} mice with decreased locomotion and exploratory behavior compared to wild-type mice. An associated decrease in food and water intake was evident in NPY and peptide YY (PYY short peptide with postprandial release by mucosal cells in the gastrointestinal tract that acts as an appetite suppressant in species including rats, nonhuman primates, and humans) double knockout mice (most consistently in females) compared to wild-type mice, but generally not in NPY or PYY knockouts alone. Consistent with the asynchronous effects in activity and feeding behavior, the knockouts (NPY and double NPY/PYY) were generally heavier than the wild-type mice (Edelsbrunner et al., 2009). Leptin deficient *Lep^{ob}/Lep^{ob}* mice exhibit a definitive role for NPY in stimulating food intake. NPY is normally overproduced in *Lep^{ob}/Lep^{ob}* mice, but *Lep^{ob}/Lep^{ob}* mice that are also deficient in NPY are less obese than *Lep^{ob}/Lep^{ob}* mice due to increased activity and decreased feed intake (Erickson et al., 1996). Systemic administration of leptin inhibits *NPY* gene expression and synthesis resulting

in suppressed feed intake and decreased body weight in normal and *Lep^{ob}/Lep^{ob}* mice, but not *Lepr^{db}/Lepr^{db}* mice that lack a functional leptin receptor (Stephens et al., 1995).

21.12.5 STEROL REGULATORY ELEMENT-BINDING PROTEIN

SREBPs (isoforms 1a, 1c, and 2) are transcription factors, which globally regulate intracellular levels of cholesterol, FAs, TGs, and PLs. The SREBP isoforms 1a and 1c are produced from a single gene (*SREBF1*) via alternate promoters, and isoform 2 is produced from a distinct gene (*SREBF2*) (Yokoyama et al., 1993). Essentially all cells produce one or more of these isoforms. The SREBP-1c isoform is expressed in especially high levels in liver, white adipose tissue, adrenal gland, and brain and skeletal muscles in adult animals (Shimomura et al., 1997).

These SREBP isoforms are inactive and bound to ER when cholesterol and FAs are available to the cell. However, when the cell is faced with low levels of cholesterol and/or FAs, the active NH₂-terminal fragments are released (via a number of steps: disassociation of Insig-1 (insulin-induced gene-1) protein from SCAP (SREBP cleavage activating protein), transport to the Golgi apparatus, and cleavage by proteases), allowing them to translocate to the nucleus (Ye and Debose-Boy, 2011). Translocation to the nucleus induces genes involved in synthesis and cellular uptake of lipids.

The three SREBP isoforms have differing efficiencies in FA and cholesterol lipid synthesis. Based on knockout mouse studies, SREBP 1c appears to primarily regulate FA- (and hepatic glucose-) synthesis-related genes, whereas the 1a isoform is involved in both FA and cholesterol synthesis, and SREBP-2 is more specific to cholesterol synthesis (Shimomura et al., 1997). Regulation of these transcription factors is controlled at the level of transcription, proteolytic cleavage of SREBP precursors, and posttranslational modification of nSREBPs, and varies between isoforms. Transcriptional regulation of liver SREBP-1c is a key for its role in lipid synthesis and can be induced by (1) feeding a high carbohydrate diet after a period of fasting (likely involving insulin signaling), (2) activation of LXR alpha, or (3) possibly through self-activation of the promoter of its own sterol response element (SRE) (Eberle et al., 2004). Activation of the promoter of its own SRE may also be involved in regulation of SREBP-2 (Schiavoni et al., 2010). Sterol-dependent regulation controls transport from the ER to the Golgi, where proteolytic cleavage occurs (Shao and Espenshade, 2012). The unique activity and regulation of each SREBP isoform is consistent with differences in isoform-related target gene specificity, and exemplifies the broad role of SREBP in lipid metabolism and homeostasis.

21.13 ANIMAL MODELS OF ALTERED LIPID METABOLISM

The number of animal models of altered lipid metabolism is vast and growing, perhaps because of the increasing recognition of lipid disorders in the most common of human diseases. The ideal animal model, with a lipid profile and response to challenge similar to that of humans does not exist. The relevance to humans of each animal model is often limited to specific lipid components or pathways. Thus, interpretation of data from these models for extrapolation to humans should always be couched with consideration of species/model differences in lipid metabolism. In addition, for a majority of these models, the age and sex reference ranges, and/or intra-study blood lipid values are not available, limiting constructive statements on general clinical pathology data interpretation. Thus, this section will discuss only some of the commonly used general models of dyslipidemia but will not focus on specific models of atherosclerosis or selective transgenic or knockout rodent strains that model specific lipid disorders.

Important factors to consider in selecting an acceptable model for study are the animal's predominant types of circulating LPs, hepatic predominance in cholesterol synthesis, and capacity for biliary excretion (Section 21.8), and the presence or absence of CETP and hepatic apoB48 production (Sections 21.4 and 21.5). Humans have a predominance of LDL cholesterol, as do a few common laboratory species including guinea pig, domestic pig, and some nonhuman primates (e.g., African green monkeys and macaques). Hamsters and rabbits have a predominance of HDL cholesterol in

blood with a standard diet but convert to a predominance of circulating LDL cholesterol when exposed to a high fat diet. Hamsters and rabbits also tend to have a level of cholesterol synthesis in the liver relative to whole body cholesterol synthesis that is more similar to humans compared to that of rats or mice. Several other species, including dog, cat, horse, ruminants, rat, and mouse have predominantly HDL cholesterol and resist dietary cholesterol challenge (in contrast to humans). Laboratory species also significantly vary CETP activity (Table 21.1, Section 21.5, and Table 21.4) with rabbits, opossums, and trout having high levels, while rats, mice, dogs, cats, pigs, and sheep show little to no detectable CETP activity. Humans have an intermediate level of CETP activity (similar to guinea pigs, chickens, toads, and some reptile species). With low CETP activity, CEs are not readily transferred from HDL to other LPs, resulting in HDL being cholesterol-rich and less dense. In general, species with low CETP activity have high blood HDL cholesterol levels, and HDL/LDL ratio.

21.13.1 LEPTIN RECEPTOR MUTANT MOUSE

The *db* mutation, one of the 14 known spontaneous mutations in the mouse leptin receptor (*Lepr*), is characterized by high plasma TGs and cholesterol, making it a good model of diabetic dyslipidemia (Kobayashi et al., 2000). The mouse becomes obese by 6 weeks of age with correlative increases in glucose, insulin, TGs, and cholesterol. The cholesterol levels are not only mainly due to relatively higher HDL cholesterol but also non-HDL cholesterol in the IDL/LDL cholesterol range. The non-HDL cholesterol proportion increased significantly with feeding of a high-fat or “Western” diet with 0.15% (wt/wt) cholesterol and 21% (wt/wt) fat. LPL in plasma and LPL mRNA expression in heart, muscle, and adipose tissue were substantially decreased in the *db/db* mice.

21.13.2 FAT-FED SYRIAN HAMSTER

The fat-fed Syrian hamster [e.g., Crl:LVG(SYR)] has been compared to the fat-fed gerbils and guinea pigs and considered a good model to study hypertriglyceridemia since the serum concentrations of TGs will remain elevated with a high-fat, high-cholesterol diet (Sullivan et al., 1993). Several studies have used hamsters as an animal model for humans because they are touted as having similar levels of plasma LDL cholesterol, rates of sterol synthesis in the liver, and LP metabolism (Wang et al., 2001; Ohtani et al., 1990). This is partly due to the presence of CE-transfer protein (CETP) in hamsters but not in mice and rats (Groot et al., 2005).

21.13.3 ZUCKER RAT

The genetically obese Zucker rat, named after its founders, has a homozygous recessive mutation (*fa* for fatty) of the leptin receptor gene (*Lepr*) (Zucker and Zucker, 1963). This model is characterized by hyperphagia, hyperinsulinemia, insulin resistance, and juvenile onset obesity with hyperlipidemia due to elevated serum TGs (as early as 2 weeks of age) and cholesterol (Godbole et al., 1978; Boulange et al., 1981).

The plasma of these animals is milky in appearance, with TG that can be several-fold greater than that in the blood of non-homozygous lean Zucker rats (Aleixandre de Artiñano and Miguel Castro, 2009). The increased circulating TG is principally due to the accumulation of VLDL attributed to exaggerated hepatic synthesis and secretion of TG-rich LPs. Increases in the blood cholesterol also reflect the increases in VLDL and also HDL but not LDL. The clearance of TG-rich particles in these homozygous (*fa/fa*) animals is not consistently different from that of the lean counterparts; however, differential clearance between tissues may help predict distribution of adiposity in that LPL levels have been reported to be increased in white adipose, and normal to decreased in brown adipose and heart tissue in the rat (Horwitz et al., 1984; Wang et al., 1984).

21.13.4 RABBITS

Rabbits have been widely used as models of hypercholesterolemia and atherosclerosis. The well-characterized models are the homozygous and cholesterol-fed heterozygous Watanabe heritable hyperlipidemic rabbit (WHHL rabbit) (Aliev and Burnstock, 1998; Atkinson et al., 1989; Buja et al., 1990; Havel et al., 1989; Shiomi et al., 2000; Tanaka et al., 1995; Zhang et al., 2009). The WHHL rabbits have an in-frame deletion in the ligand-binding domain of the LDL receptors, which prevents LDL uptake and results in high serum cholesterol levels and spontaneous development of aortic atherosclerosis (Yamamoto et al., 1986; Li et al., 1995). Chow-fed WHHL rabbits had plasma cholesterol levels at 4 months of age of 260 ± 100 mg/dL, and at 15 months of 545 ± 178 mg/dL (Nolte et al., 1990). However, due to low availability of WHHL rabbits, many researchers have moved to more accessible rabbit strains such as New Zealand white rabbits and cholesterol-feeding regimens. Dutch belted rabbits provide an alternative strain for use in hypercholesterolemic modeling (Kritchevsky et al., 1971).

21.13.5 MINIPIGS

Minipigs have been promoted for lipid metabolism research due to ready availability and similarity with humans in having LDL as the dominant blood cholesterol carrier. Pigs, including minipigs, can also develop atherosclerosis even on a typical swine diet (Skold et al., 1966). The progression of these vascular lesions, from fatty streaks to fibrous plaques to more advanced atherosclerotic lesions is similar to humans and the severity and extent increase with age, and hypercholesterolemic diet as in human. Minipigs fed a low-cholesterol diet have plasma LPs that resemble humans in the relative levels of VLDL, LDL, and HDL (Mahley et al., 1975).

Several strains of minipig have been developed but the most well-characterized strains for lipid research are the Göttingen and Yucatan strains. The Göttingen minipig has been used as a model of postprandial hyperlipidemia and metabolic syndrome (Olsen et al., 2002; Johansen et al., 2001). The Yucatan minipig has been utilized as a model of hypercholesterolemia and diabetic dyslipidemia (Sodha et al., 2008; Boullion et al., 2003). Other strains of minipig (Chinese Guizhou minipigs) have been utilized to evaluate diet-induced diabetes and atherosclerosis (Liu et al., 2007).

21.13.6 CYNOMOLGUS MONKEYS

The cynomolgus monkey (*Macaca fascicularis*) is a relatively good model for evaluation of hyperlipidemia because of similarities to humans in response to dietary lipid excess, and a susceptibility to type 2 diabetes mellitus, and naturally occurring (as well as experimentally induced) atherosclerosis. The atherosclerotic changes associated with high cholesterol also show gender-related differences as in humans (Weingand, 1989) (also see Section 21.9). The relatively low basal cholesterol synthesis in the liver of the cynomolgus monkey, which also limits capacity for hepatic bile synthesis, is similar to human and in contrast with rats and mice (Turley et al., 1995).

With cholesterol feeding of cynomolgus monkeys, hypercholesterolemia (and associated LDL cholesterol increases) occurs generally in proportion to the degree of dietary challenge (Marzetta and Rudel 1986; Rudel et al., 1986; Turley et al., 1995). However, the blood cholesterol increase is partly associated with an increase in LDL particle size in direct contrast with the pro-atherosclerotic small dense LDL profile of human (Bullock et al., 1975; Rudel et al., 1986). Cynomolgus monkeys also have a blood lipid composition that is generally similar to humans in health; however, relative concentrations of individual molecular lipid components differs (Shui et al., 2011).

21.13.7 AFRICAN GREEN MONKEYS

African Green Monkeys (*Cercopithecus aethiops*) have been proposed to be a relevant model of atherosclerosis, in part because they develop atherosclerotic lesions that follow a similar pathogenic

course as in humans (Rudel et al., 1985). They also show lesser tendency than cynomolgus monkeys for LDL particle size increase with cholesterol feeding (i.e., LDL composition more comparable to higher risk of atherosclerosis in humans) (Rudel et al., 1985). However, African green monkeys are resistant to developing an atherosclerotic lipid profile with cholesterol feeding, and have an HDL-dominant blood lipid profile in health (Thomas and Rudel, 1996; Rudel et al., 1990).

Several other nonhuman primate species have also shown selective utility as animal models of lipid research and/or diet induced-atherosclerosis. This includes other species of macaques, such as pigtail macaques and obese Rhesus macaques (*Macaca nemestrina* and *Macaca mulatta*, respectively), patas monkeys (*Erythrocebus patas*), baboons (*Papio species*), Bornean orangutan (*Pongo pygmaeus*), and gorillas species (Kritchevsky et al., 1974; Rudel et al., 1985; Schmidt et al., 2006; Thomas and Rudel, 1996). Importantly, the composition of circulating LPs, LDL particle size, and HDL cholesterol concentration, as well as the extent of hyperlipoproteinemia in response to dietary cholesterol feeding is unique to each of these species.

21.14 LABORATORY ANALYSES OF BLOOD LIPIDS AND LIPOPROTEINS

21.14.1 LIPID ANALYSIS

Samples for the analysis of blood lipids (TGs, cholesterol, NEFAs, or PLs) can be serum or plasma. For plasma, the preferred anticoagulant is disodium ethylenediaminetetraacetic acid (EDTA) or heparin. Lipid concentrations can be minimally (about 2%–5%) lower in EDTA plasma than corresponding serum (due to osmotic shift of water from cells to EDTA plasma) (Folsom et al., 1983). Samples are generally stable for up to 72 hours at 4°C, or frozen at ≤−20°C. Fasting, if indicated, should be for an appropriate time period for the animal to avoid blood lipid changes associated with physiologic lipolysis (Section 21.9).

Routine laboratory analysis of TGs and total cholesterol is conducted with enzymatic assays on an automated analyzer and requiring few microliters of sample. Most of the current commercial assays are useful for the analysis of the samples of any species. Chemical assays that differentiate between HDL and LDL cholesterol generally involve added reaction steps to precipitate or mask by inhibiting reactivity, or initial disruption of the nontarget LPs. Analysis of NEFA or PL concentrations is less routine but readily achieved with automated chemical assays. More specialized methods for some of these analyses are also briefly mentioned below.

21.14.1.1 Total Serum/Plasma TGs by Automated Chemical Analysis

TGs are measured with a two-step procedure initiated by lipase release of FAs from glycerol, which is subsequently quantified by oxidase-mediated production of hydrogen peroxide and peroxidase-linked colorimetric reaction:

1. Triglycerides + 3H₂O $\xrightarrow{\text{Lipase}}$ glycerol and fatty acids
2. Glycerol + ATP $\xrightarrow{\text{glycerol kinase}}$ glycerol-3-phosphate + adenosine diphosphate (ADP)
3. Glycerol-3-phosphate + O₂ $\xrightarrow{\text{glycerol-3-phosphate oxidase}}$ 2H₂O₂ + dihydroxyacetone phosphate
4. 2 H₂O₂ + 4-aminophenazone + 4-chlorophenol $\xrightarrow{\text{peroxidase}}$ quinoemine dye + 4H₂O + HCl

This method also measures other (mono- and di-)acylglycerides and free glycerol in serum samples; analytes that generally comprise ≤10% of the detected total TGs in healthy laboratory animals. Glycerol blanking to correct for free glycerol is a consideration, however, in animals with pathologic conditions associated with high peripheral lipolysis such as starvation, diabetes mellitus, high carbohydrate diet or catecholamine excess, or administration of mixed lipid preparations (Chatzipanteli et al., 1996; Ciralo et al., 1995; Jessen et al., 1990).

Because the mg/dL unit is based on weight, and TGs are highly heterogenous in molecular weight due to variability in FA content, reporting in millimoles per liter (mmol/L; SI units)

is the more precise unit measure (e.g., for investigative comparative assay/study purposes). If conversion is necessary for estimated value comparisons, mg/dL can be multiplied by 0.01129 (http://www.soc-bdr.org/rds/authors/unit_tables_conversions_and_genetic_dictionaries/e5196/index_en.html).

21.14.1.2 Total Serum/Plasma Cholesterol

For total cholesterol quantitation, cholesterol esterases are used to break the ester bond and release free cholesterol from LPs; this is followed by an oxidase step that generates hydrogen peroxide that together with a chromagen substrate and peroxidase generates a colorimetric reaction:

1. Cholesterol ester + H₂O $\xrightarrow{\text{cholesterol esterase}}$ cholesterol + FAs
2. Cholesterol + O₂ $\xrightarrow{\text{cholesterol oxidase}}$ cholestenone + H₂O₂
3. H₂O₂ + 4-aminophenazone + phenol + 4-aminoantipyrine $\xrightarrow{\text{peroxidase cholesterol oxidase}}$ quinoneimine dye + 2H₂O

21.14.1.3 HDL and LDL Cholesterol

Commercial assays to measure HDL or LDL cholesterol on automated platforms utilize the same cholesterol esterase–cholesterol oxidase steps for analysis of total cholesterol, after first removing (by precipitation or disruption) or masking the nontargeted cholesterol containing LPs. The accuracy of the specific assay type, however, varies considerably between species and in cases of extremes in TG, cholesterol, or apo abnormalities. Thus, due to the numerous kits available and manufacturer changes made in components, validation with appropriate species samples to determine specific assay suitability is recommended. Notably, all HDL and LDL cholesterol commercial assays are calibrated with human standards, so that species differences from humans in LP content are an inevitable source of inaccuracy. Methods utilizing antibodies to immunoinhibit reactivity, or immunoprecipitate select LPs, are also not recommended for nonhuman samples if extent of cross-reactivity is unknown.

21.14.1.3.1 HDL Cholesterol

The precipitation-based method has long been utilized for HDL cholesterol analysis (Arranz-Pena et al., 1998; Tailleux and Staels, 2011). The method uses polyanions combined with divalent cations to aggregate particles with lower density than HDL cholesterol, while HDL cholesterol remains in solution (Warnick et al., 2001). The polyanions are complex carbohydrates (such as heparin, dextran sulfate or polyvinyl sulfate, and phosphotungstate Mg²⁺) that complex with apoB-100 and apoB-48 under pH conditions that ensure these apos are positively charged. The interactions between the anionic sulfated glycans and cationic (arginine and lysine) amino acids of apoBs are believed to be primarily electrostatic. Notably, due to broad LP heterogeneity and despite assay improvements over time, precipitation methods remain somewhat imprecise.

Assay improvements have also led to homogeneous methods, for HDL cholesterol analysis without need for the added separation step of precipitation. One method (Kyowa assay) masks other LPs by the use of sulfated α -cyclodextrin and polyanion (dextran sulfate) with polyethylene glycol (PEG)-modified cholesterol esterase and cholesterol oxidase (Sugiuchi et al., 1995). The sulfated α -cyclodextrin reduces the reactivity of cholesterol in chylomicrons and VLDLs, without the need for precipitation. The modified enzymes show selective catalytic activities with increasing reactivity toward HDL over LDL and VLDL. This method may be especially appropriate for rat and rabbit samples (based on comparison of results with density ultracentrifugation (unpublished data). Another method uses a LP-selective reagent to release non-HDL cholesterol from apoB-particles, then catalyzes the esterase-oxidase reaction, and inhibits the resulting peroxidase prior to release cholesterol from HDL-particles by detergent. This method may be more accurate for mouse, hamster, cynomolgus monkey, and dog than the blocking method mentioned previously (unpublished data).

21.14.1.3.2 LDL Cholesterol

Evaluation of LDL cholesterol in nonhuman species can be even more challenging than that for HDL cholesterol, in that the specific lipid content of heterogeneous LDL particles tends to overlap with a greater variety of LPs than HDL; that is LDL lipid content variably overlaps with HDL, VLDL, and IDL in all species. The extent of this overlap varies between species and lipid-altering conditions. In particular, LDL cholesterol assays do not distinguish between LDL, and IDL (and in primates, also Lp(a)) cholesterol. Thus, values obtained with all LDL cholesterol assays with laboratory animal samples are only estimations of true LDL cholesterol.

As with HDL cholesterol assays, the LDL cholesterol precipitation methods are being replaced by homogeneous assays. The homogeneous assays use a variety of detergents and other chemicals to specifically block or solubilize LPs other than LDL, enabling LDL cholesterol to then be measured enzymatically. One homogeneous direct enzymatic methodology involves reducing the enzymatic reaction of the cholesterol measurement in VLDL and chylomicrons in the presence of magnesium. This, in combination with detergent, enables the determination of LDL cholesterol via selective micelle solubilization.

21.14.1.3.3 LDL Cholesterol by the Friedwald Formula

The Friedwald calculation is based on human blood lipid components, and the assumption that VLDLs carry the majority of serum TGs (in samples from a fasted animal). Therefore, the total TG concentration can be used to estimate VLDL cholesterol. This requires values for serum TG, total, and HDL cholesterol to estimate LDL cholesterol (Friedewald et al., 1972):

$$\text{LDL cholesterol} = \text{total serum cholesterol} - (\text{measured HDL cholesterol} + \text{estimated VLDL cholesterol})$$

With this calculation, human VLDL cholesterol is estimated as total serum TG divided by 5, a value that does not apply to nonhuman samples. However, because total serum VLDL cholesterol is proportionately minor compared to HDL and LDL cholesterol in many domestic species, the Friedwald formula without the VLDL cholesterol estimation has been commonly applied to samples from laboratory animals. Regardless, it should be emphasized that there are significant discrepancies in the calculated value compared with specific LDL cholesterol assay results with nonhuman serum samples. Further, the Friedwald formula is also not suitable for samples containing chylomicrons (which are present in health for some species and certain disease conditions even with fasting). For these reasons, in combination with the availability and ease of more direct chemical LDL cholesterol assays, the calculated value is not recommended for nonhuman samples.

21.14.1.4 Nonesterified Fatty Acids

In contrast to TG and cholesterol, NEFAs are transported in the blood bound to albumin rather than as a component of LPs. Low concentrations are found in the blood of healthy animals; increased concentrations most commonly indicate enhanced lipolysis. Serum or EDTA plasma NEFAs can be readily measured by automated chemical methods (as well as high-performance liquid chromatography [HPLC] and gas chromatography). Sample collection in heparin should be avoided to prevent increasing NEFA (and decreasing TG) values over time with endogenous LPL activation. Serum-separator tubes (SSTs) are also not ideal, because values have been reported to be artificially increased. With all collection methods, care must be taken to prevent release of FAs as the result of TG hydrolysis after specimen collections; preferably, samples are rapidly separated from cells and transferred to ice or refrigerated at 4°C. Specimens may also be mixed with paraoxon, a cholinesterase inhibitor, immediately after collection. NEFA concentrations in serum or plasma samples are generally stable at 4°C for up to 48 hours or frozen for up to 1 month but tend to increase over time, and especially when stored for even a few hours at room temperature (author experience; Menéndez et al., 2001).

Chemical (enzymatic) methods are simple (though somewhat less sensitive and do not provide information about the FA forms compared with research techniques mentioned). These assays are based on NEFAs forming acyl-CoA in the presence of acyl-CoA synthetase (and co-substrates);

generated Acyl CoA is enzymatically oxidized to produce hydrogen peroxide to form the final chromagen for spectrophotometric detection. With all of these methods, it is better to avoid samples with hemolysis or those collected immediately postprandial.

21.14.1.5 Phospholipids

PLs occur in blood in greater concentration than any other major lipid structural type; yet, their analysis is nonroutine. This may be largely due to the limited value of a single serum PL measurement because of broad and dynamic distribution of PLs in blood and among LPs even within an individual in health. This variability can confound interpretation of differences between intervals or groups. Broad species differences in circulating PLs are also well established (Diagne et al., 1984). Quantitation of total circulating (or LP fractions of) PLs, however, is sometimes conducted as an index of hepatobiliary disorders, nutritional status, dyslipoproteinemias, or in mediums other than blood (e.g., bile).

Quantification of total PLs can be achieved with automated direct, one-step chemical assays, in which PLs (and sphingomyelin) are hydrolyzed by phospholipase to phosphatidic acid and free choline. In the presence of choline oxidase and peroxidase, the free choline is then estimated colorimetrically. Analysis of specific PL forms (e.g., any of the major PLs in circulation: phosphatidylcholine [PL-C or lecithin], lysolysolecithin, or phosphatidyl ethanolamine) may be conducted by commercial chemical enzymatic assays or several research methods, including thin layer or gel chromatography, HPLC, and HPLC–mass spectrometry (MS) (Phillips, 1959; Subbaiah, 2000).

21.14.1.6 Sphingolipids

SLs, and specifically sphingomyelin, occur as a significant proportion of blood lipids. Analysis of serum/plasma sphingomyelin has been utilized to assess genetic dyslipoproteinemias and recently, to assess risk of atherosclerosis in humans and animal models with hyperlipidemia (Hidaka et al., 2008). Enzymatic assays for sphingomyelin are commercially available. These utilize sphingomyelinase to hydrolyze sphingomyelin to PL-C and ceramide. Subsequent steps are similar to those described earlier for PL quantitation. Additional (research) methods for broad SL analysis in blood and other fluids have been described in the published literature (Abnet et al., 2001).

21.14.2 LIPOPROTEIN ANALYSIS

21.14.2.1 Density-Gradient Ultracentrifugation

The gold standard for evaluation of LP levels, including the different major classes of serum LPs, is ultracentrifugation. The principal of ultracentrifugation is to separate LPs based on their hydrated density. Ultracentrifugation can also determine the predominant particle size distribution but does not provide concentrations of the LP particles themselves. Samples should be fresh or short-term refrigerated, thoroughly mixed plasma from EDTA-anticoagulated blood. Some assay methods also require smaller sample volumes that may enable in-life testing of small laboratory species. Common assay methodology has been described (Subbaiah, 2000).

However, ultracentrifugation is technically complex, and labor- and time-intensive and, except for utility as a research method and to validate new methods (e.g., HDL and LDL automated assays), is not practical for routine laboratory application. Due to broad differences in equipment, methodology, and conditions (such as salt concentrations and centrifugal forces) between laboratories, complete reproducibility between experiments is also difficult to achieve (Warnick et al., 2001; Wilcox and Heimberg, 1970). Thus, despite use as a gold standard, there are no standardized ultracentrifugation protocols, reference materials, or thresholds for subparticle distributions. Due to species differences in the specific composition of the different LP types, the density fractions collected are also highly variable between species, and can be difficult to interpret (especially if there are abnormal patterns) (Camus et al., 1983; Cole et al., 1984; Goulinet and Chapman, 1993; Hollanders et al., 1986; Lasser et

al., 1973). In summary, although ultracentrifugation is useful as a research method, it is particularly technique-dependent and fairly subjective in results interpretation.

21.14.2.2 Gradient Gel Electrophoresis and Chromatography

Polyacrylamide or agarose gel electrophoresis, high-performance liquid chromatography (HPLC), fast-performance liquid chromatography (FPLC), and size exclusion or ion exchange chromatography are other methods used for analysis of plasma LPs. These methods base distinction between LP types on charge and/or particle size. The simplest and longest standing of these, electrophoresis, has given rise to the alternative common names of the LPs in association with their electrophoretic mobility: *a* (HDL), pre- β -VLDLs and β -LDLs. Compared with ultracentrifugation, they are more equipment-intensive but less laborious, and offer the advantage of being able to “observe” the extent of heterogeneity within LP types and significant atypical LPs. Electrophoresis may also be used to test suitability of other LP analytical methods, and to analyze fractions separated initially by ultracentrifugation. However, as with ultracentrifugation, particle separation with these methods is partly subjective and technique-variable. Methods have also had issues with equipment reliability and lot-to-lot reagent (e.g., gel) differences (author experience; Subbaiah, 2000). Not surprisingly, because the composition of LP types varies between species, the location and width of the corresponding LP bands also widely varies between species. Description of select electrophoresis methodology for lipid analysis with nonhuman samples has been published (Lehmann et al., 1993).

21.14.2.3 Nuclear Magnetic Resonance Spectroscopy and Ion-Mobility Analysis

Additional methods for LP analysis include nuclear magnetic resonance spectroscopy (NMR) and ion-mobility analysis. NMR enables quantification of VLDL, IDL, LDL, and HDL and their sub-fractions by both average particle concentration and size. Lipoprotein concentrations are derived from the amplitudes of their lipid methyl group signal, and particle sizes are derived from the summed diameter of each subclass multiplied by its relative mass percentage (also based on the amplitude of its methyl NMR signal).

Ion-mobility analysis measures both the size and concentrations of LP particle subclasses based on gas-phase differential electric mobility. These methods have valuable utility with LP analysis but require specialized equipment and expertise, and reported experience with nonhuman species have not been well investigated to date.

21.15 LABORATORY ANALYSIS OF KETONES AND SELECT MEDIATORS OF LIPID METABOLISM

21.15.1 KETONES

Increased blood ketone levels indicate a metabolism shift (Section 21.7) that could be a result of physiologically altered energy demands (e.g., fasting, and prolonged exercise), a high fat diet, disease (insulin deficiency or resistance, juvenile hypoglycemia), or toxicity (e.g., resulting hypoglycemia with salicylate administration). Of the three major ketone bodies produced (acetoacetate, β -OHB, and acetone), blood levels of β -OHB (the conversion product of acetoacetate) are considered the best indicator of significant ketosis or ketoacidosis (Laffel, 1999). Indeed, as ketosis progresses, the ratio between β -OHB and acetoacetate increases, with β -OHB being the predominant ketone body contributing to ketoacidosis (Bell et al., 2005). As the acidosis (i.e., ketosis or ketoacidosis) resolves with treatment, the β -OHB is oxidized to acetoacetate and the β -OHB:acetoacetate ratio returns toward 1:1. The other major ketone, acetone, is not metabolized for energy, does not contribute to acidosis and has little diagnostic utility (Laffel, 1999).

Ketone bodies can be analyzed by chemical (automated and manual) methods in serum, plasma (with EDTA, heparin, or citrate anticoagulant), whole blood, or urine. Assays for β -OHB first convert the ketone body to acetoacetate via 3- β -OHB dehydrogenase, which concomitantly reduces

cofactor nicotinamide adenine dinucleotide (NAD). With spectrophotometric methods, the reduced NAD (NADH) and diaphorase enzyme convert a colorimetric detector to a colored product. Whole blood (point-of-care instrument) assays for β -OHB are based on the change in the electrochemical state mediated by NAD⁺/NADH and a redox mediator (Henderson and Schlesinger, 2010). Assays for acetoacetate (spectrophotometric) rely on the reverse reaction, oxidizing NADH; therefore, the chromogen is inversely related to the analyte concentration. Assays for determination of both of these ketone bodies (“total ketones”) are also available. High concentrations of vitamin C or B (more common with urine) can interfere with the accuracy of the assays (Vianey-Liaud et al., 1987).

While blood β -OHB is the most specific test to assess ketonemia, the semiquantitative urine test strip (aka dipstick) or tablets for acetoacetate are also sometimes used, especially in clinical veterinary medicine. The urine tests are based on the use of a nitroprusside reaction and give a measure of trace, moderate or strong positivity to acetoacetate, react weakly with acetone, and do not detect β -OHB. The semiquantitative methods are quick and inexpensive but less sensitive than multistep enzymatic assays, and only semiquantitative at best. The urine test strips are inferior when compared with the tablets for ketone detection, and have a considerable variability. Strongly pigmented urine and some drugs (such as valproic acid) can cause false positive readings with either of these simple urine tests. In addition, with resolving acidosis, acetoacetate levels increase relative to β -OHB. Hence, the urine acetoacetate test may give the misleading impression that ketosis is not improving.

21.15.2 CARNITINE AND AYLARNITINE

Carnitines and acylcarnitines are crucial to the catabolism of FAs in mitochondria (Section 21.7). Due to the insolubility of FAs, carnitine and acylcarnitines move FAs into the mitochondria for catabolism with the assistance of carnitine palmitoyltransferase I (CPT 1), carnitine-acylcarnitine translocase (CACT), and carnitine palmitoyltransferase II (CPT 2). Once FAs are in the mitochondria, FA catabolism results in the formation of acetyl-CoA, which generates ATP from the Krebs cycle and oxidative phosphorylation (Longo et al., 2006).

In general, there are low levels of acylcarnitines in circulation, with carnitine levels being predominantly due to free carnitine (Reuter and Evans, 2012). However, alterations in the catabolism pathway of FAs can result in dramatically different carnitine and acylcarnitine profiles in the plasma and urine. For example, if there is deficiency or inhibition of one of the enzymes that is involved in removing pairs of carbon atoms from the acylcarnitine (e.g., short-, medium-, or long-chain acyl-coenzyme A dehydrogenases; SCAD, MCAD, or LCAD, respectively), then a characteristic pattern of plasma and urine metabolites is produced. SCAD results in the alternate metabolism of butyryl-CoA and large amounts of organic acids such as ethymalonic acid and methylsuccinic acid are excreted, resulting in an abnormal urine profile (Prieto et al., 2006).

Methods for laboratory evaluation of carnitine and acylcarnitines in plasma and/or urine include spectrophotometry, HPLC, and electrospray ionization tandem mass spectrometry (McEntyre et al., 2004; Mueller et al., 2003; Longo et al., 2006). Tandem mass spectrometry allows the evaluation of an extensive panel of acylcarnitine fractions (Mueller et al., 2003).

21.15.3 LEPTIN

Leptin homology is variable across species, and does not follow a direct evolutionary path (Doyon et al., 2001). Hence, serum (or plasma) leptin analysis requires species-specific assays. Enzyme-linked immunoassay (ELISA) and/or radioimmunoassay (RIA) kits are currently available for mice, rats, dogs, and humans. As expected, these assays vary in antibody sets and detection methods, and require validation for precision, linearity, dynamic range, and accuracy with expected highest and lowest leptin concentrations. Utility (apparent cross-reactivity) of some of these assays with other species has also been reported (Kitao et al., 2011; Tsubota et al., 2008).

21.15.4 GHRELIN

Ghrelin is highly homologous across species (Tvarijonavičiute et al., 2012), and cross-reactivity of human assays has been validated for other species (rat, mouse) by some manufacturers. However, species-specific ELISAs and/or RIAs for ghrelin are also available for mice, rats, and dogs.

21.15.5 ADIPONECTIN

Adiponectin homology across species is relatively low (Jacobi et al., 2004; Li et al., 2008). Nonetheless, the published evaluations in animals have commonly relied on a commercially available human RIA, and only more recently on species-specific ELISAs for mouse/rat or for dogs. Assays for high molecular weight human adiponectin using a chemiluminescent enzyme immunoassay are also available; however, the significance of determining various molecular weight forms in dogs, cats, and horses has not been evaluated to date.

SUMMARY

Lipidology, including blood and tissue lipids and lipid transport, is a critical science in the study of human health. The differences between humans and other species, and across species overall in lipid metabolism in homeostasis, and response and adaptation to physiologic whole body perturbations are often striking. These differences largely reflect, and are in themselves, a study of species differences in natural diet, environment, and physiology. Yet, understanding of these species differences and associated physiologic mechanisms can also significantly inform, and enable their translation, the human condition. Hence, this chapter provides a unique comprehensive synopsis of the basic measurable blood lipid components, lipid metabolism, and physiologic responses in blood lipids with system perturbation in nonclinical species, as well as major animal models of lipid disorders, and the assays used to measure and interpret circulating lipids in nonclinical species. This collective information provides a reference for readers toward understanding the complexity of lipid metabolism across species, the utility of associated endpoints, and comprehension of physiologic mechanisms behind, and interpretation of, blood lipid data.

22.1 INTRODUCTION

Physiological maintenance of electrolytes, hydrogen ions, carbon dioxide, and oxygen is essential for providing a cellular environment conducive to optimal cell function. The absolute and relative amounts of these substances and their interrelationships determine the osmolality, state of hydration, and membrane potentials of the animal. They are integral to nerve conduction, muscle contraction, myocardial function, and bone formation, and they act as enzyme cofactors. Maintenance of pH within narrow limits is required for these functions and is achieved by manipulation of electrolyte and blood gas levels. Any deviation from a physiologically normal state produces a response in homeostatic mechanisms that attempt to return values to normal (Paulev and Zubieta-Calleja,

2005). Homeostatic responses are most often brought about by changes in ion channel activity. With this knowledge, manipulation of homeostatic mechanisms (such as ion channels, etc.) is sometimes utilized during drug development processes to produce pharmaceutical products. Moreover, it is important to be aware of the possibility of adverse effects drugs may have on electrolytes, blood gases, and acid–base parameters. For example, albuterol, a β agonist, can stimulate sodium–potassium adenosine triphosphatase (ATPase) pumps that result in an intracellular shift of potassium producing low blood potassium levels (Allon and Copkney, 1990). Moreover, the antiviral agent, fialuridine, has caused fatal acidosis in people by damaging mitochondrial DNA resulting in the inhibition of cellular respiration (Brahams, 1994; Honkoop et al., 1997; Guyader et al., 2002).

This chapter discusses the mechanisms resulting in changes in electrolyte and acid–base levels and the biochemical effects of these changes. Sample collection techniques and factors that influence the measurement of analytes are also addressed. Although laboratory animals are bred and housed in a uniform fashion, there are unexpected variations that can influence the electrolyte or blood gas balance. Knowledge of such conditions is essential for correct interpretation of data. Altitude, seasonal and diurnal changes, and breeding cycles need to be carefully assessed during the process of data interpretation; interspecies variation in effects should also be considered. The time at which samples are taken is an important consideration when interpreting data; intake of food, diurnal variation, and animal activity level can also produce significant changes in plasma electrolyte concentrations or acid–base parameters (Bar-Ilan and Marder, 1980; Janssen et al., 1992; Lee et al., 2003). To accurately interpret the results, data should always be considered within the framework of these factors. It should be recognized that there is little point in collecting samples for analyses of blood gases or electrolytes (or any analytes) using improper collection methodology or incomplete analysis of circumstance (e.g., inappropriate anticoagulant use, contamination with air, improper sample mixing, improper sample storage, or delayed analysis) as this will ultimately result in erroneous diagnoses and serious or fatal consequences.

22.2 ELECTROLYTES

22.2.1 BASIC CONCEPTS

The most abundant fluid in the body is water. Total body water (TBW) makes up approximately 60% of body weight in healthy adult animals and occupies three main locations: the intracellular compartment and the two extracellular compartments (interstitial fluid [ISF] and plasma). TBW volume is determined largely by water intake and renal output although metabolic synthesis of water (from cellular respiration) and dehydration synthesis contribute to water gains, and evaporation from the skin, exhalation from the lungs, and feces contribute to water losses. Typically, TBW volume remains constant with control mechanisms responding to changes in osmolarity or intravascular volume. When water losses are greater than gains, decreased blood volume leads to the activation of the renin–angiotensin–aldosterone system (RAAS) and a decrease in atrial natriuretic peptide (ANP). Osmoreceptors in the hypothalamus are activated by the increase in blood osmolality and increased angiotensin II. Baroreceptors respond to decreased arterial pressure for stimulating the thirst center in the hypothalamus and the restoration of fluid loss.

Intracellular fluid (ICF) comprises the largest percentage of the body's water (approximately 65%) and is composed primarily of a solution of potassium and magnesium ions (K^+ , Mg^{2+}), anions (organic phosphates and negatively charged protein), and protein. Control of ICF constituents is brought about by cell membranes and cell metabolism. Extracellular fluid (ECF) is mainly a solution of sodium (Na^+), chloride (Cl^-), bicarbonate (HCO_3^-) ions, and proteins. ISF, the fluid surrounding cells, is the largest component of ECF and is separated from ICF and plasma by cell membranes and capillary endothelial cells, respectively. Movement of water between ICF and the extracellular compartments is primarily accomplished by osmosis with the direction of water movement determined by the concentration of electrolytes in these fluids. Movement of anions and cations across cell membranes not only allows cells to control levels of electrolytes but also to maintain

cellular electroneutrality (a net charge of zero). There are three main mechanisms that are used to maintain fluid balance in the extracellular compartments: (1) concentration of electrolytes in ECF, (2) capillary blood pressure, and (3) concentration of protein in plasma.

The concentration of electrolytes, particularly Na^+ , determines not only the balance of fluids in the body but also osmolarity. The physiological control of Na^+ excretion is therefore vital to homeostasis and is achieved by both neurohormonal mechanisms based on extracellular volume (volume natriuresis) and changes in arterial pressure (pressure natriuresis) (Bie et al., 2004). The concentration of protein in plasma should be included in a discussion of fluid balance because of the Gibbs–Donnan effect. Although water moves freely across cell membranes and the membrane permeability to Na^+ and Cl^- ions is high, the presence of high molecular weight plasma proteins causes the ionic composition of ISF and plasma to be different. Plasma proteins are not readily able to cross cell membranes and being negatively charged they attract positively charged cations into the plasma resulting in the movement of negatively charged anions to the ISF to preserve electroneutrality (Nguyen and Kurtz, 2005).

Reference ranges for serum levels of common electrolytes are provided in Table 22.1 for laboratory animals. These levels should be considered as a guide only; absolute values can be influenced by animal handling techniques, sample collection methodology, and technique used to determine electrolyte level and should be determined empirically by individual laboratories.

22.2.2 ION CHANNELS

Cells acquire all the ions they need from the ECF through the plasma membrane. There are two mechanisms of ion movement: passive/facilitated diffusion occurring down an electrochemical gradient and active transport occurring against a concentration gradient. Both types of movement occur through transmembrane, ion channel proteins that are both gated, to regulate the permeability of the membrane, and selective in which ions can be transported. Ion channels can be distinguished based on this selectivity, their gating mechanism, and sequence similarity (Jentsch et al., 2002; Camerino et al., 2007). Passive transport gating can be facilitated by intracellular or extracellular ligands (e.g., the neurotransmitter, acetylcholine, cyclic adenine monophosphate [cAMP], cyclic guanosine monophosphate [cGMP], or ATP) and voltage (operating in response to membrane potential) or

TABLE 22.1
Reference Ranges for Electrolyte Measurements

Species	Sodium (mmol/L) ^a	Potassium (mmol/L) ^a	Calcium (mmol/L)	Chloride (mmol/L) ^a	Phosphorous (mmol/L) ^a	REFS
Rhesus Macaque (<i>Mucaca mulatta</i>)	[151.72]	[4.78]	[2.67]	[107.14]	[0.07]	Chen et al. (2009)
Cynomologous Macaque (<i>Mucaca fascicularis</i>)	[158.5]	[5.48]	[2.63]	[113.4]	[1.74]	Schuurman and Smith (2005)
Cat	146–156	4.0–4.5	1.55–2.55	117–123	1.45–2.62	Kaneko et al. (1997)
Dog	141–152	4.37–5.35	2.25–2.83	105–115	0.84–2.00	Kaneko et al. (1997)
Rabbit: New Zealand White	138–148	3.4–5.1	3.22–3.75	96–109	0.88–2.35	Hewitt et al. (1989)
Guinea Pig: Hartley	130.9–160.7	8.02–23.11	2.35–3.65	102.4–130.7	2.62–4.85	Charles River (2008a)
Rat: CrI:CD(SD)	140.0–157.0	4.00–12.20	2.35–3.35	90.0–132.0	1.07–4.33	Charles River (2006)
Rat: CrI:WI(Han)	135–151	3.31–6.11	2.28–3.03	97–107	1.18–3.46	Charles River (2008b)
Mouse: CrI:CD1(ICR)	137.7–169.3	7.84–14.18	2.47–3.10	106.1–130.7	2.55–4.55	Charles River (2008–2011)

^aValues are given either as a range or as [mean] for all ages and both sexes combined.

mechanical mechanisms (such as in response to stretch or pressure). In each case, when the channels are open, ions bind to the membrane protein and are transported down a concentration gradient.

For active transport of ions, ATP hydrolysis is coupled with the movement of ions against the concentration gradient (Glynn, 1993; Kaplan, 2002). In this way, the level of cytosolic ions can be maintained at a different level to the ECF. One example of this is the Na^+/K^+ ATPase pump that couples the hydrolysis of ATP with the movement of three Na^+ ions out of the cell followed by the import of two K^+ ions into the cell. These types of pumps are important to maintain cell membrane resting potentials and cell volume, and to drive secondary active transport mechanisms that bring glucose or amino acids into the cell using the Na^+ gradient (Lingrel et al., 1994; Jorgensen and Pedersen, 2001). Endogenous control over the activity of these pumps is exerted through hormones (thyroid hormone, aldosterone, catecholamines, and insulin); their activity may also be affected by drugs such as the cardiac glycosides (Clausen, 2002). Inherited mutations in the ion channel proteins cause diseases such as cystic fibrosis (involving chloride channel cystic fibrosis transmembrane conductance regulator (CFTR); Gadsby and Nairn, 1999), Liddle's syndrome (involving mutations in epithelial sodium channel [ENaC]; Oh and Warnock, 2000), deafness (involving mutations in potassium channel, potassium voltage-gated channel subfamily Q member 4 (KCNQ4); Nie, 2008), seizures (involving voltage gated sodium channels, sodium voltage-gated channel beta subunit 1 (SCN1B), sodium voltage-gated channel alpha subunit 1 (SCN1A) or potassium channels, potassium voltage-gated channel subfamily A member 1 (KCNA1), potassium voltage-gated channel subfamily Q member 2 (KCNQ2), potassium voltage-gated channel subfamily Q member 3 (KCNQ3); Lerche et al., 2001), or heart arrhythmias (reviewed by Delisle et al., 2004). Other types of active ion pumps include H^+/K^+ ATPase and Ca^{2+} ATPase. Not all active ion pumps use ATP hydrolysis to drive the movement of ions; in some cases, the passive movement of an ion (usually Na^+) down the concentration gradient into the cell is coincident with the movement of another molecule up a concentration gradient into the cell. These proteins are called symporters, one example being the Na^+ /glucose transporter that moves glucose out of the gut and kidney and back into the blood (Abramson and Wright, 2009; Bakris et al., 2009). An antiporter is a protein that uses the downhill movement of Na^+ into the cell to provide the energy to move another molecule out of the cell; calcium ions are moved out of the cell in this way.

22.2.3 PHYSIOLOGICAL FUNCTIONS

Steady intracellular water and osmolarity are essential for cell membrane integrity and optimal performance of cellular processes. The kidneys, specifically the proximal tubule and Loop of Henle, accomplish this by reabsorbing large quantities of sodium, water, potassium, organic solutes, urea, and phosphate. Following this large-scale reabsorption, small adjustments to the concentrations of these solutes occur in the distal tubule; it is here that homeostatic control mechanisms are focused. The first step in the filtration of blood to form urine occurs at the Bowman's capsule (glomerular capsule). Fluid from the blood is collected in the Bowman's capsule as a glomerular filtrate; this then passes through the nephrons to form urine. The glomerular filtrate contains all substances in plasma and at the same concentrations as in plasma except for high molecular weight proteins and anything bound to them. During passage through the tubules, substances move either from tubule to peritubular capillaries (reabsorption) or from peritubular capillaries to tubules (secretion). This movement occurs through channels that are regulated by hormones and neurotransmitters. For example, antidiuretic hormone (ADH, vasopressin) controls the process of water reabsorption in the collecting ducts. ADH stimulates the insertion of aquaporin-2 channels increasing water permeability and its reabsorption; low ADH levels leads to decreased water reabsorption (water diuresis). An additional form of diuresis, osmotic diuresis, occurs when urination is increased due to a rise in osmotically active substances (e.g., glucose, mannitol) in the renal tubules. This can be stimulated when hypothalamic osmoreceptors respond to increased serum osmolarity by increasing the circulating levels of ADH. ADH increases free water reabsorption from the urine yielding a low volume and relatively high osmolarity. Serum osmolarity, therefore, returns to normal. ADH is not

the only hormone that regulates kidney function; aldosterone and parathyroid hormones (PTHs) can also regulate electrolyte balance. Aldosterone is secreted from the adrenal gland largely, as a response to hypovolemia through the renin–angiotensin–aldosterone axis; secretion is also directly stimulated by increased serum K^+ levels. Aldosterone increases the reabsorption of Na^+ in the distal renal tubule and the secretion of K^+ . When this occurs, more water is retained and the hypovolemic state is corrected. Normal kidneys can maintain balanced sodium levels independently of ADH or aldosterone by varying the degree of Na^+ reabsorption in the distal tubule. PTH is responsible for the endocrine regulation of calcium and phosphorus by increasing calcium reabsorption in renal tubules and promoting phosphate excretion (Figure 22.1).

Osmolarity is a measure of solute concentration in a solution; it is related to the number of particles in the solution rather than to the solute weight or charge. Osmolarity is defined as the number of osmoles of solute per liter of solution. For nonionic compounds that do not dissociate in solution, 1 osmole is equal to the molecular weight (in grams). For ionic compounds such as salts that can dissociate in solution to their constituent ions, 1 osmole is equal to the molecular weight (in grams) divided by the number of ions formed. Multiple combinations of compounds contribute to the osmolarity of a single solution. For example, a 4 Osm solution might consist of 2 Osm $NaCl$, 2 Osm glucose and 1 Osm $NaCl$, or 3 Osm glucose and 0.5 Osm $NaCl$. Osmolality is a measure of the osmoles of solute per kilogram of solvent and represents the value most often measured in a clinical laboratory setting. It is defined more by the presence of electrolytes and small molecules (e.g., glucose) rather than the presence of larger proteins. The osmolality of serum and urine are indicators of an animal's ability to maintain a fluid balance. In conditions where urine cannot be concentrated appropriately, the osmolality of urine will be near that of plasma (approximately 290 mOsm/Kg for humans) and, in severe dehydration, serum osmolality will be increased. Changes in ECF osmolality cause water to move passively between the ECF and ICF to the compartment with lower osmolality.

FIGURE 22.1 Selected ion transport proteins in tubules and collecting duct of the kidney. Apical reabsorption of Na^+ is effected by cotransporter proteins (NHE3, NKCC2, and NCCT) or the epithelial sodium channel, ENaC, and driven by Na^+/K^+ ATPase activity on the basolateral membrane. In the proximal convoluted tubule, HCO_3^- enters the blood via the $Na^+-HCO_3^-$ cotransporter SLC4A4. Potassium is recycled over the apical membrane of the thick ascending limb and the cortical collecting duct through the ROMK channel. Chloride is reabsorbed in the thick ascending limb and distal tubule through the symporter proteins NKCC2 and NCCT and diffuses passively basolaterally through CLCNKB channels.

pH is a measure of the acidity or basicity of a solution; it is equal to the negative logarithm of the molar concentration of dissolved hydrogen ions:

$$\text{pH} = -\log[\text{H}^+]$$

Changes in hydrogen ion concentration, therefore, bring about changes in pH: when the concentration of the hydrogen rises, the drop in pH causes acidosis to develop; when the hydrogen concentration falls, the increase in pH brings about alkalosis. As different cellular components, enzymes, and other proteins have an optimal pH at which they function, the variation in pH levels is tightly regulated by acid–base homeostasis.

22.2.4 CATIONS

22.2.4.1 Sodium

Sodium is a naturally occurring mineral found in many foods and table salt. Its major role is to maintain the body's osmotic balance along with brain and neuron function. Sodium is absorbed in the small intestine in tandem with large quantities of water/fluid where it forms the major cation of the plasma. Absorption is made possible by the establishment of an electrochemical gradient for sodium across the enterocytes of the intestine. Na^+ enters through the luminal surface of epithelial cells via sodium channels and symporters (with glucose and amino acids) (Figure 22.2). Low intracellular Na^+ levels are then maintained by the presence of Na^+/K^+ ATPases on the basolateral membrane pumping Na^+ into the ICF from where it diffuses to the ECF (plasma of the villus capillaries). With the export of high concentrations of Na^+ , an osmotic gradient is established that enables water to diffuse along the same pathway (Kiela et al., 2006). This Na^+ /water balance is a major determinant of ECF osmolarity and volume.

Homeostatic control of ECF volume is vital to sustaining a constant cellular environment and occurs through a series of sensors and signals that effect changes mainly in the Na^+ concentration

FIGURE 22.2 Intestinal absorption of sodium in the epithelial cells of the small intestine and colon. Sodium–glucose ligand transport proteins (SGLT1 and SGLT2) and sodium-coupled amino acid transport proteins move sodium across the apical membrane from the lumen into the cell. The sodium–potassium adenosine triphosphatase present on the basolateral membrane of the cell maintains a low intracellular sodium concentration and electronegative cell.

via neural, hormonal, and physical responses. Normal serum sodium concentrations in humans range from 136 to 145 mmol/L and normally are maintained at a constant level. Serum sodium levels in mice are slightly higher than other mammalian species with values in the range of 137.7–169.3 mmol/L (Finch and Foster, 1973); in comparison, rabbit sodium levels range from 138 to 148 mmol/L (Table 22.1). No age, sex, or strain differences have been observed for either species. The maintenance of serum sodium concentration can be illustrated in a study conducted in a group of five trained dogs where serum sodium was measured on alternate days over the course of a week. The maximum difference in serum sodium concentrations for an individual dog was 4 mmol/L with values ranging from 144 to 148 mmol/L (Riley and Cornelius, 1989). Homeostasis is achieved by a regulated excretion of water and salt, primarily via the kidneys but also at other epithelial sites such as the distal colon (Fuller and Young, 2005; Kiela et al., 2006). To preserve an electrochemical balance, this movement of sodium ions is coupled with that of hydrogen, potassium, and chloride ions; these will be discussed in later sections (de Wardener, 1978). There are multiple control systems involved in this regulated secretion including an ADH-mediated water-retaining mechanism and sodium-retaining systems dominated by the rennin–angiotensin–aldosterone cascade. Some of the most important hormones involved in the control of renal sodium excretion are aldosterone, urodilatin, ANP, and angiotensin II (Forssmann et al., 2001; Hall, 2003). These act to either stimulate (aldosterone and angiotensin II) or inhibit (ANP) Na^+ reabsorption principally in the proximal/distal tubules or collecting ducts of the kidney by activating Na^+/K^+ pumps, Na^+/H^+ antiporters, $\text{Na}^+/\text{glucose}$ symporters, or Na^+ ion channels. An overview of the renal handling of sodium is shown in Figure 22.3 and Table 22.2.

Aldosterone and, to a minor degree, other mineralocorticoids and glucocorticoids bind to intracellular receptors; the active hormone–receptor complex interacts with DNA through hormone-responsive elements to regulate transcription of genes encoding proteins such as RAS (proto-oncogene, GTPase), corticosteroid hormone-induced factor (CHIF), serum glucocorticoid-regulated kinase 1 (SGK1), and amiloride sensitive ENaC (Bhargava et al., 2004). The result of these changes

FIGURE 22.3 Renal sodium transport. Approximately 70% of filtered Na^+ is reabsorbed in the proximal tubule through apical transport proteins driven primarily by the Na^+/K^+ ATPase antiporter in the basolateral membrane. The thick ascending limb of the Loop of Henle reabsorbs approximately 15% of filtered Na^+ through the $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ symporter, NKCC2 (SLC12A) on the apical surface of the cell; the distal convoluted tubule and collecting ducts collectively reabsorb approximately 15% of filtered Na^+ through the Na^+/Cl^- cotransporter, NCCT and the epithelial sodium channel, ENaC, respectively. In each tubule, segment Na^+ reabsorption is driven by Na^+/K^+ ATPase activity on the basolateral membrane.

in gene expression is modulation of the activity or number of ion pumps and channels (Horisberger and Rossier, 1992; Fuller and Young, 2005). Aldosterone is part of the RAAS that regulates blood pressure and water balance. When blood volume is low, the kidneys secrete renin that stimulates the production of angiotensin that in turn stimulates the secretion of aldosterone from the adrenal cortex. Angiotensin constricts blood vessels causing an increase in blood pressure; aldosterone stimulates the reabsorption of Na⁺ and water in the kidney, which also produces an increase in blood pressure (Rozansky, 2006). Other factors that stimulate aldosterone include an increase in adrenocorticotrophic hormone (ACTH) or potassium levels. Stretch receptors in the atria of the heart also bring about an increase in Na⁺ reabsorption, but from urine, sweat, and gut. Aldosterone secretion is known to have a diurnal rhythm (Hurwitz et al., 2004).

Understanding the function of the RAAS may help explain how aldosterone can be considered the key hormone responding to two seemingly opposing physiological states (the “aldosterone paradox”). In hypovolemia, aldosterone activates Na⁺ retention in the distal nephron without increasing K⁺ secretion; by contrast, in hyperkalemia, aldosterone activates K⁺ secretion in the distal nephron yet Na⁺ retention remains unchanged. How aldosterone brings about two apparently diverse responses is not entirely understood. One of the major differences between the responses to hypervolemia and hyperkalemia is the presence of angiotensin II (Arroyo et al., 2011). Recent evidence suggests angiotensin II to be an upstream regulator for the WNK lysine-deficient protein kinase (WNK) signal cascade (Talati et al., 2010). The activity and/or expression of ion transporter proteins in the distal nephron is modulated by the WNK kinase family of proteins, and evidence suggests that WNK4 plays an important role in controlling the functional state of the Na⁺ and K⁺ transport proteins (NaCl co-transporter (NCCT) and renal outer-medullary K channel (ROMKt), thereby effecting the fine tuning of Na⁺ and K⁺ homeostasis (Verrey, 2007; McCormick et al., 2008).

ANP is produced and released from cardiac atrial myocytes and can counter the increase in blood volume stimulated by the RAAS (Inagami, 1994; Forssmann et al., 1998; Inoue et al., 2001). It is released in response to a variety of stimuli including distension of the atria, angiotensin II, endothelin, sympathetic stimulation of β -adrenoceptors, and raised sodium concentration (Harris et al., 1988). ANP binds to ANP transmembrane receptors and in the kidney increases the glomerular

filtration rate (GFR) by dilating the afferent and constricting the efferent glomerular arterioles resulting in greater secretion of Na^+ and water. Sodium resorption in the distal convoluted tubule and collecting ducts is inhibited by the phosphorylation of ENaC; secretion of renin and aldosterone are also inhibited. Similar responses have been observed in dogs, rats, and humans (Haass et al., 1985; Dillingham and Anderson, 1986). Another member of this family of natriuretic peptides is urodilatin. This peptide is a differentially processed form of ANP (extended N-terminally by four amino acids compared to ANP) and is synthesized by the kidney tubular cells. It is secreted lumenally where it binds to receptors on the distal nephron, stimulates intracellular guanylyl cyclase, and activates cGMP-dependent protein kinases. In this way, urodilatin inhibits Na^+ reabsorption by closing amiloride sensitive Na^+ channels (ENaC) and enhancing dopamine-induced inhibition of Na^+/K^+ ATPase activity (Forssmann et al., 2001; Choi et al., 2011).

Pharmacologically sodium homeostasis can be influenced by the cardiac glycosides digitalis and ouabain. Both drugs bind to the alpha subunit of the Na^+/K^+ ATPase. Different isoforms of the alpha subunit can act as receptors of differing affinities but are typically used to treat congestive heart failure most likely acting by inhibiting the action of the sodium pump. More recently, endogenous ouabain has been isolated from the plasma of humans and several other mammals including rat, dog, and cow (Boulanger et al., 1993; Schneider et al., 1998). The mode of action and physiological significance of this finding is under investigation, but it has been suggested that ouabain acts to promote cell growth and stimulate the Na^+/K^+ pump (Gao et al., 2002).

22.2.4.1.1 Sodium Imbalance

22.2.4.1.1.1 Hyponatremia

Hyponatremia is an electrolyte imbalance that is defined as an elevated plasma sodium level. In humans, hyponatremia occurs when the levels exceed 145 mmol/L; however, severe symptoms usually occur when the levels reach >158 mmol/L. In dogs, hyponatremia develops when sodium concentrations exceed 150 mmol/L, yet neurological symptoms are not usually evident until the levels reach 170 mmol/L. Hyponatremia is most often caused by a water deficiency relative to electrolyte content rather than a problem with sodium homeostasis (Chumlea et al., 1999; Adroque and Madias, 2000). Usually, this occurs when there is inadequate access to water or the thirst mechanism is impaired; normally, thirst is stimulated by an increase in body fluid osmolarity. Less commonly, sodium excess can be a cause of hyponatremia usually through inappropriate ingestion or as a result of disease. Common causes of hyponatremia are presented in Table 22.3 (Agrawal et al., 2008). Higher mortality rates are associated with the acute form of the

TABLE 22.3

Causes of Hyponatremia

Water Deficit	Water and Sodium Loss	Sodium Gain
<ul style="list-style-type: none"> • Inadequate intake—either lack of access or improper thirst mechanism (adipsia) • Panting, insensible losses (respiratory tract) • Diabetes insipidus with restricted access to water • Vasopressin deficiency 	<ul style="list-style-type: none"> • Cutaneous losses—sweating, burn injuries • Gastrointestinal disorders—diarrhea, gastroenteritis, or vomiting • Osmotic diuresis as a response to hyperglycemia, high protein diet, or mannitol • Renal disease—postobstructive diuresis, diuretic phase of acute tubular necrosis • Diabetes mellitus 	<ul style="list-style-type: none"> • Consumption of seawater • Iatrogenic (caused by treatment) • Improperly formulated diet/salt poisoning/high salt diet with restricted access to water • Hyperaldosteronism (Conn's syndrome)—either primary or secondary • Hyperadrenocorticism (Cushing's syndrome)

disease where cell dehydration leads to neuronal cell shrinkage, brain injury, and possible circulatory problems (Oh and Carroll, 1992; Darmon et al., 2010). Different forms of hypernatremia can be distinguished by the volume disturbance or tonicity (osmotic pressure) that they are associated with: hypovolemic, euvoletic, or hypervolemic, and hypertonic, isotonic, or hypotonic states.

22.2.4.1.1.1 WATER DEFICIT A water deficit most commonly develops when impaired water intake is coupled with increased losses (e.g., respiratory or renal losses). The failure of the kidney to concentrate urine might also lead to a water deficit and can occur either through a failure in the hypothalamic–pituitary axis to synthesize or release sufficient levels of ADH hormone (neurogenic/central diabetes insipidus) or a failure of the kidney to respond appropriately to ADH (renal/nephrogenic diabetes insipidus). Most of the free water losses occur from intracellular and interstitial spaces, less from the ECF so blood volume usually remains within the normal range. Animals with diabetes insipidus generally do not develop hypernatremia if they are able to maintain adequate fluid intake to compensate for the losses (Agrawal et al., 2008). Rodent models of diabetes insipidus have been developed: hereditary neurogenic diabetes insipidus in the Brattleboro strain of Long-Evans rat (Moses and Miller, 1974), and nephrogenic diabetes in mice (Naik and Valtin, 1969). Experimental evidence from rats, dogs and cats in which lesions in the hypothalamus abolished the thirst centers demonstrate the development of severe hypernatremia (Gardiner et al., 1985; Morrison and Fales-Williams, 2006; Shimokawa Miyama et al., 2009). In general, any process that disrupts the hypothalamic–pituitary axis can lead to diabetes insipidus: pituitary injury, tumors, inflammatory states (encephalitis), aneurysms, drugs, or genetic defects.

22.2.4.1.1.2 HYPOTONIC FLUID LOSS (WATER AND SODIUM LOSS) Loss of water in excess of electrolytes producing hypovolemia (decreased volume) results from anything that interferes with the ability of the kidney to concentrate urine. Postobstructive diuresis and the diuretic phase of acute tubular necrosis have both been shown to contribute to a hypernatremic state (de Moraes and DiBartola, 2008). Other types of renal disease might also cause retention of sodium. The central feature of nephrotic syndrome is sodium retention and while the cause of this may not be completely understood, it has been attributed to an increase in aldosterone (Shapiro et al., 1990). More recently, the sodium retention in nephrotic syndrome has been associated with an increased activity of Na^+/K^+ ATPase and ENaC channels in conjunction with curtailment of the regulation of ANP-induced secretion of renal sodium in the collecting ducts (de Seigneux et al., 2006; Deschênes et al., 2003). In glomerulonephritis, the amount of sodium filtered is disproportionate to that reabsorbed; consequently, plasma sodium is increased. Osmotic diuresis, an increase in the osmotic pressure in kidney tubules due to the presence of substances such as glucose, causes retention of water in the tubule lumen and increased urination. This can also occur in animals fed a high protein diet where the increased production of urea acts as a diuretic and causes loss of water in excess of sodium (Godwin and Williams, 1984). Diabetes mellitus can also result in hypovolemic hypernatremia since glucose removed from the serum on administration of insulin is replaced by cellular sodium to maintain the osmotic equilibrium. Further to this, water leaves the plasma when the osmotic effects of glucose are removed. Ptyalism (profuse salivation) and diarrhea can both produce hypotonic fluid losses that result in dehydration and hypernatremia. In the dog and cat, salivary and digestive losses are more isotonic than they are in humans and other species, so they are less prone to develop hypernatremia by these means (Martin and Young, 1971).

22.2.4.1.1.3 HYPERTONIC FLUID LOSS (SODIUM GAIN) Hypernatremia is caused less commonly by hypertonic fluid losses than by hypotonic fluid loss and water deficit (Tisdall et al., 2006). Hypertonic fluid loss can be the result of improperly formulated diets, iatrogenic induction (through administration or ingestion of salt or baking soda), or variations in aldosterone hormone level. Primary hyperaldosteronism (Conn's Syndrome) is a disease of the adrenal glands characterized by the secretion of excess aldosterone (Fardella and Mosso, 2002; Nadar et al., 2003). It can be caused by adrenal

hyperplasia, adenoma, and rarely carcinoma. Increased aldosterone concentration causes an increase in Na^+ and water retention and K^+ secretion by the kidneys resulting in high blood pressure (arterial hypertension). The enhanced exchange of Na^+ for K^+ can also give rise to hypokalemia (see Section 22.2.4.2.1.2) and sometimes hypernatremia. Secondary hyperaldosteronism represent a diverse group of disorders that are characterized by the activation of the RAAS as a homeostatic mechanism to preserve serum electrolyte balance or fluid volume. As with primary hyperaldosteronism, hypokalemia is likely but hypernatremia may also occur. Possible causes include renin producing tumors, cardiac failure, and nephritic syndrome. Cushing’s disease of the pituitary gland (hyperadrenocorticism) is caused by a tumor of the pituitary gland that produces large amounts of ACTH, which in turn stimulates the release of cortisol from the adrenal glands. When Cushing’s disease is the result of adrenal gland hyperplasia or tumors, excess cortisol is secreted. This in turn inhibits Na^+ secretion by the kidney and leads to the development of hypernatremia.

22.2.4.1.1.2 Hyponatremia Hyponatremia is an electrolyte disturbance characterized by abnormally low sodium levels (<135 mmol/L) in the blood, most commonly because of an excess amount or effect of ADH (Pham et al., 2006; Kamel and Halperin, 2012). It is often a side effect of other conditions in which fluids rich in sodium are lost (vomiting or diarrhea) or water is accumulated at rate higher than it is excreted (syndrome of inappropriate ADH secretion). Serious hyponatremia occurs when the plasma sodium concentration is less than 120 mmol/L, and profound hyponatremia is seen at 100 mmol/L. In humans, clinical signs of slowly induced hyponatremia do not occur until serum sodium falls to less than 100 mmol/L. In dogs and cats, clinical central nervous system (CNS) signs are evident when serum sodium reaches ~ 115 – 120 mmol/L (Vexler et al., 1994; Brady et al., 1999). In male rats, chronic hyponatremia (induced by administration of vasopressin) with plasma Na^+ concentrations of 106–108 mmol/L results in 22%–23% mortality but no apparent changes in brain morphology. In hyponatremic male rabbits, brain edema was evident with plasma Na^+ concentrations of 118 mmol/L (Ayus et al., 2006; Vexler et al., 1994). The severities of the symptoms increase with the degree of the disease and the rapidity with which the condition develops. When sodium levels fall gradually, minimal symptoms may occur, as compensatory mechanisms have an opportunity to counterbalance the changes; for acute hyponatremia (developing in under 48 hours), a drop in the sodium level of a similar magnitude may have serious consequences (severe cerebral edema, coma, or brainstem herniation) (Soupart and Decaux, 1996; Fried and Palevsky, 1997; Tisdall et al., 2006). Different forms of hyponatremia can be distinguished by the volume disturbance or tonicity (osmotic pressure) that they are associated with: hypovolemic, euvolemic, or hypervolemic, and hypertonic, isotonic, or hypotonic states. Common causes of hyponatremia are given in Table 22.4.

TABLE 22.4
Causes of Hyponatremia

Water and Sodium Loss	Water Gain with Normal Sodium	Water and Sodium Gains
<ul style="list-style-type: none"> • Extrarenal Na^+ loss—diarrhea, vomiting, excessive sweating • Na^+ loss—diuretics (thiazide and loop), osmotic diuresis, mineralocorticoid deficiency, cerebral salt wasting deficiency — — 	<ul style="list-style-type: none"> • Disorders—“syndrome of inappropriate antidiuresis secretion,” hypothyroidism, adrenal insufficiency • Other conditions—pulmonary infections, acute lung injury, CNS disorders such as demyelination, inflammatory disorders or lesions • Drugs—diuretics, barbiturates, opioids, etc. • Increased fluid intake—primary polydipsia 	<ul style="list-style-type: none"> • Extrarenal disorders—heart failure, cirrhosis • Renal disorders—nephrotic syndrome, chronic kidney disease, acute kidney dysfunction — —

22.2.4.1.1.2.1 WATER AND SODIUM LOSS Water and sodium loss produces hypovolemic hyponatremia, when the Na^+ loss proportionally exceeds that of water. Serum osmolarity is reduced (hypotonic) and a reduction in blood volume causes an increase in ADH secretion. The resulting retention of water causes an increase in plasma dilution. Diuretics are an important cause of renal water loss. They act by inhibiting solute reabsorption in the diluting segment of the nephron and increasing Na^+ secretion. Once volume depletion occurs, the nonosmotic release of ADH causes water retention contributing to worsening hyponatremia. ADH release is enhanced by concurrent hypokalemia that causes the intracellular movement of Na^+ and worsens the state of hyponatremia (Agrawal et al., 2008).

22.2.4.1.1.2.2 WATER GAIN WITH NORMAL SODIUM Hyponatremia where TBW is increased but Na^+ levels and ECF volume remain near normal (euvoletic/dilutional hyponatremia) can be caused by a variety of disorders. In the “syndrome of inappropriate antidiuresis” (SAID, also known as “syndrome of inappropriate antidiuretic hormone secretion” [SIADH]), ADH levels are elevated; this is associated with a variety of disorders such as cancer, CNS, pulmonary and endocrine disorders, or heartworm disease (Siragy, 2006; Agrawal et al., 2008). It is reported to occur in human and dog, but the importance of this condition in other species is unclear. Adrenal insufficiency arises when a mineralocorticoid deficiency causes increased secretion of Na^+ and decreased secretion of K^+ . This results in an inability to concentrate urine and hyponatremia develops. Primary polydipsia occurs in humans and occasionally in animals when large quantities of water are consumed or there is an excretion deficiency in the kidneys. Hyponatremia can only develop when water intake exceeds the ability of the kidney to excrete water (Mallie et al., 1997). A variety of drugs can produce hyponatremia, and all operate through an ability to interfere in water excretion. Thiazide diuretics are the most common causes of drug-induced hyponatremia acting by inhibiting reabsorption of Na^+ and Cl^- through the Na^+/Cl^- symporter in the distal convoluted tubule (Hwang and Kim, 2010). In addition, a variety of drugs can precipitate increased vasopressin secretion; these include carbamazepine, chlorpropamide, clofibrate, opiates, tricyclic antidepressants, cyclophosphamide, and oxytocin (Kovacs and Robertson, 1992).

22.2.4.1.1.2.3 WATER AND SODIUM GAINS Hypervolemic hyponatremia is characterized by an increase in sodium (and therefore ECF volume) and TBW concentrations. Proportionally TBW increases are greater than Na^+ . Hyponatremia occurs when a decrease in effective circulating volume caused by cardiac failure or decreased movement of water from the vasculature to the interstitial spaces results in the activation of compensatory mechanisms including the RAAS, ADH, and norepinephrine. Water and Na^+ are retained and hyponatremia develops. Disorders that cause this sequence of events include various edematous disorders (cirrhosis and heart failure) and nephrogenic diseases (Ali et al., 2007; de Moraes and DiBartola, 2008; Farmakis et al., 2009).

22.2.4.1.1.2.4 REDISTRIBUTIVE HYPONATREMIA Hyponatremia can also develop in cases where total body sodium and water concentrations are unchanged. In these situations, increased osmotic pressure in the extracellular compartment causes water to shift from the intracellular to the extracellular compartment. Extracellular Na^+ concentrations are diluted but total body sodium levels remain unchanged. This most often occurs with hyperglycemia and administration of osmotically active molecules with mannitol treatment for brain edema (Smith et al., 2000).

22.2.4.1.2 Factors Influencing Measurement of Sodium Concentration

Serum sodium is measured in all laboratory animal species by instruments requiring a relatively large sample volume: emission flame photometer, atomic absorption spectrophotometer, and ion specific electrode (Hansen et al., 1982). Measured as part of a profile with other electrolytes having similar volume requirements, it limits the profile choices particularly as fasted mice, young rats, and other very small laboratory animals do not yield a large volume of blood. Fractional clearance or excretion of sodium (FENa) can be determined in urine specimens at different time

points daily and is often used as an estimation of sodium handling. FENa describes the proportion of sodium that is excreted in the urine compared with that filtered through the glomerulus. It may be quantified by comparison to the clearance of endogenous creatinine. This procedure simultaneously measures the electrolyte and creatinine concentration in single urine and serum samples and allows measurement of sodium clearance without knowledge of urine flow rate or volume. However, as with other methods, the small volume of blood that can be sampled daily from small laboratory animals can be a limit to experimental design using this method. FENa can be calculated using the following formula:

$$\text{FENa} = \frac{(\text{urine sodium/serum sodium})}{(\text{urine creatinine/serum creatinine})} \times 100$$

Instrument specific requirements must be taken into account. For example, lithium (lithium heparin is used an anticoagulant) interferes with Na⁺ determination by the flame photometer, atomic absorption, and ion specific electrode; therefore, instruments should be adjusted to account for this potential error (van Suijlen et al., 1990). Moreover, measurements should always be performed within a linear, analytical range and within a fixed temperature range; outside of these ranges, the results may be erroneous. Metabolic disturbances that bring about hyperlipidemia, hyperproteinemia, hyperglycemia, or dehydration may produce spurious results (Roscoe et al., 1975; Dimeski et al., 2006). The practice of fasting rodents and removing drinking water during their active period should therefore be performed only when necessary and results interpreted with caution (Ramsay and Ganong, 1977; Kleeman, 1979). Ultimately, the decision to fast or not, prior to sample collection, must be based on individual study objectives and kept consistent within a particular study (Weingand et al., 1996). Rats require 72 hours of food deprivation to become nonabsorptive, comparable to the state achieved by dogs or humans in 10–14 hours (Loeb, 1999). Since rats are night feeders, removal of food overnight prior to specimen collection ostensibly results in a 24-hour fast. Shorter periods of food deprivation result in a progressive decrease in serum glucose, triglycerides, and alkaline phosphatase, but not of cholesterol (Waner and Nyska, 1994). To our knowledge, short-duration fasting does not affect serum electrolyte concentrations. However, fasting male adult Sprague Dawley rats for a longer duration (3–6 days) can result in a 20% decrease in serum potassium but no differences in sodium and chloride concentrations; carbon dioxide content was considered unaffected (Huth and Elkington, 1959). Severe diet restriction (feed intake 25% of controls) of Sprague Dawley rats for two weeks resulted in decreases in serum potassium (~18%) and calcium (~8%), and minimal increases in sodium and chloride concentration (<5%) (Levin et al., 1993).

22.2.4.2 Potassium

Potassium is a naturally occurring mineral found in many foods, particularly fruits and vegetables. It is absorbed from the intestine and excreted in both urine and feces (Klevay et al., 2007). Its primary role is in neuron, cardiac and skeletal muscle, and enzyme functions; it also plays a role in defining the osmotic balance between cells and the ISF. Potassium is the major cation of the ICF; approximately 2% of body K⁺ is found in ECF, 98% is intracellular, located predominantly in muscle and bone (Greenlee et al., 2009). This intracellular store (150 mmol/L) can be used as a source through which the extracellular (3.5–5 mmol/L) potassium levels can be maintained at a constant level (Table 22.1). Movement of potassium between the different fluid compartments is mediated by Na⁺/K⁺ ATPase pumps and highly selective potassium ion channels in neurons and cardiac muscle (Doyle et al., 1998; Noskov and Roux, 2006).

Potassium homeostasis is principally maintained by feedback control of secretion from the kidney (90%) and gastrointestinal (GI) tract (10%) (Hayslett et al., 1982; Wang and Giebisch, 2009; Sorensen et al., 2010). The kidney is able to regulate K⁺ levels by decreasing secretion when intake is low and

increasing secretion when intake is high. Potassium continues to be lost even in the absence of any intake, in fact, K^+ homeostasis is able to be maintained until the GFR drops to 15–20 mL/min. When renal failure occurs, the colon becomes the major site of potassium secretion and is able to regulate K^+ levels. Renal secretion depends on free filtration at the glomerulus, extensive proximal tubule reabsorption, and highly regulated secretion at the distal tubule and collecting ducts (Palmer and Frindt, 2007). The collecting ducts contain two different cell types: principal cells and intercalated cells that mediate K^+ secretion and K^+ absorption, respectively. Principal cells mediate sodium reabsorption and potassium secretion, they are targets for angiotensin II, aldosterone, and potassium-sparing diuretics and use the basolateral Na^+/K^+ ATPase to drive potassium secretion through apical potassium ion channels along a favorable electrochemical gradient. Several types of channels are involved in K^+ secretion including ROMK, the ATP-dependent renal out medullary potassium channel and potassium two pore domain channel subfamily K member 1 (KCNK1), the double-pore K^+ channel (Wang and Giebisch, 2009). Controlling the balance between renal potassium excretion and sodium reabsorption is achieved (at least in part) through WNK signaling, which modulates the activity of the Na^+Cl^- symporter, NCCT, and down regulates the expression of the ROMK channel at the cell surface (Welling and Ho, 2009; Cope et al., 2006; Kahle et al., 2003) (Figure 22.4).

Factors that can affect potassium secretion from these cells include K^+ intake, intracellular K^+ levels, urine flow rate, sodium levels, and hormones (aldosterone and β -catecholamines) (Field et al., 1984). Similar processes operate in the distal colon (Giebisch et al., 2007). When plasma potassium levels are high, aldosterone release stimulates the renal Na^+/K^+ ATPases to secrete excess K^+ into the collecting duct (Wang, 2004), and when plasma potassium concentrations are low, less aldosterone is released and renal potassium secretion is minimized.

In addition to renal control of homeostasis, transcellular redistribution can help maintain constant levels of potassium. Muscle contains the majority of the body's potassium, after ingestion, insulin stimulates increased activity of the sodium pump and increased potassium uptake (McDonough et al., 2002; McDonough and Youn, 2005). Other factors such as acid–base balance can also affect the balance between cellular and extracellular K^+ concentrations. Acidosis increases plasma K^+ concentration by inducing the movement of ions from the cellular to the extracellular compartment whereas alkalosis enhances cellular uptake of potassium (McDonough and Youn, 2005; Youn and McDonough, 2009).

22.2.4.2.1 Potassium Imbalance

22.2.4.2.1.1 Hyperkalemia

Hyperkalemia is an electrolyte imbalance that is defined as an elevated plasma potassium level exceeding 5.5 mmol/L for most species; normal potassium levels range from 3.5 to 5.0 mmol/L in humans, 4.37 to 5.35 mmol/L in dogs, and 3.31 to 12.2 mmol/L in rats (Table 22.1) (Borok et al., 1987; Tran, 2005). It can arise by one of three mechanisms:

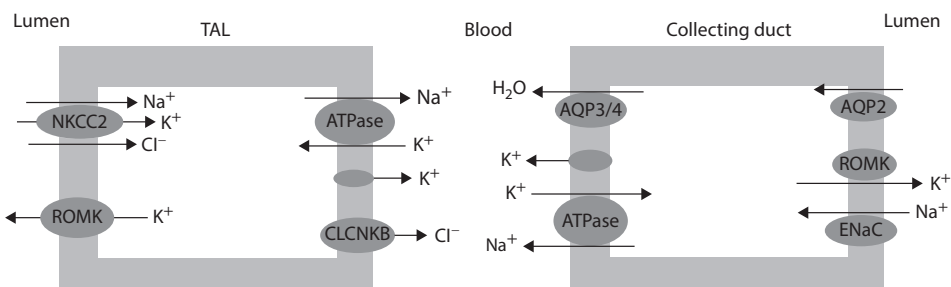

FIGURE 22.4 Renal handling of potassium. Potassium is recycled over the apical membrane of the thick ascending loop of Henle (TAL) through the ROMK channel and only a fraction on the potassium entering the cell apically exits the basolateral membrane (mechanism of transport unknown). In the collecting duct, sodium taken up by ENaC (apically) drives the secretion of potassium through the ROMK channel.

decreased excretion of potassium (particularly when coupled with an excessive intake), potassium shift from intracellular to extracellular space, or excessive intake. The latter two mechanisms are rather less common than the first (Nyirenda et al., 2009). Common causes of hyperkalemia are given in Table 22.5.

22.2.4.2.1.1.1 DECREASED EXCRETION Animals with chronic kidney disease are generally able to preserve near normal levels of K^+ as long as aldosterone secretion, aldosterone responsiveness, and the flow rate in the distal tubule of the kidney are maintained. This is in part due to the role the colon plays in the GI tract regulation of K^+ excretion. However, once the GFR drops to 15–20 mL/min or hypoaldosteronism (from with the lack or improper action of aldosterone) occurs, the ability to excrete K^+ is compromised and hyperkalemia develops (Karet, 2009). The conditions most often associated with this type of hyperkalemia are urethral obstruction, anuric, or oliguric renal failure; less commonly, it may also be caused by ruptured bladder, hyporeninemic hypoaldosteronism, and adrenal insufficiency (Kogika and de Morais, 2008). The use of drugs such as angiotensin-converting enzyme (ACE) inhibitors, NSAIDs (nonsteroidal anti-inflammatory drugs), and prostaglandin inhibitors can also play a role in the development of hyperkalemia. Failure of the RAAS alone rarely produces an increase in plasma potassium significant enough to cause hyperkalemia (Remuzzi et al., 2005).

22.2.4.2.1.1.2 EXCESSIVE INTAKE Excessive intake of potassium is an unlikely cause of hyperkalemia when coupled with normal renal or adrenal function. The kidney's ability to adapt to acute and chronic alterations in K^+ intake by renal secretion and shifts in the cellular balance of K^+ allow ingestion of almost unlimited quantities of potassium in healthy animals. Both animals and humans with impaired excretory mechanisms or transcellular K^+ mobility can develop hyperkalemia with excessive potassium intake, which also occurs with the administration of large doses of potassium penicillin or potassium salts of other drugs (Zietse et al., 2009).

22.2.4.2.1.1.3 SHIFT IN CELLULAR BALANCE OF POTASSIUM Alone, the shift in cellular balance of K^+ (from ICF to ECF) is a relatively uncommon cause of hyperkalemia; however, when coupled with excessive intake or impaired excretion, elevated potassium levels can occur. These lead to the disruption of neuromuscular, cardiac, and GI systems due to the depolarization of membrane potentials in cells. One of the conditions in which the cellular balance of K^+ is often altered is diabetes mellitus where there is an insulin deficiency or resistance. Insulin enhances the entry of potassium into cells, and deficiency or resistance therefore limits the intracellular shift of K^+ . As the major intracellular cation, K^+ is released into the extracellular space when any form of massive cell rupture occurs. Rhabdomyolysis (due to excessive exertion), tumor lysis, and hemolysis (due to blood transfusion,

sickle cell disease) are all known causes of cell rupture. Mechanisms that inhibit the Na^+/K^+ ATPase pump can result in hyperkalemia; nonspecific beta blockers and digitalis inhibit Na^+/K^+ ATPase pumps, also succinylcholine, a membrane depolarizing drug, which leads to potassium efflux from the cells (Martyn and Richtsfeld, 2006). Hyperosmolarity can lead to hyperkalemia through loss of intracellular water. As water is lost from the cell, the increasing cellular potassium concentration creates a gradient down, which moves the potassium out of the cell. In dogs, this is known to occur in cases of diabetes mellitus.

Hyperkalemia can also develop in response to the administration of the synthetic amino acid, epsilon amino caproic acid (EACA). Studies performed in dogs suggest that the similarity of EACA structure to arginine and lysine allows the synthetic amino acid to enter cells in exchange for potassium leading to an increase in the concentration of extracellular potassium (Perazella and Biswas, 1999).

22.2.4.2.1.1.4 PSEUDOHYPERKALEMIA Pseudohyperkalemia can occur when raised potassium levels are the result of a laboratory sampling error rather than a pathological condition. It can be defined as a serum potassium concentration exceeding that of plasma by more than 0.4 mmol/L, provided samples have been collected using appropriate sampling techniques, maintained at room temperature, and tested within 1 hour of collection. Under these conditions, pseudohyperkalemia appears to be the result of two independent mechanisms: (1) degranulation of aggregated platelets (providing a potassium load to the surrounding serum at the time of clot formation) and (2) transfer of a proportion of the potassium back to the red blood cells (to maintain homeostasis) leaving a significant amount of potassium in the serum (Sevastos et al., 2008). Typically, it occurs in species with a high red blood cell potassium concentration (cows, horses, and pigs), whereas erythrocytes with relatively low potassium levels (cats) rarely produce pseudohyperkalemia by hemolysis.

22.2.4.2.1.2 Hypokalemia Hypokalemia is defined as an electrolyte imbalance where the plasma potassium level is less than 3.5 mmol/L; severe hypokalemia is defined when plasma potassium is less than 2.5 mmol/L. It occurs relatively frequently in animals and may be brought about by three mechanisms: inadequate intake, excess excretion, or transcellular movement of K^+ from the extracellular to intracellular space. As potassium is largely an intracellular cation, the occurrence of hypokalemia does not always reflect a deficit in body potassium stores. Substantial losses in K^+ can be incurred without the development of hypokalemia; in humans (and most probably animals), the critical lower limit value is considered to be 2.8 mmol/L. Common causes of hypokalemia are given in Table 22.6.

22.2.4.2.1.2.1 INADEQUATE INTAKE Inadequate potassium intake alone is a rare cause of hypokalemia. Even in the absence of potassium intake, potassium is excreted at between 10 and 15 mmol/day. In animals, particularly herbivores, if poor nutrition continues for extended periods of time such as with anorexia or starvation, a significant potassium deficit can occur.

22.2.4.2.1.2.2 EXCESS EXCRETION Excess K^+ excretion is the most common cause of hypokalemia, especially when accompanied with inadequate intake. The primary cause is from the use of diuretics, which produce elevated sodium levels in the collecting duct of the kidney with simultaneous K^+ secretion (Greenberg, 2000). In adrenal disorders that lead to mineralocorticoid excess (hyperaldosteronism), aldosterone causes the renal tubules to retain sodium and secrete high levels of potassium and chloride. Some potassium is conserved by exchange with hydrogen ions, but the level is insufficient to maintain homeostasis, and compensatory metabolic alkalosis and hypokalemia ensue. A similar enhanced mineralocorticoid effect is observed with excess ACTH occurring with hyperadrenocorticism. Increased loss of potassium in the urine (kaliuresis) is associated with polyuric states such as osmotic diuresis or rapid rehydration. Moreover, penicillin and its synthetic derivatives can also promote renal potassium secretion by increasing sodium delivery to the kidney. Both conditions can result in hypokalemia (Klastersky et al., 1973; Gill et al., 1977). Hypokalemia is both a cause and a frequent consequence of metabolic alkalosis; chronic metabolic alkalosis is seen when bicarbonate retention in the kidney is increased in response to plasma chloride deficits created by loss of gastric acid (HCl). This acute increase in HCO_3^- concentration can exceed the reabsorption capacity of the proximal tubule for this anion; bicarbonate and sodium pass to the distal tubule where sodium is reabsorbed in preference to K^+ leading to increased urinary excretion of potassium and decreased serum potassium (Walmsley and White, 1984). The increase in HCO_3^- reabsorption additionally causes ECF volume contraction that induces secondary hyperaldosteronism. Hypokalemia can therefore also be driven by aldosterone-mediated collecting tubule secretion of K^+ in response to enhanced Na^+ reabsorption. Alkalosis can also cause hypokalemia by changing the cellular balance of K^+ . Potassium channels are inhibited by magnesium; therefore, low levels of magnesium (hypomagnesemia) result in a loss of intracellular K^+ , which is excreted in the urine (Elisaf et al., 1997).

22.2.4.2.1.2.3 SHIFT IN CELLULAR BALANCE The movement of K^+ from the extracellular to the intracellular space is associated with hypokalemia most often when it is accompanied by increased excretion of K^+ . Intracellular shifts are often transient changes occurring with insulin or glucose therapy (glucose stimulates insulin release). Insulin increases the activity of the Na^+/K^+ pump in muscle stimulating the intracellular movement of potassium ions. Similarly, β -adrenergic stimulation enhances potassium entry into the cells. Metabolic alkalosis causes hypokalemia not only for increasing K^+ secretion but also for shifting the cellular K^+ balance to the intracellular space. This shift may be stimulated by Na^+/H^+ exchange and the subsequent activation of Na^+/K^+ ATPase; it is considered to be a minor cause of hypokalemia (Halperin and Kamel, 1998). Potassium entry into cells can be inhibited by glucagon, α -adrenergic stimulation, or acidosis.

22.2.4.2.2 Factors Influencing Measurement of Potassium Concentration

As potassium is predominantly an intracellular ion, serum potassium levels do not give a good indication of total body K^+ but rather, reflects both the movement of potassium between intracellular and ECFs and total body homeostasis. Fractional clearance or excretion of potassium (FEK) can be determined in urine specimens at different time points daily is often used as an estimation of potassium handling. FEK describes the proportion of potassium that is excreted in the urine compared with that filtered through the glomerulus. It may be quantified by comparison to the clearance of endogenous creatinine. This procedure simultaneously measures the electrolyte and creatinine concentration in single urine and serum samples and allows the measurement of potassium clearance without the knowledge of urine flow rate or volume. As with other methods of determining

potassium concentration, the small volume of blood that can be sampled from small laboratory animals can be a limit to experimental design. FEK can be calculated using the following formula:

$$\text{FEK} = \left(\frac{\text{urine potassium}}{\text{serum potassium}} \right) \left(\frac{\text{urine creatinine}}{\text{serum creatinine}} \right) \times 100$$

When blood samples are collected, hemolysis during clot formation can increase serum potassium levels particularly in species with high intracellular potassium levels such as some dogs (Bergstrom, 1981; Nyirenda et al., 2009). This pseudohyperkalemia can be avoided by the measurement of plasma potassium (using lithium heparin) in normal cell samples, but it may not prevent it when the cells are neoplastic (O'Regan et al., 1977; Cohen, 1979). As muscle contains the bulk of body potassium, muscular activity before or at the time of blood collection can increase plasma/serum potassium levels. Animals should be taken quietly from their cages and handled gently to prevent overzealous muscular activity (Bergstrom, 1981). Erroneous values may also be obtained when animals have been treated with the penicillin family of antibiotics (especially in large doses) or when deproteinized serum or plasma samples are assayed using flame photometry (Cohen, 1979). As with the measurement of sodium levels, metabolic disturbances that bring about hyperlipidemia, hyperproteinemia, hyperglycemia, or dehydration may produce spurious results. The practice of fasting rodents and removing drinking water during their activity period should therefore be performed only when necessary, and the results should be interpreted with caution (Ramsay and Ganong, 1977; Kleeman, 1979).

22.2.4.3 Calcium

Calcium is an essential element, and it is the fifth most abundant element in the human body obtained solely from dietary sources (dairy foods and leafy green vegetables). The majority of body calcium (approximately 99%) is located in bones, and the remaining 1% is in the intracellular and extracellular compartments. Extracellular calcium occurs in three forms: free (active), protein bound complexes (binding principally to albumin, but also globulin and calmodulin), and anion bound complexes (citrate, phosphate, carbonate, lactate, or sulfate). Approximately 50% of serum calcium is in the ionized (free), active form, ~40% is protein bound, and ~10% exists as anion bound complexes. Nonbone, ionized calcium is responsible for a wide range of functions: cell signaling, nerve impulse transmission, blood coagulation, and muscle contraction; skeletal calcium is important in bone mineralization and it provides a reservoir from which intracellular and extracellular calcium levels can be maintained. Nonbone Ca^{2+} levels are homeostatically controlled within the range of 1.1–1.35 mmol/L in humans (serum Ca^{2+} levels: 2.2–2.5 mmol/L) (Peacock, 2010). In rabbits, nonbone (serum) Ca^{2+} levels are higher than other laboratory animals with normal values in the range of 3.22–3.75 mmol/L. In comparison, dogs have serum calcium levels ranging from 2.25 to 2.83 mmol/L and mice from 2.47 to 3.1 mmol/L (Table 22.1). Rabbits also differ from other laboratory animals by excreting a higher fraction of calcium in the urine; studies show New Zealand White rabbits excrete 47% calcium in the urine (and 53% in the feces), whereas urinary fractional excretion in rats is less than 2% (Buss and Bourdeau, 1984). Some variation of Ca^{2+} levels has been observed with age in BALB/c, C57BL/6, and outbred mice with higher levels occurring in younger animals. Likewise, some gender differences in nonbone Ca^{2+} levels have been observed in mice (Barrett et al., 1975; Frith et al., 1980).

Calcium is absorbed into the body through the small intestine and is excreted in the urine by the kidney. As bone is the major reservoir of calcium, maintaining metabolic balance in bone is an important aspect of Ca^{2+} homeostasis. The balance between the rate of bone formation and reabsorption changes throughout life; in young life, bone formation occurs in preference to reabsorption; in later life, this is reversed (Manolagas, 2000; Peacock, 2010). Homeostasis is regulated largely by

hormones that maintain serum ionized (free) calcium levels while also allowing calcium to move in and out of the bone reservoir. Intracellular calcium does not appear to play an active role in homeostatic regulation except in the parathyroid gland where the intracellular concentration increases in response to changes in the extracellular concentration and alters the rate of PTH secretion. Hormones playing a role in homeostasis are as follows: PTH, calcitonin, and calcitriol (1,25-dihydroxyvitamin D; $1,25(\text{OH})_2\text{D}$); they regulate Ca^{2+} transport in the gut, kidney, and bone (Jurutka et al., 2001; Potts and Gardella, 2007). A decrease in serum calcium concentration inactivates the calcium-sensing receptor (CaSR) in the parathyroid gland, increasing PTH secretion. PTH acts at three sites in the body by (1) increasing the production of calcitriol (the active form of vitamin D) from the proximal tubule of the kidney, which activates receptors in gut to increase intestinal absorption, (2) enhancing the reabsorption of calcium and magnesium in renal distal tubules of the kidney, and (3) releasing calcium from osseous tissue (Coetzee and Kruger, 2004; Poole and Reeve, 2005). The system is principally controlled by the negative feedback of calcium on PTH secretion; however, the calcium regulatory hormones also interact with each other providing a further level of regulation. Central to this process is the G-protein coupled CaSR located on the surface of the parathyroid cells and regulating the release of PTH (Taylor and Bushinsky, 2009) (Figure 22.5).

Calcium, phosphorous, and vitamin D metabolites play a role in regulating PTH release and synthesis (Kumar and Thompson, 2011). Phosphorous forms calcium phosphate complexes with serum calcium, thereby reducing the level of the free, ionized form and triggering CaSR to increase PTH secretion. Calcitonin, released from the thyroid gland, acts mostly by inhibiting osteoclastic activity. By preventing the resorption of bone, this hormone has the opposite effect to PTH of inhibiting Ca^{2+} release from bone. Vitamin D metabolites regulate expression of the calcitonin gene. Calcitonin effects a role in maintaining blood Ca^{2+} levels by inhibiting absorption in the gut and increasing reabsorption of both Ca^{2+} and Mg^{2+} in the kidney tubules (Carney, 1997). This hormone is important in counteracting the effects of PTH. Species differences in the importance of calcitonin as a factor affecting homeostasis occur. In rodents, calcitonin appears to play a significant role in calcium homeostasis; whereas, in humans, the role of calcitonin appears to be minor (Zaidi et al., 2002; Hoff et al., 2002).

22.2.4.3.1 Calcium Imbalance

22.2.4.3.1.1 Hypercalcemia Hypercalcemia is an electrolyte imbalance characterized by elevated serum calcium levels: greater than 2.5 mmol/L for serum calcium or 1.4 mmol/L for ionized (free) calcium in humans. It is a disorder commonly affecting dogs, most often as a result of neoplastic disease. The most severe symptoms are generally seen in animals with serum calcium levels greater than 4.0 mmol/L. Hypercalcemia not only develops as a direct result of an electrolyte imbalance but it can also occur secondary to disorders of serum proteins. It affects nearly every organ system, particularly the kidney and CNS; cardiac arrhythmias are also reported due the inotropic effect of calcium. The clinical signs of hypercalcemia depend on the rapidity of condition onset.

Hypercalcemia can be caused by three primary mechanisms: increased intestinal absorption of Ca^{2+} , decreased renal secretion, and excessive skeletal calcium release. These mechanisms can be either mediated by PTH (primary hyperparathyroidism) or non-PTH-mediated. Primary hyperparathyroidism is the excessive secretion of PTH and usually arises as a result of adenoma of the parathyroid gland. PTH regulates serum Ca^{2+} levels through effects on kidney, intestine, and bone. Nonhyperparathyroidism-mediated hypercalcemia is usually associated with malignancy (cancer in the absence of bone metastasis), most commonly squamous cell carcinoma, renal cell carcinoma, and mammary gland, prostate, or ovarian cancer. Tumors secrete PTH-related peptide (PTHrP), a protein in the same family as PTH. As both PTHrP and PTH stimulate the same receptor (PTHrP) in bone and kidney, they can both regulate calcium ion homeostasis. Malignancy can lead to changes in calcium homeostasis: excessive bone reabsorption and hypercalcemia (Strewler, 2000; Wysolmerski, 2012). Increase in Ca^{2+} concentration can also result from increased osteoclastic activity in bone or increased vitamin D levels (usually in granulomatous disorders). Common

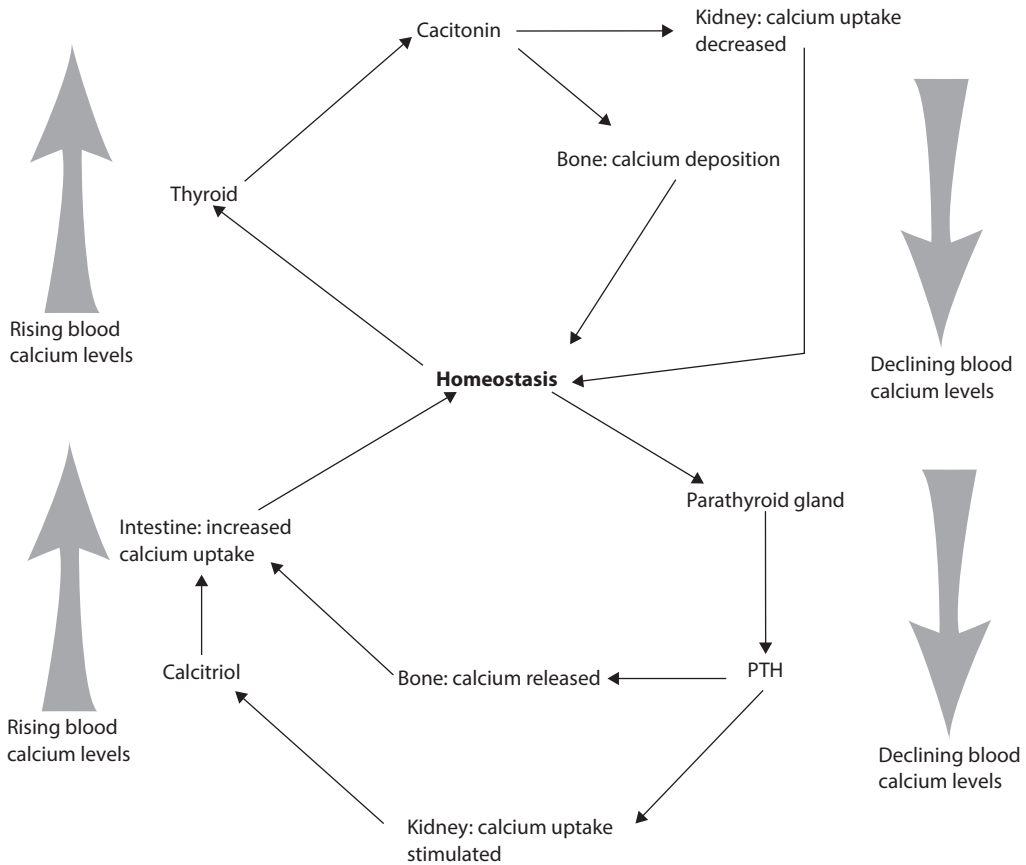

FIGURE 22.5 Calcium homeostasis is maintained through the action of three hormones: PTH, calcitonin, and calcitriol. Release of calcitonin from the thyroid gland in response to increased blood calcium levels inhibits renal absorption of calcium and promotes mineralization of bone, thereby effecting a reduction in blood calcium levels. Release of PTH in response to falling blood calcium levels stimulates bone demineralization, increases reabsorption of renal calcium, and stimulates the biosynthesis of calcitriol, thereby increasing intestinal uptake of calcium and raising blood calcium levels.

causes of hypercalcemia shown in Table 22.7 are grouped by the major organ effector sites although the development of hypercalcemia invariably involves multiple sites/mechanisms.

22.2.4.3.1.1.1 INCREASED INTESTINAL ABSORPTION Primary hyperparathyroidism, the excessive secretion of PTH, occurs most often as a result of an adenoma of the parathyroid gland and as such it is not a common finding in young laboratory animals. Hyperplasia, carcinoma, or familial endocrine disorders are other known causes; all can lead to elevated Ca^{2+} levels. Neoplasia is the most common cause of hypercalcemia in dogs often associated with apocrine gland adenocarcinoma of the anal sac. Calcium absorption is not only regulated by PTH but also calcitriol, the biologically active form of vitamin D (Holick, 2004). Calcitriol mediates its effect by binding to the calcitriol (vitamin D) receptor (VDR). VDR is a member of the nuclear receptor family of transcription factors that regulate the transcription of hormone sensitive genes. In addition, VDR autoregulates its own expression by repressing the expression of the proximal activator of calcitriol, 1- α hydroxylase, and inducing the expression of the calcitriol inactivating enzyme 24-hydroxylase (CYP 24) (Fleet and Schoch, 2010; Xue and Fleet, 2009). Excess vitamin D can thereby lead to hypercalcemia. This can occur as a result of poisoning when calciferol-containing rodenticides or vitamin

TABLE 22.7
Causes of Hypercalcemia

Increased Intestinal Absorption	Bone Remodeling	Renal Excretion
<ul style="list-style-type: none"> • Primary hyperparathyroidism • Chronic kidney disease • Vitamin D poisoning/excess (hypervitaminosis D) • Granulomatous diseases—sarcoidosis, tuberculosis, Hodgkin’s lymphoma, non-Hodgkin’s lymphoma 	<ul style="list-style-type: none"> • Primary hyperparathyroidism • Chronic kidney disease • Vitamin A excess • Malignancy • Immobilization 	<ul style="list-style-type: none"> • Primary hyperparathyroidism • Chronic kidney disease • Familial hypercalciuric hypercalcemia • Drugs—thiazide diuretics • Sodium depletion

D glycoside-containing plants are consumed. In granulomatous diseases, sarcoidosis, tuberculosis, Hodgkin’s lymphoma, and non-Hodgkin’s lymphoma increased intestinal Ca^{2+} absorption is induced by high serum calcitriol levels produced at extrarenal sites by macrophages within the granulomas (Barbour et al., 1981). Normally the activation of calcidiol to calcitriol in the kidney is under the control of PTH and serum phosphate concentration (Insogna et al., 1988). Physiological compensation for the extrarenal production of calcitriol by macrophages involves the suppression of PTH and prevents the development of hypercalcemia but may ultimately lead to hypoparathyroidism. This condition is exacerbated by high levels of estradiol and prolactin (Subramanian et al., 2004). Studies show the production of calcitriol is increased by prolactin in primary chick kidney cell cultures (Spanos et al., 1981) and estradiol has a stimulatory effect on the renal $1\text{-}\alpha$ hydroxylase enzyme, which results in a positive correlation between serum calcitriol and estradiol levels (Verhaeghe and Bouillon, 1992; Cheema et al., 1989). Chronic kidney disease can lead to hypercalcemia by a combination of mechanisms that include vitamin D overdose and calcium ingestion; when the amount of Ca^{2+} absorbed in the gut exceeds the excretory ability of the kidneys, hypercalcemia develops (Pieper et al., 2006).

22.2.4.3.1.1.2 BONE REMODELING Primary hyperparathyroidism and malignancy are the two most common causes of bone remodeling sometimes associated with hypercalcemia. The excess secretion of PTH in hyperparathyroidism increases bone resorption by osteoclasts; however, this rarely induces elevated calcium levels or hypercalcemia because most of the PTH-induced breakdown of bone is balanced by hypercalcemic-induced bone deposition. Hypercalcemia is frequently associated with malignant tumors, in particular bone metastases that cause an imbalance between bone formation and bone resorption and result in the release of calcium to the blood; approximately 80% of malignancy-related hypercalcemias are caused by bone metastases. Cancers most likely to induce bone remodeling Ca^{2+} release are hematological cancers of the bone marrow (multiple myeloma, leukemia) and solid tumors that primarily metastasize to bone (breast, prostate, and lung cancers). The common mechanism of action for all malignancies is increased osteoclastic activity in the bone promoting calcium release; it may be brought about by either osteoclastic activating factors (produced by osteolytic metastasis of solid tumors) or a PTH-related protein that increases bone resorption. A third mechanism shown in animals (but not humans) is increased prostaglandin synthesis (Tashjian et al., 1972; Raisz et al., 1977). Chronic kidney disease can result in hypercalcemia when adynamic bone disease (low bone turnover) is present. In these cases, a reduced level of calcium uptake for bone formation produces excess serum calcium (Parfitt, 2003; Andress, 2008). Prolonged immobilization and hypervitaminosis A can also lead to the production of excess calcium due to bone loss (Gault et al., 1968).

22.2.4.3.1.1.3 RENAL EXCRETION Dysregulation of renal calcium excretion can occur at two levels: either tubular reabsorption or calcium load. In chronic kidney disease with a reduced GFR, even calcium concentrations in the normal physiological range can give rise to hypercalcemia when the amount of calcium ingested exceeds the rate renal secretion (Goodman, 2005; Pieper et al., 2006). Other causes of increased tubular reabsorption of calcium include primary hyperparathyroidism and sodium depletion. Drugs such as thiazide diuretics increase Ca^{2+} reabsorption in the distal convoluted tubules by activation of transcellular Ca^{2+} transport systems and up regulation of the apical calcium channels transient receptor potential cation channel subfamily V member 5 (TRPV5), Calbindin 1 (CALB1), and S100 calcium binding protein G (CALB3) (Lee et al., 2004). In humans, familial hypercalciuric hypercalcemia is an autosomal defect that is most often associated with loss of function mutations in the CaSR gene expressed in parathyroid and kidney tissue. This is recognized as a lack of calcium by the parathyroid, which in turn produces constitutively high levels of PTH leading to hypercalcemia. Renal failure in dogs is a known cause of hypercalcemia; in other species, renal failure does not usually given rise to this condition (Ferguson and Hoenig, 2003).

22.2.4.3.1.1.4 OTHER CAUSES Hypercalcemia can occur secondary to disorders of serum proteins rather than as a consequence of changes in ionized (free) calcium levels. Any change in serum albumin level or binding capacity will be reflected as a change in total body calcium. However, as no changes occur in the ionized (free) fraction of calcium no clinical manifestations are apparent. Consequently, hypoalbuminemia occurring with normal serum calcium is interpreted as hypercalcemia. In acidosis, the amount of calcium bound to albumin is reduced; whereas, in alkalosis, the bound fraction of calcium is increased (Tietz, 1976; Girndt et al., 1979).

22.2.4.3.1.2 Hypocalcemia Hypocalcemia is an electrolyte disturbance characterized by low calcium levels: less than 2.1 mmol/L for serum calcium or 1.1 mmol/L for ionized (free) calcium in humans and 2 mmol/L for serum calcium or 0.31 mmol/L in dogs. Clinical signs are usually evident when serum levels fall below 1.62 mmol/L for both species. Hypocalcemia not only develops as a direct result of an electrolyte imbalance but also secondary to disorders of serum proteins. The main effect is seen in the contractility of muscles. The primary mechanisms that produce hypocalcemia include reduction in (1) plasma proteins, (2) absorption of calcium, (3) bone mobilization, (4) reabsorption of calcium in the kidney, (5) magnesium concentration, (6) concentration of calcitriol, and (7) increases in phosphate concentration. These are shown in Table 22.8 grouped by major organ effector sites although invariably, the development of hypocalcemia involves multiple mechanisms.

22.2.4.3.1.2.1 REDUCED INTESTINAL ABSORPTION Hypocalcemia is rarely caused by a low dietary intake of calcium; however, vitamin D deficiencies have been reported and these can lead to hypocalcemia through the reduction of calcium absorption in the gut (Linnebur et al., 2007). Dietary

TABLE 22.8
Causes of Hypocalcemia

Reduced Intestinal Absorption	Bone Remodeling	Renal Excretion
<ul style="list-style-type: none"> • Chronic kidney disease • Hypoparathyroidism • Hyperphosphatemia • Acute pancreatitis • Low dietary intake • Vitamin D deficiency—small bowel diseases, liver disease 	<ul style="list-style-type: none"> • Postparathyroidectomy recalcification tetany • Hypoparathyroidism • Hyperphosphatemia • Osteoblastic metastatic bone cancer 	<ul style="list-style-type: none"> • Chronic kidney disease • Hypoparathyroidism • Hyperphosphatemia • Hypomagnesemia

vitamin D deficiency can be the result of reduced absorption in the intestine or a reduction in the conversion of calcidiol to active calcitriol. Numerous conditions can impair absorption or activation of vitamin D including celiac disease, gastric bypass, steatorrhea, liver, and pancreatic disease as well as inherited conditions such as pseudovitamin D deficiency rickets (type I) or hereditary vitamin D resistance rickets (Johnson et al., 2006). Chronic kidney disease leads to the development of hypocalcemia by two concurrent intestinal routes: first, a reduction in vitamin D activation; second, a decreased intestinal Ca^{2+} absorption. Hypoparathyroidism, common in dogs, is characterized by decreased secretion of PTH, and it causes a reduction in Ca^{2+} absorption. It may occur spontaneously or be induced by a variety of factors including neck irradiation therapy, surgical removal of parathyroid, and infiltrative diseases such as hemochromatosis or granulomatous diseases (Burch and Posillico, 1983). Acute pancreatitis in dogs is often associated with hypocalcemia. This inflammatory condition can reduce serum Ca^{2+} concentrations by causing calcium precipitation; decreased PTH secretion and calcitonin release may also play a role (Sánchez et al., 1996).

22.2.4.3.1.2.2 BONE REMODELING Hypocalcemia as a result of bone remodeling can occur when the rate of skeletal mineralization exceeds the rate of osteoclast-mediated bone resorption and occurs primarily when surgical correction of primary or secondary hyperparathyroidism produces a rapid drop in PTH levels and results in a rapid increase in bone remodeling (termed “hungry bone syndrome” in humans). Other conditions that cause mineralization of bone matrix include correction of thyrotoxicosis, vitamin D therapy for osteomalacia, and hematological or metastatic (to bone) tumors (Brasier and Nussbaum, 1988). Hypoparathyroidism causes hypocalcemia through bone remodeling because the reduction in PTH levels prevents the activation of osteoclasts and bone resorption, thereby preventing the release of calcium. Conditions that give rise to hypoparathyroidism are described in the previous section. Elevated levels of phosphorous (hyperphosphatemia) caused by phosphorous administration, tumor lysis, or rhabdomyolysis can also result in hypocalcemia as increased calcium deposition takes place in bone or extra-skeletal sites (Wilson and Berns, 2012; Peacock, 2010).

22.2.4.3.1.2.3 RENAL EXCRETION Hypocalcemia arising from decreased tubular calcium reabsorption occurs primarily as a result of hypoparathyroidism. PTH has a calcium-retaining effect on the distal tubule of the kidney; when the levels of PTH are low, calcium reabsorption does not occur; ionized (free) calcium level in the serum is reduced and urinary calcium concentration increased. Hypomagnesemia is also associated with low PTH level, the loss of Mg^{2+} from the kidney or GI tract inhibits PTH secretion and decreases the function of the calcium pump. Hypocalcemia as a result of chronic kidney disease is produced by several mechanisms including decreased conversion of vitamin D to calcitriol and a reduction in the GFR (to below 30 mL/min); an increase in PTH level leads to increased calcium and phosphorous absorption and deposition at extraskeletal sites.

22.2.4.3.1.2.4 OTHER CAUSES Hypocalcemia can occur secondary to disorders of serum proteins rather than as a consequence of changes in ionized (free) calcium levels. Any change in serum albumin level or binding capacity will be reflected as a change in total body calcium. For example, in respiratory or metabolic alkalosis, the amount of calcium bound to albumin is increased resulting in decreased concentrations of ionized (free) calcium and pseudohypocalcemia.

22.2.4.3.2 Factors Influencing Measurement of Calcium Concentration

Although total calcium is a convenient measure of clinical conditions, it is ionized calcium that is physiologically active and under homeostatic control and therefore provides a better indicator of calcium imbalances. A variety of mathematical formulae have been proposed for calculating ionized calcium levels or total calcium corrected for serum albumin concentrations but these do not always provide accurate estimations (Clase et al., 2000). The equilibrium between total and ionized calcium fractions is dependent on a variety of factors including pH, temperature, and concentration

of serum proteins particularly albumin. To accurately measure ionized calcium, samples must be procured anaerobically (to minimize loss of carbon dioxide) and processed quickly to reduce lactate generation. Total calcium concentration is not affected by changes in pH, yet a change in the pH of the assayed sample (e.g., a decrease caused by glycolysis) will affect the ionized calcium portion (Ng, 1987). Acidosis decreases binding of calcium to albumin and increases the ionized fraction; an acidotic animal may therefore have no clinical signs of hypocalcemia yet have a measured value that is sufficiently low to indicate the presence of hypocalcemia. Conversely, alkalosis decreases the ionized calcium fraction such that animals may show signs of hypocalcemia yet have a calcium value within the normal reference range. Moreover, as the degree of calcium dissociation increases with the rising temperature, samples should be measured at a constant temperature (Metzger and Kenny, 1987). Oxalate, EDTA, citrate, and heparin decrease calcium available for analysis by most methods of analysis because they bind calcium. The more common measurement of calcium level in serum is therefore total calcium (the sum of ionized and nonionized (primarily bound to albumin but also to other anions) components) and this should be used whenever serum albumin levels are not within normal ranges, or when a calcium disorder is suspected despite normal total calcium levels. The amount of total calcium varies with the level of plasma proteins (particularly albumin), such that a 250 mmol/L decrease in albumin raises the serum calcium by 0.2 mmol/L.

Measurement of total serum calcium can be performed using colorimetric methods but this method is not always reliable as it is affected by variables such as recent food ingestion (producing lipemia). Fasting animals prior to sample collection may be necessary (Ferguson and Hoenig, 2003). Ion selective electrodes can be used to measure ionized calcium based on changes in the thermodynamic activity of calcium ions. However, to ensure accurate electrolyte determination, samples must be maintained anaerobically at 37°C (Burnett et al., 2000). Urinary calcium excretion can be used to differentiate changes in calcium homeostasis. The amount of calcium excreted over a 24-hour period is measured in a 24-hour urine sample. Alternatively, the fractional clearance or excretion of calcium (FECa) on samples of serum and urine can be measured, although as discussed previously (for sodium and potassium) the amount of serum that can be collected daily from small laboratory animals (particularly mice) can be a limiting factor in experimental design. FECa can be calculated using the following formula:

$$\text{FECa} = \frac{(\text{urine calcium/serum calcium})}{(\text{urine creatinine/serum creatinine})} \times 100$$

22.2.4.4 Magnesium

Magnesium is an essential element and the fourth most abundant cation in the body obtained solely from dietary sources (green vegetables, nuts, whole grains, and seafood). It is the second most prevalent intracellular cation and plays a critical role in many cellular pathways including DNA and protein synthesis, enzyme activation (including most enzymes in phosphorylation reactions), and PTH synthesis (Soave et al., 2009). As Mg^{2+} is a cofactor for ATP, this element has wide-ranging effects on processes: muscle contraction, protein, fat and carbohydrate metabolism, cell growth and division, membrane permeability, and immune responses. Similar to calcium, the body's magnesium is distributed among bone, intracellular space, and extracellular space. Approximately 99% of total body magnesium is located in the bone and intracellular compartments. Only ~1% is found in the serum and ISF. The majority of intracellular Mg^{2+} is complexed with organic molecules (DNA, enzymes, etc.) or sequestered in organelles (mitochondria or endoplasmic reticulum); only ~1%–3% exists as the free, ionized (active) form, and this level is tightly regulated by the sequestration and organic molecule binding processes. Serum Mg^{2+} is also complexed, in this case, to either serum proteins or anions; however, the majority of serum magnesium exists in the free, ionized (active) form (Kulpmann and Gerlach, 1996; Thienpont et al., 1999).

Relatively little is known about the mechanisms involved in Mg^{2+} absorption by the GI tract. Vitamin D appears to play a role in increasing Mg^{2+} absorption, but significant absorption can occur independently of vitamin D (Hardwick et al., 1991). As with other cations, homeostatic control is brought about by the action of the kidneys. Ionized and complexed Mg^{2+} are approximately 70% of the total serum Mg^{2+} and are filtered freely by the glomerulus and then largely reabsorbed in the tubules such that only 3% of filtered Mg^{2+} is finally excreted in the urine, 97% is reabsorbed (Musso, 2009). Unlike sodium and potassium, reabsorption primarily occurs in the thick ascending Loop of Henle (TAL), and the fine control occurs in the distal convoluted tubules. High levels of natriuresis, osmotic load, and metabolic acidosis can all cause an elevation in the level of Mg^{2+} excreted from the kidney; whereas, a reduction in the level of Mg^{2+} excreted occurs in response to some hormones (PTH, calcitonin) and metabolic alkalosis.

22.2.4.4.1 Magnesium Imbalance

22.2.4.4.1.1 Hypermagnesemia Hypermagnesemia is an electrolyte imbalance characterized by the elevated levels of magnesium in the blood (greater than 0.95 mmol/L in humans). Plasma magnesium concentrations normally range from 0.75 to 0.95 mmol/L in human. Magnesium toxicity occurs in humans when levels exceed 1.74–2.61 mmol/L. This condition occurs rarely because the kidney is very effective at excreting excess magnesium (Musso, 2009). When it does occur, hypermagnesemia is almost exclusively associated with chronic kidney disease particularly when coupled with excessive Mg^{2+} intake (Moe, 2005). In this condition, Mg^{2+} levels can be maintained until the GFR falls to below 20 mL/min. At this point, hypermagnesemia can develop particularly when the fall in Mg^{2+} excretion is accompanied by increased intake (vitamins, antacids, laxatives). Other causes of decreased renal magnesium secretion leading to hypermagnesemia are lithium therapy, adrenal insufficiency (decreased levels of cortisol and aldosterone), and familial hypocalciuric hypercalcemia. In the latter condition, the loss of function mutations in the CaSR gene prevents the feedback inhibition of PTH, and it results in elevated blood calcium levels and increased Mg^{2+} reabsorption in the Loop of Henle (Pearce et al., 1995). As an intracellular cation, massive tissue damage can cause elevation of Mg^{2+} levels (also phosphorous and potassium), but this is an uncommon mechanism of hypermagnesemia unless accompanied by renal failure.

22.2.4.4.1.2 Hypomagnesemia Hypomagnesemia is an electrolyte imbalance characterized by abnormally low levels of magnesium in blood (less than 0.7 mmol/L in humans). It can be caused by three mechanisms: inadequate intake, redistribution from extracellular to intracellular space, or excessive gastrointestinal/renal loss. Common causes are given in Table 22.9.

22.2.4.4.1.2.1 INADEQUATE INTAKE Nutritional deficiency alone does not commonly cause hypomagnesemia; magnesium absorption in the gut can increase up to 40% compared to normal when low levels of magnesium are detected. Malnutrition, however, can lead to Mg^{2+} deficit and hypomagnesemia when coupled with alcohol dependency or enteric diseases (Molina-Perez et al., 2000).

22.2.4.4.1.2.2 EXCESS EXCRETION The most common causes of excessive loss of magnesium leading to hypomagnesemia are renal disease and diuretic use. Tubular dysfunction and increased tubular flow decrease magnesium reabsorption in the thick ascending limb of the Loop of Henle and cause hypomagnesemia in many renal conditions: the diuretic phase of acute tubular necrosis, postobstructive diuresis, and renal tubular acidosis. Experimental evidence in rats shows a similar mechanism of action whereby reabsorption of Mg^{2+} decreases with increased tubular flow (Levine et al., 1982). Increased tubular flow rates can be caused by volume expansion, which in turn may be brought about by saline infusion or hormonally by hyperaldosteronism (Topf and Murray, 2003). Drugs can also cause hypomagnesemia, the most common are loop diuretics. These block ion channels in the Loop of Henle, thereby preventing reabsorption of Mg^{2+} (Topf and Murray, 2003).

TABLE 22.9
Causes of Hypomagnesemia

Inadequate Intake	Excess Excretion	Shift in Cellular Balance
<ul style="list-style-type: none"> • Malnutrition • Enteric disease—chronic diarrhea, inflammatory bowel disease 	<ul style="list-style-type: none"> • Gastrointestinal loss—vomiting, diarrhea • Inherited renal tubular defects • Drugs—diuretics, chemotherapeutics • Hypercalcemia • Chronic metabolic acidosis • Volume expansion • Osmotic diuresis • Primary hyperaldosteronism • Renal disease—diuretic phase of acute tubular necrosis, postobstructive diuresis, renal tubular acidosis 	<ul style="list-style-type: none"> • Post parathyroid surgery recalcification tetany • Acute pancreatitis • Posttreatment of diabetic ketoacidosis • Excessive lactation

Similarly, when hypercalcemia is associated with hypomagnesemia, the activation of CaSRs in the ascending Loop of Henle closes the Na/K/2Cl pump and inhibits magnesium reabsorption. Osmotic diuresis produced by glycosuria in diabetes mellitus is also associated with hypomagnesemia (Schnack et al., 1992).

22.2.4.4.1.2.3 SHIFT IN CELLULAR BALANCE Low serum Mg²⁺ as a consequence of a shift to the intracellular compartment is significant following parathyroidectomy to correct primary or secondary hyperparathyroidism. A rapid drop in the PTH level causes mineralization of osteoid and a rapid decrease in serum calcium, magnesium and potassium levels, hypocalcemia, and hypomagnesemia (Al-Ghamdi et al., 1994). Hypomagnesemia can also occur with acute pancreatitis (Liamis et al., 2001), excessive lactation or after insulin therapy for diabetic ketoacidosis where the insulin administered may drive magnesium, along with potassium and phosphorus, into the intracellular compartment.

22.2.4.4.2 Factors Influencing Measurement of Magnesium Concentration

Measurement of plasma magnesium levels does not always correlate with total body magnesium concentrations. Clinically, significant Mg²⁺ imbalance is more tightly correlated with intracellular magnesium levels than blood concentrations because of the roles this element plays. Accurate assessments can be obtained by measuring magnesium contained in erythrocytes or inferred from a 24-hour urine sample (Gullestad et al., 1992). For erythrocyte magnesium concentrations, the same site must always be used for collecting blood because of the erythrocyte volume differences between arterial and venous blood; magnesium may leak from erythrocytes under hypoxic conditions.

22.2.5 ANIONS

22.2.5.1 Chloride

Chloride is a naturally occurring mineral found in many foods and table salt. It is the principal anion in the body combining with sodium to form sodium chloride and potassium to form potassium chloride. Normal serum chloride levels in humans are in the range 98–108 mmol/L, tissue concentrations are almost negligible in normal circumstances; however, chloride enters damaged cells (Bergstrom, 1981). Little interspecies variation in the concentration of serum chloride is evident among common

laboratory species (Table 22.1). In rat, chloride concentrations range from 90.0 to 132.0 mmol/L; whereas, in mice, chloride is present in the range 106.1–130.7 mmol/L (Table 22.1). With sodium, Cl^- shares the function of maintaining serum osmolarity and fluid balance; it also helps to maintain acid–base equilibrium and the electrical neutrality of extracellular bicarbonate and sodium. Chloride levels generally mirror sodium levels such that losses in sodium are usually followed by losses in chloride. Conversely, chloride has an inverse relationship with bicarbonate anions (Powers, 1999). The kidneys and gastrointestinal tract regulate chloride homeostasis. In the intestine, chloride is actively and passively absorbed. Passive absorption occurs when chloride follows sodium across the intestinal wall; active absorption occurs when bicarbonate moves from the blood to the intestine and is exchanged for chloride ions to maintain electrical neutrality. In the kidney, the majority of filtered chloride is passively reabsorbed with sodium in the proximal tubule. Active reabsorption of chloride occurs in the TAL, forcing the simultaneous passive movement of sodium to maintain electrical neutrality. In the distal tubule, passive and active reabsorption of smaller amounts of chloride refine chloride balance. Factors that regulate sodium reabsorption also control chloride levels. The WNK-SPAK (SPS1-related proline/alanine-rich kinase)/OSR1 (oxidative stress-responsive kinase 1) signaling pathway regulates cation–chloride coupled cotransporters $\text{Na}^+ - \text{K}^+ - 2\text{Cl}^-$ cotransporter (NKCC) 1 (NKCC), solute carrier family 12 member 1 (NKCC2), and, under certain conditions, NCCT. Phosphorylation of these proteins by the WNK-regulated kinases OSR1 and SPAK is associated with their increased activation (Hoorn et al., 2011; Huang et al., 2008).

One of the most important functions of chloride is maintaining acid–base balance. One of the ways this can be achieved is through a process known as the chloride shift whereby chloride is exchanged for bicarbonate ions across the membranes of cells. Carbon dioxide dissolved in tissue fluid diffuses into capillaries where most reacts with water to produce carbonic acid (H_2CO_3). Immediately on entry into erythrocytes, this breaks down into H^+ and HCO_3^- increasing the intracellular bicarbonate concentration. The H^+ attaches to hemoglobin and the bicarbonate passes from the erythrocyte to the plasma. To maintain electrical neutrality, as bicarbonate ions enter the plasma, chloride ions move into the erythrocyte (Powers, 1999). The movement of these ions is effected through an anion antiporter, the chloride/bicarbonate exchangers. As a consequence of this exchange, a higher chloride value is found in arterial blood than in venous blood (Wagner et al., 2009).

Dysregulation of chloride movement can have profound effects as is seen with the genetic disease, cystic fibrosis. The cystic fibrosis transmembrane conductance regulator (CFTR) is a chloride channel located on the apical membranes of airway, intestine, sweat gland, and pancreas epithelial cells (Li and Naren, 2010). It plays a key role in determining ion concentration, fluid balance, and transepithelial salt transport by regulating the movement of Cl^- across the epithelium. Disruption of Cl^- movement has wide-ranging clinical effects in different organ systems (airway disease, pancreatic failure, infertility, and elevated levels of salt in sweat) (Sheppard and Welsh, 1999; Hwang and Sheppard, 2009).

22.2.5.1.1 Chloride Imbalances

22.2.5.1.1.1 Hyperchloremia Hyperchloremia is an electrolyte imbalance characterized by elevated serum chloride levels, greater than 108 mmol/L in humans. It is associated with a variety of clinical conditions, which can be grouped according to whether a proportional change in sodium concentration occurs with Cl^- excess or not. The primary cause of sodium associated hyperchloremia is a water loss in excess of sodium making the causes of hyponatremia also the primary causes of hyperchloremia. Elevated chloride concentrations that are not associated with a proportional increase in sodium are usually associated with acid–base imbalances such as hyperchloremic metabolic acidosis or respiratory alkalosis (Durward et al., 2001). The primary causes of hyperchloremia are shown in Table 22.10.

22.2.5.1.1.1 INCREASE IN CHLORIDE PROPORTIONAL TO SODIUM INCREASE Conditions that cause an elevation of serum Cl^- concentration and a corresponding increase in serum Na^+ level generally result from fluid loss or Na^+ excess. Fluid losses may be pure water or hypotonic. Pure water losses

TABLE 22.10

Causes of Hyperchloremia**Increase in Cl⁻ Proportional to Na⁺ Increase**

- Pure water loss—dehydration, renal losses
- Hypotonic fluid loss—diarrhea, burns, renal losses
- Sodium excess

Increase in Cl⁻ Disproportional to Na⁺ Increase

- Recovery from diabetic acidoketosis
- Respiratory alkalosis
- Hyperchloremic metabolic acidosis
- Renal tubular acidosis
- Urinary diversion
- Early renal failure
- Primary hyperparathyroidism

most often result from increased sweating, inadequate water intake, thyrotoxicosis, or conditions such as central or nephrogenic diabetes insipidus. Hypotonic fluid loss commonly occurs in diarrhea, burns, in renal conditions such as osmotic diuresis, postobstructive diuresis, or with diuretic use. As sodium concentration changes are mirrored by changes in the chloride level, the clinical conditions that give rise to these forms of hyperchloremia also produce hyponatremia and have been discussed in detail previously (Agrawal et al., 2008).

22.2.5.1.1.1.2 INCREASE IN CHLORIDE DISPROPORTIONAL TO SODIUM INCREASE Elevated serum chloride concentration without an increase in serum sodium is associated with hyperchloremic metabolic acidosis when the rise in Cl⁻ levels accompanies a fall in blood pH (to below pH 7.35). Disorders that give rise to hyperchloremia metabolic acidosis include renal tubule acidosis, ureteral diversion procedures, the early stages of chronic renal failure, the recovery phase of diabetic acidoketosis, and primary hyperparathyroidism (Batlle and Kurtzman, 1982; Basic et al., 2007; Liborio et al., 2008). These conditions all result in the inhibition of bicarbonate reabsorption, bicarbonate deficits, or the hyper absorption of Cl⁻. Renal tubule acidosis can be caused by damage to renal tubules (e.g., interstitial nephritis) or drugs such as carbonic anhydrase inhibitors used as a diuretic or to treat a variety of other conditions. Bicarbonate reabsorption is blocked creating an acidemic blood pH in association with nonacidic urine. Hyperchloremic metabolic acidosis also occurs in the early stages of chronic renal failure especially in cases where renal damage is also present (Handy and Soni, 2008). The recovery phase of diabetic acidoketosis is responsible for elevated Cl⁻ because the loss of ketone bodies in the urine prevents their conversion to bicarbonate in the liver, thereby causing bicarbonate deficits. The reduction in plasma carbon dioxide in respiratory alkalosis (occurring with hyperventilation) lowers plasma bicarbonate concentration and results in increased serum Cl⁻ to replace lost bicarbonate (Unwin et al., 1997).

22.2.5.1.1.2 Hypochloremia Hypochloremia is an electrolyte imbalance characterized by serum chloride levels lower than their normal range. It is associated with a variety of clinical conditions that can be grouped according to whether a proportional change in sodium concentration occurs with Cl⁻ depletion or not. The main causes of hypochloremia associated with a decrease in sodium concentration are a total body depletion of Cl⁻ or retention of water causing dilutional hypochloremia (Madias et al., 1984). They are usually associated with acid–base imbalances such as metabolic acidosis or compensated respiratory acidosis (Levitin et al., 1958). The primary causes of hypochloremia are shown in Table 22.11.

22.2.5.1.1.2.1 DECREASE IN CHLORIDE PROPORTIONAL TO SODIUM LOSS Total body chloride depletion can be caused by extrarenal and renal conditions. Hypochloremia caused by extrarenal Cl⁻ loss results from inadequate intake, gastrointestinal loss and burns; these conditions produce low concentrations of Na⁺ and Cl⁻ in the urine and ECF volume reduction (Madias et al., 1984). Renal

TABLE 22.11
Causes of Hypochloremia

Decrease in Cl⁻ Proportional to Na⁺ Loss

- Total body depletion
 - Inadequate NaCl intake
 - Fluid loss—vomiting, diarrhea, burns
 - Drugs—diuretic use
 - Interstitial nephritis
 - Adrenal insufficiency
- Dilutional
 - Increased effective circulatory blood volume—infusion, hyperglycemia
 - Normal effective circulatory blood volume—excess water intake, hypothyroidism, renal disease, SIADH
 - Decreased effective circulatory blood volume—edema

Decrease in Cl⁻ Disproportional to Na⁺ Loss

- Compensated respiratory acidosis
- Metabolic alkalosis

causes of hypochloremia include diuretic use (particularly loop diuretics), osmotic diuresis (from mannitol or diabetic acidoketosis), renal diseases, and deficiency in glucocorticoids or mineralocorticoids (adrenal insufficiency). In these conditions, the concentration of Na⁺ and Cl⁻ in the urine is elevated yet the ECF volume is still reduced. Dilutional hypochloremia is associated with normal or increased total body content of sodium and chloride coupled with ECF volume expansion. As sodium concentrations changes are mirrored by changes in the chloride level, the clinical conditions that give rise to these forms of hypochloremia also produce hyponatremia and have been discussed in detail in the previous section (Agrawal et al., 2008).

22.2.5.1.1.2.2 DECREASE IN CHLORIDE DISPROPORTIONAL TO SODIUM LOSS Metabolic alkalosis occurs when metabolic increases in bicarbonate levels elevate the pH of the blood beyond the normal range (greater than pH 7.45). This occurs when chloride depletion results in ECF volume reduction and there are decreased levels of filtered chloride available for reabsorption by the kidney tubules. This leads to increased bicarbonate reabsorption and elevated blood pH. Metabolic alkalosis increases potassium secretion by the kidneys, which can also lead to hypokalemia (Galla, 2000). In respiratory acidosis, elevated carbon dioxide levels increase the secretion of H⁺ in the kidney tubules. This leads to the retention of sodium as sodium bicarbonate rather than sodium chloride to resolve the acidemia. The increase in serum bicarbonate causes a reciprocal decrease in chloride concentration and hypochloremia can develop. Thiazide diuretics enhance sodium chloride excretion in the distal convoluted tubule causing metabolic alkalosis by chloride depletion (and enhancing potassium and hydrogen ion secretion).

22.2.5.1.2 Factors Influencing Measurement of Chloride Concentration

A wide variation in the normal range for chloride concentration makes it difficult to attach biological significance to changes in serum values except those at the extreme ends of the range. Determination of chloride in the serum or plasma can, however, be a useful indicator of the acid–base status of the animal. If chloride levels are high, bicarbonate is likely to be low, suggesting a metabolic acidemia. The reverse situation suggests metabolic alkalemia, but strict interpretation of these changes should be treated with caution owing to the wide, normal range for chloride. Ions such as Br⁻, SH⁻, CN⁻, and CNS⁻ are not differentiated from chloride in most laboratory titrations; this interference can give spurious chloride levels and should be taken into account when assaying samples. A common use of bromide is potassium bromide given as an adjunct therapy for phenobarbital in dogs.

Postprandial hypochloremia can occur when measurement of chloride levels is performed after the administration of food. Two potential mechanisms operate to cause this effect: (1) chloride ions are secreted into the stomach lumen after a meal, along with hydrogen ions, (2) postprandial hyperlipidemia. The postprandial secretion of Cl^- into the stomach after a meal causing temporary depletion of chloride ions is not indicative of true hypochloremia. Pseudohypochloremia can be indicated in cases of hyperlipidemia or hyperproteinemia when chloride concentration is measured in a reference volume of fluid. The errors occur because both lipid and protein occupy part of the measured volume but do not contain chloride (Dimeski et al., 2006).

22.2.5.2 Bicarbonate/Total Carbon Dioxide

Biochemical processes that occur in all cells are dependent on a very narrow pH range. Carbon dioxide/bicarbonate plays a vital part in the pH buffering system that restricts changes in intracellular and extracellular pH. Carbonic acid maintains equilibrium with CO_2 and H_2O and, along with bicarbonate, constitutes the major buffer pair in body fluids. As CO_2 is acidic and can freely diffuse across membranes while bicarbonate is basic and moves through specific transport channels, cellular and extracellular pH can be maintained by the movement of these ions. Under normal physiological conditions, the majority of this buffer pair is found as bicarbonate (at approximately 25 mmol/L in humans) (Casey, 2006). Total carbon dioxide content is typically measured as an estimator of serum bicarbonate because of the labile nature of bicarbonate ions. Total CO_2 represents the amount of serum bicarbonate, carbonic acid, and dissolved carbon dioxide present.

Bicarbonate is one of the major anions of the ECF (the other being Cl^-) produced when CO_2 diffuses into erythrocytes and is converted by carbonic anhydrase to HCO_3^- . To prevent buildup of HCO_3^- in the cells, high levels of anion exchanger 1 (AE1, the HCO_3^- transport protein) are expressed, and these allow the movement of HCO_3^- out of the cell. To preserve electrical neutrality, Cl^- moves into the cells at the same rate (Alper et al., 2002). Movement of bicarbonate ions therefore affects three different processes: HCO_3^- metabolism, regulation of pH, and regulation of cell volume (effected by coordinated activation of $\text{Cl}^-/\text{HCO}_3^-$ transporters with H^+/Na^+ transporters) (Mason et al., 1989; Cordat and Casey, 2009). Primary changes in plasma bicarbonate concentration lead to metabolic acid–base disorders. Moreover, decreased bicarbonate results in decreased carbon dioxide and hydrogen ions; whereas, increased bicarbonate results in increased CO_2 and hydrogen ions.

The process of bicarbonate reabsorption occurs predominantly in the proximal tubules of the kidney, the remainder in the thick ascending limb of the loop of Henle and the collecting duct (Boron, 2006). Under normal conditions, the kidney is able to reabsorb all filtered bicarbonate, which is important to maintain the acid–base balance. It is achieved by secreted H^+ , combining with filtered HCO_3^- to form CO_2 and H_2O . These can be passively reabsorbed and the H_2O broke down intracellularly to OH^- and H^+ . Reaction of OH^- and CO_2 then leads to the reformation of HCO_3^- . The net effect of this absorption is the loss of one H^+ in exchange for one HCO_3^- . Reabsorption of bicarbonate is affected by many factors: potassium balance, volume status, and renin/angiotensin levels (Boron, 2006) (Figure 22.6).

22.2.5.2.1 Hyperbicarbonatemia

Hyperbicarbonatemia is an electrolyte disturbance characterized by the elevated levels of bicarbonate in the blood, and it is almost always indicative of metabolic alkalosis; however, it can occur primary or secondary to respiratory acid–base disorders. Elevated bicarbonate levels are associated with hypercapnia, hypokalemia, or hyperchloremia. Metabolic alkalosis secondary to respiratory acidosis associated with an increase in the partial pressure of carbon dioxide (PCO_2) and decrease in pH due to the high levels of H^+ in the blood. This leads to the renal retention of bicarbonate, elevated serum bicarbonate, and metabolic alkalosis. The development of alkalosis occurs in an attempt to correct the primary respiratory acidosis. Metabolic alkalosis, respiratory acidosis, and hypercapnia are all indicative of hyperbicarbonatemia; they are not generally the cause. Elevated

FIGURE 22.6 Bicarbonate reabsorption in the proximal tubule of the kidney. H^+ secreted into the tubule lumen is used to titrate the HCO_3^- to CO_2 and H_2O . These reenter the cell across the apical membrane and recombine to produce H^+ and HCO_3^- that moves out across the basolateral membrane.

TABLE 22.12

Causes of Hyperbicarbonatemia

Renal

- Bicarbonate retention—compensation for respiratory acidosis
- Diuretic use
- Mineralocorticoid excess—hyperaldosteronism, hyperadrenocorticism (Cushing's disease)
- Potassium deficiency

Gastrointestinal

- Bicarbonate administration
- Gastrointestinal loss—vomiting, chloride diarrhea, gastric suction

HCO_3^- concentrations are due to bicarbonate retention by the kidney, ingestion of bicarbonate, or loss of H^+ from the body (vomiting). Common causes of elevated HCO_3^- level are shown in Table 22.12.

22.2.5.2.1.1 Renal Respiratory acidosis is characterized by decreased respiration and causes a decrease in blood pH and an increase in PCO_2 . Metabolic alkalosis developing secondary to this condition occurs when high levels of H^+ are present in blood promoting increased renal retention of HCO_3^- . This compensating response requires days to develop and results in a rise in the serum bicarbonate levels. The extent of the rise in plasma bicarbonate is determined by the increase in renal hydrogen secretion (Capasso et al., 2002). The factors that maintain elevation of bicarbonate levels are the same as those involved in the maintenance of metabolic alkalosis: chloride depletion, potassium depletion, ECF volume depletion, and reduction of GFR. Chloride depletion from the loss of bicarbonate-poor, chloride-rich ECF as occurs with thiazide or loop diuretics ultimately lead to a decrease in ECF volume (contraction alkalosis). As the original bicarbonate now exists in a smaller ECF volume, the elevation of bicarbonate concentration occurs. This mechanism of bicarbonate elevation however only causes small increases of at most, 2–4 mmol/L. In chloride depletion, there are also fewer chloride ions available to be exchanged with HCO_3^- , in the collecting duct of the kidney. This impairment of the kidney's ability to excrete bicarbonate leads to excess serum bicarbonate. Potassium depletion occurring in cases of mineralocorticoid excess/hyperaldosteronism (and hyperadrenocorticism) results in increased bicarbonate reabsorption in both the proximal and distal tubules of the kidney. Elevated aldosterone levels lead to increased distal tubular Na^+ reabsorption and increased K^+ and H^+ losses. The increased H^+ losses are matched by increased bicarbonate

losses and can result in hyperbicarbonatemia, hypochloremia, and hypokalemia (Khanna and Kurtzman, 2001).

22.2.5.2.1.2 Gastrointestinal Metabolic alkalosis can be caused both by an increase in bicarbonate intake and an inhibition of bicarbonate secretion in the kidney. Increase in bicarbonate intake or alkali gain in the ECF is rarely a cause of persistent metabolic alkalosis or hyperbicarbonatemia because the kidney is so effective at excreting bicarbonate. Whenever plasma bicarbonate levels rise above 24 mmol/L, the kidney excretes HCO_3^- . This response effectively corrects the imbalance so even when sodium bicarbonate is directly infused, with normal renal function, bicarbonaturia follows and the rise in plasma bicarbonate is brief (Singer et al., 1955). Transient increases in bicarbonate level can also be brought about by infusion of bicarbonate base equivalents such as citrate in transfused blood or treatment of ketoacidosis or lactic acidosis. When these organic anions are metabolized to bicarbonate, a temporary increase in bicarbonate concentration ensues (Galla, 2000). Elevation of bicarbonate concentration can also be brought about by mechanisms that induce H^+ loss from the gut (through vomiting of acidic gastric contents). The loss of acidic gastric contents by vomiting can result in alkaline diuresis where the kidney reabsorbs sodium without chloride by an accelerated sodium–cation exchange. This process induces hyperbicarbonatemia and potassium depletion (Schwartz and Cohen, 1978). The sodium loss is small but volume is conserved, which is more important than the maintenance of normal acid–base or potassium balance (Kassirer and Schwartz, 1966).

22.2.5.2.2 Hypobicarbonatemia

Hypobicarbonatemia is an electrolyte disturbance characterized by abnormally depleted levels of bicarbonate in the blood. Bicarbonate concentrations of 8–10 mmol/L are incompatible with life in humans if they are maintained for more than a short period of time (Narins et al., 1980). Hypobicarbonatemia is almost always indicative of metabolic acidosis; it also occurs with progressive kidney disease (Shah et al., 2009). As with hyperbicarbonatemia, the metabolic changes associated with this condition may be primary or secondary to primary respiratory disorders. Causes of low plasma bicarbonate levels can be divided into renal and metabolic changes. The decrease in bicarbonate concentration can be due to loss from either the gastrointestinal tract or kidney. Additionally metabolic combination of bicarbonate with H^+ from acids such as lactic acid and keto acids can cause hypobicarbonatemia. These mechanisms are shown in Table 22.13.

22.2.5.2.2.1 Renal Excretion Renal loss of bicarbonate can be a compensatory mechanism for respiratory alkalosis or renal disease (renal failure or renal tubular acidosis). Respiratory alkalosis is associated with a decrease in PCO_2 and an increase in pH due to decreased circulating hydrogen ion concentration concurrent with a decrease in ionized calcium concentration causing symptoms of hypocalcemia. It is brought about by hyperventilation and may be seen in animals in pain, under psychological stress or in nonsweating animals, as they use respiratory evaporative processes for

TABLE 22.13

Causes of Hypobicarbonatemia

Renal Excretion

- Respiratory alkalosis—increased bicarbonate loss
- Renal failure—decreased renal excretion
- Renal tubular acidosis
- Mineralocorticoid deficiency

Metabolic

- Increased acid production (acidosis)—diabetic ketoacidosis, lactic acidosis, ethanol consumption, salicylate, methanol, and ethylene glycol toxicity
- Diarrhea, pancreatic fistula, urinary diversion—increased loss of bicarbonate

heat loss (Carlson, 1989). The initial response to respiratory alkalosis is a slight decline in ECF bicarbonate concentration; this occurs through cellular buffering. A slower renal response ensues to further decrease in HCO_3^- levels by decreasing renal bicarbonate reabsorption. The decline in bicarbonate is partially offset by chloride retention for preserving electrical neutrality. This mechanism can produce a 12–15 mmol/L (12–15 mmol/L) decrease in bicarbonate in humans (Carlson, 1989). In renal tubular acidosis, a defect in proximal tubule HCO_3^- reabsorption or distal tubule H^+ secretion (or both) cause low plasma bicarbonate levels and blood to remain considerably acidic (hyperchloremic metabolic acidosis). Mineralocorticoid deficiency also causes acidosis; low aldosterone levels result in a decline in sodium reabsorption by the distal tubule. Na^+ is lost in the urine and H^+ retained, so the normal acid load is not excreted. The buffering action of bicarbonate for this acid prevents normal regeneration reclamation from occurring and low plasma bicarbonate results.

22.2.5.2.2 Metabolic Metabolic acidosis is an acid–base disorder characterized by a decrease in pH that results from either a primary decrease in plasma bicarbonate concentration or an increase in hydrogen ion concentration (Kraut and Madias, 2010). ECF buffers, primarily bicarbonate–carbonic acid, bring about initial buffering of acid load. The most common causes of metabolic acidosis are shown in Table 22.14 and include ketoacidosis, lactic acidosis, diarrhea, and renal failure. In general, conditions that result in the excess production of acids cause a depletion of bicarbonate by the increased need for buffering. When coupled with a reduction in the GFR and a corresponding decrease in the kidney’s capacity to reabsorb bicarbonate, the use of bicarbonate exceeds production and hypobicarbonatemia ensues. Ketoacidosis occurs when the body produces high levels of ketone bodies through the metabolism of fatty acids. It is often associated with diabetes mellitus as insulin production slows the process of ketosis. The body initially buffers the acidity of the ketone bodies with bicarbonate–carbonic acid; bicarbonate and ketones are lost in the urine. Common types of ketoacidosis are diabetic and alcoholic ketoacidosis; they occur with drug use (ethanol, ethylene glycol, methanol, aspirin, iron, and acetazolamide [a carbonic anhydrase inhibitor]), starvation, pregnancy, or myocardial infarction. Most animals (including dog, cat, rat, and guinea pig) develop only slight ketosis when starved; in humans and nonhuman primates, starvation ketosis is a regular phenomenon (Friedemann, 1926). Lactic acidosis is a state of acidosis characterized by the elevated levels of plasma lactate. The breakdown of lactate releases H^+ , this is in turn buffered by bicarbonate and leads to bicarbonate depletion (Nadiminti et al., 1980). Fatal concentrations of lactate in humans are 7–8 mmol/L (Oliva, 1970). Normal concentrations in dogs range from 0.4 to 2.6 mmol/L, with a median value of 1.7 mmol/L (Thorneloe et al., 2007). Diarrhea (caused by infectious agents and osmotic effects), pancreatic fistula, or urine diversion can also lead to depleted bicarbonate levels.

TABLE 22.14
Causes of Metabolic Acidosis

High Anion Gap

- Ketoacidosis—diabetes, poor nutrition
- Lactic acidosis—shock, seizures, excessive exercise, carbon monoxide, or cyanide poisoning
- Renal failure
- Metabolism of toxins to acids—methanol, ethylene glycol, salicylates

Normal Anion Gap

- Gastrointestinal bicarbonate loss—diarrhea, uterosigmoidostomy
 - Renal bicarbonate loss—renal tubule acidosis, hyperparathyroidism
 - Ingestion or infusion—ammonium chloride, arginine, calcium chloride, magnesium sulfate
 - Hypoaldosteronism
 - Hyperkalemia
-

22.2.5.2.3 Factors Influencing Measurement of Bicarbonate/ Total Carbon Dioxide Concentration

Measurement of total carbon dioxide represents the amount of serum bicarbonate, carbonic acid, and dissolved carbon dioxide present. It is typically measured as an estimator of serum bicarbonate because of the labile nature of bicarbonate ions. Bicarbonate concentration can then be calculated from PCO_2 and pH. A small error may occur when it is calculated rather than measured because the ionic strength of samples varies. An indirect titrimetric method determining total CO_2 can be used; however, it must be corrected for carbamate and carbonate. An altered bicarbonate value must be accompanied by other data for proper interpretation. Obtaining a satisfactory arterial sample from dogs, cats, rabbits, pigs, horses, cows, goats, sheep, and primates is not difficult. In rodents, it can probably be obtained by permanent surgical exteriorization of the carotid artery to permit arterial catheterization. The method of restraint used when obtaining cardiac blood from rats can have an effect on acid–base balance and plasma calcium and magnesium levels. Manual restraint can increase blood acidity and plasma calcium and magnesium levels whereas little difference in effect is observed when ether, pentobarbitone sodium, or fentanyl plus droperidol were used. In a study of Wistar rats treated with anesthesia, bicarbonate levels were between 19.44 and 22.25 mmol/L; however, when manually restrained the level was 14.44 mmol/L (Upton and Morgan, 1975). Changes in pH or temperature are important to accurately determine the values of bicarbonate; likewise the exposure of blood samples to air or plastic containers that absorb carbon dioxide produces a loss of this volatile acid; air bubbles erroneously lower PCO_2 by dilution (Beetham, 1982). When performing a complete clinical chemistry panel on samples, it is necessary to analyze a separate aliquot of blood for bicarbonate in order to minimize the amount of time the sample is exposed to air in the analyzer while other endpoints are determined. Acidic heparin should be avoided; heparin should be sterile, isotonic, and have a neutral pH (Beetham, 1982). Addition of heparin should be minimal and constant, as it is equilibrated with atmospheric gases. Normally, the proximal tubule reabsorbs almost all filtered bicarbonate so urinary bicarbonate is barely detectable and fractional excretion of bicarbonate (FEHCO_3^-) is <5% of the glomerular filtered load. However, FEHCO_3^- is a useful measure of renal tubular acidosis. In proximal renal tubular acidosis, bicarbonate is increased, usually to approximately 15% and in distal renal tubular acidosis urine pH is high but plasma bicarbonate concentration remains low or normal (<5%–10%) (Bagga et al., 2005; Unwin, 2001). FEHCO_3^- can be calculated using the following formula:

$$\text{FEHCO}_3^- = \frac{(\text{urine bicarbonate/serum bicarbonate})}{(\text{urine creatinine/serum creatinine})} \times 100$$

22.2.5.3 Inorganic Phosphorus (Phosphate)

Phosphorus is a naturally occurring element present in many foods. It is a major intracellular anion existing in two forms: dihydrogen phosphate (H_2PO_4^-) and mono-hydrogen phosphate (H_2PO_4^-) at normal blood pH levels. Approximately 85% of total body phosphorus is in the bone where it forms part of the mineralized extracellular matrix (crystalline hydroxyapatite) and creates a reservoir for maintaining homeostasis. The remaining phosphate is found in the soft tissues where the majority of the phosphorus is intracellular, complexed with carbohydrates, lipids, and proteins. It forms an essential part of cell structures including nucleic acids, cell membrane phospholipids, and mitochondria. Phosphate is necessary for many enzymatic reactions (in glycolysis, ammoniogenesis, and oxidative phosphorylation) and plays an important role in energy metabolism, storing energy in the chemical bonds between phosphate groups in ADP and ATP. In addition, it influences the oxygen carrying capacity of hemoglobin by its role in the regulation of 2,3-diphosphoglycerate (2,3-DPG) synthesis. Inorganic phosphate is present as a very minor component of serum, in the

range 1.12–1.45 mmol/L in adult man. Inorganic phosphate levels are higher in rodent species than other laboratory animals, which are in the range of 2.55–4.55 mmol/L in mice (1.07–4.33 mmol/L in rats) compared to 0.88–2.35 mmol/L in rabbits. No diurnal variation or gender differences have been observed in phosphate levels; however, some differences have been observed between different breeds of rabbits. In mice, rats, and dogs, phosphate levels decrease with age (Loeb et al., 1996); younger animals have higher phosphate requirements due to active skeletal growth. Dietary intake and acid–base balance also play a role in determining the phosphate level of an animal.

Passive and active absorption of phosphate in the GI tract occurs by paracellular pathways (by passive diffusion between cells) and transport channels (antiporters). The uptake by luminal cells may be dependent on intraluminal sodium and is also vitamin D and calcium dependent. The kidney is the major route of phosphate secretion and controls homeostasis. Under normal conditions, approximately 85%–90% of filtered phosphorus is reabsorbed. The reabsorption is passive and linked to sodium transport, occurring largely in the proximal tubules. In some circumstances (in response to glucose and insulin administration), phosphate is reabsorbed independently of sodium. Reabsorption is inhibited by PTH, and may be influenced by vitamin D metabolites and calcium (Patel and Singh, 2009; Bergwitz and Juppner, 2010).

22.2.5.3.1 Phosphate Imbalances

22.2.5.3.1.1 Hyperphosphatemia Hyperphosphatemia is a rare electrolyte disturbance characterized by increased phosphate levels. Elevated serum phosphate levels occur by three general mechanisms: excess intake, reduced renal excretion, and shifts in cellular balance. One of the most common clinical conditions associated with hyperphosphatemia is chronic renal failure (Rosol and Capen, 1996; Moe, 2008). Common causes of hyperphosphatemia are shown in Table 22.15.

22.2.5.3.1.1.1 EXCESS INTAKE With properly functioning renal excretion mechanisms, an excess intake of dietary phosphorus is an uncommon cause of hyperphosphatemia. Mechanisms for renal excretion allow virtually unlimited intake of phosphate while still maintaining homeostatic control. In addition to the intake of phosphate, hypervitaminosis D can also cause increased gastrointestinal and renal absorption of phosphate (and calcium) and elevated phosphate levels. In conjunction with renal insufficiency, either mechanism can lead to hyperphosphatemia.

22.2.5.3.1.1.2 REDUCED RENAL EXCRETION Decreased excretion of phosphate, especially when accompanied by excess intake, is the most frequent cause of hyperphosphatemia; this is most commonly associated with reduced renal excretion in renal failure. When the GFR falls to below 25 mL/min, the excretion of ingested phosphate is insufficient to maintain homeostasis and hyperphosphatemia develops. In hypoparathyroidism, phosphate is retained through failure to inhibit proximal tubule reabsorption. Similar mechanisms are in action in severe hypomagnesemia and pseudohypoparathyroidism in which PTH secretion is impaired or there

TABLE 22.15
Causes of Hyperphosphatemia

Excess Intake	Reduced Renal Excretion	Shift in Cellular Balance
<ul style="list-style-type: none"> • High dietary phosphate • Hypervitaminosis D • Phosphate enema • Intravenous phosphate 	<ul style="list-style-type: none"> • Renal Failure • Hypoparathyroidism • Endocrine disorders—hyperthyroidism • Pseudohypoparathyroidism • Magnesium deficiency • Tumoral calcinosis 	<ul style="list-style-type: none"> • Tumor lysis • Rhabdomyolysis • Respiratory acidosis

is a failure of PTH action in renal tubules; these all result in hyperphosphatemia. In other endocrine disorders such as acromegaly, excess growth hormone leads to increased tubular reabsorption of phosphate and high serum phosphate levels. Tumoral calcinosis is also characterized by decreased renal excretion of phosphate and hyperphosphatemia; this condition is caused by inactivating mutations in proteins that control urine phosphate levels (fibroblast growth factor 23 (FGF23), polypeptide *N*-acetylgalactosaminyltransferase 3 (GALNT3), or KL) (Prie et al., 2005).

22.2.5.3.1.1.3 SHIFT IN CELLULAR BALANCE Alone, the movement of phosphate from the intracellular to the extracellular space is an uncommon cause of hyperphosphatemia. A shift in the cellular balance of phosphate causing hyperphosphatemia occurs with rhabdomyolysis or tumor lysis. Rarely, acidosis or insulin deficiency may cause cellular shifts in phosphate.

22.2.5.3.1.2 Hypophosphatemia Hypophosphatemia is a disturbed electrolyte balance characterized by a reduced serum phosphate level. Acute clinical manifestations are rare in laboratory animals; in human, clinical consequences are usually observed when hypophosphatemia is severe (<0.32 mmol/L). There are three primary mechanisms that lead to hypophosphatemia: low dietary intake, increased phosphate excretion (from the GI tract or kidney), and a shift in cellular balance from extracellular to intracellular compartments (Moe, 2008; Shaikh et al., 2008). Table 22.16 shows the common causes of hypophosphatemia.

22.2.5.3.1.2.1 INTAKE DEFICIENCY Insufficient dietary intake of phosphate is an uncommon cause of hypophosphatemia because of the prevalence of phosphate in foods. However, in conditions of starvation (not uncommon in experimental animals used in drug development) or chronic alcoholism and in combination with renal insufficiency, hypophosphatemia may occur. Decreased intestinal absorption can also lead to a deficiency of phosphate; this can occur with diarrhea, severe vomiting, or malabsorption conditions. The use of large amounts of aluminum-containing antacids can cause depletion of phosphate by binding phosphate in the gut and preventing absorption of ingested and secreted phosphate (Bates, 2008). Vitamin D deficiency decreases gut absorption of calcium and phosphate. It also increases renal excretion of phosphate and decreases bone resorption resulting in hypophosphatemia and hypocalcemia.

22.2.5.3.1.2.2 INCREASED RENAL EXCRETION The major cause of phosphate loss is increased renal excretion. Usually, this occurs as a result of excess PTH (primary or secondary hyperparathyroidism),

TABLE 22.16
Causes of Hypophosphatemia

Intake Deficiency	Increased Renal Excretion	Shift in Cellular Balance
<ul style="list-style-type: none"> • Poor dietary intake/starvation • Malabsorption • Hypovitaminosis D • Phosphate binders—antacids • Diarrhea/vomiting 	<ul style="list-style-type: none"> • Hyperparathyroidism • Sodium bicarbonate infusion/extracellular volume expansion • Renal tubule defects—Fanconi syndrome • Diuretic use—loop diuretics, thiazides, or carbonic anhydrases inhibitors • Osmotic diuresis • Renal tubular acidosis • Hypokalemia/hypomagnesemia 	<ul style="list-style-type: none"> • Respiratory alkalosis • Hyperalimentation • High carbohydrate diet • Glucose ingestion/administration • Insulin administration • Diabetic ketoacidosis

which stimulates the kidneys to excrete phosphate. Loss may also be the result of extracellular volume expansion with sodium or bicarbonate. The resulting dilution of serum calcium causes an increase in PTH release stimulating renal secretion of phosphate. Diuretic use can lead to phosphate depletion by interfering with the ability of the proximal tubule to reabsorb phosphate; hyperphosphaturia follows and hypophosphatemia can develop. Osmotic diuresis depletes phosphate by increasing its renal clearance, it can occur in conditions such as hyperosmolar hyperglycemic syndrome. Other conditions that can result in increased phosphate secretion by the kidney include Fanconi syndrome in dogs (characterized by failure to reabsorb amino acids, glucose, and phosphate), congenital defects, or estrogen down regulation of a renal sodium phosphate cotransporter (Faroqui et al., 2008; Rastegar, 2009).

22.2.5.3.1.2.3 SHIFT IN CELLULAR BALANCE Hyperventilation leading to respiratory alkalosis can be caused by a variety of conditions including diabetic ketoacidosis or salicylate toxicity. It activates phosphofructokinase stimulating intracellular glycolysis, leading to phosphate consumption and the movement of phosphate from the extracellular to the intracellular compartment (Datta and Stone, 2009). A high carbohydrate diet or glucose administration lower serum phosphate levels by stimulating the release of insulin, which enhances the intracellular movement of phosphate and glucose into cells. It may also cause cells to switch to an anabolic state whereby serum phosphate is depleted through incorporation into the cells (Mehanna et al., 2009). Diabetic ketoacidosis is also an important cause of hypophosphatemia. In this condition, serum phosphate levels are initially higher due to metabolic acidosis and insulin deficiency shifting the intracellular phosphate stores to the extracellular compartment. This leads to urinary loss (Nowik et al., 2008). With insulin treatment, phosphate is translocated back into the cells resulting in a decrease in serum phosphate levels.

22.2.5.3.2 Factors Influencing Measurement of Phosphate Concentration

Since phosphate is predominantly an intracellular cation, hyperphosphatemia does not always reflect a true increase in total body phosphate stores. Moreover, cellular damage releases intracellular phosphate and can cause spurious hyperphosphatemia. Measurement of urine phosphate in samples obtained from the bottom of rodent cages has no credence; many detergents contain phosphate, and there is contamination by feces, hair, and microorganisms. As phosphate homeostasis is primarily regulated at the level of the proximal renal tubule, plasma phosphate levels are indicators of renal tubular handling. The fractional excretion of phosphate determined in urine specimens at different time points daily is often used as an estimation of phosphate handling. As tubular reabsorption of phosphate depends on plasma phosphate and GFR, it is not a good indicator of tubular phosphate handling. Increasingly, “tubular maximum for phosphate corrected for glomerular filtration rate” has been employed to assess renal phosphate handling. This provides an index of the renal threshold for phosphate that can be determined on timed urine samples and can be calculated as follows: $\text{plasma phosphate} - (\text{urine phosphate} \times \text{plasma creatinine}) / \text{urine creatinine}$ (Bagga et al., 2005). However, the small volume of blood that can be sampled daily from small laboratory animals can be a limit to experimental design when using this method.

22.2.5.4 Sulfate

Sulfate is the fourth most common anion in plasma, and it is known to play an essential role in a wide variety of physiological processes: particularly, the sulfation of exogenous and endogenous compounds (steroids, anti-inflammatory agents, and adrenergic blockers). Sulfation provides a mechanism of biotransformation of these compounds and in most cases leads to increased urinary excretion (Falany, 1997). One of the most important roles for sulfate is in the biosynthesis of 3'-phosphoadenosine-5'-phosphosulfate (PAPS), which is the active sulfate used in the biosynthesis of many essential endogenous compounds (i.e., heparin and gastrin) that are necessary for the biosynthesis of cell membranes and tissues (proteoglycans) (Beck and Silve, 2001). Inorganic sulfate accounts for 90%–95% of naturally occurring sulfated compounds, the remaining 5%–10% of total

body sulfate occurs as sulfoconjugates. Plasma sulfate concentration varies with age in mammals; in humans, it is 0.47 mmol/L at birth but decreases with age to 0.33 mmol/L in adults (Cole and Scriver, 1980; Bakhtian et al., 1993; Pena and Neiberger, 1997).

Although an essential anion, sulfate is infrequently assayed in clinical chemistry. Serum sulfate is strongly influenced by a variety of physiological factors such as age, diet, and drugs and is difficult to measure accurately. Quantitation of serum sulfate is achieved by ion conductimetry after anion-exchange chromatography (Cole and Evrovski, 1997, 2000). Little is known of the factors that regulate sulfate homeostasis in mammals; the role of changes in sulfate metabolism in the pathogenesis of disease is largely unknown. Sulfate homeostasis is achieved by three mechanisms: dietary intake, intestinal absorption, and renal secretion. In the intestine, approximately 90%–95% of sulfate ingested is absorbed. Uptake by the enterocytes occurs through Na^+ -dependent transports and Na^+/Cl^- exchangers (Langridge-Smith and Field, 1981; Schron et al., 1987; Florin et al., 1991). The kidneys primarily control sulfate homeostasis; sulfate is freely filtered from the glomerulus and is reabsorbed in the proximal tubules. Approximately 80%–95% of filtered sulfate is reabsorbed; the remainder is excreted in the urine (Beck and Silve, 2001; Markovich, 2001). Regulation of proximal tubule reabsorption is largely unexplored. Factors known to regulate sulfate levels include vitamin D, which modulates Solute Carrier Family 13 Member 1 (NaS1) transport protein, thyroid hormone (hyperthyroidism in humans is associated with increased serum sulfate levels and hypothyroidism with decreased sulfate levels), and dietary sulfate intake (dietary sulfate levels regulate renal sulfate transport) (Markovich et al., 1998). More recently, knockout mouse models have highlighted factors that regulate sulfate homeostasis in mammals and the physiological consequence of homeostasis disruption. Functional characterization of the sulfate anion transporter, NaS1, knockout mouse model has shown the essential role played by this protein in mediating proximal tubule sulfate reabsorption. Targeted disruption of this gene leads to hyposulfatemia and hypersulfaturia in NaS1 knockout mice indicating that NaS1 is critical for maintaining sulfate homeostasis. Changes in blood sulfate levels affect a wide range of physiological functions including the metabolism, growth, fecundity, behavior, gut physiology, and liver detoxification (Markovich, 2011a, b).

22.2.5.4.1 *Hypersulfatemia*

Elevated levels of serum sulfate characterize hypersulfatemia; it occurs in chronic renal failure with reduced GFRs. The mechanisms involved in the development of hypersulfatemia are unknown but likely involve a decrease in the amount of sulfate transporter proteins, NaS1 and Sat1, leading to increased sulfate secretion (Beck and Silve, 2001).

22.2.5.4.2 *Hyposulfatemia*

Decreased levels of serum sulfate characterize hyposulfatemia; however, little is known about the clinical significance or factors that give rise to this condition. Studies in knockout mice show that the sodium-sulfate cotransporter NaS1 plays a pivotal role in maintaining serum sulfate levels within the normal physiological range. This gene is expressed predominantly in the kidney and intestine and is regulated by environmental factors (including diet and hormones); in NaS1 null mice, hyposulfatemia develops (Dawson et al., 2003; Markovich and Aronson, 2007).

22.3 BLOOD GASES

The process of respiration can be divided into four phases: ventilation, alveolar gas exchange, transport of gases in blood, and gas exchange in the tissues. Beginning with an exchange of air between the atmosphere and alveoli (ventilation), oxygen and carbon dioxide then move between alveolar air and capillary blood for transport to tissues. Ventilation is controlled by partial pressures of oxygen (PO_2) and carbon dioxide (PCO_2) and the concentration of hydrogen ions. Although gases are transported across the alveolar wall by passive diffusion, concentration gradient is not the primary determinant of rate of exchange. This is because when dissolved in body fluids, O_2 and CO_2 are mostly bound to

hemoglobin (O_2) or exist as HCO_3^- (CO_2). As the bound molecules are not free to diffuse, partial pressure (measured in millimeters of mercury, mmHg or kilopascals, kPa) is considered a more accurate measure of the ability of the gas to move. Partial pressure (or tension) of a single gas (PO_2 or PCO_2) in a gaseous mixture is defined by the pressure exerted by that gas alone. Alveolar gases are comprised of oxygen, nitrogen, carbon dioxide, and water vapor. O_2 and CO_2 each rapidly diffuse down their own partial pressure gradient, which drives O_2 from the alveolus to the blood and CO_2 from the blood to the alveolus. The rate of O_2 diffusion is influenced by several factors: diffusion gradient, total surface area, respiratory membrane thickness, and respiratory rate. Diffusion rates can be reduced when the PO_2 gradient declines (reduced ventilation or perfusion), the surface area for gas exchange is reduced (emphysema), the respiratory membrane is abnormally thickened (pulmonary edema, pneumonia), or respiratory rates are depressed (barbiturates, anesthesia) (Misasi and Keyes, 1996).

Oxygen is transported in the blood primarily bound to hemoglobin (97%), ~3% of oxygen is dissolved in plasma, and it is this that accounts for the PO_2 of blood. A high PO_2 level in blood (occurring in the lungs) causes a rise in the amount of oxyhemoglobin formed; when PO_2 falls in the tissues, oxyhemoglobin breaks down and releases O_2 . Oxyhemoglobin formation is also favored by lower PCO_2 and a rise in pH. Oxygen saturation is a measure of how much of the hemoglobin in red blood cells is carrying oxygen; it is typically >95%. Carbon dioxide is transported in three ways: the most important means is as bicarbonate ions (60%–80%); it is also attached to hemoglobin (23%) and dissolved in plasma (7%). The latter determines the PCO_2 value and obeys Henry's law stating that dissolved CO_2 increases linearly with PCO_2 (Wieth et al., 1982). Carbon dioxide in the form of bicarbonate ions represents one of the body's primary buffering systems for pH maintenance at a physiological optimum (pH 7.4) (Kellum, 2000; Dash and Bassingthwaigite, 2006); higher levels of CO_2 produce more H^+ and lower pH according to the equilibrium shown as follows:

The Henderson–Hasselbalch equation applied to the HCO_3^-/H_2CO_3 buffer pair is expressed as follows:

$$pH = 6.1 + \log_{10} \left[\frac{HCO_3^-}{H_2CO_3} \right]$$

where 6.1 is the pK_a for the HCO_3^-/H_2CO_3 buffer pair at 37°C and pH 7.4 (Paulev and Zubieta-Calleja, 2005). $[HCO_3^-]$ represents the bicarbonate concentration expressed in millimoles per liter. $[H_2CO_3]$ consists of (1) physically dissolved carbon dioxide—99% (arterial PCO_2), and (2) hydrated carbon dioxide—1% (H_2CO_3). By controlling ventilation rates, the respiratory system therefore plays a primary role in regulating pH (Beetham, 1982). The role bicarbonate plays in acid–base balance will be discussed in more detail in a later section.

In tissues, O_2 and CO_2 diffuse down their partial pressure gradient defined by the fact that PO_2 in arterial blood > PO_2 of ISF > PO_2 ICF. The gradient is maintained because O_2 is continuously used in metabolism, and the release of O_2 from oxyhemoglobin maintains the PO_2 of blood. For carbon dioxide, the PCO_2 of arterial blood is less than that of ISF, which is less than that of ICF. CO_2 therefore moves out of the cell on a gradient maintained by the continual production of CO_2 by cellular processes.

Arterial blood gas is a collective term used to describe three measurements: pH, PCO_2 , and PO_2 . Although hydrogen is not present in blood as a gas and therefore does not exert a partial pressure, pH is a measure of hydrogen ion concentration and forms part of arterial blood gas measurements. Together, these measurements provide an assessment of acid–base status, ventilation, and arterial oxygenation. Each of these components is discussed individually below.

22.3.1 pH

Although hydrogen is not present in blood as a gas and therefore does not exert a partial pressure, pH is a measure of hydrogen ion concentration and forms part of arterial blood gas measurements. The normal range for blood pH varies little between species and is 7.32–7.5; a value less than 7.2 is considered life threatening in humans (Narins et al., 1980). Venous pH is lower than arterial pH. Moreover, in dog, the mean difference is 0.038 units (Zweens et al., 1977). Women have higher pH values than men, and pH decreases in old age (other species may be similar to humans in this respect). pH is defined as follows:

$$\text{pH} = -\log_{10} [\text{H}^+]$$

Normal H⁺ concentration is 0.0004 mmol/L and is a measure of the acid–base status of blood. As enzymatic reactions operate within a tightly defined pH range, regulation of the acid–base balance is strictly controlled. Disturbances in pH result in abnormal respiratory and cardiac functions, abnormal blood clotting, and drug metabolism.

Small amounts of hydrogen ions are generated during the oxidation of amino acids and the anaerobic metabolism of glucose to lactic and pyruvic acid; however, the largest source of H⁺ in the body is generated as a result of CO₂ production from metabolism according to the relationship below:

This carbonic acid/bicarbonate equilibrium therefore forms one of the most important systems in the body for limiting changes in pH. H⁺ homeostasis is maintained by three mechanisms: buffers that limit changes in H⁺ concentration (especially carbonic acid/bicarbonate), the lungs (which control PCO₂), and the kidneys (which regulate plasma bicarbonate). As carbon dioxide is the primary source of H⁺, the respiratory system is the primary regulator of H⁺ concentration. Arterial PCO₂ is inversely proportional to alveolar ventilation, so profound changes in H⁺ levels and pH are affected by changes in ventilation. The kidneys also play a role in H⁺ homeostasis as tubule cells can excrete H⁺ and regenerate bicarbonate ions (Gumz et al., 2010). Furthermore, the kidney is one of the primary sites for homeostatic control of electrolyte balance and therefore influences acid–base balance. Hydrogen ions are actively secreted into the kidney tubule lumen where they combine with bicarbonate to form carbonic acid. Carbonic acid dissociates to form CO₂ and H₂O catalyzed by luminal carbonic anhydrase. The CO₂ diffuses into the tubular epithelial cells where it combines with water again to form carbonic acid. Carbonic acid then dissociates into bicarbonate and H⁺, which are excreted from the cell (McMurtrie et al., 2004; Purkerson and Schwartz, 2007). Hydrogen passes back into the blood in exchange for Na⁺ and counter to Cl⁻ to maintain electrical neutrality. This elimination occurs by active secretion against a steep concentration gradient in the proximal and distal tubules. Urine is buffered from the constant influx of H⁺ by phosphate and ammonia (Hamm and Simon, 1987).

22.3.2 HYDROGEN IMBALANCE

22.3.2.1 Acidemia

Acidemia is defined as increased H⁺ in blood plasma; it can be caused by metabolic or respiratory changes and can lead to acidosis. Moderate acidosis develops in most animals at pH 7.25–7.3, severe acidosis at pH 7.2–7.25 and grave acidosis at pH 7.0–7.1. In general, a rise in H⁺ is associated with conditions such as lactic acidosis, ketosis, hyperventilation, urinary obstruction, or renal failure

(Charney and Feldman, 1984). Tubular dysfunction can cause hydrogen ion accumulation when electrolyte exchange or bicarbonate reclamation mechanisms fail or ammonia production is reduced and its buffering action lost (Bonilla-Felix, 1996).

22.3.2.2 Alkalemia

Alkalemia is defined as decreased H^+ in blood plasma; it can be caused by metabolic or respiratory changes and can lead to the development of alkalosis (blood pH >7.45). In general, a fall in H^+ is associated with a variety of factors including increased intake of bicarbonate, citrate or lactate, dehydration (contraction alkalosis), increased acid secretion, potassium depletion, gastrointestinal loss (vomiting), or decreased renal elimination (Tannen, 1987; Khanna and Kurtzman, 2001). Mechanistically, these conditions cause alkalemia in the following ways. Increased oral intake of weak bases (citrate, lactate) increases the total plasma base and causes secondary decrease in H^+ concentration. Loss of extracellular potassium can lead to hydrogen losses when the extracellular K^+ losses cause intracellular K^+ loss; as potassium is exchanged for H^+ , the intracellular pH decreases and the extracellular pH rises. Vomiting causes the loss of H^+ and Cl^- from the gastric contents; this causes plasma bicarbonate to rise which in turn causes an alkali diuresis. Potassium and a small amount of sodium and chloride are lost in the urine promoting hydrogen secretion and bicarbonate reabsorption (Norris and Kurtzman, 1988). Loss of H^+ can also be a secondary or a compensatory response: increased arterial PCO_2 results in a decrease in H^+ concentration through increased urine excretion. Likewise, sodium and chloride depletion with the resultant secondary aldosteronism causes increased renal acid secretion, as sodium is retained under the influence of aldosterone while H^+ are lost.

22.3.2.3 Factors Influencing Measurement of Hydrogen Concentration

Accurate results for pH measurement depend on proper collection and handling techniques. The most common problems include nonarterial sampling, temperature, length of storage, improper sample mixing, and inappropriate use of anticoagulant. Precise pH levels require anaerobic collection of arterial blood samples from an undisturbed, unanesthetized animal. Consideration should be given to the use of heparin as an anticoagulant: in the acidic form it produces a small error in pH and, in large volumes it affects the PCO_2 and PO_2 levels as both are heparin soluble (Hamilton et al., 1978). On storage, glycolysis can increase the titratable hydrogen ion concentration by 0.5 mmol/L per hour at room temperature and 0.1 mmol/L per hour at 0–4°C. The increase is greater when leukocytosis is present (Siggaard Andersen, 1979). Performing blood gas analysis within 95 minutes of sample collection can minimize this effect (Brito et al., 2008). Additionally, hemolysis can cause an erroneously low pH (Siggaard Andersen, 1979); this can occur when samples are incorrectly mixed or placed on ice. Blood pH decreases as the body temperature rises so sample analyzers should be adjusted to body temperature or a correction factor applied. Characterization of the physiological effects of isofluorane anesthesia on neonatal mice has shown significant changes in arterial pH in anesthetized animals (Loepke et al., 2006). Implanting arterial catheters has allowed blood gas analysis in conscious unrestrained animals (Lee et al., 2008; Brun-Pascaud et al., 1982). In one study of mice in which femoral arterial catheters were implanted, the measurement of pH was successfully performed by the rapid collection of blood samples (60 μ L) and immediate analysis using an automated analyzer (Lee et al., 2008). The limitation of this technique is its cumbersome and invasive nature. Instrumentation used in measuring blood gases and pH is vital to obtain accurate results. In recent years, portable “point of care” systems (e.g., i-STAT 1 analyzer) have been validated for use in research laboratories. These typically require small volumes of blood and have been used successfully to assess pH in whole blood from dogs (Verwaerde et al., 2002) and blood gas CO_2 in mice (Sahbaie et al., 2006).

22.3.3 CARBON DIOXIDE

Carbon dioxide is present in blood in three different forms: bicarbonate ions (60%–80%), protein bound (23%), and dissolved in plasma (7%). The latter determines the PCO_2 value, which is typically in the range of 28–40 mmHg in arterial blood and 28–42 mmHg in venous blood in laboratory animals. It does not vary significantly with age but is lower at higher altitudes where ventilation is stimulated. Arterial PCO_2 values are fairly constant, venous values are higher and vary considerably, depending on the site, temperature, and muscular or metabolic activity. The most important CO_2 binding protein is hemoglobin; reversible binding of CO_2 to the amino groups of the polypeptide chain produce carbaminohemoglobin that transports CO_2 from the tissues after O_2 dissociation. Carbon dioxide can also bind to the amino groups of other plasma proteins.

Carbon dioxide homeostasis is achieved by three mechanisms: buffering of pH changes (largely achieved with the $\text{H}_2\text{CO}_3^-/\text{HCO}_3^-$ pair), control of arterial PCO_2 (effected by the lungs), and regulation of plasma bicarbonate level (by the kidneys). The fundamental relationship in this process is the equilibrium between dissolved CO_2 , H_2CO_3^- , and HCO_3^- (shown above). The consequence of this is that dissolved CO_2 is directly proportional to arterial PCO_2 . Processing of CO_2 occurs predominantly in erythrocytes (and renal tubular cells) catalyzed by the intracellular enzyme, carbonic anhydrase (Purkerson and Schwartz, 2007).

22.3.3.1 Carbon Dioxide Imbalances

22.3.3.1.1 Hypercapnia (Hypercarbia)

Hypercapnia is characterized by elevated CO_2 levels in blood (>50 mmHg results in moderate hypercapnia in most laboratory animal species), and it leads to a decrease in blood pH and acidosis. Respiratory acidosis is an associative effect to hypercapnia rather than a causative one, brought about by primary disturbances in arterial PCO_2 . Changes in bicarbonate level can cause metabolic acid–base disorders. Both forms of acid–base disturbance bring about a compensatory response in an attempt to return blood pH to normal; this may cause hypercapnia. Elevated CO_2 levels develop when there is an imbalance between the CO_2 produced by the body and that excreted by the lungs. The source of this imbalance can occur anywhere from the initiation of ventilation to gas exchange at the alveolar membrane. Many clinical conditions contribute to inadequate removal of CO_2 from the blood including paralysis of the respiratory muscles, lung diseases, central respiratory drive depression, or exposure to unusually high levels of carbon dioxide. The ability of the body to adapt to these changes depends on whether the condition is acute or chronic; with chronic pulmonary diseases, the persistent elevation of PCO_2 leads to effective compensatory mechanisms and less of a clinical impact. Respiratory acidosis rarely develops because any increase in PCO_2 rapidly causes a large increase in ventilation.

Elevated PCO_2 can occur by three mechanisms: increased metabolic production of CO_2 , decreased alveolar ventilation, and increased inspired carbon dioxide (Pahari et al., 2006). The most common cause is decreased alveolar ventilation; this can result from a defect in diaphragmatic and intercostal muscle contraction, paralysis, muscle degeneration, or pain. Increased resistance to air movement, as seen with obstruction, edema, bronchiolar constriction, and loss of surfactant, reduces minute volume and can also lead to hypercapnia. Increased inspired carbon dioxide produces a relatively small change in PCO_2 because of the strong opposing ventilatory response (Wasserman et al., 1975). A twofold increase in metabolism causes a 10% increase in PCO_2 ; however, this effect is offset by ventilation and rarely leads to hypercapnia. Deficiency or inhibition of carbonic anhydrase activity can produce hypercapnia, as the conversion of carbonic acid to CO_2 and water is slowed. Table 22.17 shows common causes of hypercapnia.

Biochemically, an increase in PCO_2 drives the CO_2 /bicarbonate equilibrium to the right increasing the concentration of H^+ and HCO_3^- in erythrocytes. The rise in H^+ is buffered by hemoglobin preventing an increase in pH. HCO_3^- moves out of the cell to the plasma and to maintain electrical neutrality within the erythrocyte. Chloride ions move into the erythrocyte. This exchange

TABLE 22.17**Causes of Hypercapnia**

- CNS related—central respiratory depression, trauma, infection, hypoxia, spinal trauma
- Nerve or muscle disorders—spinal muscular atrophy, muscle dystrophies
- Airway disorders—upper airway obstruction, asthma
- Lung or chest wall defects—pneumonia, pulmonary edema, trauma
- Hypercatabolic disorders—malignant hyperthermia
- Increased intake of CO₂—rebreathing of expired air, addition of CO₂ to inspired air

TABLE 22.18**Causes of Hypocapnia**

- Hypoxemia—high altitudes, pulmonary disease
- Pulmonary disorders—pneumonia, pulmonary edema
- Cardiovascular disorders—congestive heart failure
- Metabolic disorders—acidosis, liver failure
- CNS related—pain, anxiety, fever, meningitis, encephalitis
- Endocrine related—pregnancy, hyperthyroidism
- Drugs—salicylates, progesterone

of bicarbonate and chloride ions across the erythrocyte membrane is known as the chloride shift (Hamburger shift). In acute hypercapnia, the movement of bicarbonate is small (3–4 mmol/L); in chronic hypercapnia, it is larger (~40 mmol/L) but in both cases the changes are physiological responses and not part of a buffering mechanism (Cogan, 1984; Hirakawa et al., 1993).

22.3.3.1.2 Hypocapnia (*Hypocarbica*)

Hypocapnia is a condition of unusually low arterial PCO₂ levels. If there is no compensation and no other acid–base disorder, this will lead to an increase in arterial pH and a corresponding decrease in bicarbonate concentration. As with hypercapnia, primary disturbances in arterial PCO₂ have an associative effect with respiratory acid–base imbalance (alkalosis), not a causative one. Hypocapnia develops when there is an imbalance between the CO₂ produced by the body and that excreted by the lungs (Laffey and Kavanagh, 2002). Under normal circumstances, the volume of inspired CO₂ is negligible and increased CO₂ production is unusual. Consequently, low PCO₂ is most often the result of an increased elimination of CO₂. The principal physiological causes of hypocapnia are related to hyperventilation. Hyperventilation is stimulated when chemoreceptors in the brain and carotid bodies sense an increase in hydrogen ions. The increased rate of alveolar ventilation is disproportional to the rate of metabolic carbon dioxide production. Common causes of hypocapnia are listed in Table 22.18 (Laffey and Kavanagh, 2002).

Biochemically, a decrease in PCO₂ drives the CO₂/bicarbonate equilibrium to the left. Indirectly, hypocapnia decreases renal bicarbonate resorption because low PCO₂ inhibits renal acid secretion (Schwartz and Cohen, 1978). The latter effect is a compensatory change brought about by alteration in the tubular chloride transport and is independent of plasma pH (Schwartz and Cohen, 1978). In dogs with chronic hypocapnia, the plasma bicarbonate is decreased 0.50 mmol/L for every millimeter of mercury decrease in PCO₂ (Schwartz and Cohen, 1978).

22.3.3.2 Factors Influencing Measurement of PCO₂ Concentration

Accurate results for PCO₂ measurement depend on proper collection and handling techniques. The most common problems include nonarterial sampling, air bubbles, temperature, length of storage, and inappropriate use of anticoagulant. Precise PCO₂ levels require anaerobic collection of arterial

blood samples; contamination by a venous blood may produce a falsely increased PCO_2 . The effect of sampling from different sites (arterial or venous) has been evaluated in dogs and horses and showed consistent differences between arterial and venous blood (Carlson, 1989). Removal of air bubbles from sampled blood is important in preventing the equilibration of CO_2 from the air with the collected sample as this would result in a reduction of the PCO_2 (air has essentially no CO_2). Likewise, the presence of liquid heparin in the collection syringe can sometimes cause erroneous PCO_2 measurements when carbon dioxide from the air equilibrates with heparin before sample collection (Higgins, 2007). When samples are stored at room temperature, glycolysis causes an increase in PCO_2 of approximately 5 mmHg/hour at 37°C . The rate is reduced by a factor of 10 if the sample is cooled to 2°C – 4°C but the maximum storage time prior to analysis should be less than 1 hour at 2°C – 4°C (Tietz, 1976). Since the measurement of PCO_2 is dependent on temperature, blood samples not measured at body temperature (preferable) will need a correction factor. The PCO_2 of blood decreases by approximately 5% per degree centigrade increase in temperature because the solubility of CO_2 in plasma is decreased (Beetham, 1982). Moreover, protein buffer dissociation affects the temperature response of PCO_2 (Beetham, 1982). Finally, significant errors arise when PCO_2 is calculated from the Henderson–Hasselbalch equation because samples with abnormal protein, lipid, and ionic composition alter the pK of carbonic acid and the solubility coefficient of CO_2 . Optimally, arterial blood samples should be collected in a plastic syringe with a tight fitting cap (to prevent air equilibration) and processed immediately. Values collected from blood gas machines should be corrected for the body temperature of the animal (IFCC, 2001).

22.3.4 OXYGEN

Oxygen is essential for aerobic metabolism, normal oxygen tension (normoxia) is usually approximately 80–100 mmHg for human arterial blood and 30–50 mmHg for venous blood. The arterial PO_2 is influenced by atmospheric pressure, composition of alveolar air, rate, and depth of breathing, cardiac function, and blood flow and distribution. Central and peripheral receptors control and modulate lung, heart, and vascular activity. The PO_2 is under both voluntary and involuntary control. Oxygen is carried in the blood in two forms: dissolved and bound to hemoglobin. Dissolved O_2 obeys Henry's law stating that the amount of dissolved O_2 is directly proportional to the PO_2 (Habler and Messmer, 1997). The solubility coefficient of oxygen at 37°C in plasma is $0.00126 \text{ mmol/L}^{-1}/\text{mmHg}^{-1}$ and for whole blood, $0.00140 \text{ mmol/L}^{-1}/\text{mmHg}^{-1}$ in humans (Thomas, 1997). It is reduced by increased ionic strength and protein concentration, and it is elevated by an increase in lipid content. The contribution of dissolved oxygen to arterial oxygen content is very small and does not provide sufficient amounts of O_2 to the tissues to sustain metabolism. Hemoglobin, the major oxygen transporting protein in the erythrocytes, carries oxygen bound reversibly to ferrous iron. It has four binding sites for oxygen and under normal conditions hemoglobin is approximately >95% saturated in arterial blood and 70% in venous blood. Oxygen saturation is the ratio of the amount of O_2 bound to hemoglobin to the oxygen carrying capacity of hemoglobin. The O_2 carrying capacity is determined by the amount of hemoglobin in the blood, and the amount of O_2 bound is determined by the partial pressure of O_2 . In the lungs, PO_2 is high and therefore hemoglobin binds oxygen. In tissues, the PO_2 is lower and O_2 is released. This release and uptake of oxygen by hemoglobin is carefully controlled (Meldon, 1985; Jensen, 2004). The sigmoid shape of the oxyhemoglobin dissociation curve (Figure 22.7) reflects the changes in hemoglobin affinity for oxygen (Takano et al., 1979; Rees et al., 1996).

The position of the curve indicates the available oxygen supply to the tissues. Displacement to the right indicates decreased oxygen affinity and easier unloading of oxygen. The following conditions shift the curve to the right:

1. Increased hydrogen ion concentration (Bohr effect) ($\Delta \log \text{PO}_2/\Delta \text{pH} = 0.040$ to 0.050 for most mammals) binds deoxyhemoglobin more actively than hemoglobin, which reduces the affinity of hemoglobin for O_2 and promotes O_2 dissociation (Kister et al., 1988).

FIGURE 22.7 Oxyhemoglobin dissociation curve.

2. Increased CO₂ causes a decrease in blood pH as described previously (Jensen, 2004).
3. Increased temperature denatures the bond between O₂ and hemoglobin, which increases the amount of free O₂ and hemoglobin and decreases the concentration of oxyhemoglobin (Cambier et al., 2004).
4. Increased 2,3-DPG; as the primary organic phosphate in mammals, 2,3-DPG binds hemoglobin, modifies the conformation, and decreases its oxygen affinity (di Bella et al., 1996).
5. Hemoglobins with low oxygen affinity (human Hb Seattle and Kansas).
6. Increased ATP influences intracellular pH and may cause a conformation change in hemoglobin that reduces the binding to O₂ (Shappell and Lenfant, 1972).
7. Inorganic phosphate and other anions influence intracellular pH and may act in the same way as 2,3-DPG to modify hemoglobin conformation.
8. Anemia, the effects are mainly due to increased ATP.
9. Hyperthyroidism, the effect is mainly due to increased erythrocyte 2,3-DPG content.
10. Age of erythrocytes influences the affinity of hemoglobin for oxygen, and younger erythrocytes have lower affinity possibly as a result of 2,3-DPG level in the cells (Haidas et al., 1971).
11. Aldosterone and cortisol may decrease hemoglobin–oxygen affinity (rabbits) (Bauer and Rathschlag-Schaefer, 1968).

The curve is shifted to the left when the foregoing conditions are reversed and by the presence of fetal hemoglobin, abnormal hemoglobins (human Hb Yakima, Malmo, Rainier), or hexokinase deficiency (Jensen, 2004). Both carbon monoxide and methemoglobin increase oxygen affinity of the unused heme groups and shift the curve to the left (Sharan and Popel, 1989). For most species, PO₂ values increase from birth and reach adult values by several months of age. A slight aging-related decrease in PO₂ occurs in humans and may be present in other animals. There are no sex differences in oxygen pressures.

22.3.4.1 Oxygen Imbalances

22.3.4.1.1 Hyperoxemia

Hyperoxemia is defined as a higher than normal oxygen tension in the blood. It occurs when hyperbaric oxygen is administered. Administration of 100% oxygen under pressure saturates hemoglobin but also causes increased dissolved oxygen in the plasma (hyperoxygenation) due to Henry's

law. The increased plasma oxygen content compensates for the vasoconstriction that occurs with hyperoxemia (Bird and Telfer, 1965). Oxygen toxicity causes blindness, chest pain, cough, tinnitus, decreased pulmonary function, muscle twitching, dizziness, vasoconstriction of cerebral vessels, convulsions, coma, and death (Carraway and Piantadosi, 1999).

22.3.4.1.2 Hypoxemia

Hypoxemia is defined as a lower than normal oxygen tension in arterial blood (<60 mmHg, 8 kPa) or a hemoglobin oxygen saturation of less than 90%. It is a pathological condition distinct from hypoxia, which is a decrease in an adequate supply of oxygen. Hypoxemia can be one of the characteristics of hypoxia but it is also possible for hypoxia to occur with a low oxygen content and high arterial PO₂. In chronic hypoxemia, hemoglobin has a reduced oxygen affinity and increased heme–heme interactions, which result in increases in the availability of O₂ to tissues (Waltemath, 1970). If the decrease in PO₂ is sufficiently rapid and falls below 35 mmHg in humans, aerobic metabolism is replaced by anaerobic metabolism, and lactic acid concentration rises (Forsythe and Schmidt, 2000). Hypoxemia causes increased concentrations of inorganic phosphate, urate, and hypoxanthine. There are five primary causes of hypoxemia, and these are shown in Table 22.19.

When alveolar ventilation is low, inadequate amounts of O₂ are delivered to the alveolar respiratory surfaces; this can cause hypoxemia and occurs as a result of a variety conditions (some shown in Table 22.19). A reduction in the partial pressure of inspired oxygen will also result in hypoxemia, and it can occur when breathing at high altitudes with reduced barometric pressure or with an accidental reduction in fractional oxygen content under anesthesia. The peripheral chemoreceptors, aortic, and carotid bodies respond immediately to a fall in PO₂ and stimulate respiration (Berger et al., 1973). Hyperventilation is not marked until the PO₂ falls to approximately 60 mmHg when it can cause hypocapnia. An anatomic shunt from the right side to the left side of the circulation can be intracardiac or intrapulmonary. It occurs when a portion of blood bypasses the lungs and can be caused by congenital abnormalities or disease states. In pneumonia or pulmonary edema, a portion of the cardiac blood enters the pulmonary vasculature without contacting the alveolar air because of fluid in the alveolar spaces. With both conditions blood is prevented from normal access to alveolar air and is improperly oxygenated. Ventilation–perfusion inequality is the most common cause of hypoxia. This is the result of a change in the relationship between alveolar PO₂ and PCO₂ caused by differences in the ratio of alveolar ventilation to perfusion. Rarely hypoxemia can occur because of impaired diffusion across alveolar membranes. Diseases such as interstitial lung disease can result in increased thickness of the gas exchange barrier; coupled with a shortened pulmonary transit time, reduced PO₂ can result.

Primary hemoglobin deficiency (anemia) is not generally considered a cause of hypoxemia because the reduced delivery of O₂ to the tissues is the result of a lack of O₂ binding protein rather than a decrease in the partial pressure of oxygen in blood (Habler and Messmer, 1997).

TABLE 22.19

Causes of Hypoxemia

- Hypoventilation (low alveolar ventilation)—diseases of respiratory muscles, depression of CNS, airway obstruction
 - Low inspired oxygen (low PO₂)—decreased barometric pressure, decreased fractional oxygen content
 - Right to left shunt—congenital abnormalities, pulmonary edema, pneumonia
 - Ventilation–perfusion inequality—lung disease
 - Diffusion impairment—interstitial lung disease
-

22.3.4.2 Factors Influencing Measurement of PO₂ Concentration

Accurate results for PO₂ measurement depend on proper collection and handling techniques. The most common problems include nonarterial sampling, exposure to air, temperature, length of storage, improper sample mixing, and inappropriate use of anticoagulant. Precise PO₂ levels require anaerobic collection of arterial blood samples; especially when the arteriolar PO₂ is high because of the inherent characteristics of hemoglobin–oxygen dissociation. Satisfactory blood gas samples may be obtained with relative ease from most laboratory species. Rats and mice present more of a problem because of their limited blood volume and small size but implantation of arterial catheters has been successfully utilized to intermittently sample and monitor blood gases in conscious and anesthetized animals (Pakulla et al., 2004; Lee et al., 2009). This technique, however, is limited by its cumbersome and invasive nature, requiring surgery, which unless performed sufficiently in advance of sampling, can affect the accuracy of blood gas measurement. Blood gas samples can also be obtained by cardiac puncture but the utility of this method is limited as continuous monitoring is not possible. An alternative, noninvasive technique that has been successfully utilized for blood gas analysis with dogs, mice, rats, rhesus monkeys, guinea pigs, and rabbits is transcutaneous monitoring in which a heated probe (comprised of a Clark-type polarographic electrode) is applied to the skin (Stout et al., 2001; Sahbaie et al., 2006). When sampling, exposure to air should be minimized to prevent equilibration of the sample with air; this can increase PO₂. Likewise, the presence of heparin can cause erroneous PO₂ measurements when oxygen from the air equilibrates with heparin before sample collection (Higgins, 2007). On storage, glycolysis causes an increase in PO₂, as it is liberated from oxyhemoglobin. The opposing effect of O₂ consumption in cellular respiration creates a net loss of PO₂ of approximately 0.4 kPa/hour at 37°C (Travis et al., 1971). As the PO₂ measurement is dependent on temperature, if the blood sample is not measured at body temperature (preferable), a correction factor needs to be applied. The O₂ solubility and equilibrium between oxyhemoglobin and dissolved oxygen are affected by temperature (Yamaguchi et al., 1987; Cambier et al., 2004).

22.4 ACID–BASE BALANCE

Acid–base balance is the balance of the body between acidity and alkalinity. Metabolic processes produce acid that must be excreted or metabolized to prevent a fall in pH. The acids produced by the body can be classified as either respiratory or metabolic (Kellum, 2000). One of the major respiratory acids produced is carbonic acid. Carbon dioxide, while strictly not an acid, is converted to carbonic acid and is often considered a respiratory acid. It is produced by cells in large quantities as an end product of metabolism and excreted from the lungs. All acids other than carbonic acid are metabolic and are not excreted by the lungs; they include lactate, phosphate, and sulfate. They are produced due to nutrient breakdown or as a normal intermediary to metabolism and are all excreted by the kidney. For acid–base balance to be maintained, the amount of acid produced must equal the amount excreted to sustain a physiologically normal pH. Free H⁺ must be removed from the ECF and eliminated from the body, and mechanisms must be in place to compensate if the ECF becomes alkaline. Conditions that cause a rise in hydrogen ion concentration in the blood cause a pH decrease (acidosis) and a fall in H⁺ causes a rise in pH (alkalemia). To prevent acid–base disturbances, the body responds in three ways: (1) intracellular and extracellular buffering, (2) respiratory control of alveolar ventilation to alter arterial PCO₂, and (3) renal regulation of HCO₃⁻/H⁺ secretion (Adroque and Adroque, 2001). By regulating blood chemistry, these systems are able to maintain electrical neutrality and a constant pH.

22.4.1 BUFFER SYSTEMS

Buffering is an immediate physiochemical response to changes in body pH. A buffer consists of a weakly dissociated acid and the salt of that acid, and they are able to take up and release H⁺ and thereby limit changes in pH. The buffering systems of the body include extracellular buffers,

intracellular buffers, and bone. Extracellular buffers are bicarbonate ($\text{HCO}_3^-/\text{H}_2\text{CO}_3$), phosphate ($\text{HPO}_4^{2-}/\text{H}_2\text{PO}_4^-$), and plasma proteins. The intracellular buffers include protein, organic and inorganic phosphates, and hemoglobin. In bone, carbonate forms a large buffer reservoir used particularly during chronic metabolic acidosis (Bushinsky, 2001; Arnett, 2008). Experimental evidence in the dog and cat shows that after 5 hours of acidosis, most of the tissue buffering is performed by bone (Bettice and Gamble, 1975). As bone contains no salts of acids weaker than carbonic acid, it buffers very little of the change in respiratory acidosis. Proteins (mainly intracellular) form the most important buffers in the body, and they possess both basic and acidic groups that can act either as H^+ acceptors or donors as needed. Hemoglobin buffers against changes associated with CO_2 transport. Buffers are most effective when the pH is equal to their pK ; the phosphate buffer pair has a pK of 6.8. As this is near physiological normal, this is a moderately efficient buffer pair. It is mainly intracellular although its presence in the ECF makes it an important urinary buffer. Although $\text{H}_2\text{CO}_3/\text{HCO}_3^-$ plays an integral role in regulating pH, their role is not as a buffer system. The pK of this pair is 6.1 and so far from normal physiological pH (7.4) that they are not effective buffers.

In the blood, hemoglobin acts as a primary intracellular buffer in erythrocytes. The exchange of oxygen with hemoglobin is associated with a simultaneous exchange of hemoglobin and hydrogen ion. Hemoglobin combines with oxygen and a hydrogen ion is released, whereas when oxygen is released, hydrogen ion is accepted. The result of this process is an arteriovenous pH difference of approximately 0.01–0.02 units (Siggaard Andersen, 1979). Hemoglobin–hydrogen ion exchange produces bicarbonate; carbonic acid (formed from erythrocytes by the continuous hydration of CO_2) donates a proton to hemoglobin, and the residual bicarbonate diffuses into the plasma. The departing bicarbonate is replaced by chloride from the plasma in a process known as the chloride shift (Hamburger shift) and as a result hemoglobin effectively buffers CO_2 (Crandall et al., 1981).

22.4.2 RESPIRATORY BALANCE

Steady PCO_2 levels are important for reducing pH changes and are maintained by the excretion or retention of CO_2 by the lungs. Alterations in ventilation rate can rapidly bring about changes in PCO_2 . Respiratory control can operate on two levels, preventing changes in PCO_2 and compensating for changes in PCO_2 . By preventing changes in PCO_2 when alteration in other acids or bases occurs, a significant pH effect is prevented. Compensation by the respiratory system for changes in pH can be effected by corresponding changes in PCO_2 . In this way, increased CO_2 excretion by hyperventilation results can correct respiratory acidosis, compensate for metabolic acidosis, and also produce respiratory alkalosis.

22.4.3 RENAL BALANCE

The renal system controls ECF volume and composition through balance of electrolyte levels, and it assists in maintaining pH at 7.4. This process of control is considerably slower than respiratory control, taking days to effect change (Harrison, 1995). The kidneys excrete excess acids or bases (except carbonic acid) from the ECF to maintain homeostasis and maintain the pH in the normal range. If there is a deficiency of acid or base (other than carbonic acid), the kidneys are unable to restore normality. When high PCO_2 causes a low pH, the kidneys excrete acid, H^+ and Cl^- , NH_4 and Cl^- , or 2Na^+ with Cl^- and H_2PO_4 to raise the pH to normal. The outcome is renal venous blood with a higher pH than normal and this raises the pH of systemic blood. As the H^+ concentration is lowered, the conversion of carbonic acid to bicarbonate and H^+ is increased.

22.4.4 ANION GAP

The anion gap (AG) represents the difference between the sum of the major anions and cations in the plasma. Under normal circumstances, in humans, routinely measured anions account for all

TABLE 22.20
Laboratory Animal Anion Gap Reference Values

Species	Anion Gap (mmol/L)
Cat ^a	13.0–27.0
Dog ^a	12.0–24.0
Sprague Dawley rat ^b	14.9–24.8
F344 rat ^b	15.2–23.7
ICR mouse ^b	23.3–27.3
Guinea pig ^b	13.7–23.2

^a Kaae and deMarais (2008).

^b Clinical chemistry values from Hilltop Lab. Animals, Inc. <http://hilltoplabs.com/public/blood.html>

except 8–16 mmol/L (mean 12) of the total anions (Emmett and Narins, 1977). Reference values for the AG in common laboratory species are shown in Table 22.20.

Negatively charged proteins make up the majority of the unmeasured anions with approximately 10% being plasma anions; acid anions such as lactate, sulfate, and pyruvate also contribute (Coude et al., 1982). Under most circumstances, the value of unmeasured cations (proteins, magnesium, calcium, and others) is small, and their contribution to a disturbance is usually not significant. AG can be calculated from the following formula:

$$AG = [Na^+] + [K^+] - [Cl^-] - [HCO_3^-]$$

The AG for most species of domestic animals appears to be similar to that defined for human subjects (10–20 mmol/L). In horses, age-related changes in AG have been reported with foals having a larger AG than horses (Gossett and French, 1983). The major use of AG measurements is in the interpretation of clinical data to enable categorization of acid–base disorders such as situations in which acidosis is not accompanied by decreased pH or an increase in free hydrogen (Kraut and Madias, 2007). This enables metabolic acidosis to be divided by the magnitude of the AG. For example, with inorganic metabolic acidosis (hyperchloremic acidosis) where Cl[−] replaces HCO₃[−], the AG remains normal yet, and when lost bicarbonate ions are replaced by an unmeasured acid anion, the AG is increased. It is therefore apparent that while increased AG arises from conditions that cause acidosis, not all causes of acidosis increase the AG. Any decrease in routinely unmeasured cations and/or increase in unmeasured anions cause a raised AG; it can be associated with elevated organic acids (lactic acid, keto acids) in hypovolemia, shock, diabetes and ketosis, or raised nonmetabolizable acids (inorganic acid such as sulfate or phosphate) associated with excesses of compounds such as salicylates (Coude et al., 1982), methanol, or ethylene glycol. Acidoses that are the most common cause for increased AG include ketoacidosis, lactic acidosis, and uremic acidosis; additionally, salicylate, oxalate, or acetate toxicity can raise the AG (Fulop, 1993; Messa et al., 2001). Dehydration and alkalosis are minor causes of increased AG.

Decreased AG arises from increases in the unmeasured cations and/or decreases in the unmeasured anions. The most common cause of decreased AG is hypoalbuminemia. Albumin is the major unmeasured anion, making up almost the entire value of the AG. Hypoalbuminemia (reduced albumin concentration) therefore results in a low AG; a one gram decrease in albumin reduces the AG by 0.25 mmol/L (Figge et al., 1998; Carvounis and Feinfeld, 2000). Moreover, rarer causes include cationic protein (immunoglobulin) increases, which occur in polyclonal gammopathy or multiple myeloma (Qujeq and Mohiti, 2002).

22.4.5 ACID–BASE IMBALANCE

Acid–base disturbances, characterized by changes in hydrogen ion concentration affect the ionization of molecules and reactive groups (Takeda et al., 1987). Proteins and other substances become more or less charged as pH is altered. Changes in acid–base balance can have wide-reaching effects on many organ systems in the body, as enzyme reactions are optimal at narrow pH ranges. Acid–base disturbances are diagnosed from arterial blood measurements because they reflect both respiratory and metabolic disturbances (Kellum, 2000).

22.4.5.1 Classification of Acid–Base Disturbances

Acid–base disturbances are classified in several ways according to the following:

1. The underlying cause. Acid–base disturbances are respiratory when the primary change is an alteration in the partial pressure of CO_2 and metabolic when the primary change is an alteration in bicarbonate concentration. Carbonic acid is produced endogenously, and its blood concentration is regulated by respiration. Metabolic conditions result from alterations in the nonvolatile or fixed acids. Respiratory and metabolic disturbances may be present concurrently as a mixed disturbance.
2. The course of the condition. Acid–base disturbances may be acute, or longer than a few hours in duration, in which case they are termed chronic.
3. The severity and response to the condition. Acid–base disturbances are uncompensated, partially compensated, and compensated. Metabolic disturbances are largely mitigated by respiratory compensation, whereas compensation for a respiratory disturbance is mainly by renal mechanisms.

Each condition should be identified by the primary cause, duration, and degree of compensation. A primary change in PCO_2 is a respiratory disturbance. Mechanisms that react to the altered PCO_2 by changing bicarbonate are secondary or compensatory mechanisms. A primary change in bicarbonate is a metabolic disturbance, and the mechanisms that operate to change the PCO_2 as a result of the bicarbonate change are secondary or compensatory mechanisms. Compensations for changes in blood pH are affected by respiratory and renal systems. Respiratory compensation is rapid, whereas renal compensation may take several days.

22.4.5.1.1 Metabolic Acidosis

Acidosis is an increased acidity in the blood where arterial pH is less than 7.35. Metabolic acidosis arises as a result of conditions that cause a primary decrease in bicarbonate concentration. Bicarbonate concentration can either be reduced by increased endogenous production of acids or reduced through gastrointestinal loss or failure of the kidney to excrete the normal acid load. Metabolic acidoses can be subdivided into high AG and normal AG forms. Common causes of metabolic acidosis are given in Table 22.14 (Kreisberg and Wood, 1983; Wagner, 2007).

Acidosis with a high AG can be caused by ketoacidosis and is associated, most commonly, with diabetes mellitus. Under these conditions, free fatty acids are converted to keto acids, acetoacetic acid, and β -hydroxybutyrate by the liver; as these are all unmeasured anions, they increase the AG. In lactic acidosis, lactate accumulates from both excess lactate formation and decreased usage. An increase in lactate formation occurs with anaerobic metabolism, and decrease in usage usually occurs with liver dysfunction. Renal failure can result in decreased acid excretion and decreased HCO_3^- reabsorption. In these cases, the high AG is caused by an accumulation of sulfates and phosphates.

Metabolic acidosis with a normal AG occurs when HCO_3^- is lost from the GI tract (diarrhea or uterosigmoidostomy) or kidney. In renal tubular acidosis, either tubular reabsorption of bicarbonate or tubular hydrogen ion secretion is defective or both. The inability to excrete H^+ load is also a cause for normal AG acidosis in cases of hypoaldosteronism. Likewise an increased H^+ load with the ingestion of ammonium chloride causes acidosis.

22.4.5.1.2 Compensation

The onset of metabolic acidosis causes a compensatory respiratory response; increased ventilation quickly reduces the PCO_2 , which minimizes the fall in pH. This response is minimal in both humans and other animals because as PCO_2 falls, the cerebrospinal fluid pH rises and inhibits ventilatory drive. Maximal respiratory compensation occurs in humans in 24–36 hours. Other buffers, including bicarbonate, oxyhemoglobin, hemoglobin, phosphate, and protein buffers, act in defense of pH when a strong acid is added to the blood. Slower mechanisms of long-term correction for the acidosis require renal retention of bicarbonate and increased excretion of renal acid as the ammonium ion. The increase in ammonia formation takes several days to reach its maximum (Lane and Walker, 1987).

22.4.5.1.3 Respiratory Acidosis

Respiratory acidosis is defined as an increase in PCO_2 and subsequent to this, a proportionate increase in the carbonic acid concentration in blood (Epstein and Singh, 2001). The pH may remain unchanged, that is, acidemia may be absent. Elevated PCO_2 is caused by a greater tissue CO_2 output or (more commonly) as a consequence of inadequate alveolar ventilation; an immediate increase in bicarbonate concentration is produced. Moderate elevations in PCO_2 usually do not alter pH, however, when the PCO_2 is greater than 80 mmHg in humans, acidemia always develops (Adrogue and Madias, 1985). Elevated PCO_2 does not cause a corresponding increase in the metabolic acids in dogs or humans (Brackett et al., 1965). Intracellular acidosis is produced rapidly in this condition because dissolved CO_2 crosses cell membranes readily; in fact, the initial buffering of acid occurs by intracellular buffers. One third of the acute increase in hydrogen ions is buffered by hemoglobin and two thirds by tissue buffers (Bear and Gribik, 1974). The principal extracellular buffer system, carbonic acid/bicarbonate, is not able to respond to respiratory acidosis.

Respiratory acidosis can be caused by any disorder that interferes with effective ventilation and can result from CNS, pulmonary, or iatrogenic changes. Most commonly pulmonary diseases such as pneumonia, obstructive, or restrictive airway diseases are the basis of the condition. Diseases or drugs that impair the CNS respiratory drive and conditions that impair neuromuscular transmission or muscle weakness can also produce a profound respiratory acidosis.

22.4.5.1.4 Compensation

The compensating response for respiratory acidosis is the retention of bicarbonate by the kidney. As this response is slow to develop, it is only significant to conditions of chronic respiratory acidosis. Steady state chronic respiratory acidosis is reached in dogs in 3–5 days, in humans in 2–4 days, and even more rapidly in the rat (Carter et al., 1959). It induces less of a pH change than the acute condition owing to increased renal acid secretion and the generation of bicarbonate by the kidney. The tubular exchange of hydrogen is also stimulated by hypercapnia, and plasma bicarbonate is elevated (Schwartz and Cohen, 1978; Hansen et al., 1979). As the sodium exchanged for hydrogen ions is not reabsorbed with chloride, chloriuresis also occurs (Schwartz and Cohen, 1978). The amount of urinary ammonia excreted may increase 10-fold due to formation from glutamine in both acute and chronic acidoses in humans, rats, and dogs (Pollak et al., 1965; Fine, 1982; Garibotto et al., 2009).

22.4.5.2 Alkalosis

22.4.5.2.1 Metabolic Alkalosis

Metabolic alkalosis is characterized by an increase in bicarbonate ion concentration and pH and/or a decrease in hydrogen ion concentration (Khanna and Kurtzman, 2001; Foy and de Moraes, 2008). It results from excessive loss of fixed acids, intracellular shift of H^+ , HCO_3^- retention, or alkali administration. Regardless of the mechanism that causes alkalosis, maintenance of the state indicates that HCO_3^- reabsorption is increased in the kidneys. Metabolic alkalosis can be classified as follows:

1. Volume contracted, reduced ECF volume, loss of Na^+ and Cl^- -containing fluid without loss of HCO_3^- (Kassirer, 1974).

2. Volume expanded, excreting large amounts of sodium chloride with bicarbonate production predominating over bicarbonate excretion (Adroge and Madias, 1981).
3. Chloride wasting, caused by impaired chloride resorption and seen with hypercalcemia and severe hypokalemia (Narins et al., 1982).

Volume contraction and chloride wasting are the most important stimuli for increased HCO_3^- reabsorption, and the common causes of metabolic alkalosis are shown in Table 22.21.

The most common cause of metabolic alkalosis is gastrointestinal H^+ loss due to vomiting. Excessive renal acid loss associated with mineralocorticoid excess, diuretic use (particularly loop or thiazide diuretics), or low chloride intake can also contribute to the development of metabolic alkalosis. Most of these conditions are associated with Na^+ and Cl^- depletion and so also the result in volume contraction. Mineralocorticoid excess (Cushing's or Addison's disease) induced alkalosis is brought about by steroidal action on the distal tubule. Excess steroid enhances cation exchange, and hence both sodium and bicarbonate are retained, and hydrogen ions and potassium lost. Water retention and an expanded plasma volume result from the excess retained sodium. The expanded plasma volume, in turn, increases the GFR. This results in the filtration of more sodium chloride and so the loop continues at the expense of homeostasis. Potassium depletion (hypokalemia) can cause hydrogen loss through intracellular movement of ions from the ECF. Administration of excess bicarbonate is usually well tolerated by animals, however, coupled with volume contraction or potassium/chloride depletion, renal excretion of the excess base is impaired and alkalosis occurs.

Maintenance of metabolic alkalosis is characterized by the continued deficiency of renal bicarbonate excretion, which can be the result of decreased glomerular filtration or (more commonly) increased bicarbonate reabsorption. It is associated with potassium depletion and/or chloride depletion that are the renal response to volume contraction. Sodium reabsorption is increased to correct the low circulating volume, which leads to reabsorption of an anion (proximal tubule) and excretion of a cation (distal tubule) for preserving electrical neutrality. The anion is usually chloride; the cations are either H^+ or K^+ . In the rat, uncomplicated potassium and chloride depletion produce metabolic alkalosis; however, in dogs and humans, these methods alone do not produce alkalosis (Aquino and Luke, 1973).

Urine pH is usually low with metabolic alkalosis. Once considered to be due to potassium depletion, this paradoxical aciduria is considered to be due to the pairing of bases such as sulfate with cations, Na^+ , K^+ , or H^+ before renal excretion. As neither sodium nor potassium is available, hydrogen ions perform this function and are excreted in the urine.

22.4.5.2.2 Compensation The respiratory center response to metabolic alkalosis is hypoventilation, increasing PCO_2 . The degree of this compensatory response is proportional to the degree of arterial hydrogen ion depression (Aquino and Luke, 1973). Additionally, bicarbonate excretion by the kidney is enhanced within the first hour of the disturbance.

TABLE 22.21
Causes of Metabolic Alkalosis

Bicarbonate Excess	Cl^- Responsive	Cl^- Resistant
<ul style="list-style-type: none"> • Excess alkali administration—bicarbonate containing IV fluids • Massive blood transfusion 	<ul style="list-style-type: none"> • Loss of gastric secretions—vomiting • Loss of colon secretions—villous adenoma 	<ul style="list-style-type: none"> • Hyperaldosteronism, excess mineralocorticoids • Diuretic use—thiazide and loop
<ul style="list-style-type: none"> • Intravenous penicillin — — 	<ul style="list-style-type: none"> • Diuretic use—thiazide and loop • Posthypercapnia • Cystic fibrosis 	<ul style="list-style-type: none"> • Potassium depletion • Hypomagnesemia —

TABLE 22.22**Causes of Respiratory Alkalosis**

- Hypoxemia related—severe anemia, right to left shunts, high altitudes
- CNS related—pain, fear, anxiety, tumor, trauma
- Endocrine related—hyperthyroidism, pregnancy
- Pulmonary related—pneumonia, edema, asthma, emphysema
- Drug related—nicotine, salicylates, progesterone, catecholamines
- Congestive heart failure
- Hepatic failure
- Mechanical ventilation
- Heat exhaustion, panting

22.4.5.2.3 Respiratory Alkalosis Respiratory alkalosis is a reduction in PCO_2 in the blood and an increase in pH (Foster et al., 2001; Jensen, 2004); it develops when the lungs remove more carbon dioxide than is produced metabolically by the tissues. There is no renal loss of bicarbonate with this condition. The hyperventilation that produces respiratory alkalosis can be stimulated by a wide variety of conditions; these are described in Table 22.22.

22.4.5.2.4 Compensation The initial response to acute respiratory alkalosis is a decline in extracellular bicarbonate concentration as a result of cellular buffering (not renal loss). Bicarbonate is reduced by the release of hydrogen ions from hemoglobin and tissue buffers and by a small increase in lactic acid. Hemoglobin accounts for approximately one third of this effect; the remainder is tissue buffers. There is no loss of bicarbonate in acute respiratory alkalosis. Chronic respiratory alkalosis takes several days to develop and occurs when pH has been returned to normal while PCO_2 remains lowered. Renal reabsorption of bicarbonate is reduced, decreasing ECF bicarbonate concentrations in parallel with the fall in CO_2 (Bettice et al., 1984; Adroque and Madias, 1985). To maintain electrical neutrality chloride retention partially compensates for HCO_3^- loss.

Paradoxical respiratory alkalosis accompanies rapid recovery from metabolic acidosis. It develops because the bicarbonate concentration is slow to equalize across the blood–brain barrier. The respiratory center remains stimulated by the acidic cerebrospinal fluid even though the plasma hydrogen ion concentration has normalized.

22.4.6 MIXED ACID–BASE DISORDERS

Mixed acid–base disorders occur when several primary acid–base imbalances are present simultaneously (Adroque, 2006). Some examples of this condition are high AG and normal AG acidosis, chronic respiratory acidosis and metabolic alkalosis, or normal AG acidosis and metabolic alkalosis. As a general rule, when a normal pH is seen with abnormal bicarbonate or CO_2 , a mixed disorder is expected. When the pH moves in the opposite direction to that predicted for the primary disturbance, a mixed disturbance exists.

To interpret an acid–base disturbance correctly, the following information is required: (1) the environment, (2) state of hydration, (3) body temperature, (4) respiratory rate and character, (5) evidence of diarrhea, vomiting, and excoriation, (6) physical appearance, and (7) duration of the condition. The normal expected compensatory adjustments are calculated in order to categorize a set of acid–base values. Clinical input is needed to explain why compensation may not be as expected. For example, pain and decreased compliance hinder respiratory compensation, and urine retention limits renal compensation.

In summary, the complex interplay of electrolytes, hydrogen ions, carbon dioxide, and oxygen provides a framework in which optimal cell function is ensured. Homeostatic regulation of these parameters allows cells to function effectively in a broad range of conditions; however, when these

are not maintained. there are serious clinical consequences. A change in the clinical chemistry profile of an animal therefore provides valuable information on the functional status of different organ systems. When multiple endpoints are assayed, disease- and treatment-related effects become evident; interpretation of results with respect to the normal reference range of values, however, should occur with the knowledge that variation in analytical technique can have profound effect on outcome.

Addendum: Gene Symbols and Descriptions

Gene Symbol Used in Chapter	HUGO Gene Nomenclature	Gene Name
AE1	SLC4A1	Solute carrier family 4, anion exchanger
AQP2	AQP2	Aquaporin 2
AQP3	AQP3	Aquaporin 3
AQP4	AQP4	Aquaporin 4
CALB1	CALB1	Calbindin 1, 28 kDa
CALB3	S100G	S100 calcium binding protein G
CaSR	CaSR	Calcium-sensing receptor
CHIF	FXYP4	FXYP domain containing ion transport regulator 4
CLCNKB	CLCNKB	Chloride channel, voltage-sensitive Kb
CFTR	CFTR	Cystic fibrosis transmembrane conductance regulator (ATP-binding cassette subfamily, C, member 7)
CYP24	CYP24A1	Cytochrome P450, family 24, subfamily A, polypeptide 1
ENaC	SCNN1	Sodium channel, nonvoltage gated 1
FGF23	FGF23	Fibroblast growth factor 23
GALNT3	GALNT3	UDP-N-acetyl-alpha-D-galactosamine: polypeptide N-acetylgalactosaminyltransferase 3
GLUT2	SLC2A2	Solute carrier family 2 (facilitated glucose transporter), member 2
KCNA1	KCNA1	Potassium voltage-gated channel, shaker-related subfamily, member 1
KCNK1	KCNK1	Potassium channel, subfamily K, member 1
KCNQ2	KCNQ2	Potassium voltage-gated channel, KQT-like subfamily, member 2
KCNQ3	KCNQ3	Potassium voltage-gated channel, KQT-like subfamily, member 3
KCNQ4	KCNQ4	Potassium voltage-gated channel, KQT-like subfamily, member 4
KLOTHO	KL	Klotho
NaS1	SLC13A1	Solute carrier family 13 (sodium/sulfate symporters), member 1
NCCT	SLC12A3	Solute carrier family 12 (sodium/chloride transporters), member 3
NCX1	SLC8A1	Solute carrier family 8 (sodium/calcium exchanger) member 1
NHE3	SLC9A3	Solute carrier family 9 (sodium/hydrogen exchanger), member 3
NKCC	SLC12A	Solute carrier family 12 (sodium/potassium/chloride transporters)
NKCC2	SLC12A2	Solute carrier family 12 (sodium/potassium/chloride transporters), member 1
OSR1	OSR1	Odd-skipped related 1
RAS	RAS	Rat sarcoma viral oncogene homolog
ROMK	KCNJ1	Potassium inwardly rectifying channel, subfamily J, member 1
SAT1	SAT1	Spermidine/spermine N1-acetyltransferase 1
SCN1A	SCN1A	Sodium channel, voltage-gated, type 1, alpha subunit
SCN1B	SCN1B	Sodium channel, voltage-gated, type 1, beta subunit
SGLT1	SLC5A1	Solute carrier family 5 (sodium/glucose cotransporter), member 1
SGLT2	SLC5A2	Solute carrier family 5 (sodium/glucose cotransporter), member 2
SGK1	SGK1	Serum/glucocorticoid-regulated kinase 1
SLC4A4	SLC4A4	Solute carrier family 4, sodium bicarbonate cotransporter, member 4
SPAK	STK39	Serine threonine kinase 39
TRPV5	TRPV5	Transient receptor potential cation channel, subfamily V, member 5
VDR	VDR	Vitamin D (1,25-dihydroxyvitamin D3) receptor
WNK	WNK	WNK lysine-deficient protein kinase

23.1 INTRODUCTION

The rudimentary concept of internal secretions can be traced back to the second century AD in writings of the Greek physician Galen. His idea of *bodily humors* and the relationships between imbalances in them and disease (termed *dyscrasia*, from the Greek, *a bad mixture*) continued, in one form or another, to be prevalent through the medieval period and into the eighteenth century. During that time, blood letting and other purges were employed medically to rid the body of a harmful surplus of *humor*. In fact, use of the adjective *humoral* has persisted in reference to elements in the blood or other body fluids. However, it was not until Claude Bernard described his work on the release of glucose from liver glycogen in the mid-nineteenth century (reviewed by Young, 1957) that the first convincing demonstration of systemic effects from the secretion of chemical substances into the blood was provided.

Fascination with this idea of chemical messengers quickly began to surface in both the scientific and lay communities at the conclusion of the nineteenth century with the (subsequently disproven) claim by physiologist Charles–Edouard Brown–Séguard that his self-administration of extracts of animal testes caused an increase in physical strength, improvements in intellectual capacity, and an augmentation in sexual prowess (Brown–Séguard, 1899a,b). At the same time, the English physician George Murray presented evidence (Murray, 1891) that thyroid extracts were able to improve myxoedema, a skin and tissue disorder that typically developed in response to severe, prolonged hypothyroidism. Many physiologists have come to believe that these two reports were seminal to the emergence of the new field of Endocrinology. However, it was not until a 1904 address to the Royal College of Physicians by Ernest Starling, professor of physiology at the University College, London, describing collaborative work on the pancreatic response to intestinal secretin that the term *hormone*, from the Greek word *to excite or arouse*, entered the medical lexicon (Starling, 1905). Endocrinology then began to acquire an identity with a foothold as a separate discipline.

23.2 DEFINITIONS AND CLASSIFICATION OF HORMONES

As originally characterized during those early, heady days of endocrine discovery, hormones were chemical substances secreted by glandular tissue and carried through the circulation to impose regulatory effects on other cell populations. This classic mechanism of hormone action has expanded to include forms of paracrine communication between adjacent or nearby cells and autocrine signaling involving individual cells. Various terms, such as *cybernins* and *intracrines*, have been proposed to capture the extent of these types of communication. Neurotransmitters secreted from neurons are also known to act as blood-borne endocrine factors. Dopamine, for example, functions as an inhibitory regulator of prolactin (Prl) secretion following its release from brain hypothalamic nerve terminals into the portal vasculature that extends to the anterior pituitary. Under the large umbrella of hormonal chemicals, three basic criteria are classically met: (1) the biological activity must be established, (2) a specific and saturable receptor needs to be identified, and (3) with the notable exception of hormones binding to nuclear receptors, a second messenger has to be determined. Although this broadened definition of signaling molecules encompasses a considerable range of endogenous chemicals, endocrine factors tend to populate one of the three classes: (1) Protein and polypeptide hormones comprised of chains of amino acids, (2) lipid or phospholipid hormones, including the steroid hormones, generated from cholesterol, and (3) the amine-related hormones, containing an NH₂ group at the end of the molecule that are derivatives of the amino acids tyrosine and tryptophan. The abovementioned neurotransmitter dopamine falls into this group, along with epinephrine, norepinephrine, and serotonin (discussed in Section 23.4.4.4).

23.2.1 HORMONE RECEPTORS

The binding of a hormone to a specific protein receptor initiates its appropriate cellular response. With the exception of the members of the nuclear receptor superfamily (encompassing steroid androgen, estrogen, progesterone, and thyroid hormone receptors), amino acid-derived receptors and peptide hormone receptors are present in the plasma membrane. Multiple receptor isoforms have been discovered for different hormones and amine-related neurotransmitters that serve functionally diverse roles. The structures of these receptors vary, with some being present as single membrane-spanning configurations, while others are polypeptide chains that stretch multiple times back and forth through the membrane. The binding of the hormone ligand to the receptor will then initiate a metabolic response via second messenger and phosphorylated protein transducers.

Steroid hormone receptors can be present as multiple isoforms. They are intracellular in location, although there is now good evidence for androgen, estrogen, and progesterone receptors that are also resident in the plasma membrane (e.g., Boonyaratanakornkit and Edwards, 2004; Michels and Hoppe, 2008; Prossnitz et al., 2008; Roepke et al., 2009) and exert rapid effects on intracellular

signaling pathways independent of gene transcription. Intracellularly, steroid receptors are present in the cytosol and, upon binding to their particular steroid ligand, translocated together to the nucleus. These receptors may also reside in the nucleus until activated by an individual steroid hormone. In the nucleus, the hormone–receptor complex associates with cofactors, general transcription factors and RNA polymerase II, binding to particular sequences on DNA to stimulate or suppress the activity of individual genes that direct the synthesis of specific proteins (see Trapman and Dubbink, 2007 for review).

23.2.2 BOUND VERSUS FREE HORMONES

Hormones that are released into the blood circulate as either free hormone or bound to carrier or binding proteins. In general, the protein and peptide hormones (in addition to the amine-derived factors) circulate in their free form, while the tyrosine-derived hormones thyroxine (T4) and triiodothyronine (T3) are mostly carrier bound. This binding functions to impede hormonal degradation by plasma proteases, thereby increasing the half-lives of the hormones. In contrast, circulating steroid hormones exist primarily in a bound form, with only 1%–10% of individual hormones in plasma present in the free state, the fraction considered to be the biologically active form. Here, the bound fractions tend to regulate steroid activity by limiting the biological availability of the hormone. Furthermore, free steroid molecules are poorly soluble in aqueous media. By increasing the solubility of the normally hydrophobic steroids, the carrier molecules also serve to increase circulating plasma concentrations beyond what would otherwise be possible.

23.3 HORMONE ASSESSMENT

Although gas chromatographic/mass spectrometric (GC/MS) and liquid chromatographic techniques have been employed to assess hormonal concentrations, immunoassays have been the standard analytical approach in veterinary medicine and animal research. They have mostly replaced bioassays, which provided a quantifiable cellular response to hormonal stimulation, but were frequently difficult to properly validate (Kalia et al., 2004). Unlike immunoassays, such bioassays are able to provide an indication of the biological activity of a hormone, which may vary depending upon a number of factors, including the degree of glycosylation/sialylation (discussed further in Sections 23.4.3.1.2 and 23.4.3.3.2) or the presence of cofactors required for steroid receptor binding. On the other hand, immunoassays are typically rapid, sensitive, and cost effective, with a diverse assortment of commercial kits appearing regularly that require a relatively modest degree of expertise for proper use.

23.3.1 POLYCLONAL VERSUS MONOCLONAL ANTIBODIES

The distinguishing nature of the immunoassay is based on the ability of a specific immunoglobulin antibody to recognize and bind to a particular three-dimensional configuration on the surface of a molecule (the epitope). This configuration exists as an orientation of residues that can be shaped by a folding within the structure of the molecule. Both polyclonal and monoclonal antibodies are commonly used in various types of immunoassays. For protein and polypeptide hormones, they are typically species-specific, although some degree of cross-species reactivity can exist. Polyclonal antibodies raised in host animals are derived from different lymphocyte B-cell lines that are mixtures of immunoglobulins recognizing various epitopes on a hormonal antigen. In contrast, monoclonal antibodies are monospecific, recognizing a single epitope. This antibody is produced by a single B-lymphocyte clone, and all are therefore identical. Each has distinctive advantages for hormonal assessment. Polyclonal antibodies typically have a higher affinity and wider reactivity, but a lower specificity than monoclonals. They are able to detect multiple epitopes in different orientations. In general, polyclonal antibodies are easier to produce. However, there is considerable animal-to-animal variability in antibodies from noninbred animals, meaning that dissimilar epitopes can

be recognized and the potencies can be quite different. Consequently, an individual animal host generating a particularly valued polyclonal is highly coveted. Moreover, such an antibody from a larger animal will provide a sizeable volume of antibody-rich serum. Nevertheless, a healthy animal is limited by its lifespan to serve as a source of that antibody, and recurring immunizations with a particular antigen may generate a new mixture of polyclonal antibodies against that antigen. Should that animal die and the antibody stock become depleted, alternative sources must be sought that will likely produce antibodies with different reactivities and titers. Monoclonals, on the other hand, are very specific and can be generated as a potentially inexhaustible supply from a continuous culture. Their production had been time consuming and often frustrating, but the market for the therapeutic application of monoclonal antibodies has rapidly grown and the early technical difficulties in their preparation in numerous cases have been overcome (reviewed by Tabrizi et al., 2009).

23.3.2 COMPETITIVE VERSUS SANDWICH IMMUNOASSAYS

The great majority of immunoassays fall into one of two groups, competitive and sandwich-type assays. Competitive radioimmunoassays (RIAs) originated from the groundbreaking work of Berson and Yalow (1957, 1959) and are based on the competition of a hormone sample with a radiolabeled form of the same hormone (the tracer) for binding to an immunoglobulin antibody (Figure 23.1, upper panel). The greater the amount of hormone in the sample to be measured, the greater is the ability of this antigen to compete with a known level of tracer radioactivity. Unknown samples are run in parallel with a standard series with identified hormone concentrations. A second antibody generated by a different animal species against the first or primary antibody will then bind to the primary antibody–hormone or primary antibody–tracer combinations, forming a large complex. This complex can then be precipitated by centrifugation, and the supernatant, containing unbound standards or sample hormone, and unbound radioactivity is aspirated off. Alternatively, staphylococcal protein A (Gupta and Morton, 1979) and polyethylene glycol (PEG) have been employed as a precipitant instead of a second antibody. Staph protein A has the property of binding to immunoglobulin antibodies of a wide variety of mammalian species (Groves et al., 1970), and most immunoglobulins are insoluble in 20% PEG, unlike smaller, soluble albumins and other antigens (Creighton et al., 1973). PEG combined with a second antibody has also been used for increasing the rate of precipitation. Radioactivity remaining in the precipitated pellet can subsequently be counted. As mentioned above, increasing concentrations of the hormone to be measured will be better able to compete against the tracer for the primary antibody and show corresponding decreases in the pellet radioactivity. Units of radioactivity can then be compared against the standard series to quantify the unknown concentrations. Instead of adding hormones and antibodies separately, some commercial kits are supplied with the antibody previously coated to the walls of tubes provided in the kit, precluding the need to precipitate the antibody–antigen complexes. Such kits also typically include vials containing a radionuclide-labeled hormone and a defined standard series against which the unknown samples are compared. One reservation with this type of immunoassay, however, is that the antibody adsorption to the tube can potentially mask immunoreactive sites.

Competitive immunoassays are still commonly employed today for the measurement of steroids and peptide hormones of varying sizes, although there has been a trend away from the use of radioactive-labeled materials, toward the broad application of enzyme-linked sandwich assays and increasing numbers of chemiluminescent immunoassays that have undergone validation for use (e.g., Singh et al., 1997; Scott-Moncrieff et al., 2003; Russell et al., 2007). Sandwich immunoassays, in contrast, employ a *capture antibody* that binds one site on the sample and a *detection antibody* directed against a second site. In the kit form, they are typically supplied with a monoclonal antibody adsorbed on to a plastic microtiter plate (Figure 23.1, lower panel). This *capture antibody* will bind the target antigen from a sample. A *detection antibody* is then added, and it binds to a separate site on the target antigen, forming a sandwich of the antigen between the two antibodies. It is common to have an enzyme attached to the detection antibody (known as enzyme-linked

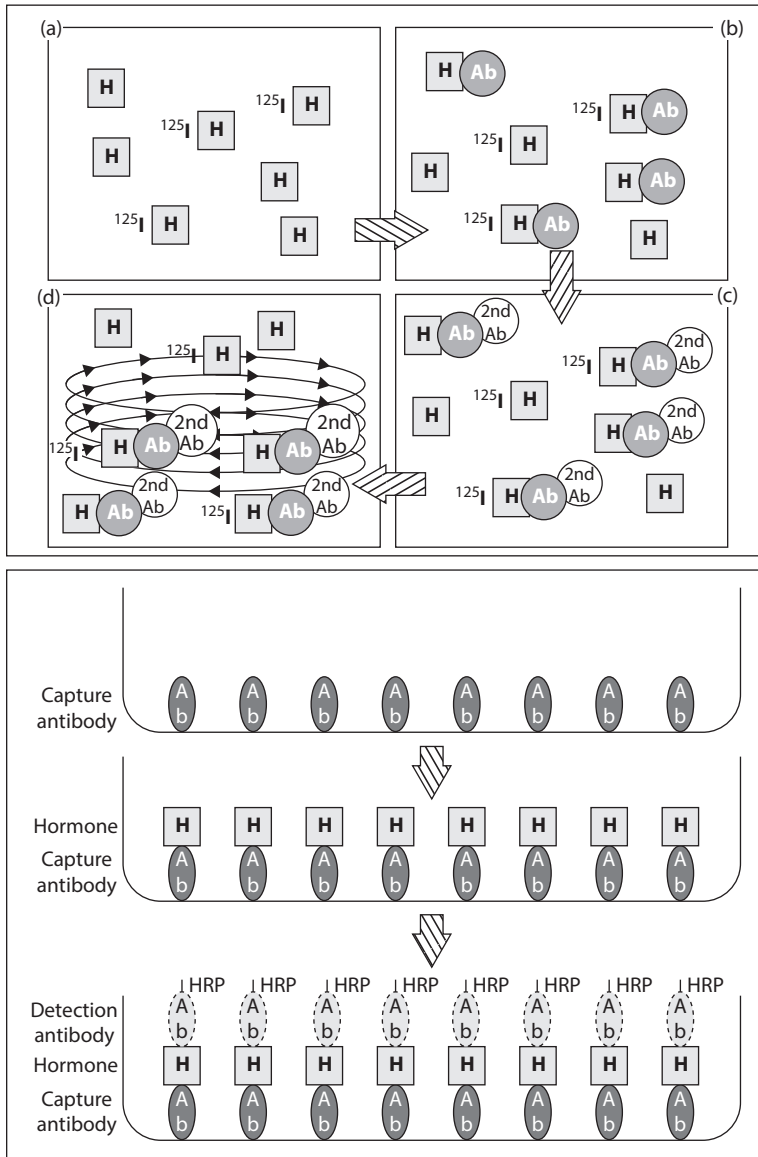

FIGURE 23.1 (Upper panel) Illustration depicting the basic steps in a classic competitive radioimmunoassay. A mixture (a) of both the hormone to be quantified and a defined radioactive (¹²⁵I) aliquot of that hormone are exposed to a specific antibody (first antibody), allowing both hormones to compete for the antibody (b). A second antibody targeted to the immunoglobulin configuration of the first antibody (c) creates a large structure that can be pelleted by centrifugation (d), thus separating hormone-antibody complex from non-antibody-bound hormones. Following aspiration of the supernatant containing the unbound hormone, radioactivity in the pellet is then counted and compared against the radioactivity present in a series of concurrently run standards containing defined concentrations of that hormone. (Lower panel) As opposed to the competitive immunoassay, sandwich assays in kit form are provided with a microtiter plate containing a capture antibody that recognizes an epitope on the hormone. A second or detection antibody conjugated to a detection enzyme (in this example, horseradish peroxidase [HRP]) then recognizes a separate epitope on the hormone, sandwiching the hormone between the two antibodies. After washing out unbound HRP, the substrate for the enzyme is added and allowed to incubate for a defined period of color development before the reaction is stopped. A readout of the detection signal is then performed. In this case, the amount of color generated by a reaction to the signaling molecule is compared against a standard series of known hormone concentrations.

immunosorbant assays [ELISAs]), which can generate a colorimetric signal that is proportional to the amount of target antigen in the sample. Comparisons can then be made against a standard series of known concentrations. The two different epitopes for the two antibodies must spatially be some distance apart, lest the bound capture antibody interfere with binding of the detection antibody. Consequently, when employed, sandwich assays have been more confined to the measurement of larger peptide hormones (e.g., growth hormone [GH] and gonadotropins), whereas, as indicated above, smaller peptides (e.g., gonadotropin-releasing hormone [GnRH], corticotropin-releasing hormone [CRH], and adrenocorticotrophic hormone [ACTH]) and steroid (e.g., progesterone, testosterone, and estradiol) hormones are frequently measured by competitive immunoassay. Smaller peptide hormone concentrations can, however, be determined using a sandwich assay by increasing the apparent mass of the hormone via conjugation to a larger molecule, such as a protein.

More recently, platforms of multiplexed sandwich ELISA arrays have become commercially available, allowing combinations of a sizable number of distinct hormones to be measured simultaneously on a single 96-well plate (e.g., Nielsen and Geierstanger, 2004; Liew et al., 2007). Sample volumes are small, and the high throughput nature of the assay allows for a large number of hormones to be assessed in a relatively rapid period of time. As the veterinary demand for such ELISAs grows, more combinations of multiplexed arrays will appear on the market.

The antibodies employed in validated commercially available competitive and sandwich immunoassays will exhibit some variations in cross-reactivity, so that binding can occur to substances beyond the targeted hormone analyte. Efforts are made in developing a commercial assay to keep cross-reactivity to a minimum, and such data are commonly provided with the assay materials. As a rule, serum or plasma samples that are grossly hemolytic, lipemic, or show considerable turbidity should not be used. Other factors present in the blood or added to the assay buffers may also affect the obtained results. ACTH in the obtained serum or plasma, for example, is particularly vulnerable to proteolytic degradation (Meakin et al., 1960). Plasma–ethylenediaminetetraacetic acid (EDTA) collections are recommended because the hormone in serum is degraded to some extent while blood is clotting, and the protease inhibitor aprotinin has been used to retard such degradation. Heparin, however, is not useful as an anticoagulant because it promotes the formation of high molecular weight aggregates that affect the assay (Dupouy et al., 1986). Moreover, small peptides such as ACTH can stick to glass, and it is recommended that samples be kept frozen in siliconized tubes prior to assay. For more comprehensive discussions of these types of interference, the reader is referred to a number of reviews (Levinson, 1992; Selby, 1999; Evans et al., 2001; Griffin and Auchus, 2004).

Capillary electrophoretic immunoassays (e.g., Taylor et al., 2001; Shinichi et al., 2005) are the more recent developments, although their use has not been commercialized and consequently is more limited compared to the sandwich and traditional radionuclide-based assays. However, the very small sample volumes required, improved detection limits, and relatively rapid results are attractive possibilities for specific needs.

Kit materials obtained from different commercial sources using a diversity of polyclonal or monoclonal antibodies will commonly exhibit discrepant results with the same samples, something that is discussed further in Section 23.4.2. Nevertheless, in the conduct of all such immunoassays, an understanding of a particular assay's specificity and sensitivity is paramount. In this regard, it is essential to define the appropriate assay performance criteria. For an individual assay, the incorporation of defined quality control samples is necessary to ensure consistency of results both within and among multiple assay runs. When comparing the samples of interest against a known series of standards covering a range of hormonal concentrations, it is imperative that the unknown samples not fall at the extremes of the standard series, something that would meaningfully impair the accuracy of the data. Moreover, as mentioned previously, it is also important to know the extent to which any confounding factor(s) may impact the utility of the results. For a further discussion of issues and requirements concerning the quality of the different endocrine assay techniques, there are several publications (e.g., Rosner et al., 2007; Stenman, 2013) and websites (e.g., Center for Disease Control and Prevention [www.cdc.gov/labstandards/hs.html]) that detail the best laboratory practices needed for an accurate detection and interpretation of hormonal values.

23.4 ENDOCRINE PHYSIOLOGY

23.4.1 ENDOCRINE HOMEOSTASIS

23.4.1.1 Insulin, Glucagon, and Glucose

The ability to maintain an internal physiological environment within a tolerable range is a fundamental characteristic of living systems. The interaction and integration of the extensive variety of hormonal signals in the mammalian body are the essential components of homeostatic regulation. The classic example of a physiological homeostatic relationship is the balance between insulin and glucagon to maintain blood glucose within a narrow range. Both hormones are secretory products of the pancreas, insulin by the pancreatic beta cells and glucagon by the alpha cells. As the blood glucose level increases, after a meal for example, insulin secretion increases, causing cellular glucose uptake. Glucagon secretion then is very low or absent. However, when circulating glucose is low, insulin production is suppressed and there is an increase in alpha cell glucagon secretion, stimulating the liver to release glucose stored as the glucose polymer glycogen. This classic interactive mechanism of homeostatic regulation is now known to involve in the participation of a family of gut hormones, which includes glucose-dependent insulinotropic polypeptide (GIP), glucagon-like peptide-1 (GLP-1), and peptide YY (PYY). They are secreted in response to nutrient absorption—GIP by K cells of the upper small intestine, GLP-1, and PYY cosecreted from L cells of the distal intestine (reviewed by Dumoulin et al., 1995; Gautier et al., 2008; Bauer et al., 2016). GIP and GLP-1 are able to stimulate the biosynthesis and secretion of insulin in a glucose-dependent manner, and GLP-1 has been found to suppress glucagon secretion, although the mechanism of effect, be it direct or indirect, is still being investigated. Moreover, GLP-1, but not GIP, acts to inhibit gastric emptying (Hansotia and Drucker, 2005). Both have a short half-life and are rapidly degraded by the enzyme dipeptidyl-peptidase IV. PYY, which has also been identified in the brain hypothalamic region (Ekblad and Sundler, 2002), is essentially an antisecretory peptide. It has been found to mediate satiety signaling and inhibit many gastrointestinal functions, including gastric acid secretion, gastric emptying, and small bowel and colonic chloride secretion (Ballantyne, 2006; Ueno et al., 2008).

One of the most frequently diagnosed endocrine disorders in cats and dogs is diabetes mellitus, characterized by an elevation in blood glucose. In dogs, the more common form is type 1 or insulin-dependent diabetes, in which activated lymphocytes target pancreatic islets destroying the β -cells and abolishing insulin production. Type 1 has been reported in approximately half of diabetic dogs (Elle and Hoenig, 1995). Type 2, or noninsulin-dependent diabetes, is more frequently seen in cats, accounting for 80%–95% of cases (Rand, 1999). It is referred to as adult-onset and involves an insulin resistance, wherein cells are unable to use insulin properly. The condition may be accompanied by a reduction in insulin secretion.

23.4.1.2 Rhythmic Secretions and Singular Events

The secretory activity of a diverse variety of endocrine factors that maintain physiological homeostasis commonly exhibits a characteristic pulsatility. This is true for a growing number of hormones, including hypothalamic, pituitary peptide (Figure 23.2), adrenal, and thyroid hormones (e.g., Moor and Younglai, 1975; Dluzen and Ramirez, 1987; Larsen and Odell, 1987; Martin and Thiéry, 1987; Irvine and Alexander, 1988; Günzel-Apel et al., 1994; Kempainen and Peterson, 1996; Kooistra and Okkens, 2001; Gan and Quinton, 2010). For various peptide hormones, this pulsatile secretion, characterized by recurrent peaks and valleys, acts to prevent the emergence of a desensitization of second messenger mechanisms caused by a constant exposure of receptors to increased levels of a hormone (Li and Goldbeter, 1989; Goldbeter et al., 2000). However, such is not the case for all hormones that exhibit rhythmic secretion. For example, gonadal hormones, which are pulsatile in nature, exhibit comparable effects with rhythmic or continuous exposure. Their secretion is a consequence of the upstream pulses of pituitary gonadotropins, which themselves are a response to secretory variations in brain hypothalamic GnRH (a relationship detailed in Section 23.4.3.1).

FIGURE 23.2 Pulsatile secretion of luteinizing hormone (LH) in the adult female Fischer 344 rat. In the five individual examples shown, animals were ovariectomized 4 weeks prior to sampling of blood from surgically implanted jugular catheters. Ovariectomy abolished the negative feedback by ovarian steroids, causing an enhancement in the concentrations of circulating LH. Small quantities of blood, with saline replacement, were withdrawn every 10 minutes over the course of 1 hour. Values were determined by radioimmunoassay using the following materials provided by the National Hormone and Pituitary Program: iodination preparation I-9, reference preparation RP-3, and rabbit anti-rat antiserum S-11.

The pulsatile secretion of a hormone can also be embedded within a diurnal rhythm. Corticosterone secretion in the female rat, for example, shows pulses that occur approximately every hour over the course of the day. Pulse amplitude increases during the latter half of the light portion of the photoperiod, resulting in an overall rise in circulating concentrations over the day (Lightman et al., 2000). Similar diurnal patterns have been reported for pulsatile luteinizing hormone (LH) and testosterone in young adult male rhesus monkeys (Winters et al., 1991; Schlatt et al., 2008). Some pulsatile secretion can also have marked valley-to-peak excursions. For example, beagle dogs can show three to nine pulses of GH over a 6-hour period that can rise as much as fivefold greater than nadir concentrations (Lee et al., 2003).

The pulsatile secretion of hormones may show differences between genders. For example, during the summer breeding season for horses, mares tend to exhibit about one large amplitude pulse of GH every 6 hours that can be in excess of ninefold over baseline, while stallions show 2–2.5 smaller amplitude pulses over the same time (Thompson et al., 1992). In rats, it is the male that shows a marked pulsatile elevation in GH with large bursts occurring at 3–4 hour intervals. In contrast, pulse amplitudes are lower in females, but the interpulse concentration of GH is higher than in the male (see Jansson et al., 1985 for a review of this sexual dimorphism).

However, the most salient differences in endocrine homeostasis between males and females are those changes that are tied to the ovarian cycle. In spontaneously cycling animals, circulating concentrations of the gonadotropins (LH and follicle-stimulating hormone [FSH]) exhibit sharp mid-cycle elevations or surges that serve as functional endocrine events, stimulating ovarian follicles to ovulate (LH) or undergo maturational changes (FSH). A further discussion of the importance of the gonadotropin surge in females and the consequences of various forms of insult will be presented in Sections 23.4.3.1.2 and 23.4.3.1.5.

23.4.2 SAMPLING OF ANALYTES

Given that hormonal concentrations can show diurnal variations or alterations over an ovarian cycle, it is imperative that the sampling of biological material for analysis be performed with an understanding of the nature of these normative changes. Consequently, the most appropriate sampling parameters can vary, depending upon what is to be measured and, for various diagnostic tests, the purpose of a reaction to a challenge. The focus can be on a stimulation or suppression at various

time points in response of one hormone to an administration of another. For the test to be useful, a selection of sampling times must allow for a definitive characterization of the response.

Species differences can exist in the periodicity of hormonal concentrations, which can dictate when samples are taken. For example, there is an apparent absence of rhythmic diurnal glucocorticoid changes in dogs and cats (e.g., Johnston and Mather, 1978, 1979), while rats will show basal corticosterone levels during the early morning period, which begin to rise at midday and exhibit elevated concentration late in the afternoon (e.g., Allen and Kendall, 1967; Allen-Rowlands et al., 1980). In animals that show a diurnal rhythm for a particular hormone, nadir concentrations of that hormone may fall at or near the level of sensitivity for that individual assay. For a condition in which the hormone is decreased, the lower circulating concentrations may not be detectable or be of questionable validity, providing no indication of the magnitude of the effect. In this situation, it may be more appropriate to sample during the period in which concentrations would normally be elevated. The opposite would then be true for a suspected condition that caused a marked increase. Sampling at a time when the synthesis of an individual hormone is typically activated and the secretory levels are highest may not show a comparable percentage rise in concentration as a sample taken during the diurnal nadir.

Hormones that respond to nutrient ingestion will show dramatic postprandial changes, so that sampling after meals will not provide any indication of basal values but may show alterations in the normative endocrine responsiveness to a defined quantity of nutrient. Adult male rhesus monkeys, for example, will show a diurnal rhythm of LH, with elevated nighttime circulating concentrations that begin to rise in response to an afternoon meal. Consequently, sampling for baseline values needs to take this into consideration. Elimination of that meal revealed an absence of the rhythm, and a delay in the meal time showed a corresponding shift in the diurnal rise (Mattern et al., 1993). Fasting in dogs has been reported to attenuate ACTH-stimulated serum cortisol concentrations, but not thyroid hormones increased by thyroid-stimulating hormone (TSH; Reimers et al., 1986). If a short-lived rise in the circulating concentrations of a hormone serves as the impetus for other critical changes, which occurs with the gonadotropin surges, any concerns about a suppression in this elevation would require that samples be obtained over a window of time that would normally encompass the event.

Animals diagnosed with various endocrinopathies may require hormonal treatments. Dogs suffering from hypothyroidism (discussed in Section 23.4.3.3.4) that are treated with thyroid hormone supplements must be monitored for circulating thyroid hormone and TSH concentrations. The time of sampling relative to the treatment has a major influence on the obtained hormone concentrations and dosing adjustments, with 4–6 hours postadministration optimal for testing (e.g., Dixon et al., 2002; Le Traon et al., 2009).

The responsiveness of a variety of hormones to novel and/or stressful situations is a factor of concern in endocrine assessments. Stress as a category, however, is not easily definable. It was originally conceptualized by Hans Selye in the 1930s as the state of the organism as it responded and adapted to the environment. Although definitions are imprecise, it is well-established that stressful conditions will cause increases in the circulating concentrations of glucocorticoids (see section 23.4.3.2). Other endocrine factors, moreover, have been found to be altered as a consequence of the glucocorticoid elevation (see Section 23.4.3.2.4). Stressors and stressful conditions come in many forms, and a diversity of mammalian species can exhibit distinctive patterns of endocrine responses to these stressors (e.g., Lenox et al., 1980). Introduction to a novel environment can be stressful in various species and cause elevations in glucocorticoid levels (Coe et al., 1982; Brett et al., 1983; Weinberg and Wong, 1986; Gust et al., 1994) that may obscure the cause of other effects on adrenal homeostasis. Disease states are undoubtedly stressful and cause independent disruptions in an endocrine profile. Such medical conditions may be the focus of a diagnostic evaluation or cause unwelcome disruptive effects on other assessments.

Administered anesthetics also constitute a form of insult to the system. Sampling under anesthesia can reveal significant alterations in circulating hormone concentrations, and the effects can vary

with the type of inhaled or injected anesthetic employed. For example, pentobarbital, ketamine, halothane, and isoflurane have been found to stimulate adrenal activity and elevate glucocorticoid concentrations in various species, which include monkeys, dogs, cats, rabbits, and rats (e.g., Puri et al., 1981; Fox et al., 1994; Illera et al., 2000; Ambrisko et al., 2005; Gil et al., 2007). A number of anesthetics are also able to alter the levels of circulating Prl (e.g., Quadri et al., 1978; Puri et al., 1981; Furudate, 1991); in mated female rabbits, ketamine–xylazine was reported to attenuate the rise in blood concentrations of FSH (Mills and Copland, 1982). Pentobarbital will suppress the pre-ovulatory surge of luteinizing hormone in female rats (Gosden et al., 1976; ter Haar and MacKinnon, 1976), something that has also been seen in the baboon (Hagino, 1979). These findings underscore the caution that must be exercised in evaluations of hormonal concentrations obtained by sampling under anesthesia.

For the subsequent discussion of individual hormones, values for those that are considered to be clinically important will not be provided, since the normal ranges can vary for diverse species at different sampling times and for assorted immunoassays of the same hormone using different polyclonal or monoclonal antibodies (e.g., Taylor et al., 1994; Barbé et al., 1995; Niccoli et al., 1996; Boots et al., 1998; Steinberger et al., 1998; Stanczyk et al., 2003). For example, reference materials provided by the US National Hormone and Pituitary Program that had previously been used (reference preparation-1) and are currently being employed (reference preparation-2 or -3) to set up standards for a rat LH RIA will generate concentrations for identical samples that differ by 61-fold. Rat and mouse serum estradiol concentrations showed wide variation when samples for each were split into aliquots and run using different commercial kits (Ström et al., 2008; Haisenleder et al., 2011). In women taking the oral estradiol Estrace®, assay values in serum using a commercial chemiluminescent kit were reported to be approximately 1/3 of those estradiol concentrations determined with an RIA kit (Hershlag et al., 2000). Whether the discrepancies in this study were attributable to differences in antibody specificity, the nature of the assay platform employed, or a contribution of both, were not clear. It is important, then, for referencing of immunoassay results to normative endocrine levels for individual hormones that the same assay materials and parameters be employed.

A number of hormones, as indicated above, will exhibit rhythmic changes over the day; in cycling females, the circulating concentrations of sex steroids and some peptide hormones will shift quite markedly over the cycle. Consequently, it is critical for any hormonal evaluations to reference concentrations to the appropriate controls, which for clinical purposes are frequently established historically. Again, it must be reemphasized that referencing clinical results against such historical values should be restricted to a common assay platform and its provider. For this chapter, most of the descriptive information about the various hormones and normal endocrine homeostatic interactions will rely on the rat as a representative mammalian species. Although various interspecies disparities do exist, rodents have been commonly employed as valued model systems for describing endocrine functions and interrelationships, which in the main hold true for other mammals. Nevertheless, information about other species has been included as well, particularly in those subsections that focus on pathological alterations in the various endocrine axes.

23.4.3 ENDOCRINE AXES

As indicated above, maintenance of physiological homeostasis relies heavily on the systems of communication among organs and tissues. The overarching term *endocrine system* really embraces multiple, yet interrelated, systems, within which feedback loops of hormonal messengers serve to regulate activity among organs subserving particular physiological functions. These subsystems of hormones have been termed *axes* that are typically identified by the individual network of organs involved. The pituitary is an integral component of these axes and, unless otherwise indicated, refers to the anterior pituitary (adenohypophysis). During embryogenesis it arises from Rathke's pouch, a depression in the roof of the developing mouth and, unlike the posterior pituitary (neurohypophysis), receives no neuronal fibers from the brain hypothalamic region, only blood-borne contact.

23.4.3.1 Hypothalamic–Pituitary–Gonadal Axis

Communication among the hypothalamus, pituitary, and gonads is essential for the regulation of reproductive activity. The principal hormones involved are GnRH, LH, and FSH and, in the female, the gonadal steroids progesterone and estradiol (Figure 23.3). In the male, the primary circulating androgen is testosterone; whereas, in the prostate, the concentration of 5α -dihydrotestosterone (DHT) is the principal and most potent form (Bruchovsky, 1971). A range of factors also is able to influence activity within the axis. Noradrenergic input from neurons whose cell bodies reside in the brain stem locus coeruleus acts as a permissive factor, allowing other processes to proceed. Excess or insufficient input will adversely affect axis functions. γ -Aminobutyric acid (GABA) and opioid input have inhibitory roles, as dose increasing the activity of CRH neurons.

In the females of all mammalian species, an abrupt rise in the blood concentrations of LH serves as a trigger for the process of ovulation. Those species that give birth to live young have been traditionally dichotomized into spontaneous or induced ovulators. Spontaneous ovulators (e.g., rat, mouse, hamster, guinea pig, dog, horse, cow, sheep, human, and nonhuman primates) undergo hormonally regulated ovarian cycles at recurrent intervals. Some cycles, as those in dogs, exhibit periods of anestrus with minimal ovarian activity between cycles. Such anestrus intervals may be seasonal, as in sheep and horses. In contrast to spontaneous ovulators, induced ovulators (e.g., rabbits, cats, ferrets, mink, voles, llamas, and camels) show a surge of LH and ovulate in response to sensory stimuli associated with mating. However, there are various examples of different regularly cycling species (Jöchle, 1975) undergoing ovulatory induction. Female rats, for example, that exhibit a persistent anestrus under constant light exposure can be induced to ovulate by coitus (Brown-Grant et al., 1973).

23.4.3.1.1 Gonadotropin-Releasing Hormone

GnRH (also referred to as LH-releasing hormone [LHRH]) is a decapeptide that is cleaved post-translationally to its final form from a higher molecular weight prohormone.

In evolutionary terms, GnRH is an ancient peptide and forms have been identified in a wide range of invertebrates, including mollusks, nematodes, and even coral (reviewed by Kah et al., 2007). As the name indicates, mammalian GnRH acts to stimulate the pituitary secretion of the gonadotropins, LH, and FSH. In primitive species, it is believed to initiate gamete release either directly or indirectly by an effect on nerve cells. In mammals, GnRH neurons migrate during embryogenesis

FIGURE 23.3 Using the rat as a representative example, the hypothalamic–pituitary–ovarian axis showing stimulatory and feedback relationships among gonadotropin-releasing hormone (GnRH), LH/follicle-stimulating hormone (FSH), and estradiol and progesterone. Feedback from the testis in the male to pituitary and hypothalamus is shown in the box at the right.

from the olfactory placode into the brain, ending their journey in the rostral portion of the hypothalamus (Schwanzel-Fukuda and Pfaff, 1989; Torbet et al., 1997). Nerve fibers from these cell bodies reach the median eminence at the base of the brain (Figure 23.4) where the hormone is released from terminals into a discrete grouping of portal vessels that descend to the anterior pituitary. Although GnRH has been found to bind to gonadal receptors (e.g., Bourne et al., 1980; Clayton et al., 1980; Uemura et al., 1994), systemic circulating concentrations are uniformly low, frequently difficult to quantify accurately and are typically of limited diagnostic value. In mammalian females that exhibit recurring ovarian cycles, a shift in the pulsatile secretion of GnRH in response to ovarian steroid feedback parallels a large surge in the release of both gonadotropins from the pituitary (e.g., Clarke et al., 1987; Gore, 2002). Castrated, testosterone-replaced males also show an increase in responsiveness (defined as an increase in the expression of LH subunit mRNA) that is dependent upon the frequency of exogenously applied pulses of GnRH (Haisenleder et al., 1987).

In mammals, two forms of GnRH, designated types I and II, have been found in distinct GnRH neurons and differ one from the other by three amino acid residues. The functional relationship between these two forms, GnRH-I and GnRH-II, still remains to be completely resolved (Pawson et al., 2003; Urbanski, 2012), although there is recent evidence in female rhesus macaques that these two types of neurons respond differently to estradiol (Urbanski, 2015). The data suggest that it is the GnRH-II neurons that play a predominant role in stimulating the female ovulatory surge of LH described in Section 4.3.1.2.

One type of input to GnRH neurons has now emerged as a major factor in GnRH secretion. Kisspeptin peptides released from neurons (termed KiSS1 neurons) concentrated in the hypothalamic periventricular region appear to be the most potent endogenous stimuli for GnRH release that serves to initiate the LH surge. They were originally identified as metastatic inhibitors in cultures of human melanoma cells and are members of the growing RFamide family of peptides that contain the Arg-Phe-NH₂ sequence at their amino-terminus. Fibers from these neurons have been demonstrated to terminate at GnRH neurons, and the secreted kisspeptins bind there to resident G-protein receptors (GPR54 receptors, currently designated as KiSS1 receptors), triggering pro-GnRH synthesis and GnRH secretion into the portal vasculature (e.g., Navarro et al., 2005; Seminara, 2007). Moreover, in mammals, it now appears that this relationship between kisspeptins and GnRH is a major factor in the transition through puberty (Kuohung and Kaiser, 2006). Another hypothalamic RFamide neuropeptide has recently been found to exert a suppressive effect on GnRH secretion. This gonadotropin-inhibitory hormone (GnIH), a dodecapeptide in its final posttranslational form, was initially characterized in chicken and quail. Orthologs of this avian RFamide (RFRP-1 and RFRP-3) were subsequently identified in a growing number of mammalian species, including rats, hamsters, sheep, cattle, and primates (Kriegsfeld et al., 2006; Kadokawa et al., 2009; Tsutsui, 2009; Ubuka et al., 2009); RFRP-3 was reported to act centrally to suppress LH (Anderson et al., 2009). Both the kisspeptins and GnIH would appear to play complementary roles in mediating the feedback

FIGURE 23.4 Photomicrograph of the rat median eminence, located at the base of the third ventricle. It is the site of release for hormones that in turn affect the secretion of the various pituitary peptide hormones. This particular image shows immunostaining of GnRH axons that project from neuronal cell bodies located primarily within a region termed the organum vasculosum of the lamina terminalis.

effects of sex steroids at the hypothalamus (Kriegsfeld, 2006; Wahab et al., 2015), although the complex of relationships in mammals among GnRH, kisspeptins, neurotransmitters/neuromodulators, and these GnRH orthologs under different physiological conditions still remains to be clarified.

23.4.3.1.2 *Luteinizing Hormone and Follicle-Stimulating Hormone*

LH is a glycoprotein that is composed of two α - and β -subunits connected by disulfide bridges. The α -subunits are common to both LH and FSH, along with TSH, whereas the β -subunits differ among the three hormones and confer specific biologic action in response to binding to their hormone-associated receptors. The α -subunit has been preserved throughout evolution, with some modifications in amino acid sequences. In an extension of the work cited above, demonstrating a relationship between GnRH pulse frequency and LH subunit transcription, Burger et al. (2008) have indicated that differential changes in pulse frequency regulate the transcription of either the β -subunit for LH (8–60-minute pulse intervals) or the β -subunit for FSH (>120-minute pulse intervals). Subunits of LH and the other glycoprotein hormones contain oligosaccharides that show different degrees of sulfation and sialylation, the basis for multiple isoforms of each hormone (Wilson et al., 1990a). This also results in a charge heterogeneity, with the more sialylated forms being more acidic and having longer circulatory half-lives (e.g., Burgon et al., 1996; Ulloa-Aguirre et al., 1999). On the other hand, the less sialylated variants exhibit higher receptor binding and greater biological activity (Ulloa-Aguirre et al., 2001a), although at least one oligosaccharide moiety is required for the full expression of bioactivity (Sairam, 1989). Families of LH isoforms have been described in humans (Ulloa-Aguirre et al., 2001b), nonhuman primates (Khan et al., 1985), horses (Irvine, 1979), pigs (Nomura et al., 1989), sheep (Keel et al., 1987), goats (Rojas-Maya et al., 2007), cattle (Zalesky and Grotjan, 1991), and rodents (Robertson et al., 1982). The relative proportions of these isoforms in males and females are not stable and are influenced by alterations in the endogenous steroid milieu.

LH principally functions in the male to promote the production of androgens in the testes. In the female, it stimulates ovarian follicular androgen synthesis. Aromatase activity then converts the androgens to estrogens. As indicated above, females who are spontaneous ovulators show a distinctive large midcycle surge of LH that serves to initiate the final stages of follicular and oocytic maturation that culminate in the release of one or more oocytes. Female rats have a cycle of 4–5 days and will typically ovulate 10–12 hours after the surge. In dogs, ovulation will take place about 48 hours from the surge peak (Bouchard et al., 1991). For rhesus monkeys, the time between the onset of the surge and follicle rupture is 36–40 hours (Stouffer, 2002), while the interval from the peak LH concentration to ovulation was reported to be approximately 22 hours (Pauerstein et al., 1978). Cats are considered to be induced ovulators, but have a cycle of 2–3 weeks, with a seasonal anestrus during the short days of autumn and winter. As in rabbits, they will only show a surge and ovulation in response to male cervical stimulation. The rise in LH in cats occurs within minutes of copulation, and ovulation will take place within 24–32 hours post coitum (Shille et al., 1983), whereas the postcopulatory interval in rabbits is about 11–12 hours (Milligan, 1982). For induced ovulators, genital stimulation activates brainstem noradrenergic neurons, which project to the hypothalamus to promote the secretion of GnRH from median eminence nerve terminals (Caba et al., 2000; Bakker and Baum, 2000). This pathway in primate, rodent, and canine spontaneous ovulators is also a component of the mechanisms involved in the secretion of GnRH (see Section 23.4.4.4).

The LH surge, then, is a functional endocrine event, and a suppression will block ovulation (discussed below in Section 23.4.3.1.5). Eliminating recognition of GnRH pulses by the pituitary with a constant exposure to elevated GnRH concentrations will cause a desensitization of the mechanisms of LH secretion. This would effectively suppress the gonadotropins and cause a chemical castration. In young girls exhibiting a precocious puberty caused by a premature activation of hypothalamic GnRH neurons, the administration of long-acting GnRH agonists has been used to postpone the emergence of menses, ovulation, and secondary sexual development (reviewed by Mansfield et al.,

1983; Boepple et al., 1986; Mul and Hughes, 2008). In precocious puberty, these agonists also serve to slow the increased maturational tempo of skeletal growth that would then be followed by an accelerated senescence at the bone growth plates.

As previously mentioned, the second gonadotropin, FSH, is also a glycoprotein, sharing a common α -subunit with LH. Both are secreted from gonadotrophs in the anterior pituitary and together in the mammalian female serve a coordinate function. LH functions to trigger the final maturational changes in ovarian follicles that conclude in ovulation. FSH, following a surge-like rise and fall, stimulates the growth of a cohort of immature follicles to a mature preovulatory stage to await action by a surge of LH during the next cycle. In the male, FSH supports the function of the testicular Sertoli cells, which sustain the maturing spermatozoa. FSH receptor knockout mice show underdeveloped testes, poor sperm quality, and a 50% reduction in Sertoli cells (Krishnamurthy et al., 2000; Sairam and Krishnamurthy, 2001).

As a glycoprotein, FSH also exists as different isoforms. When compared to LH, it tends to contain more sialic acid moieties on its oligosaccharide structures (Ulloa-Aguirre et al., 1995; Green and Baenziger, 1988), consequently increasing its circulating half-life. In adult male rats, multiple isoforms exhibited half-lives between 13 minutes and several hours, with the longer-lived forms that were more heavily sialylated predominating (Blum and Gupta, 1985).

23.4.3.1.3 Gonadal Hormones

The steroidogenic pathway synthesizing the sex steroids begins with the translocation of cholesterol from the outer to the inner mitochondrial membrane. This is a rate-determining process involving a signaling complex composed of steroidogenic acute regulatory protein (StAR) and a translocator protein (the peripheral benzodiazepine receptor) (Liu et al., 2006). After transport through the membrane, cholesterol is converted to pregnenolone by cytochrome P450_{scc} (P450 side chain cleavage, or CYP11A) before entering the $\Delta 4$ or $\Delta 5$ pathway (Figure 23.5). In the $\Delta 4$ path, pregnenolone is converted first to progesterone by 3β -hydroxysteroid dehydrogenase (3β -HSD) and then to 17α -hydroxyprogesterone. In the $\Delta 5$ direction, 17α -hydroxylase/ $17,20$ lyase (CYP17) converts pregnenolone to 17α -hydroxypregnenolone and dihydroepiandrosterone. Species differences exist in the substrate preferences of the $17,20$ lyase. In humans (Weusten et al., 1987), rabbits, dogs, and cows (Fortune, 1986), the preferred substrate is 17α -hydroxypregnenolone; whereas, in the rodent (Brock and Waterman, 1999), ferret (Kintner and Mead, 1983), chicken, mare, and some macaques (Weusten et al., 1990), the preference is for 17α -hydroxyprogesterone. This preference can be influenced by shifts in concentrations of other hormones. For example, in hamster preovulatory ovarian follicles, $\Delta 5$ predominates before and up to 2 hours after exposure in vitro to LH. There then occurs a switch to the $\Delta 4$ direction as the major pathway (Makris et al., 1983), markedly increasing the formation of progesterone from exogenously provided pregnenolone. Both paths will generate androstenedione, which can then be converted to testosterone by the action of 17β -hydroxysteroid dehydrogenase (17β -HSD), or to estrone by P450_{arom} (P450aromatase, CYP19). CYP19 will also catalyze testosterone to estradiol, whereas estrone and estradiol can be interconverted by 17β -HSD. In the prostate, 5α -reductase will catalyze the production of 5α -DHT from testosterone.

23.4.3.1.3.1 Estrogens As mentioned above, the two most common circulating estrogens are estradiol and estrone. A third, estriol, is short acting and in women likely has some role in parturition (e.g., Inoue et al., 1971; Lintner et al., 1988), being produced in large quantities by the fetoplacental unit during the latter stages of pregnancy. The affinity of estriol to the estrogen receptor, however, is reduced relative to the other estrogens. 17β -Estradiol is the principal estrogen and is produced in ovarian granulosa cells from androgen precursors transported from the thecal layer (see Figure 23.6a). During particular segments of the estrous/menstrual cycle, it serves to increase the responsiveness of participating hypothalamic mechanisms, a shift possibly associated with a lessening of an inhibitory restraint on GnRH neuronal activity (Gibson et al., 2008). In addition, estradiol (a) has a role in pubertal development and

FIGURE 23.5 Steroidogenic pathway, depicting cholesterol transport from the outer to the inner mitochondrial membrane, with steps up through the synthesis of the testosterone, estrone, and estradiol. Both the $\Delta 4$ and $\Delta 5$ paths (see text) are shown against a shaded background. (Redrawn from Elsevier Press, Vol. 11, 2nd edition, Perreault, S.D. et al., Targeting female reproductive function during follicular maturation, ovulation, and fertilization: Critical windows for pharmaceutical or toxicant action, pp. 399–417, 2010, with permission from Elsevier.)

sexual behavior (e.g., Ojeda et al., 1983, 1986), (b) induces progesterone receptors to prepare the uterine endometrium for the action of progesterone (e.g., Okulicz et al., 1989; Kurita et al., 2001), (c) plays an important role in regulating the uterine immune system (Wira and Sullivan, 1981), (d) helps maintain the size and density of mammary tissue (e.g., Pompei et al., 2005; Fendrick et al., 1998), although excess amounts will increase the risk of some forms of breast cancer, (e) decreases the development and activity of bone-clearing osteoclast cells and increases the bone-building ability of osteoblast cells (e.g., Lafferty et al., 1964; Ernst et al., 1988; Saintier et al., 2006), and (f) acts as a neuroprotective factor within the brain (e.g., Green et al., 2001; Fujita et al., 2006). In laboratory animals, estradiol is also known to affect food intake, acting as a modulatory factor to decrease consumption. Daily food intake in female rats will differ over the estrous cycle, with the lowest consumption taking place during the periovulatory period, when circulating estradiol concentrations show proestrus peaks and then begin to fall over the evening transition to estrus (e.g., Asarian and Geary, 2006). Gonadectomized females will eat more, in contrast to gonadectomized males, who will decrease their consumption (Gentry and Wade, 1976; Chai et al., 1999). During meals, a peptide hormone, cholecystokinin, is released from the small intestine and binds to receptors in the brain, providing satiety signals. Results from studies using ovariectomized rats have demonstrated that estradiol will increase the potency of exogenously administered cholecystokinin (Butera et al., 1993).

FIGURE 23.6 Photomicrographs of an ovarian follicle and male testicular tubules and interstitial cells. (a) Confocal laser scanning micrograph of a mature rat preovulatory follicle showing the outer theca cell layers and inner granulosa cells separated by the basal lamina. The oocyte, within the antral cavity, is surrounded by cumulus cells. (b1) Photomicrograph of tubules within the rat testis are shown at different maturational stages of spermiogenesis designated with roman numerals; (b2) An enlarged portion of seminiferous epithelium of one tubule containing spermatocytes and Sertoli cells; (b3) A further enlargement of the interstitial space between tubules showing the testosterone-secreting Leydig cells. (Testicular images courtesy of Dr. Gary Klinefelter, US EPA, Follicular image in (a). Reprinted from Elsevier Press, Vol. 11, 2nd edition, Perreault, S.D. et al., Targeting female reproductive function during follicular maturation, ovulation, and fertilization: Critical windows for pharmaceutical or toxicant action, pp. 399–417, 2010, with permission from Elsevier.)

A single intravenous administration of ^3H -17 β -estradiol in the female rat showed two component clearance curves. The first pool was cleared relatively rapidly (5.5 minutes, plasma half-life), while the second pool disappeared more slowly (half-life of 31 minutes in plasma) (Littleton and Anderson, 1972). Table 23.1 shows metabolic clearance rates (MCR, expressed as L/day/kg) for estradiol in female rat, rabbit, dog, and nonhuman primates.

In the cell nucleus, signaling by estrogens is mediated by two types of evolutionarily conserved receptors, estrogen receptor- α (ER α), and estrogen receptor- β (ER β), which are produced from separate genes located on different chromosomes (Pavao and Traish, 2001). Both are members of the nuclear receptor family of transcription factors and serve to translocate estrogens into the cell nucleus to link with DNA. In a form unbound to its estrogen ligand, cytosolic estrogen receptors are associated with a complex of chaperones, including heat-shock protein 90, which maintains the receptor in an inactive condition, but prepared for binding to the hormone (Pratt and Toft, 1997). Estrogen receptors can also be present in the plasma membrane and induce a rapid nongenomic signal (e.g., Márquez and Pietras, 2001; Micevych and Mermelstein, 2008). ER α and ER β can coexist in populations of neurons, although they also show distinctive distributions and selectivity to estrogenic compounds in addition to a differential transcriptional regulation (Laflamme et al., 1998; Shughrue et al., 1998; Haeger et al.,

2006). ER α is now understood to mediate effects of estradiol on the hypothalamic periventricular kisspeptin neurons that coordinate with GnRH in initiating the LH surge (Roa et al., 2008).

In males, the presence of testicular aromatase activity (Dorrington et al., 1978; Valladares and Payne, 1979) and concentrations of male gonadal fluid estrogens in various species (e.g., Ganjam and Amann, 1976; Eiler and Graves, 1977; Claus et al., 1992) have been reported since the 1970s. Estrogen receptors are also present in testicular tissue. Of the two estrogen receptor subtypes, ER β appears to be much more prevalent than ER α (Saunders et al., 1998; Nie et al., 2002). The function of male gonadal estrogens is still unclear, but they may play some role within the efferent ductules positioned between the rete testis and caput region of the epididymis, contributing to the reabsorption of rete testis fluid that concentrates sperm prior to their entry into the tubules of the epididymis (Hess, 2003), the structure in which sperm gain motility and fertilizing capacity.

23.4.3.1.3.2 Progesterone The name progesterone is a compilation of the term *progestational steroidal ketone* (Allen, 1970). Discovered in the 1930s, it is synthesized from pregnenolone by the action of 3 β -HSD (see Figure 23.5) and is a product of both ovarian granulosa and adrenal cortical

cells (e.g., Armstrong, 1968; De Geyter et al., 2002) and placenta (e.g., Schubert and Schade, 1977), in addition to some synthesis by brain astrocytes (Micevych and Sinchak, 2008) and cerebellar Purkinje cells (Tsutsui, 2008). It binds to a receptor that exists in three isoforms (Kastner et al., 1990; Wei et al., 1997), each with a high affinity for the hormone and each having a differential specificity for target genes in the nucleus.

Work performed in the rat has shown that the disappearance curve for progesterone consists of two components (Pepe and Rothchild, 1973). The first component is rapidly cleared, with a half-life in ovariectomized females of 2.7 minutes, whereas the second disappears more slowly, having a half-life of 18 minutes. In the cow, this can range up to 36 minutes (Pineda, 2003). MCRs for progesterone in L/day/kg body weight for female rabbit, rat, dog, and nonhuman primate are listed in Table 23.1.

As is true for estradiol, progesterone serves a number of functions. It (a) prepares the uterus to receive the embryo (e.g., Glasser and Clark, 1975; Yochim, 1986), (b) maintains the uterus during pregnancy (Csapo and Wiest, 1969; Takayama and Greenwald, 1972), (c) stimulates mammary gland growth (e.g., Humphreys et al., 1997; Ismail et al., 2003), (d) acts to increase the loss of sodium in the kidney (e.g., Wambach and Higgins, 1978), (e) has a mild catabolic effect (Landau and Lugibihl, 1961a,b), and (f) is involved in mechanisms regulating gonadotropin secretion (e.g., Karsch, 1987; Evans et al., 2002). During pregnancy, an increased level of progesterone receptor transcriptional activity maintains a uterine quiescence (Mendelson and Condon, 2005). In pregnancies of subprimate placental mammals, a significant fall in circulating progesterone occurs near term (reviewed by Zakar and Hertelendy, 2007). As contractions increase at labor, all progesterone receptor isoforms show a sharp decrease (Goldman et al., 2005), which parallels a series of biochemical events that serve to lower progesterone receptor function (Mendelson and Condon, 2005).

Over the course of the normal ovarian cycle in regularly cycling mammals, the feedback of ovarian estradiol (augmented by progesterone) sensitizes or upregulates the hypothalamic mechanisms stimulating the increase in the pulsatile release of GnRH from the median eminence into the portal vessels, triggering the LH surge. It has been argued that the role of estradiol in the surge is secondary to that of progesterone (Zalányi, 2001), with estradiol feedback serving to increase the production of hypothalamic neuroprogesterone (Micevych et al., 2003; Micevych and Sinchak, 2008). Around the appearance of the surge, progesterone rises in concert with the fall in estradiol. In dogs, the elevation has been reported to be greater than 100-fold over the anestrus nadir (Olson et al., 1982). Circulating concentrations secreted from ovulated follicles (transformed to corpora lutea) will initiate a series of cellular changes in the uterine endothelia, both permitting embryonic blastocysts to adhere initially to the endometrial surface of the uterus and inducing a decidualization of endometrial stromal fibroblasts that converts them into secretory cells to provide the blastocysts with early nutrient support as they penetrate and settle within the endometrium. If the implantation of one or more fertilized ova takes place, the progesterone will remain elevated and serve to maintain the pregnancy and also suppressing the LH surges during this time. If implantation does not occur, the corpora lutea will undergo luteolysis, and progesterone levels will decline, removing the restraint on the ovulatory LH stimulus. In fact, a number of third generation progestin-only oral contraceptives for women have been demonstrated to target the hypothalamus and pituitary, mimicking this progesterone restraint on the surge and ovulation (Faundes et al., 1991; Couzinet et al., 1999).

An additional source of progesterone is the placenta, and there are marked species differences in the relative contributions of luteal and placental progesterone in pregnancy maintenance. For example, in the pig, goat, dog, and rat, the progesterone secreted from the corpora lutea is required throughout the pregnancy, whereas a shift to placental progesterone during the second half of pregnancy occurs in the ewe and mare (reviewed by Geisert and Conley, 1998).

23.4.3.1.3.3 Testosterone Testosterone, the principal male sex steroid, is synthesized from androstenedione by the action of 17β -hydroxysteroid dehydrogenase and has a reported half-life in the rat of about 30 minutes (Nett, 1989). In the male, it is secreted from the interstitial Leydig cells within the testis (Figures 23.6b1 through 23.6b3). In the female testosterone produced in the ovarian

theca cells is transported into the granulosa cell layer (Figure 23.6a), where it is aromatized to estradiol. The growth and differentiated function of the Leydig cells are dependent upon the stimulatory effect of LH from the pituitary (Ewing and Zirkin, 1983). Within the prostate, testosterone is rapidly converted to a number of metabolites, the major one being DHT. MCRs for testosterone in male rabbit, rat, dog, and nonhuman primate are shown in Table 23.1.

The primary action of androgens is to regulate gene expression through the androgen receptor (AR), which, like the estrogen receptors, belongs to the superfamily of nuclear receptors. Two isoforms of the AR (A and B) exist. They appear to be structurally similar to the two progesterone receptor isoforms (Wilson and McPhaul, 1996). The B isoform is present in much lower levels than the A form, and its role is unclear. As is the case for the other sex steroids, when the AR is inactive, it is bound to heat-shock proteins in the cytoplasm. Binding of testosterone to the receptor dissociates the heat-shock proteins, and the hormone-bound receptor is translocated into the nucleus to activate genes involved in cell growth (e.g., Veldscholte et al., 1992; Zoubeidi et al., 2007).

In the male, testosterone is the androgenic hormone that is primarily responsible for the normal growth and development of male reproductive organs and spermatogenesis (e.g., Sharpe et al., 1990; Kerr et al., 1993; Walker, 2009), along with the development of secondary sexual characteristics. A suppression of testosterone in male rats caused a depletion of elongated spermatids that is apparently due to a detachment of the round spermatid precursors from their association with testicular Sertoli cells (O'Donnell et al., 1996), which normally provide nutritional and structural support (Figure 23.6b3) for germ cell spermatogenic maturation. The hormone promotes protein biosynthesis that underlies the hormone's anabolic characteristics. As such, it accelerates the building of muscle (Florini, 1970), increases erythropoiesis (Fisher et al., 1971), promotes the catabolism of body fat (Xu et al., 1990), and shortens the recovery time after injuries (Ehrlich and Hunt, 1969; Brown et al., 1999). In prostate, DHT is the principal androgen that stimulates normal prostatic development, growth, and function (e.g., Tenniswood et al., 1982). In men, the production of DHT is also involved in androgenic pattern baldness, although this condition appears to have no homolog in nonhuman primates, and an androgen-associated alopecia normally is absent in other species. Dog hair follicles only exhibit a minor conversion of DHT from testosterone (Bamberg et al., 2004). In mice, treatment with DHT has been reported to affect hair follicle growth, and AR knockout mice show fur that is longer and thicker than wildtype littermates (Naito et al., 2008).

23.4.3.1.4 *Activins, Inhibins, and Follistatin*

Although not typically presented as components of the hypothalamic–pituitary–gonadal (H–P–G) axes, the integrated actions of activin, inhibin, and follistatin hormones contribute to homeostatic regulation of the reproductive system in both males and females. Both activin and inhibin are dimeric glycoproteins that have a similar β -subunit, with activin being a homodimer (β/β -subunits) and inhibin a heterodimer (α/β -subunits). The β -subunits have been shown to exhibit a remarkable degree of homology across mammalian species and show a good deal of structural conservation throughout vertebrate evolution (Ge et al., 1993). The two glycoproteins are both members of the transforming growth factor- β (TGF- β) superfamily, which acts to modulate growth and developmental processes in most tissues, including the pituitary. They were originally discovered to stimulate (activins) or inhibit (inhibins) the secretion of FSH (for review, see Vale et al., 1990), although gene expression is present elsewhere, including mammary and adrenal tissues. In mammary tissue, activin is generally characterized as an inhibitor of cell proliferation, since activin treatment *in vitro* will arrest the growth of breast cancer cells (Reis et al., 2004). Beyond a role in FSH secretion, it appears to participate as an early component of the inflammatory cascade (Phillips et al., 2005).

Activin is present in two biologically active forms, A and B (Vale et al., 1990). Activin A has been shown to have marked stimulatory effects on the secretion of pituitary FSH that principally occur via gene transcription of the FSH β -subunit (Suszko et al., 2003). In male rat gonads, activin A is produced in the seminiferous epithelium, particularly in Sertoli cells. In the testes, activin A

predominantly has a local paracrine action, regulating Sertoli cell number and germ cell maturation (e.g., de Kretser et al., 2001; Sofikitis et al., 2008). It may have a similar paracrine effect on FSH, since subunits are expressed locally in adult pituitary gland (Roberts et al., 1989). In the female rodent, activin A is produced in granulosa cells and has a stimulatory effect on granulosa cell proliferation and the growth of preantral follicles (Findlay et al., 2001). As in the male, it likely serves a similar local regulatory effect on pituitary FSH. The contributions of activin B to gonadal activity are still unclear, although some evidence suggests that it also plays a paracrine role in pituitary FSH production (Corrigan et al., 1991). Greater clarification requires the development of more specific activin B immunoassays, which have now only begun to appear (Ludlow et al., 2008).

Whereas activin stimulates the synthesis of FSH and its secretion from pituitary gonadotropes, the inhibins act as potent activin antagonists. There are two forms of inhibin, A and B, which have inhibitory effects on ovarian folliculogenesis (Findlay, 1993) and pituitary FSH secretion (Woodruff et al., 1993). In males, inhibin production by Sertoli cells provides endocrine feedback to the pituitary to antagonize activin signaling in gonadotropes. Increased inhibin-like immunoreactivity was reported in dogs with a Sertoli cell tumor that correlated with reductions in FSH, LH, and testosterone concentrations (Peters et al., 2000). Inhibin A and B antagonism of activin is mediated by membrane polysaccharides known as betaglycans that act as co-receptors (Lewis et al., 2000; Chapman et al., 2002), so that a stable complex is formed with activin receptors and interferes with the ability of activin to bind. The extent of inhibin glycosylation will decrease its bioactivity, something that is apparently due to a reduced affinity for betaglycan (Makanji et al., 2007).

The third of the glycoproteins in this category of FSH regulatory factors is follistatin. These molecules are ubiquitous throughout the body in nearly all higher animals and in the pituitary are produced by the folliculostellate cells (Gospodarowicz and Lau, 1989). Over the reproductive cycle, they act in conjunction with the activins to adjust a differential production of FSH from gonadotropes via their ability bind activins and bionutralize them. Two molecules of follistatin have been reported to envelop the activin dimer, covering a large portion of its surface and preventing activin from associating with its receptor (Thompson et al., 2005).

23.4.3.1.5 *Pathological Alterations in the H–P–G Axis*

Adverse effects on the process of ovulation can be the result of insult to one or more sites within the H–P–G axis. A direct impairment in the hypothalamic mechanisms underlying the increase in the secretion of GnRH is not subject to in-life assessments, particularly since concentrations of GnRH entering the circulation are frequently too low to assess by common immunological methods. Alternatively, plasma or serum levels of the gonadotropins are measurable and can often provide valuable information, since they are conveyed to the gonads via the general circulation. In cycling females, alterations in the midcycle LH and FSH surges can be assessed by serially sampling blood (or possibly urinary [Jeffcoate and England, 1997]) gonadotropin concentrations over the over the normal window of appearance. A number of compounds, including opiates, dithiocarbamate, and formamidine pesticides, shown to target mechanisms of GnRH secretion will suppress the LH surge and block an ensuing ovulation (e.g., Gosden et al., 1976; Parvizi et al., 1976; Hagino, 1979; Goldman and Cooper, 1993, 2010; Goldman et al., 1994, 2008; Cooper et al., 2000; Stoker et al., 2005).

A distinction between a primary site of impairment within an endocrine axis and one that represents a secondary response to the primary insult can often be made by evaluating whether stimulation can elicit a normal endocrine response from components of the axis. For example, a single exposure in female rats to the fungicide metam sodium (sodium *N*-methylthiocarbamate) during a sensitive window hours prior to the anticipated appearance of the LH surge was found to block the surge and ovulation (Goldman et al., 1994). Its effectiveness when administered during this time indicated that the primary target was either at the level of the hypothalamus or the pituitary. In this case, a concurrent treatment with GnRH was able to overcome the effect of metam sodium and

induce a normal ovulatory response, indicating that the hypothalamus and not the pituitary was the target site for the insult.

In the normally functioning male H–P–G axis, normal gonadotropin and steroid concentrations, along with spermatogenesis, are under close regulation. Dysfunctional alterations in the hypothalamus or pituitary can lower the circulating gonadotropin and testosterone concentrations, decreasing testicular stimulation and affecting sperm production. Conversely, should damage occur to the testes, for example by chemical or physical trauma, a decline in gonadal Leydig or Sertoli cell activity would cause a persistent gonadotropin elevation by lowering negative feedback to the pituitary. Such an elevation in response to two-week treatments with LH in both intact and hypophysectomized male rats, in addition to increasing testosterone production, caused Leydig cells to undergo hyperplastic alterations (Kerr and Sharpe, 1986; Mendis-Handagama et al., 1998).

Testicular Leydig and Sertoli cell tumors are both frequently found in mature and old dogs and in the latter can be as high as 60% (Mosier, 1989). In those dogs with Leydig cell tumors, circulating concentrations of LH were decreased and negatively correlated with testosterone, estradiol, and inhibin. Dogs with Sertoli cell tumors, as previously mentioned in Section 23.4.3.1.4 showed reductions in FSH, LH, and testosterone, along with increases in inhibin immunoreactivity (Peters et al., 2000).

Measures of male serum testosterone have been an integral part of assessments of insults caused by endocrine-disrupting chemicals. The alkylating agent ethane dimethane sulfonate (EDS) has been found to be a Leydig cell toxicant, and the resultant decline in testosterone in response to EDS exposure will eliminate the negative feedback and cause a rise in LH and FSH (Bartlett et al., 1986). A number of environmental toxicants (e.g., phthalates and dicarboximide fungicides) have also been found to act as antiandrogens. In developmental studies of male rats, the antagonism of AR activity has been reported to reduce anogenital distance, cause nipple retention, and induce genital malformations such as cleft phallus and hypospadias (Gray et al., 1994; Hotchkiss et al., 2002; Foster, 2006). Sertoli cell toxicants, such as 2,5-hexanedione, will induce long-lasting testicular atrophy with the almost complete absence of spermatogonia from seminiferous tubules (Allard and Boekelheide, 1996).

Pubertal development in both sexes can be affected by environmental compounds that interfere with those endocrine mechanisms underlying this transition to sexual maturity. The nonsteroidal estrogen, diethylstilbestrol, will advance puberty in female mice (Honma et al., 2002) and rats and disrupt subsequent estrous cyclicity (Nass et al., 1984). For reviews of the processes of normal pubertal development and the effects of endocrine disrupting chemicals on sexual maturity that have been a focus of the US Environmental Protection Agency (US EPA) under its Endocrine Disruptors Screening Program, the reader is referred to two companion monographs (Goldman et al., 2000; Stoker et al., 2000).

In the prostate, the binding of the androgen–nuclear receptor complex to androgen-regulated genes is essential for normal prostatic development and can also be responsible for the pathogenesis of the prostate neoplasms in humans and prostatic hyperplasia, for example, in humans, dogs, and rodents (e.g., Berry and Isaacs, 1984; Bartsch et al., 2002; Nantermet et al., 2004). In contrast, pharmacological agents with antiandrogenic properties can produce atrophy of the prostate (e.g., Iswaran et al., 1997; Mylchreest et al., 1998), in addition to Leydig cell hyperplasia due to the suppression of inhibitory testosterone feedback to the pituitary.

23.4.3.2 Hypothalamic–Pituitary–Adrenal Axis

The hypothalamic–pituitary–adrenal (H–P–A) axis is an endocrine unit that functions to maintain basal and stress-related homeostasis by incorporating a wide variety of signals. The integrative core components of the axis are hypothalamic corticotrophin-releasing hormone (CRH), pituitary ACTH, and the adrenal glucocorticoids (the corticotropins cortisol and/or corticosterone; Figure 23.7). Input to the axis from peripheral sympathetic neuronal activity, circulating cytokines (e.g., interleukins and tumor necrosis factor alpha), posterior pituitary hormones (oxytocin and vasopressin), and central noradrenergic stimulation will collectively initiate a behavioral reaction, encompassing what is

FIGURE 23.7 Representative rat hypothalamic–pituitary–adrenal axis depicting the relationships among corticotrophin-releasing hormone (CRH), adrenocorticotropic hormone (ACTH), and corticosterone, along with central modulatory effects from neurotransmitters and neuropeptides.

termed the stress response. In addition, activity within the H–P–A axis serves other roles beyond reactions to distress. For example, glucocorticoids have an important role both peripherally and centrally in the control of energy homeostasis by regulating carbohydrate and protein metabolism (e.g., Hopgood et al., 1981; McMahon et al., 1988; O’Callaghan et al., 1989; Wang, 2005).

23.4.3.2.1 Corticotropin-Releasing Hormone

CRH is a member of the corticoliberin family of related neuropeptides that includes the urocortins and urotensin. In evolutionary terms, its 41-amino acid sequence is fairly well conserved, with a primary structure that is identical in primates, carnivores, and rodents (Shibahara et al., 1983; Mol et al., 1994; Rivier et al., 1983). In the hypothalamus, it is first synthesized as a larger prohormone and then transported to nerve terminals in the median eminence for release into the portal vasculature, where it is conveyed to the pituitary, stimulating the secretion of ACTH. Measurements of CRH, using immunohistochemical methods, western blot peptide identification, or northern blot detection of the prohormone message are not performed “in-life,” which make them much less useful than clinical assessments of other factors linked to correlative activity within the axis.

CRH and its related peptides are found in the gastrointestinal, cardiovascular, reproductive, and immune systems, being involved in a wide spectrum of stress-associated responses. Members of this family fall into one of three groupings based upon their receptor binding. The CRH subfamily will selectively bind to CRFR1 receptors, whereas urocortins II and III bind to CRFR2 receptors. Urocortin I and urotensin I are nonselective for the CRF receptors (Dautzenberg and Hauger, 2002). In mediating the stress response, the two CRF/urocortin receptors were found to have distinctive roles in both the regulation of behavioral reactions (Bale et al., 2002) and centrally and peripherally mediated energy homeostasis (Carlin et al., 2006; Kuperman and Chen, 2008). They show conspicuous differences in their distribution. The location of CRFR1 mRNA in mouse is basically comparable to that in rat and is widely expressed in the brain, predominating in the pituitary, cerebral cortex, arcuate nucleus, hippocampus, amygdala, olfactory bulb, and cerebellum. In the pituitary, rat and mouse displayed a CRFR1 mRNA signal throughout the intermediate lobe and in a subset of anterior lobe cells. The highest density of CRFR2 neuronal expression was found in the lateral septal nucleus, bed nucleus of the stria terminalis, ventromedial hypothalamic nucleus, olfactory bulb, amygdala, and mesencephalic raphe nuclei. In the pituitary, CRFR2 transcripts were expressed mainly in the posterior lobe (Van Pett et al., 2000).

23.4.3.2.2 *Adrenocorticotrophic Hormone*

ACTH, also known as corticotropin, was the first pituitary hormone to be synthesized (Li et al., 1955). It is proteolytically cleaved from a larger glycosylated precursor protein, proopiomelanocortin (POMC), which is expressed in the pituitary by two cell types, corticotropic cells and melanotropic cells. In addition to ACTH, a variety of biologically active products are generated: β -lipotropin, α - and β -melanocyte stimulating hormones, and the endogenous opioids β -endorphin and met-enkephalin. POMC has likely emerged from an ancestral gene, and among mammalian species, there is a considerable degree of sequence homology in the active core of ACTH (e.g., Stewart and Channabasavaiah, 1979).

Classically, the role of ACTH is to stimulate the adrenal glands to release glucocorticoids in situations of stress. In this capacity, it stimulates the transcriptional activity of those genes involved throughout the steroidogenic pathway (e.g., Waterman and Bischof, 1996; Sewer and Waterman, 2003). In adrenal cortical cell cultures, cholesterol transport from the outer to the inner mitochondrial membrane was promptly enhanced following ACTH exposure, along with an increase in side chain cleavage activity (DiBartolomeis and Jefcoate, 1984). It also has indirect mitogenic effects on capillary epithelial cells. Adrenal cortical tissue is abundantly vascularized with a dense blood capillary network, and ACTH has been reported to be involved in the development of this vasculature via an induction of the angiogenic signaling protein, vascular endothelial growth factor (VEGF) (Thomas et al., 2003).

The presence of ACTH immunoreactivity in the brain was reported in the 1970s and 1980s (Larsson, 1978; Joseph, 1980), findings that have been observed, with some variation in ACTH fiber distribution, in a variety of mammalian species (e.g., Abrams et al., 1980; Coveñas et al., 1996; Pesini et al., 2004). The role of these fibers still remains to be elucidated, although there are apparent relationships to various neurotransmitter systems (Azmitia and de Kloet, 1987; Liang et al., 1992).

23.4.3.2.3 *Cortisol and Corticosterone*

The mammalian adrenal gland is composed of two developmentally dissimilar tissues, the adrenal cortex and a core region, the adrenal medulla. The cortex is comprised of three concentric zones, first labeled by Julius Arnold in 1866 as the zona glomerulosa, zona fasciculata, and zona reticularis. These zones have functionally distinct roles in steroid hormone production. The glucocorticoids cortisol and corticosterone are synthesized in the zona fasciculata, whereas the zona glomerulosa synthesizes mineralocorticoids and the zona reticularis produces adrenal androgens (although in rats this appears at best to be quite limited). The synthetic pathway for these two glucocorticoids is shown in Figure 23.8. The ratio of one to the other varies among mammals. Rats, mice, and rabbits, for example, secrete corticosterone, with little or no cortisol, unlike in dogs, sheep, humans, and nonhuman primates where cortisol predominates. Hamsters produce both glucocorticoids (Ottenweller et al., 1985); whereas, dairy cows show different ratios, depending upon the breed (Venkataseshu and Estergreen, 1970). The absence of cortisol in the adult rat has generally been considered to be due to a repressed adrenal expression of the CYP17 gene (Van Weerden et al., 1992; Brock and Waterman, 1999). Recent evidence has implicated DNA methylation in silencing of the gene (Missaghian et al., 2009). There is, however, cortisol production in prepubertal males and females (Pignatelli et al., 2006), along with some reports of adult rat adrenal tissue steroid production from 17-hydroxylation (e.g., Vinson et al., 1978; Bell et al., 1979).

As mentioned in Section 23.4.1, corticosterone secretion is pulsatile in nature, something that is also true for cortisol. In the female rat, a pulse of corticosterone occurs approximately once every hour. This secretion reflects an episodic activation and inhibition of the H-P-A axis and results in a refractory period, during which the axis becomes nonresponsive to the presence of a mild stressor (Windle et al., 1998). The activity of the H-P-A axis is also dampened during the latter portion of pregnancy, reflecting a reduced activation of CRH neurons (Brunton et al., 2008). This may function

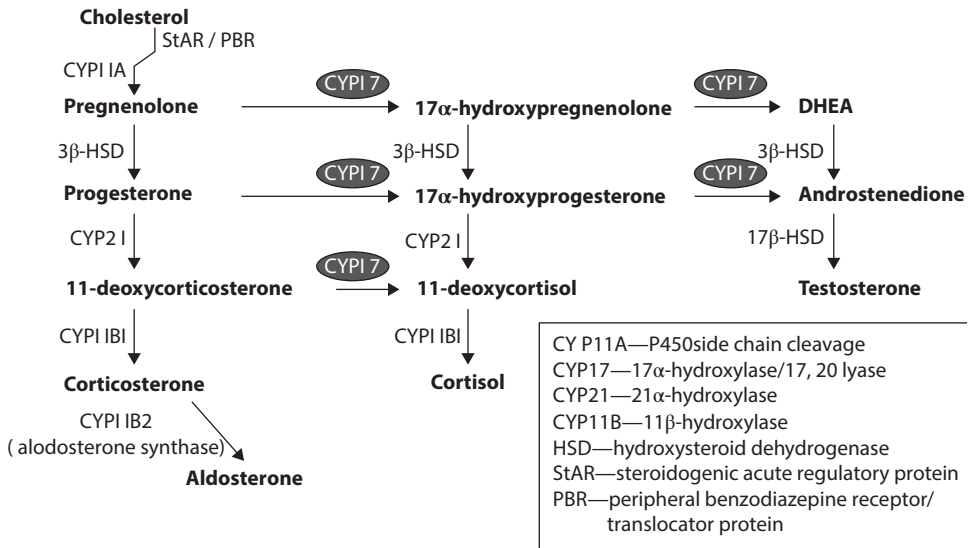

FIGURE 23.8 Steps in the adrenal synthesis of the glucocorticoids cortisol and corticosterone and the mineralocorticoid aldosterone. Unlike human adrenals, rat adrenals show a repressed (or negligible) expression of the gene for CYP17 (17α-hydroxylase/17,20 lyase), blocking 17-hydroxylation and preventing (or almost entirely impeding) the production of cortisol.

to avert the adverse influence of stress on the mother and offspring. The underlying mechanism still remains to be elucidated, but now appears to involve an upregulated endogenous opioid response to allopregnanolone, the neuroactive steroid metabolite of progesterone (Brunton et al., 2009).

The great majority of circulating cortisol is bound to a plasma protein, termed transcortin (or corticosteroid-binding protein [CBP]). In dogs, for example, only 5%–12% exists in the biologically active free form (Meyer and Rothuizen, 1993). A product of the liver, this protein is also able to bind aldosterone (Section 23.4.4.6) and shows varying degrees of glycosylation, affecting its half-life (Avvakumov, 1995). The physiological effects of glucocorticoids are mediated via binding to its intracellular receptor, which is predominantly present in the cytoplasm. When activated by glucocorticoid binding, this receptor undergoes a conformational change and is translocated to the cell nucleus (Picard and Yamamoto, 1987), where it initiates transcriptional activity by associating with specific DNA response elements. In the liver, glucocorticoids serve an important regulatory role in energy metabolism/glucose utilization, and the translocated receptors appear to target directly more than 50 genes (Phuc Le et al., 2005). The hormones are also able to influence fat deposition, but show differential effects for peripheral and central lipids, increasing lipolysis in peripheral fats (Slavin et al., 1994), while promoting lipogenic pathway activity in central fat (Gaillard et al., 1991). Their anti-inflammatory role is well known, and pharmacological glucocorticoid doses are effective in immunosuppressing macrophage activation and T-cell receptor expression (reviewed by Sternberg, 2001).

23.4.3.2.4 Pathological Alterations in the H–P–A Axis

The significance of adverse effects on the functioning of the H–P–A axis has long been known. Human adrenal insufficiency was first described in 1849 by Thomas Addison (reviewed by Bishop, 1950) and is typically caused by an autoimmune attack on the adrenal glands (primary hypoadrenocorticism). Its symptoms include low blood pressure, constipation or diarrhea, nausea, vomiting, weight loss, increased desire for salty foods, lack of appetite, and hyperpigmentation. An Addison-like hypoadrenocorticism, with accompanying lethargy, anorexia and weight loss has been described in dogs and cats (reviewed by Greco, 2007). An experimental animal model of Addison's

disease (experimental autoimmune adrenalitis) has also been produced in guinea pigs, rabbits, rats, monkeys, and mice by an injection of adrenal homogenates mixed with various adjuvants (e.g., Fujii et al., 1992).

In humans, a hyperadrenocorticism syndrome is characterized by a prompt gain in weight, excess sweating, polyuria, persistent hypertension, gastrointestinal problems, hyperglycemia, osteoporosis, and possible hirsutism. Harvey Cushing first described such a condition in the 1930s that was due to a benign pituitary ACTH-secreting adenoma (Cushing, 1932), and it has since come to bear his name. Pituitary adenomas have been found to be the cause of a majority of the cases of Cushing's syndrome. There also is an adrenal Cushing's syndrome, in which elevated concentrations of cortisol are attributable to adrenal gland tumors, hyperplastic adrenal glands, or adrenal glands with nodular adrenal hyperplasia. Hyperadrenocorticism with alterations in ACTH secretion, hyperglycemia, polyuria, polydipsia, and polyphagia is also observed in cats and dogs (more commonly in middle or old age). There are elevations in serum alkaline phosphatase and cholesterol, low urine specific gravity, and proteinuria. Diagnostically, the condition is identified by ACTH stimulation and cortisol analysis and a low dose dexamethasone suppression test (LDDS). In the latter test, the normal decline in cortisol seen after an injection of dexamethasone is not present in dogs with Cushing's disease, and these levels remain high. The tests can, however, generate some false-negative and false-positive results. Some dogs have shown classic signs of hyperadrenocorticism with a typical biochemical profile, but exhibit a normal response to ACTH administration or an LDDS test. This atypical Cushing's disease may be due to increased levels of intermediate steroids within the adrenal steroidogenic pathway. For a more comprehensive presentation of adrenocortical pathology, its diagnosis and treatment in dogs and cats, along with discussions of other endocrinopathies, the reader is referred to the text, "Endocrinology for the Small Animal Practitioner" by Panciera and Carr (2006).

As in humans, the hyperadrenocorticism can be due to hyperplastic changes in the pituitary or adrenals (reviewed by Feldman and Nelson, 1994; Meij et al., 1997; Chiaramonte and Greco, 2007). Rats have also been reported to exhibit an adrenocortical hyperplasia (Kaspereit-Rittinghausen et al., 1990). In horses, a Cushing's-like syndrome, characterized by excessive ACTH secretion, is due to a benign tumor of the pituitary pars intermedia (for review, see Love, 1993; Schott, 2002).

In the rat brain hippocampal dentate gyrus, granule cells are enriched with glucocorticoid receptors. It appears that these cells require corticosterone levels to be within a physiological range, since in the absence of corticosteroids, apoptotic cell death is enhanced (Joëls, 2007). However, a prolonged excess of corticosterone will suppresses neurogenesis in the region and could make the cells more vulnerable to delayed cell death (Sapolsky et al., 1988; McEwen and Magarinos, 1997) and impair learning (Luine et al., 1994).

The H-P-G axis will show suppression in activity in response to stress. Cycling rodents and nonhuman primates with normal menstrual cycles may stop ovulating (e.g., Roozendaal et al., 1995; Cameron, 1997). Central administration of CRH inhibits pulsatile LH (Rivier and Vale, 1984; Williams et al., 1990), and the effect can be reversed by antagonists to CRH (Tsukahara et al., 1999). This suppression appears to be mediated, at least in part, by CRFR2 receptors, since the central administration of urocortin II, which specifically binds to these receptors, resulted in a dose-related inhibition of the pulses (Li et al., 2005).

23.4.3.3 Hypothalamic-Pituitary-Thyroid Axis

The thyroid is one of the largest endocrine glands in the body. Interest in its functions as a focal point in human health and disease dates back to the middle ages, when surgical explorations in pigs were conducted at the southern Italian Medical School of Salerno (Scuola Medica Salernitana), modern civilization's oldest school of medicine (see de Divitiis et al., 2004; Bifulco and Cavallo, 2007). Similar to the gonads, thyroid activity is under hypothalamic-pituitary control, functioning within a classic physiological axis that comprises signaling among thyrotropin-releasing hormone, TSH and the two thyroid hormones, thyroxine and triiodothyronine (Figure 23.9).

23.4.3.3.1 Thyrotropin-Releasing Hormone

Hypophysiotropic thyrotropin-releasing hormone (TRH) neurons are located in the periventricular region of the hypothalamus. The hormone, whose primary structure pGlu-His-Pro-NH₂ is conserved across vertebrates, undergoes processing in the cell bodies from a translated prohormone and is axonally transported to the median eminence region. There, it is released in the portal vessels and binds to receptors on pituitary thyrotrophs, triggering secretion of TSH. Using GH₃ rat anterior pituitary cells, two TRH receptor isoforms have been reported that appear to be functionally comparable (de la Peña et al., 1992). TRH neurons receive input from various neuronal populations, coordinating effects on feeding behavior and energy homeostasis, autonomic regulation, thermogenesis, and locomotor activation (reviewed by Lechan and Fekete, 2006; Chiamolera and Wondisford, 2009). In addition to its stimulatory effect on TSH, this hormone is also able to trigger Prl release from pituitary lactotrophs (e.g., Takahara et al., 1974; Chen and Meites, 1975; Smith and Convey, 1975).

23.4.3.3.2 Thyroid-Stimulating Hormone

TSH is a glycoprotein secretory product of pituitary thyrotrophs. As is the case for LH and FSH, TSH possesses a common α -subunit, with the β -subunit conferring receptor specificity. Free α - and β -subunits, however, have essentially no biological activity. Moreover, TSH is also produced and released into the circulation as multiple isoforms with different oligosaccharide configurations. The half-life in the rat of deglycosylated bovine TSH has been reported to be 3.8 minutes (Constant and Weintraub, 1986), although as for the other glycoprotein hormones, the number will be influenced by the extent of glycosylation. However, the prolongation in half-life with increased glycosylation is correlated with a diminished intrinsic bioactivity (Szkudlinski et al., 1993).

Circulating TSH is commonly used as a reliable index of thyroid status in humans and various other mammalian species. That said, it should be reemphasized that competitive immunoassays employing different antibodies can yield quite discrepant results, so it is important that the values for referenced normal ranges be generated using the same primary antibody. TSH functions primarily to stimulate the synthesis and release of thyroid hormones by binding to receptors on the surface of thyroid epithelial cells. One critical component of the TSH receptor is the presence of a disialoganglioside glycolipid, which forms a tight complex with the glycoprotein component of

FIGURE 23.9 Representative rat hypothalamic–pituitary–thyroid endocrine axis showing relationships among thyrotropin-releasing hormone (TRH), thyroid stimulating hormone (TSH), and the thyroid hormones (THs) T₃ and T₄, with TH feedback to brain and pituitary, along with an additional arrow indicating TH impacts on other tissue and organ systems. As in Figures 23.3 and 23.7, central modulatory effects from neurotransmitters and neuropeptides are indicated.

the receptor and is involved in the coupling of the receptor to its second messenger complex (Kohn et al., 1989). The binding of TSH to the receptor initiates the first step in the thyroid hormone synthetic process—the uptake of iodide from the blood by the thyroid gland. In addition, TSH is also involved in the regulation of skeletal morphogenesis and remodeling (see Iqbal et al., 2009 for review of this role).

23.4.3.3.3 *Thyroid Hormones: Thyroxine (T4) and Triiodothyronine (T3)*

Thyroid epithelial cells have an iodide trap or sodium-iodide symporter on their outer plasma membrane that serves to convey iodine into the cell. The synthesis of the thyroid hormone thyroxine (T4) by the enzyme thyroperoxidase is based upon the iodination of tyrosines on a large epithelial cell glycoprotein, thyroglobulin. This glycoprotein prohormone is the most abundant protein in the thyroid and is the only protein in the mammalian body to contain significant amounts of iodine. Thyroperoxidase acts on thyroglobulin to generate T4 from two iodotyrosines. The more biologically active thyroid hormone, triiodothyronine or T3, is produced within the thyroid gland and in extrathyroidal tissues by a deiodination of T4 (reviewed by Köhrle et al., 1999). A large percentage of circulating T4 is bound to proteins in the serum. In dogs, for example, only about 0.1% in the blood is present in the free form (Ferguson, 1995). The major carrier of thyroid hormones in humans and nonhuman primates is thyroxine-binding globulin (TBG). Dogs have only about 15% of the TBG present in humans, while cats and rabbits have none and instead show binding to a thyroxine binding prealbumin (Larsson et al., 1985). In rats, TBG shows an initial postnatal surge, but then is virtually absent in the adult (Rouaze-Romet et al., 1992), with T4 principally bound to transthyretin and the prealbumin (Chanoine et al., 1992).

In the pituitary, the activity of T4-5'-deiodinase type II (T4-5'-DII) is primarily responsible for the conversion of T4 to T3, and the presence of T3 concentrations there is the main inhibitor of TSH secretion (e.g., Larsen et al., 1981). In addition, both T3 and T4 feed back directly on TRH neurons within the brain periventricular nucleus to inhibit the biosynthesis of pro-TRH (Dyess et al., 1988; Kakucska et al., 1992). Hypothyroidism, then, will cause both an increase in the content of pro-TRH mRNA in this area and an elevation in blood levels of TSH (Segerson et al., 1987). Overall, the deiodination of T4 also generates a number of iodothyronines. Both diiodothyronines (T2) and a monoiodothyronine (T1) are present in the circulation (DiStefano and Feng, 1988), but are physiologically of minor importance. An isomer of T3, termed reverse triiodothyronine (rT3) is also generated that has been found to be a potent inhibitor of T4-5'-DII (St Germain, 1986; Gavin et al., 1988).

In rat, the half-life of the thyroid hormones is significantly affected by their binding to the above-mentioned serum proteins. It ranges up to 24 hours for T4 and approximately 6 hours for T3, much shorter than the 5–9 days and 1 day reported, respectively, for T4 and T3 in humans (Tucker, 1997; Jahnke et al., 2004). The metabolism and action of thyroid hormone takes place within the cell, and the uptake of T4 and T3 into cells within different tissues is facilitated by the participation of several forms of transporters. A number of those transporters belong to the monocarboxylate family, so named because the first four members of the family are able to transport lactate and pyruvate (Halestrap and Meredith, 2004). One member, monocarboxylate transporter 8 (MCT8), has been found to be an active transporter of thyroid hormones in rats (Friesema et al., 2005). Within the cell, the thyroid hormones interact with their nuclear receptor and then bind to specific recognition sequences on DNA, resulting in a transcription/translation of DNA/RNA to increase protein synthesis specific for that cell. In the rat, thyroid hormone receptors are present in two primary isoforms, with splice variants of different amino acid lengths existing for each (Tomura et al., 1995).

Thyroid hormones are important for normal growth and development, regulating intermediary metabolism in order to maintain metabolic stability. They are involved in mitochondrial oxygen consumption and gene expression (Mutvei et al., 1989a,b; Wrutniak-Cabello et al., 2001), thermogenesis (e.g., Dauncey, 1990; Bianco et al., 2005), and serve as a major physiological regulator of mammalian brain, bone, and body development, coordinating diverse developmental events (e.g., Anderson et al., 2003; Bassett and Williams, 2008; Sanders and Harvey, 2008). For example, T3

appears to be important in the proliferation and further differentiation of precursor brain cerebellar GABAergic cells (Manzano et al., 2007). Thyroid hormones are critical to neuronal migration, myelination (Gravel et al., 1990; Schoonover et al., 2004), and synaptogenesis in the developing brain. The process of neuronal migration involves the presence of an actin cytoskeleton, and it now appears that T4 and rT3 function nongenomically to modulate this organization (Farwell et al., 2005; Leonard, 2008). In this context, T3, the transcriptional activator, is inert. On the other hand, T3 is acknowledged as a major regulator of mitochondrial activity, and mitochondrial T3 receptors have been identified (e.g., Scheller et al., 2003; Psarra et al., 2006). The hormone is also able to upregulate the number of β -adrenergic receptors in cells of the heart, increasing their sensitivity to catecholamines (Bahouth, 1991).

23.4.3.3.4 Pathological Alterations in the H–P–T Axis

Pathological alterations in thyroid activity can be genetically based, a consequence of chemical exposure, or assigned categorically to uncertain etiology. The most common hormonal dysfunctions seen by veterinary medical personnel in both dogs and cats are thyroid disorders. In dogs, autoimmune thyroiditis appears to be present in the great majority of cases and has a genetic basis (Bush, 1969). Autoantibodies can be present against thyroglobulin, thyroid hormones, and thyroid peroxidase. But because T4 and T3 are small molecules, they will not by themselves cause an immune response, and a thyroid hormone epitope must be linked to an immunogenic molecule like thyroglobulin.

In hypothyroidism, low thyroid hormone concentrations typically fall well before outward signs (e.g., weakness, lethargy, weight gain, hair loss, cardiac arrhythmias, gastrointestinal disorders, diarrhea, and vomiting) appear. TSH concentrations are elevated, which is at least partly attributable to an increase in TSH subunit transcription (Shupnik and Ridgeway, 1985) and partly to an enhancement in TSH glycosylation (DeCherney et al., 1989) prolonging the metabolic clearance of the hormone. Testing for the condition can be performed after puberty and during the quiescent anestrus period of the cycle in female dogs, when the influence of sex steroids is minimal. A TSH test, given primarily to dogs and horses, involves an intravenous administration of bovine TSH, which can often provide a clear distinction between a euthyroid condition and hypothyroidism. Thyroid hormones are then sampled at particular times postdosing (Beale et al., 1990; Sojka et al., 1993), revealing that hypothyroid animals are relatively nonresponsive to TSH administration.

In cats, hypothyroidism is rarely present, while hyperthyroidism is the thyroid disorder more commonly seen in the clinic, occurring most often in older animals. It can be present in males and females, neutered or intact. This hyperthyroid condition is dissimilar from the autoimmune hyperthyroid Graves disease and appears to be linked to an excessive growth of some thyroid cells (Peterson, 2014). The condition causes weight loss, an increase in blood pressure, cardiac arrhythmia, hyperactivity, polyuria, kidney damage, and intestinal problems (Bustad and Fuller, 1970; Peterson et al., 1983). Often an enlargement of the heart, vomiting and diarrhea are present. T4 concentrations can be as high as threefold greater than normal, although a growing number of cats have clinical signs of hyperthyroidism, with enlarged thyroid glands, but have baseline serum total thyroid hormone values within the normal or borderline range (Peterson et al., 1987). While TSH is normally able to induce a marked increase in thyroid hormone secretion, hyperthyroid cats will typically show minimal elevations after administration of bovine TSH (Mooney et al., 1996). This lack of a robust response has been attributed to either a dysregulation in the relationship between TSH and T4, or to a near maximal rate of T4 production that has depleted its reserve capacity.

Goiter has been identified in all domestic mammals and is a non-neoplastic, noninflammatory enlargement of the thyroid gland. There is a hyperplasia of thyroid follicular cells that can be a response to diets deficient in iodine, an iodide excess, or inherited enzymatic defects in thyroid hormone synthesis, all of which will result in a decrease of circulating thyroid hormones and a responsive increase in TSH. In adults, goiter typically does not have the clinical impact that the

condition does in the developing fetus or newborn, and an iodine deficiency can be treated with iodized salt. Large goiters in pregnant females can prolong gestation, and the fetal placenta is often retained. Newborns frequently show hair loss and have an increased incidence of mortality. For a more comprehensive review of the thyroid and thyroid disorders, the reader is referred to Capen and Martin (2003).

Some rat strains are genetically susceptible to autoimmune thyroiditis. This is true for inbred Biobreeding rats (e.g., Wilson et al., 1990b) and, when provided with excessive amounts of dietary iodine, the Buffalo rat (Cohen and Weetman, 1988). However, most of the published descriptions of rodent thyroid disorders have been from chemically induced alterations. It is their ability to decrease circulating concentrations of thyroid hormones, by affecting their biosynthesis, storage, transport or catabolism that has been the defining characteristic of thyroid toxicants (Brucker-Davis, 1998). Perchlorate has been found in the groundwater in the near industries of the United States that involved in the manufacture of rockets, explosives, and fireworks (Motzer, 2001). Its toxicity appears to be caused by an inhibition in thyroid iodide uptake (Van Sande et al., 2003); in the rat, increasing doses will disrupt homeostasis in the hypothalamic–pituitary–thyroid (H–P–T) axis (Wolff, 1998). However, there are species differences in the susceptibility to perchlorate, with rats being much more susceptible to thyroid disruption than rabbits (Lewandowski et al., 2004).

Probably the best known of the thyrotoxicants is 6-propyl-2-thiouracil (PTU). It is used pharmaceutically in humans to treat hyperthyroidism (including Graves disease), decreasing the amount of thyroid hormone produced by the thyroid gland. It inhibits the activity of thyroperoxidase that catalyzes the addition of iodide to tyrosine residues on thyroglobulin thereby generating T₄ (Shiroozu et al., 1983). In animal research, it has been employed as the prototypical thyroid toxicant, either as a positive control in toxicological studies or for investigations of thyroid hormone physiology. Its effect, however, is not likely restricted to thyroid function. There have been reported alterations in the steroidogenic pathway (Chiao et al., 2002; Chen et al., 2003, 2010), and PTU can cause disruptions in the rat estrous cycle (Hatsuta et al., 2004). Thyroidectomy will also cause similar cyclic alterations in both rat (Hatsuta et al., 2004) and Japanese macaque (Nozaki et al., 2002). In ewes, fertility was reduced, but not completely eliminated, suggesting to the authors that there was a reduction in gonadal hormones and possibly gonadotropins (Brooks et al., 1964). At least in rats, the impact on cyclicity was reversed after T₄ administration, a treatment that also improved the fertility of hypothyroid males of the mutant *rdw* line (Jiang et al., 2000), implying a role for thyroid hormones in the regulation of reproductive activity.

A variety of other chemicals, both pharmaceutical and environmental, have been shown to affect circulating levels of thyroid hormones. As pharmaceuticals, the abovementioned perchlorates have been used to treat thyroid disorders for more than 50 years (e.g., Godley and Stanbury, 1954; Crooks and Wayne, 1960). Along with their use as oxidizers in rocket fuel and explosives, potassium perchlorate and ammonium perchlorate are employed extensively within the pyrotechnics industry. They have been found to be inhibitors of the sodium-iodide symporter, blocking the uptake of iodide into the cell. Polychlorinated biphenyls (PCBs) have been reported in rats to decrease thyroid hormone concentrations and induce ultrastructural lesions in thyroid follicular cells, effects that were time- and dose dependent (e.g., Collins et al., 1977; Kasza et al., 1978). There is some evidence that the decrease in circulating thyroid hormones is linked, at least partly, to an increase in hepatic metabolism (Bastomsky and Murthy, 1976; Yang et al., 2008) and/or a tissue accumulation (Kato et al., 2007). The herbicide, thiazopyr, has been found to cause rat thyroid follicular-cell tumors by a putative effect on thyroid homeostasis. The postulated pathway of effect (Dellarco et al., 2006) begins with an induction of hepatic T₄-uridine diphosphate glucuronyl transferase (UGT) activity, leading to a subsequent increase in T₄ metabolism. T₄ levels then fall, triggering an increase in pituitary TSH synthesis and secretion. A prolonged elevation in concentrations of circulating TSH causes a similar increase in thyroid hormone production and receptor-mediated follicular cell hypertrophy and potential hyperplasia (e.g., Thomas and Williams, 1999).

23.4.3.4 Growth Hormone Axis

The classic characterization of the GH axis encompasses, at core, hypothalamic growth hormone releasing hormone (GHRH), pituitary GH, and a hypothalamic GH release-inhibiting hormone (GHIH) or somatostatin. The organization of these relationships is unlike the H–P–G, H–P–A, and H–P–T axes in that it is not based on a tripartite regulatory structure involving three distinct organs. Its signaling activity fundamentally involves endocrine interrelationships among the two hypothalamic releasing and inhibiting hormones and the pituitary, in addition to regulatory input from a number of brain-gut peptides. Figure 23.10 shows a simplified depiction of various interrelationships. For a more detailed discussion of the axis, the reader is referred to a review by Giustina and Veldhuis (1998).

23.4.3.4.1 Growth Hormone Releasing Hormone

GHRH is a peptide related to the “brain-gut” family of peptides. Members include glucagon, gastric inhibitory peptide, vasoactive intestinal polypeptide, and the intestinal peptide secretin. It is initially produced as a prohormone, primarily in neurons residing within the hypothalamic arcuate nucleus. GHRH neurons have also been found in other brain regions (i.e., ventromedial nucleus, periventricular nucleus, and amygdala (Muller et al., 1999), from which GHRH projections have no direct involvement in the control of pituitary secretion. It has also been detected in the pancreas (Bosman et al., 1984) and human gastrointestinal tract (Shibasaki et al., 1984).

GHRH plays a critical role in the cellular proliferation of pituitary somatotrophs during development and stimulates the synthesis and secretion of GH from secretory granules in these cells by binding to its transmembrane receptor, a member of cytokine receptor superfamily. GHRH receptor expression in the rat pituitary is sexually dimorphic (Ono et al., 1995; Mayo et al., 2000), suggesting that this may contribute to the sex difference observed in postpubertal GH secretion. In addition to its effect on GH synthesis and secretion, GHRH has been reported to augment the stimulation by FSH of ovarian granulosa cell steroidogenesis (Moretti et al., 1990) and amplify the effect of gonadotropins on male testicular Leydig cells (Ciampani et al., 1992). Although the role of GHRH is fundamental to the activity of the GH axis, other assessments of functioning within this axis are employed diagnostically.

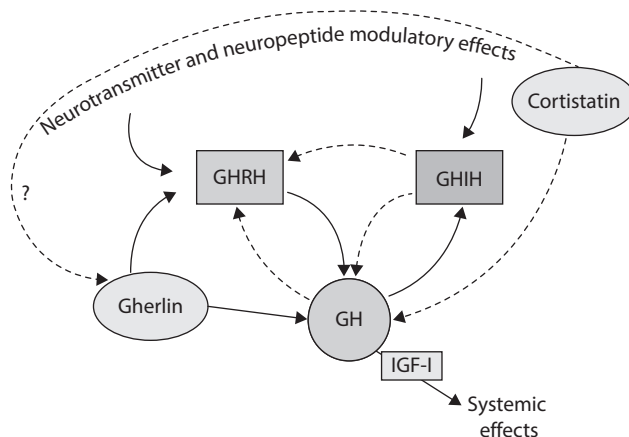

FIGURE 23.10 Generalized depiction of relationships among hypothalamic growth hormone releasing hormone (GHRH), somatostatin or growth hormone inhibitory hormone (GHIH), and pituitary GH, along with input from circulating gastric ghrelin, brain cortistatin, and other modulatory neurotransmitters and neuropeptides. GH influence on growth and metabolism are mediated via effects on insulin-like growth factor-1 (IGF-1). Unbroken lines with filled arrowheads indicate stimulatory effects, whereas dotted lines with open arrowheads show reported inhibition.

23.4.3.4.2 *Somatostatin (Growth Hormone Inhibiting Hormone)*

In this axis, somatostatin and GHRH have been depicted as classic opposing forces in the regulation of GH. However, the regulatory mechanisms influencing GH release involve levels of various factors beyond a straightforward stimulation and suppression by these two peptides. A range of neurotransmitters (e.g., norepinephrine, GABA, and glutamate) and neuropeptides (e.g., TRH, CRH, galanin, and neuropeptide Y [NPY]) are now known to exert functional control over GH. In addition to coverage of TRH and CRH as part of the respective H–P–T and H–P–A axes, two of these neuropeptides, ghrelin and cortistatin will be briefly discussed in Section 23.4.3.4.4.

The peptide somatostatin is synthesized as two bioactive peptides (SRIF-14 and SRIF-28) in populations of neurons located within various hypothalamic areas, including the periventricular and paraventricular nuclei, along with scatterings in the suprachiasmatic, arcuate, dorsomedial, and ventromedial regions. Fibers from periventricular and paraventricular somatostatinergic neurons project to the median eminence, where the hormone is released into the portal vessels. Upon reaching the pituitary, somatostatins bind to the members of a family of five somatostatin receptor subtypes (SSTR1–5) (e.g., Guillermet-Guibert et al., 2005). The receptors are located on various types of pituitary cells, and there appears to be some differential specificity for the somatostatin peptides. While SSTR1–4 have been reported to show similar affinities for both SRIF-14 and SRIF-28, SSTR5 has a greater affinity for SRIF-28 (Reisine and Bell, 1995).

The simplified depiction of the GH axis depicted in Figure 23.10 showing interrelationships among GHRH, somatostatin (GHIH), and GH, with inputs from ghrelin and cortistatin (see section 23.4.3.4.4), also includes the umbrella category of modulatory factors (mentioned above) found to colocalize with GHRH or GHIH perikarya/fibers (for review, see Muller et al., 1999; Cocchi et al., 1999; Fodor et al., 2006).

23.4.3.4.3 *GH and Insulin-Like Growth Factor*

Mammalian GH is present in multiple isoforms generated during posttranslational processing. These isoforms may exist as monomers, or various oligomers composed of noncovalently associated or disulfide-connected isoforms (Baumann, 2009). Under basal conditions, approximately 50% of circulating GH is bound to growth hormone binding protein (GHBP). GHBP serves as a buffer/reservoir for the GH isoforms, prolonging their half-lives in plasma (Baumann, 2001). As previously mentioned, GH secretion shows bursts of release and in the rat exhibits a sex difference, with male peak-to-valley excursions much larger than those seen in females. The bursts in males are unchanged throughout the day and night, while female rats shift at night from more extended secretory valleys to rapid, short duration bursts of increased amplitude (Clark et al., 1987). This pulsatile secretion can also be seasonally dissimilar. For example, during the autumn and early winter (April–June in the southern hemisphere), red deer stags had frequent GH pulses of low amplitude. In contrast, the amplitude of pulses in spring (August and September) were higher and more frequent, resulting in a high mean plasma level of circulating GH, effects that were tied to an increase in antler growth (Suttie et al., 1989).

Dog breeds can differ markedly in circulating concentrations of both GH and IGF-1. In large breeds, the relatively extended persistence of elevated levels of GH and IGF-1 at a young age is a primary factor in their increased body size (e.g., Eigenmann et al., 1984; Rijnberk et al., 2003). In poodles, the short stature of the miniature breed is associated with low serum levels of IGF-I. Standard poodles are taller and have considerably higher serum levels of IGF-1 (Guler et al., 1989).

The receptor for GH belongs to the superfamily of transmembrane proteins that includes the Prl receptor and a number of cytokine receptors. GH causes a dimerization of this receptor at the cell surface and this appears to be a prerequisite for biological activity of the hormone (see Postel-Vinay and Finidori, 1995 for review). The extracellular domain of the full-length membrane receptor is

also found soluble in the circulation and has been identified as the above-described GH-binding protein (Postel-Vinay, 1996).

23.4.3.4.4 *Ghrelin and Cortistatin*

Ghrelin (from *ghre*, the Indo-European root of the word grow) is a peptide that is produced mainly in the stomach, but has also been found to be expressed in the hypothalamus, pituitary, gonads, intestine, kidney, pancreas, and heart. It is a member of a group of brain-gut peptides that have GH-stimulating properties, although the effects are not limited to GH; ghrelin is also able to stimulate the secretion of pituitary Prl and CRH (Arvat et al., 2001; Wren et al., 2002). It acts as an appetite stimulant by what appears to be a complex response that involves an increase in NPY (see Section 23.4.4.7) and inhibition of POMC (Toshinai et al., 2003). Ghrelin and other growth hormone secretagogues (GHS) are endogenous ligands for a previously discovered orphan receptor, originally cloned in 1996 and now abbreviated as GHS-R. GHS-R is also expressed in the hypothalamus, pituitary, neuronal cells of the gut, stomach tissue, gonads, and heart, in addition to adrenals, thyroid, spleen, and pancreas (Shuto et al., 2001; Gnanapavan et al., 2002), suggesting that the GHS peptides have paracrine effects.

Cortistatin was initially identified in rat as a cortical hormone structurally related to GHIH/somatostatin, and its mRNA was reported to be restricted to GABA neurons in the cerebral cortex and hippocampus (de Lecea et al., 1997), but also appears, with somatostatin, to be present in cells of the immune system (Dalm et al., 2003). Cortistatin binds with high affinity to all of the somatostatin receptor subtypes, and like somatostatin, it inhibits in vivo GH release in man and rats (Luque et al., 2006). It also has been found, at least in humans, to bind to GHS-R and inhibit ghrelin secretion (Broglia et al., 2002), an effect not seen for GHIH/somatostatin, adding an additional layer of regulatory complexity to the GH axis.

23.4.3.4.5 *Pathological Alterations in the GH Axis*

Acromegaly is characterized by a chronic excessive secretion of GH by the pituitary. Although infrequently seen in cats, the most common cause in these animals is a hypophyseal tumor, which when present can often occur with a GH-induced insulin-resistant diabetes mellitus (e.g., Hurty and Flatland, 2005; Niessen et al., 2007). The detection of elevated circulating concentrations of both GH and IGF-1 are both useful in the diagnosis of the condition.

GH undersecretion in dogs is relatively uncommon, but can occur in adults and puppies. In the puppy, it results in dwarfism, while hair loss is the major symptom in adults. In cats, progestins can stimulate the production of GH from mammary tissue and the induction of mammary fibroadenomas (Mol et al., 2000). This is also true for dogs. As opposed to pituitary GH secretion, progestin-induced mammary GH is not released in a pulsatile pattern, and is not stimulated by GHRH or inhibited by GHIH/somatostatin (Mol et al., 1996). Acromegaly is also seen in dogs, but the condition is more commonly attributable to progesterone-induced hypersecretion of GH from mammary tissue and not to a pituitary tumor, as seen in cats. In this case, a demonstration of an inability to suppress these high GH levels is important for the diagnosis (Eigenmann, 1984), and the condition can be treated with a progesterone receptor antagonist (Bhatti et al., 2006). In contrast, the induction of mammary GH production by progestin administration has been employed for the treatment of GH deficiency (Rijnberk et al., 2003).

As the main regulator of IGF-1 production, GH may also be an important factor in the incidence of at least some types of mammalian cancer (e.g., Waters and Conway-Campbell, 2004). Experiments in the rat have shown that advanced mammary cancers are dependent on GH and/or IGF-1 for their survival (Shen et al., 2007). Moreover, GH receptors are expressed, for example, in a number of canine mammary tumor cell types (Van Garderen et al., 1999). The administration of GHRH receptor antagonists has been reported to decrease serum and tumor IGF-1 and inhibit the growth of and enhance apoptosis in estrogen-independent methotrexate (MTX) mouse mammary

cancers (Kahan et al., 2000; Szepeshazi et al., 2001). GH production can be induced by progestins in the dog mammary gland (Selman et al., 1994), and female dogs treated with progestins show in a dose-dependent development of mammary tumors, suggesting a potential role of GH in the tumor formation. Such interactions in various mammalian species among local mammary progesterone, GH, and the GH receptor have also contributed to the debate on the risk of breast cancer in postmenopausal women on hormone replacement therapy (reviewed by Rijnberk et al., 2003).

23.4.4 OTHER HORMONES

The list of endogenous biochemicals acting as endocrine factors has been continuously expanding. However, rather than attempting to be all-encompassing, this section will focus on a shorter list of additional hormone/endocrine factors that have been shown to be important participants in various physiological activities.

23.4.4.1 Prolactin

Prl is a pituitary peptide hormone that is principally secreted by the lactotropes. It is closely related to GH and belongs to a large family that, in addition to these two hormones, also includes placental lactogens and Prl-like proteins. As had been found for GH, changes in Prl occurred more rapidly during a period of primate evolution, leading to marked differences in amino acid sequences between human and nonprimate mammalian Prl (Wallis et al., 2005). In addition to its presence in lactotropes, Prl has also been found to colocalize with GH in a small population of anterior pituitary cells termed mammosomatotrophs (Nikitovitch-Winer et al., 1987; Yeung et al., 2006). It appears likely that both were the result of duplication of an ancestral gene. As is the case for the other pituitary peptide hormones, Prl is synthesized as a prohormone and posttranslationally cleaved. In male rats, it has a reported half-life of about 7 minutes (Chi and Shin, 1978).

The conventional role of Prl, for which it was named, is the stimulation of lobuloalveolar growth in the mammary gland and milk production by the alveoli. However, its metabolic actions are much more widespread, and its functions can be subsumed under two general headings, reproduction and homeostasis. Prl has been demonstrated to have a role in the transition to sexual maturity in female rats. When introduced into the median eminence region of immature females, it was able to advance puberty (Clemens et al., 1969). In contrast, a chronic suppression of Prl from prepubertal day 22 onward caused a marked delay (Advis et al., 1981).

In addition to its lactational role in reproduction, Prl has a luteotrophic function in some species. For example, in rodents, dogs, and skunks, it is required for pregnancy maintenance. Rodents, for example, exhibit diurnal and nocturnal surges of Prl that are required during the early stages of the pregnancy to sustain necessary progesterone secretion from the corpora lutea. Prl may also be luteolytic and induce programmed cell death in the rat corpora lutea if copulatory cervical stimulation does not occur (Wuttke and Meites, 1971). The influence of Prl on parenting behavior has been extensively studied, most frequently in the rat, and its effect has been reported for mice, rabbit, hamsters, and sheep (Bridges, 1994; Numan, 1994). The hormone is also involved in a variety of other functions, including the suppression of lipid storage, growth support of pancreatic islets, stimulation of insulin secretion, and an increase in citrate production in the prostate (reviewed by Ben-Jonathan et al., 2006).

Prl has also been observed to have marked effects on immune function. Mouse lymph node lymphocytes have Prl receptors (Gala and Shevach, 1993), and antibodies to Prl were shown *in vitro* to inhibit lymphocyte proliferation (Hartmann et al., 1989). In humans, the hormone has been demonstrated to homeostatically enhance the restoration of immunity after chemotherapy and bone marrow transplantation (reviewed by Redelman et al., 2008). Prl has also been reported to have effects on the development of blood vessels and appears to have opposing actions, in that the parent Prl molecule can promote angiogenesis, whereas proteolytic processing results in a peptide fragment that has antiangiogenic properties (Corbacho et al., 2002). Overall, it appears that Prl has a

modulatory role in several aspects of immune function, but data have indicated that it is not strictly required for immune activity.

The neurotransmitter dopamine, released into the portal blood from neurons within the arcuate nucleus that project to the median eminence (the tuberoinfundibular pathway) serves as a negative regulator of lactotrope Prl secretion, binding to the dopamine D2 receptor. TRH, in addition to its role in TSH secretion, will also trigger Prl release (e.g., Takahara et al., 1974; D'Angelo et al., 1975). Beginning in 1998, Hinuma and colleagues first reported the existence of another prolactin-releasing peptide (PrRP), an RFamide family member whose cell bodies were located in the dorsomedial hypothalamus, among other brain regions (Hinuma, 1998; Matsumoto et al., 1999). However, unlike the other classical hypophysiotropic hormones, no immunopositive PrRP fibers were detected in the external layer of the median eminence (Yamakawa et al., 1999), and the Prl-releasing potency of PrRP has been reported to be less than that of TRH (Samson et al., 1998), raising doubts about its physiological importance as a Prl-releasing factor.

The receptor for Prl belongs to the cytokine receptor superfamily, and isoforms have been described in different tissues (e.g., Davis and Linzer, 1989), but having extracellular domains that are identical (Kelly et al., 1991). In the rat ovary, short and long forms of Prl receptor mRNA are present and appear to be involved in different functions during ovulation. It is believed that mRNA for the long form of the receptor is involved in folliculogenesis, whereas mRNA for the short form may play a role in the formation and maintenance of the corpus luteum (Kinoshita et al., 2001).

Chronic hyperprolactinemia can be induced in rats by grafting pituitary fragments under the kidney capsule, removing inhibitory dopaminergic regulation. This protocol has been used to advance puberty in immature female rats (Gonzalez et al., 1984), an effect consistent with the aforementioned administration of Prl into the median eminence. The same protocol for producing elevated levels of Prl was employed in adult male rats and mice and was found to reduce levels of copulatory behavior (Svare et al., 1979). In cycling female rats, the administration of ovine Prl over the course of the estrous cycle completely blocked the LH surge and ovulation (Wise, 1986). Similar results were seen in females inoculated with a Prl/GH-secreting pituitary tumor (Nass et al., 1983). In these rats, ovarian estradiol decreased, while circulating progesterone was elevated.

Dogs have been reported to show an elevation in Prl in a pituitary-dependent hyperadrenocorticism that was considered to be due to a neoplastic transformation of pituitary corticotropic cells that then co-secreted ACTH and Prl (Meij et al., 1997). There also has been speculation that Prl is involved in the growth of mammary tumors in dogs and mice. Mice with grafted pituitary fragments were found to have areas of mammary hyperplasia within dilated ducts (Huseby et al., 1985), and those with transplanted mammary tumors have shown modest responsive growth to the hormone (Koseki et al., 1987). Furthermore, Prl receptors have been found in approximately 28% of dog mammary tumors (Rutteman et al., 1986), and it is possible that, in some dogs, tumor growth may be linked to a hyperresponsiveness of Prl secretion to stimulation (Rutteman et al., 1989). However, the relationship between Prl and tumorigenesis is still unclear.

23.4.4.2 Oxytocin and Vasopressin

In the supraoptic and paraventricular nuclei of the hypothalamus are several thousand magnocellular neurons that project to the neurohypophysis or posterior lobe of the pituitary. Roughly, half of these primarily make one of two hormones, oxytocin, or vasopressin. They are peptide hormones and, similar to others in this class, are initially synthesized as larger prohormones. Both of these hormones are, respectively, stored within large numbers of vesicles in the terminal axonal regions and released in response to electrical action potentials at the terminals. Vasopressin is also synthesized and secreted by the adrenal medulla in many species including humans and is often referred to as *antidiuretic hormone* because one of its principal physiologic effects is the retention of water by the kidney. It also increases the resistance to vascular blood flow, elevating arterial blood pressure. A deficiency in vasopressin or a failure of the kidney to respond to the hormone is the pathological basis for diabetes insipidus.

Oxytocin is one of the most potent agents able to overcome relaxation of the muscular wall of the uterus and in pharmaceutical form has been used clinically to induce labor in mammals. Uterine oxytocin receptors are regulated by the steroid environment (e.g., Soloff, 1975), and before the onset of labor there is an increase in the sensitivity of the uterus to oxytocin that is accompanied by an upregulation of myometrium oxytocin receptors (Gimpl and Fahrenholz, 2001). This is also the case in decidual tissue where the hormone stimulates prostaglandin F₂ α (PGF₂ α) secretion (see Section 23.4.4.5.3). Binding to its receptors in the brain, oxytocin plays an important role in milk ejection (e.g., Nishimori et al., 1996) and establishing maternal behavior around the time of parturition (see Poindron, 2005 for review). It also has been reported to be synthesized in the ovaries and may serve as a luteolytic factor, stimulating prostaglandin (PG) secretion (Luck, 1989). Oxytocin is produced within the mammalian male hypothalamus in similar quantities to the female. In several species, an increase in circulating oxytocin appears to be associated with ejaculation, stimulating smooth muscle cells (Ivell et al., 1997). Studies have also shown that oxytocin is synthesized locally within the testis, where it likely serves, via an autocrine/paracrine action, to modulate steroid metabolism (Nicholson et al., 1991) and affect seminiferous tubule contractibility (Harris and Nicholson, 1998). Recent studies on both vasopressin and oxytocin have focused on their potential roles in social bond formation (e.g., Young and Wang, 2004; Lim and Young, 2006) and speculation that human genetic variations in them may contribute to the dysregulation seen in autism spectrum disorders (Lim et al., 2005; Hammock and Young, 2006).

23.4.4.3 Natriuretic Peptides

Atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), and C-type natriuretic peptide (CNP) are hormonal factors that serve important functions in the regulation of cardiovascular homeostasis, causing both arterial and venous dilatation that serves to control blood pressure and extracellular fluid volume (reviewed by Woodard and Rosado, 2008). They are processed from larger pro-forms, and along with their receptor subtypes, NPR-A, NPR-B, and NPR-C, all are found in the hypothalamus, pituitary, and adrenals. ANP and BNP bind to NPR-A, whereas CNP will preferentially bind to NPR-B and the three peptides have similar affinities for NPR-C. Natriuretic peptides in the hypothalamus have been found to inhibit oxytocin and vasopressin, along with CRH and GnRH (Samson et al., 1993). BNP can increase the glomerular filtration rate and thus alter kidney hemodynamics. Also, ANP and CNP have been identified in the gastrointestinal tract and are able to stimulate basal as well as induced pancreatic secretion and alter the secretion of bicarbonate and chloride (Sabbatini, 2009). Moreover, CNP and NPR-B are present in uterus and ovaries, and marked CNP mRNA expression has been found in the placenta, suggestive of a role in gestation, antagonizing the vasoconstrictive function of angiotensin II (Walther and Stepan, 2004; see Section 23.4.4.6).

There are indications that elevations in one or more of these natriuretic peptides can serve as useful indicators of cardiac pathology. Dogs and cats with clinical signs of heart failure were found to have had significantly elevated pro-forms of ANP and BNP (Boswood et al., 2003; Connolly et al., 2008; Tarnow et al., 2009). Whereas, these pro-natriuretic peptides may be informative as biomarkers, recent research has suggested that BNP infusion can have beneficial effects on cardiac functioning following the induction of acute myocardial infarction (He et al., 2009; George et al., 2010).

23.4.4.4 Neurotransmitters as Endocrine Agents

Neurotransmitters had traditionally been described as local tissue factors located and released in the brain that convey an impulse from one nerve cell to another by means of an association with specific receptors. However, the distinction between local tissue factors and blood-borne secretions acting at a distance has become less clear. Some neurotransmitters are now known to fill both roles. The classic neurotransmitter dopamine is concentrated within various brain regions and has been reported to participate in motor activity, attention and learning, sleep, and reward. In terms of a traditional role as a hormone, it was previously mentioned to

be an inhibitory regulator of Prl secretion. It is released from nerve terminals in the median eminence for transport in the portal blood to the anterior pituitary, where it binds to one particular form of the five identified dopamine receptors, the D2 variant. Dopamine is generated within a synthetic pathway that is shared by epinephrine and norepinephrine. L-tyrosine is first converted to L-dihydroxyphenylalanine (L-DOPA) by the enzyme tyrosine hydroxylase (Figure 23.11a). DOPA decarboxylase then catalyzes L-DOPA to form dopamine, which in the presence of dopamine- β -hydroxylase, can be further converted to norepinephrine (noradrenaline [NE]). Epinephrine (adrenaline) can then be generated by the action of phenylethanolamine *N*-methyltransferase (PNMT). Dopamine and norepinephrine are two of the principal transmitters in the brain. Although it is primarily localized in the adrenal medulla, PNMT activity has also been demonstrated in kidney, spleen, lung, skeletal muscle, thymus, retina, and different parts of the brain (e.g., Ziegler et al., 2002).

In the brain, NE functions as a classical neurotransmitter, modulating the activity of the hypothalamic components of the aforementioned axes (see Figures 23.3, 23.7, and 23.8; e.g., Kalra and Kalra, 1983; Tapia-Arancibia et al., 1985; Alonso et al., 1986; Malozowski et al., 1990; Goldman et al., 2008). Its modulatory responses can be excitatory or inhibitory, and in some cases noradrenergic input provides a necessary permissive tone that allows other processes to proceed. Perturbations of NE in either direction can be disruptive. Acute stress can activate noradrenergic neuronal pathways extending to various brain regions from cell populations residing in the area of the brain stem locus coeruleus that, along with adrenal secretory activity, elicit a variety of neuroendocrine, autonomic, behavioral, and cognitive participants in the organism's response to stress (for review, see Morilak et al., 2005). Chromaffin cells in the adrenal medulla synthesize and secrete both NE and epinephrine, whereupon the two chemicals act as blood-borne hormonal factors that (1) increase heart rate, (2) stimulate lipolysis in fat cells, contributing fatty acids to the production of energy, (3) induce lung bronchiole and pupil dilation, (4) cause widespread vasoconstriction that elevates arterial blood pressure, and (4) increase the body's metabolic rate.

NE binds to two main groups of adrenergic receptors, α or β , each of which has several subtypes. α 1 and α 2 receptors are principally involved in smooth muscle contraction, causing vasoconstriction in many blood vessels. In addition to vasoconstriction, α 1 receptors participate in GnRH secretion (Le et al., 1997), the inhibition of insulin release in pancreas (e.g., Drews et al., 1990; Debuyser et al., 1991) and induction of glucagon release from the pancreas (e.g., Vieira et al., 2004). The involvement of β -adrenergic activity in cardiac function has been known for some time, and a persistent elevation in β -adrenergic receptor stimulation is believed to contribute to congestive heart failure (Lefkowitz et al., 2000).

The monoamine serotonin (5-hydroxytryptamine [5-HT]) has traditionally been identified as a neurotransmitter that is synthesized in brain stem neurons from the amino acid L-tryptophan (Figure 23.11b). These neurons extend throughout the central nervous system and comprise an expansive neurochemical network. In addition to the central nervous system, serotonin is present in the intestinal wall (e.g., Hansen and Witte, 2008) and large blood vessels (e.g., Ramage and Villalón, 2008). Functionally, it is involved in the control of appetite, sleep, memory, and learning, temperature regulation, cardiovascular function, muscle contraction, and the regulation of other endocrine factors. In humans, a large number of publications have shown a link to mood and depression (see Lowry et al., 2008 for review). As an endocrine factor itself, serotonin acting through 5-HT2B receptors has a role in bone metabolism (Collet et al., 2008) and gastrointestinal cell proliferation (Wouters et al., 2007). Serotonin associations with this same receptor subtype have also been reported to contribute to pulmonary cell proliferative activity (Esteve et al., 2007). Both serotonin receptors and estrogen receptors are present in cells within various tissues, and it has been argued that many estrogenic effects in these tissues may be mediated by estradiol's stimulative effect on serotonin synthesis (Rybaczyk et al., 2005). Neuronal projections of serotonergic fibers from the brain stem raphe nuclei to the basal hypothalamus are known to cause elevations in pituitary Prl

FIGURE 23.11 (a) Catecholamine synthetic pathway from tyrosine to epinephrine. For individual tissues and organs, the particular end-product within the pathway will depend on the presence of the enzymes necessary for its synthesis. For example, since dopamine- β -hydroxylase is absent within the brain caudate nucleus, the predominant catecholamine neurotransmitter, there, is dopamine. L-DOPA = L-3,4-dihydroxyphenylalanine. (b) Synthesis of the neurotransmitter serotonin (5-hydroxytryptamine) from the amino acid tryptophan that first undergoes hydroxylation followed by decarboxylation.

secretion (Fessler et al., 1984), an effect mediated through the 5-HT₄ receptors that likely involves a disinhibition of dopamine regulation.

The acetylcholine is a neurotransmitter generated from the amino acid choline by the action of choline acetyltransferase. It is involved in autonomic nervous system stimulation of the heart and smooth muscles, in both complementary parasympathetic (muscle relaxation, slowing of heart rate) and sympathetic (heart rate acceleration, blood vessel constriction, and increase in blood pressure) activity. Cholinergic receptors are present in two forms, nicotinic and muscarinic, both of which exist in multiple subtypes. They were named according to their responsiveness to the acetylcholine agonist drugs, muscarine, and nicotine. Although their tissue distributions can overlap, these receptors subserve different functional roles. For a review of the relationships of these two receptors to acetylcholine activity, the reader is referred to chapters by Sastry and Robertson (2004) and Taylor (2004), both in the same volume.

23.4.4.5 Prostaglandins

PGs are a family of lipid messenger molecules derived from the enzymatic activity of cyclooxygenase (COX) and specific PG synthases on arachadonic acid. They belong to the larger category of eicosanoids, which includes thromboxane and leukotrienes, and all participate in inflammatory responses. COX activity generates prostaglandin H₂ (PGH₂), which serves as the common precursor for the other PGs and thromboxane A₂ (Figure 23.12). A number of leukotrienes have been identified. Of those, leukotriene B₄ is a strong chemoattractant for leukocytes, whereas leukotrienes C₄, D₄, and E₄ act to constrict smooth muscle and increase vascular permeability. Thromboxane A₂ is also a vasoconstrictor and proaggregatory chemical that is synthesized in platelets. Its overproduction in these cells will lead to thrombosis.

In tissues, PGs are present in low levels, but have profound biological activities there (Moncada and Van, 1979). They bind to their corresponding G-protein coupled receptors on the cell surface, initiating a specific signaling cascade and downstream effects. Among their effects, PGs, as mentioned above, are largely known for their role in pain and inflammation. Nonsteroidal anti-inflammatory drugs (NSAIDs) are commonly used as treatments and act by blocking the formation of PGs, specifically by nonselectively inhibiting the activity of COX-1 and COX-2. However, the ubiquitous nature of PGs allows for a wide variety of additional roles. Different forms of PGs may act in an opposing manner to regulate certain processes. For example, prostaglandin E₂ (PGE₂) promotes wakefulness (Huang et al., 2003) and suppresses food intake (Ohinata et al., 2006), while prostaglandin D₂ (PGD₂) promotes sleep (Huang et al., 2007) and food intake (Ohinata et al., 2008).

23.4.4.5.1 Cyclooxygenase (COX-1 and COX-2)

COX enzymes act as the rate-limiting step in the conversion of arachadonic acid to the intermediate PGH₂. COX-1 is constitutively expressed in most cell types and is responsible for the production of PGs under homeostatic conditions, for example, maintenance of gastric mucosa, platelet function, and renal autoregulation. In contrast, COX-2 is generally absent and only induced under pathological conditions such as cancer, infection, and arteriosclerosis (Buczynski et al., 2009). In addition to being elevated in various forms of cancer in mammals, including cats and dogs (Dore, 2010), increased COX-2 enzymatic activity is a key mechanism underlying neurotoxicity in disorders such as Parkinson's disease and stroke (Liang et al., 2005). As mentioned above, NSAIDs nonspecifically block COX to relieve pain and inflammation. The discovery of COX-2 represented a significant breakthrough in the early 1990s and allowed the development of COX-2-specific NSAIDs that were able to eliminate the negative side effects of nonselective COX inhibition, such as gastric erosion and platelet dysfunction (Robertson and Taylor, 2004). Although they have been consistently used in humans since that time, COX-2-specific drug use

FIGURE 23.12 Prostaglandin, thromboxane, and leukotriene mediators of inflammation are generated via the cyclooxygenase and lipoxygenase pathways from the 20-carbon unsaturated fatty acid, arachidonic acid. Both 5- and 12-hydroperoxyeicosatetraenoic acids (HPETEs) are within the lipoxygenase pathway.

in veterinary medicine did not emerge until a decade later. However, marked interspecies differences have been found in clearance and elimination. A third form, COX-3, a splice variant of COX-1, was subsequently discovered to be involved in the regulation of fever. Recent studies have demonstrated that acetaminophen apparently exhibits both COX-3 (Botting et al., 2005) and COX-2 (Hinz et al., 2008) inhibition.

23.4.4.5.2 Prostaglandin E₂

PGE₂ is the most thoroughly characterized PG and is widely studied for its roles in parturition, bronchial dilation, pain, cancer, inflammation, atherosclerosis, and smooth muscle control (Buczynski et al., 2009). There are four G-protein coupled receptors (EP 1–4) that mediate PGE₂ actions. In general, EP1 and EP3 induce smooth muscle contraction, while EP2 and EP4 induce smooth muscle relaxation. PGE₂ is also important in renal homeostasis, with different receptor isoforms mediating opposing functions. EP1 and EP3 mediate PGE₂-induced salt excretion and diuresis, while EP4 mediates salt and water absorption (Breyer et al., 1998). In dogs, PGE₂ contracts the urinary bladder and relaxes the urethra and differences in gene and protein expression of the receptors there has been reported to differ between sexes, and among regions of the urinary tract (Ponglowhapan et al., 2010). As mentioned above, it has also been shown that PGE₂ suppresses food intake via the EP4 receptor and promotes wakefulness (Ohinata et al., 2008). Moreover, PGE₂ acts as an immunosuppressant by inhibiting production of inflammatory cytokines and helper T cell differentiation (Sakata et al., 2010). In the pig endometrium, PGE₂ is thought to increase vascularization and support early pregnancy (Kaczmarek et al., 2008). Via binding to its EP1 receptor, PGE₂ is also responsible for maintenance and cytoprotective actions in the gastrointestinal tract of rats, reducing the degree of damage done by harmful agents or conditions (Araki et al., 2000).

23.4.4.5.3 Prostaglandin F_{2α}

PGF_{2α} is largely recognized for its involvement in the mammalian female reproductive system. It is present in corpora lutea from a wide range of mammalian species, including horses, cows, rabbits, sheep, rats, pigs, and primates (Wiltbank and Ottobre, 2003). It has a prominent role in the regression of ovarian corpora lutea, increasing over the later luteal stages and serving as a luteolytic signal for the decrease in progesterone (Diaz et al., 2002). The secretion of PGF_{2α} by luteal cells can also feed back on corpora lutea to further amplify PGF_{2α} during the luteolytic process (Tsai and Wiltbank, 1997). PGF_{2α} is also known to cause contraction of smooth muscle in the uterus (Crankshaw and Gaspar, 1995), gastrointestinal (Stein et al., 1994), and respiratory (Karlsson et al., 1993) tracts, effects that also involve the participation of oxytocin (Russ et al., 1992; Qin et al., 2009). A knockout of the gene encoding the receptor for PGF_{2α} showed a failure of normal parturition in pregnant mice (Sugimoto et al., 1997), an effect that was attributable to the absence of the progressive decline in progesterone late in pregnancy (see Section 4.3.1.3.2). In the 1970s, PGs were also discovered to modulate intraocular pressure and blood flow. Since then, a variety of synthetic analogs of PGF_{2α} have emerged for the treatment of glaucoma and other eye conditions in both human and veterinary medicine (Lee et al., 1984; Gum et al., 1991; Kurashima et al., 2010).

Uterine diseases in dogs are typically accompanied by elevations in PGF_{2α}. Such is the case in canine pyometra, which is seen within weeks of a female's period of heat. In the condition, abnormal sex steroid levels will stimulate a thickening of the uterus, accompanied by an increase in uterine fluid that can lead to an infection and accumulation of pus. Plasma levels of endotoxin are increased and correlate with elevations in the PGF_{2α} metabolite 15-keto-(13,14)-dihydro-PGF_{2α} (Hagman et al., 2006). An increased presence of this metabolite has also been observed in cat inflammatory uterine diseases (Hagman et al., 2009).

23.4.4.5.4 Prostaglandin D₂

PGD₂ is the most abundant PG in the central nervous system, having roles in sleep (Hayaishi, 1991), pain, and as a key mediator of allergic inflammatory response. There are two receptor forms to which PGD₂ binds. Initially, it was believed that most of the biological actions of PGD₂ were mediated by what is now known as DP₁. However, a second receptor, DP₂, was found to be expressed on Th₂ cells, a subset of T-lymphocytes. These lymphocytes secrete a number of interleukin signaling molecules that in the immune system serve as cytokine chemical messengers in the cross-talk among leukocytes. A major role of PGD₂ is the promotion of an allergic reaction, with each receptor mediating unique responses (Pettipher, 2008). Peripherally, PGD₂ promotes vasodilatation, constriction of the bronchioles, and inhibits platelet aggregation (Liang et al., 2005).

In addition to those discussed above, other eicosanoids exist, including prostacyclin (PGI₂) and thromboxane A₂. In general, research on PGs is largely conducted with human interests in mind, with less known about PGs in domesticated species. Some work that has been done, however, suggests that homology exists in PGs and COX enzymes across species (Lin and London, 2010; Bhattacharjee et al., 1997; Bennett and Moore, 1991; Setty et al., 1991). Nonetheless, species differences in PG activity or responses have also been shown (Chand and Altura, 1980; Taniguchi et al., 1982; Lee et al., 1984; Henderson et al., 1988), so cross-species generalizations about this highly functional family of lipids can be inappropriate.

23.4.4.6 Aldosterone and Cardiac Glycosides

Aldosterone is a mineralocorticoid hormone, a designation that is derived from an effect on mineral metabolism. It is generated within the adrenal cortex zona glomerulosa from progesterone through deoxycorticosterone and corticosterone, with aldosterone synthase catalyzing the final conversion from corticosterone (see Figure 23.8). Aldosterone acts on the nuclear mineralocorticoid receptors in the distal tubule and collecting ducts of the kidney, increasing sodium reabsorption, potassium secretion and water retention by the kidneys. An rise in the level of circulating potassium ions, a drop in the level of sodium ions, or a persistent fall in blood pressure stimulates the release of the peptide renin from the kidneys and the globulin angiotensinogen from the liver. Angiotensinogen is converted in sequence to angiotensins I and II, and the latter directly raises blood pressure by vasoconstriction and stimulates the adrenals to produce aldosterone and the posterior pituitary to secrete vasopressin. Aldosterone, in turn, promotes sodium and water retention by the kidneys, which then serves to increase blood pressure. The secretion of aldosterone, both basal and stimulated, is inhibited by natriuretic peptides (e.g., Richards et al., 1993), and is potentiated by serotonin (Rocco et al., 1990). Serotonin is directly able as well to stimulate aldosterone synthesis from adrenocortical cells (Al-Dujaili et al., 1982). Renin and angiotensin also have a role in the regulation of water balance by stimulating the release of vasopressin from the posterior pituitary to increase the permeability of the kidney collecting ducts to water.

Given their interrelationships, renin, angiotensin, and aldosterone are physiologically often grouped as a single system (i.e., the renin–angiotensin–aldosterone system), which is central to the pathogenesis of hypertension, cardiovascular disease, and kidney disease. Pathological changes in the levels of aldosterone are more often than not entwined with alterations in the other two participants. The development of chronic renal failure and proteinuria is frequently associated with an elevation in adrenal aldosterone production that can be attributable to an upregulation in the renin–angiotensin system (Endemann et al., 2004). Elevated circulating aldosterone levels and dysregulation in renin and angiotensin activity are also associated with impaired cardiovascular function (e.g., Rossi et al., 2005; Cachofeiro et al., 2008; Gaddam et al., 2009).

Cardiac glycosides are a class of adrenal steroid hormones that influence the active sodium pump and intracellular free calcium concentrations. They enhance the vagal tone in the heart, affecting the force of cardiac muscle contraction and slowing the heart rate. The existence of such substances in nature has long been known. Herbal concoctions that influenced the functioning of the heart were employed by

the ancient Romans, Syrians, and Chinese. In 1775, the English physician William Withering reported using extracts from the foxglove plant to treat patients suffering from dropsy, an earlier term for congestive heart failure (see Norman, 1985 for review). The effectiveness of the treatments, although initially given by him in excessive dosages, was attributable to the fact that the plant contained the glycoside digitalis. The discovery that digitalis and other similar steroids inhibited the sodium pump, leading to an increase in intracellular calcium ions and hypertension, was an early impetus for a search for endogenous cardiotoxic substances. One digitalis-like steroid, similar to the plant toxin ouabain, was reported to be synthesized in adrenals, although it has also been identified in the hypothalamus and pituitary (Hamlyn et al., 1998). It appears that progesterone and pregnenolone can serve as intermediate precursors (Perrin et al., 1997; Komiyama et al., 2001) for this ouabain-like compound (OLC). However, the synthetic pathway has been reported to diverge in different cultured cell types (Perrin et al., 1997; Lichtstein et al., 1998). The endogenous OLC is regulated by both catecholamines and angiotensin II (Laredo et al., 1997, 2000), indicating a functional interplay with the renin–angiotensin system.

In addition to foxglove, a variety of plants contain glycosides that are toxic upon ingestion, and this accounts for many cases of animal poisonings and death due to heart failure. The evergreen ornamental shrub oleander, for example, contains the glycoside oleandrin, and all parts of the plant are toxic. Pheasant's eye is a perennial plant, and its many stems and serrated leaves contain toxic cardiac glycosides similar to those of digitalis. Other plants include milkweed, Christmas rose, lily of the valley, and white water lily. The animals that appear most affected by ingesting these plants are cattle, sheep, and goats, although poisonings have been detected in horses and deer. As a rule, herbivores in the wild will avoid the plants, making cases of such poisonings relatively rare (for review, see Joubert, 1989). The venom gland of cane toad (*Bufo marinus*) contains large quantities of cardiac glycosides, and toad venom poisoning is similar to digitalis toxicity. All toads produce venom, but the toxicity varies by species and is attributable to several chemicals, including catecholamines in addition to glycosides. These chemicals are expressed onto the surface of the skin when the toads are under threat. Toads are a common cause of dog poisonings, although toxic exposures have also been reported in cats, which typically occur in both when they mouth the toad. Symptoms begin promptly and usually consist of abundant drooling and vomiting, which can persist for hours. Affected animals can also exhibit seizures or convulsions.

23.4.4.7 Leptin and Neuropeptide Y (NPY)

Leptin is a hormone that was first identified in the laboratory of Jeffrey Friedman at Rockefeller University (Zhang et al., 1994) in mice from the Jackson Laboratory that showed a random mutation, causing them to become markedly obese (Ingalls et al., 1950), as much a four times heavier than littermates. It is principally described as a hormone of white fat, tissue which has also been found to secrete a variety of endocrine factors (i.e., adipokines and cytokines), including adiponectin, resistin and tumor necrosis factor- α (reviewed by Rondinone, 2006). In addition, leptin has been observed in placental syncytiotrophoblasts, ovaries, skeletal muscle, stomach, mammary epithelial cells, bone marrow, pituitary, and liver (Margetic et al., 2002). Its receptors exist in at least five different isoforms. One form of the receptor, OB-Rb, has a long intracellular domain, essential for intracellular signal transduction, and is highly expressed in brain hypothalamus and cerebellum (Burguera et al., 2000).

Leptin is now known to have various roles that encompass the regulation of energy balance, (1) conveying information to the hypothalamus about energy stores, (2) acting as a permissive factor for puberty, (3) being involved as a satiety hormone in the attenuation of food intake, and (4) interacting with other hormonal metabolic regulators as insulin, glucagon, cholecystokinin, POMC, GH, and IGF-1 (for review, see Moschos et al., 2002; Meier and Gressner, 2004). The metabolic signaling conveyed by leptin now appears to act as a gating factor for the maturational processes taking place during puberty. This hormone provides cues to the brain that sufficient energy stores are available to meet the metabolic demands needed for the transition to sexual maturity. As mentioned in Section 23.4.3.1.1, this transition is now believed to require kisspeptin activity, and

recent evidence has implicated a serine/threonine kinase (also known as the mammalian target of rapamycin, or mTOR) as a critical intermediary in linking leptin signals to kisspeptin activation during this time (Roa et al., 2009).

One of the more intriguing lines of research in recent years has focused on the role of leptin in the assembly of tubulin into microtubules. Leptin has been found to regulate the phosphorylation of the microtubule-associated tau protein, which promotes this assembly. A hyperphosphorylation of tau results in the formation of tangles of microtubule filaments, something that is implicated in the pathogenesis of Alzheimer's disease in humans. Treatment of human and rat neuronal cell lines with leptin (Greco et al., 2008, 2009) was found to inhibit tau phosphorylation and reduce the levels of amyloid β that is a component of the neuritic plaques present in the Alzheimer's brain, suggesting a potential therapeutic approach to the disease (reviewed by Signore et al., 2008; Tezapsidis et al., 2009). Amyloid β deposits are found in the brains of aged dogs and cats (e.g., Head et al., 2005; Bernedo et al., 2009), and the senile dementias do show neurodegenerative changes and cognitive impairments. In dogs, amyloid plaques are present, although they diffuse and are conformationally different than those seen in Alzheimer's disease. Tau protein hyperphosphorylation has been reported, and as in humans, the process of phosphorylation presumably involves the participation of leptin. However, the hyperphosphorylation was not related to any neurofibrillary and neuritic changes and was not observed to be localized in the area of these diffuse plaques (Pugliese et al., 2006).

NPY is the most abundant peptide in the brain and appears to be highly conserved throughout evolution. It functions there, in sympathetic neurons and in various other organ systems, as a neurotransmitter that is implicated in several physiological processes through binding to five different forms of the receptor: Y1, Y2, Y4, Y5, and Y6. Activation of the sympathetic nervous system in physical exercise, stressful situations, and hypoxia will stimulate NPY release from peripheral nerves or the adrenal medulla (reviewed by Pedrazzini et al., 2003). It has a role in the interaction between cardiac sympathetic and parasympathetic nerves (Ilebekk et al., 2005), and its cardiovascular effects could be related to modulation of the renin–angiotensin system (Pedrazzini et al., 2003). In the renal vasculature, NPY and NE have been found to be colocalized, and NPY contributes, with an activation of sympathetic neurons by the renin–angiotensin system, to the development of high blood pressure (Pedrazzini et al., 2003).

NPY is additionally present in the plexus of enteric nerves in the submucous coat of the intestine, where it functions, along with its related PYY (see Section 23.4.1.1), in the coordination of intestinal motility and in the regulation of ion and water transport (Cox, 2008). As an appetite stimulant, NPY is a principal factor in the regulation of food intake. The combination of NPY and leptin, with profusion of inputs from insulin, glucagon, cholecystokinin, GIP, GLP-1, PYY, GH, IGF-1, and POMC, in addition to TRH, CRH, and oxytocin, comprise a complex interactive system of central and peripheral signals that modulate the individual response to nutrient ingestion (for review, see Valassi et al., 2008).

Mammalian reproduction is a physiological process that consumes significant amounts of energy. It is well known that marked reductions in body weight that deplete energy reserves can both suppress female adult reproductive functions and inhibit sexual maturation in immature animals (see Wade and Schneider, 1992 for review). Information about metabolic status is communicated to the brain from both central (e.g., NPY) and peripheral (e.g., leptin, ghrelin, and insulin) signaling. In general, these signals are not inducers, but are seen more as factors that convey the availability of sufficient or insufficient metabolic stores to support reproductive activity.

23.5 SUMMARY

The broadened description of a hormone as any endogenous chemical that controls and regulates the activity of organs or specific cell groups means that the individual hormones presented here

comprise only a portion of this category. A more inclusive coverage could easily be expanded beyond a chapter into an entire book, particularly as these chemicals more specifically relate to individual laboratory animal species. Those endocrine factors not discussed in this chapter include the following:

- Placental chorionic gonadotropins—equine, porcine, and human chorionic gonadotropins that help prevent degeneration of the corpora lutea and maintain progesterone production during pregnancy
- Pineal melatonin—important in the regulation of circadian rhythms
- Melanocyte-stimulating hormone—pituitary hormone that stimulates melanin production
- Parathyroid hormone—acts to increase Ca^{2+} concentrations in the blood
- Calcitonin—reduces blood Ca^{2+} , opposing the action of parathyroid hormone
- Gastrin—stimulates the secretion of acid by the stomach
- Secretin—intestinal hormone that stimulates bicarbonate secretion by the pancreas, inhibiting gastrin production
- Vitamin D3 (cholecalciferol)—a steroid-like prohormone that, through conversion to 1,25-dihydroxyvitamin D3, regulates calcium and phosphorus levels in the blood and promotes phagocytosis
- Neuromedin B—widely distributed and is involved in cell growth, body temperature, and glucose regulation
- Placental lactogens—related to Prl and acts in concert with it in various animal species to stimulate maternal behavior, maintain luteal progesterone secretion, and facilitate energy supply to the growing fetus
- Galanin—wide tissue distribution, released from hypothalamus into portal vessels and involved in regulating secretion of other hypothalamic hormones
- Vasoactive intestinal peptide—plays a role in muscle relaxation, coronary vasodilation, adrenal activity, LH, and Prl gene expression
- Nesfatin-1—a satiety peptide present in several brain areas, involved in energy balance and H-P-A activation
- Thymosins—peptides originally identified in thymus, although there is wide tissue distribution, involved in modulating immune activity, cellular growth/survival
- Erythropoietin—glycoprotein hormone promoting red blood cell production
- Endogenous opioid peptides—functional roles in pain and analgesia, drug tolerance, reproductive regulation, learning and memory, food intake, immunological responses, and gastrointestinal, renal, and hepatic functions

This list will continue to expand along with our progressive understanding of the intricacies of cellular communication and the normal roles for (and aberrant shifts in) the multiplicity of endocrine factors across species.

ACKNOWLEDGMENTS

The authors wish to express their appreciation to Ms. Ashley Murr (US EPA) for her excellent technical contributions and to Dr. Michael Narotsky (US EPA) for providing valuable comments on the manuscript. Material described in this chapter has been reviewed by the National Health and Environmental Effects Research Laboratory, US EPA and approved for publication. Approval does not signify that the contents necessarily reflect the views and policies of the Agency, nor does the mention of trade names or commercial products constitute endorsement or recommendation for use.

24.1 INTRODUCTION AND BRIEF HISTORY

The initial indications that food components may be linked to health are described in the writings of ancient Greek philosophers in the fourth and fifth centuries BC. An Egyptian medical text, the *Papyrus Ebers* (written about 1550–1570 BC) contains references that described liver as a potential treatment to improve vision including night blindness. In China, descriptions related to the husbandry and nutritional care of horses also occurred at about this time (Lusk, 1922).

In the mid-1700s, a number of documents focusing on the treatment of specific diseases acknowledged the curative effects of given foods. As an example, James Lynn, a physician in England, developed his treatise that fresh fruits and vegetables seemed effective in treating scurvy (Carpenter, 1986). By the late 1800s, an association between corn and pellagra (niacin deficiency) was made. Another conceptually important observation was the connection between the consumption of polished rice and polyneuritis (associated with the nutrition disease beriberi). Although the concept of vitamins was not fully established at this time, studies in the late 1800s and early 1900s that focused on defining food components relevant to disease were the first to utilize experimental animals in controlled settings (Goldblith and Joslyn, 1964). Concerning essential minerals, French agricultural chemist Jean Boussingault first suggested that iodine compounds might be able to cure goiter only 50 years after its discovery as an element in 1811 (Hetzel, 1996). A key factor in this advance was analytical procedures were in place for iodine by the mid-1800s. Thus, relationships between low iodine levels and goiter could be made.

The next advance in identifying essential functions and requirements came in the early to mid-1900s. In the United States, the Bureau of Animal Industries accelerated both governmental and academic research to combat major animal diseases and improve animal food production. Much of this work represented the underpinnings and early financial success of many current vitamin and pharmaceutical manufacturers and feed companies.

Now, there is constant awareness and sensitivity to the possibility of dietary vitamin deficiencies (and excesses), particularly diets containing a limited (or restricted) number of dietary ingredients. Or, when subsidiary and contributory factors lead to vitamin-related diseases (compromised food intake), loss of appetite (anorexia), impaired absorption and/or utilization, and the presence of antagonists.

24.2 DEFINITIONS, NOMENCLATURE, AND GENERAL PROPERTIES

24.2.1 VITAMINS

Vitamins have been defined as organic substances present in minute amounts in natural foodstuffs that are essential to normal metabolism, the lack of which causes given deficiency signs and syndromes. For a compound to be considered a vitamin it must be shown to be a dietary essential; that is, its elimination from the diet must result in defined sets of deficiency-related signs and symptoms. Restoration or repletion must be able to reverse the disorder. Merely demonstrating that a compound has a pharmacological activity, however, does not classify a compound as a vitamin, even when found in common foodstuffs. Moreover, the broad range of vitamin functions has also made the development of a systematic nomenclature even more challenging. Likewise, classifications based on chemical properties have proved problematic, although noting the solubility in aqueous or lipid solvents has been useful as a starting point, even for the development of physiological concepts. For example, vitamins that are soluble in lipid solvents (vitamins A, D, E, and K) are absorbed and transported physiologically by conventional lipid transport processes. For water-soluble vitamins, their respective solubility coefficients are major factors that dictate bioavailability and ease of absorption.

When the vitamins were originally discovered they were isolated as chemically or physically defined fractions or factors from selected foods, but their exact chemical composition was seldom known. The designation of vitamins by letters was not systematically pursued in many cases (Goldblith and Joslyn, 1964), particularly when functions ascribed to given factors were discovered to be due to other substances (e.g., an essential amino acid). What are in place today are designations

and nomenclature that have evolved somewhat independently for each of the compounds designated as a vitamin. The International Union of Pure and Applied Chemistry and the International Union of Biochemistry (IUPAC-IUB) Joint Commission on Biochemical Nomenclature (JCBN) are responsible for nomenclature designations. In some cases, trivial names were maintained and utilized along with a letter designation (e.g., pyridoxine for the vitamin B-6 family of vitamers). The commission, as needed, rectifies controversies and inconsistencies in nomenclature.

24.2.2 MINERALS

Of the 103 elements in the periodic table, about 30 are presently considered essential or important for the normal health and growth of animals. Of these, 16 are often described as “essential trace elements,” a classification initially based on the difficulty of measuring such elements with precision (Reilly, 2004). As the designation implies, trace minerals are found and needed in relatively low concentrations in cells and tissues. Herein, 6 of the 16 trace elements are highlighted, because nutritional or toxicological concerns involving them are encountered.

Regarding functions, essential elements are distinguished because of their association with the functions of specific organic molecules, mostly proteins with enzymatic properties. When metals function to facilitate enzymatic catalysis they usually fall into two categories, metals necessary to metalloenzymes or metal–enzyme complexes. The stability of the interaction (e.g., the magnitude of the association or disassociation constants) helps to define whether metalloenzyme or metal–enzyme complex is the best designation. Metalloenzymes have metal-binding constants of 10⁸–10⁹ or greater. Metal–protein complexes have constants of 10⁵ or less (Harris, 2014). Trace elements that are nutritionally essential are localized to the fourth and fifth rows of the periodic table and have incompletely filled *d* orbitals, except for Cu and Zn. How a given metal facilitates catalytic functions is related in part to its ability to engage in redox, act as a Lewis acid, or modulate an energy excitable transition state during a catalytic event. Like the vitamins, the designation of given minerals as essential requires that their elimination from the diet result in a defined set of deficiency-related signs. It is also critical to identify a mechanism of action in association with a metalloprotein or metal complex with a known function.

24.2.3 REQUIREMENTS

For both vitamins and minerals, when expressed on an energy basis, metabolic requirements are most often of the same order of magnitude from one species to the next. When differences in the dietary requirement for a given nutrient between species do occur, in contrast to a physiological or metabolic need, the differences are usually due to the presence of unique pathways for production, degradation, and/or disposal of the nutrient. In some cases (e.g., requirements for ferrets, rabbits, dogs), more data may be needed to define an actual dietary, physiological, or minimum need. A particular concern is the expression of requirements for various breeds of dogs. Differing species of dogs can vary in body weight by two orders of magnitude. Expression of requirements based directly on body weight (e.g., amount/kg) grossly overestimates the need in large species and underestimates the need in smaller species (Subcommittee on Dog and Cat Nutrition et al., 2006).

Some examples are given in Tables 24.1 through 24.3. Note that requirements of trace elements also scale allometrically in a manner that is similar in principle to scaling algorithms for basal metabolism (e.g., $kWt^{3/4}$, Figure 24.1). Given that a common set of biological or evolutionary principles are involved in the selection of the elements essential to life, it follows that nutritional requirements might also be influenced by the same principles (Rucker and Storms, 2002; Rucker, 2007). Indeed, a strong case can be made that when expressed per unit of food-derived energy or relative to metabolic body size; requirements for essential elements and vitamins are similar to a diverse

TABLE 24.1
Fat-Soluble Vitamin Requirements^{a,b}

Species ^d	Vitamin			
	A	D	E	K
	Amount/kg Diet or Dry Matter (~3,200 kcal/kg DM) ^c	Amount/kg Diet or Dry Matter (~3,200 kcal/kg DM) ^c	Amount/1,000 kcal (4.2 MJ)	Amount/kg Diet or Dry Matter (~3200 kcal/kg DM) ^c
	Amount/1,000 kcal (4.2 MJ)	Amount/1,000 kcal (4.2 MJ)	Amount/1,000 kcal (4.2 MJ)	Amount/1,000 kcal (4.2 MJ)
Mouse ^a 15–25 g	2,000–4,000 Units (0.7–1.4 mg as retinol)	1,000 Units (0.025 mg as D ₃)	312 Units (0.008 mg as D ₃)	1 mg as phyloquinone
Rat ^a 175–250 g	2,300 Units (0.8 mg as retinol)	1,000 Units (0.025 mg as D ₃)	312 Units (0.008 mg as D ₃)	1 mg as phyloquinone
Hamster ^a 75–125 g	9,000 Units (18 mg as retinoyl palmitate)	480 Units (0.012 mg as D ₃)	150 Units (0.004 mg as D ₃)	2.4 mg as menadione
Guinea pig ^a 500–850 g	6.6 mg as retinol (28 mg as β-carotene)	1,000 Units (0.025 mg as D ₃)	312 Units (0.008 mg as D ₃)	5 mg as menadione
Dog ^a 1–50 kg	4,040 Units (1.2 mg as retinol)	442 Units (0.01 mg as D ₃)	136 Units (0.003 mg as D ₃)	1.3 mg as menadione
Cat ^a 4–8 kg	2,664 Units (0.8 mg as retinol)	224 Units (0.006 mg as D ₃)	70 Units (0.002 mg as D ₃)	0.8 mg as menadione
Ferret ^{a,b} 500–2,000 g	~30,000 Units (9 mg as retinol)	~3,000 Units (0.075 mg as D ₃)	~940 Units (0.024 mg as D ₃)	3.3 mg as menadione

All numerical values listed in this table are in milligrams.

^b Additional sources for the nutrient requirements for ferrets: Fekete et al. (2005) and Bell (1999).

^c Metabolic energy per kg dry matter in typical laboratory diets.

^d Typical weight at sexual maturity or adulthood for species used as laboratory animals.

^e A need for cobalt beyond that found in vitamin B12 has not been defined for most animals. The value indicated for the rabbit reflects the ability of nonruminant herbivores to synthesize vitamin B12. Synthesis occurs in the cecum and the vitamin is acquired by direct absorption from the intestine or by reingestion and absorption following coprophagy. If a requirement exists in nonherbivores beyond the need for vitamin B12, it is most likely less than 200 µg/1,000 kcal dry matter (DM) consumed. MJ, megajoule; NE, requirement is not well documented or established.

^f The need for the molybdenum is most likely less than 200 µg/1,000 kcal dry matter (DM) consumed; the amount required to produce the Molybdenum cofactor. NE = requirement is not well documented or established.

FIGURE 24.1 Daily intake of selected minerals for mice, rats, chickens, dogs, humans, and pigs versus their respective body weights in kilograms. The data for individual minerals plotted in this fashion result in reasonably linear plots with slopes that range from 0.6 to 0.8. A slope of ~ 0.75 represents the active tissue mass or metabolic mass. As noted in the small figure insert, for any given mineral, plots of daily intake versus body weight are not linear and require polynomial equations to describe the function. (From Rucker, R., and Storms, D., *J Nutr*, 132, 2999–3000, 2002.)

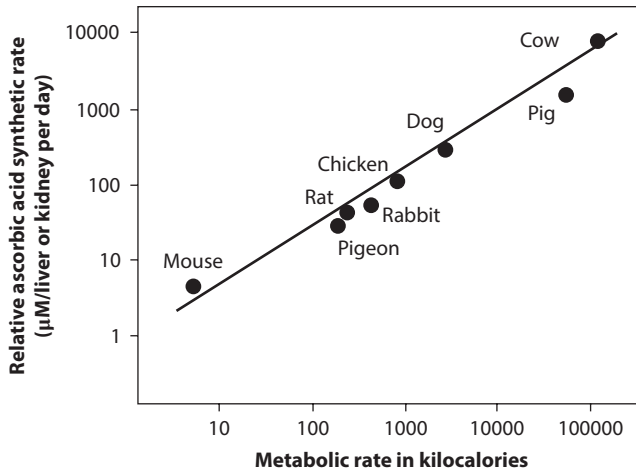

FIGURE 24.2 Ascorbic acid production and basal energy expenditure are functions of metabolic size. The principles that control ascorbic acid production appear to follow the same allometric relationships as energy expenditure among homeothermic animals (e.g., as a function of $(Wt_{kg})^{3/4}$). (From Rucker, R.B., *J Anim Physiol Anim Nutr (Berl)*, 91, 148–156, 2007.)

array of species. To illustrate this point, the relationship between the ascorbic acid (vitamin C) requirements is given in Figure 24.2. Most mammals that require ascorbic acid meet their needs at intakes of 20–80 mg per 1000 kcal (4.184 megajoule or MJ). This amount corresponds to what may be extrapolated from synthetic rates in animals that are known to produce ascorbic acid (Rucker, 2007). Examination of genetic animal models, such as the gulonolactone oxidase null mouse and

the osteogenic disorder Shionogi (ODS) rat, both of which cannot synthesize ascorbic acid, is also illustrative of the concept. The L-ascorbic acid requirement for normal growth and metabolism in these two animal models is of the same order as the amount produced by normal rats and mice (Rucker, 2007), as well as that needed by guinea pigs for optimal growth (Table 24.2).

24.2.4 NUTRITIONAL DEFICIENCIES AND TOXICITIES

Why do deficiencies or excesses occur? Primary deficiencies often happen when monotonous diets or limited combinations of foods are consumed. For certain mineral elements (e.g., selenium), a deficiency may arise if the foodstuff comes from a single region deficient in the nutrient. Secondary mineral and vitamin deficiencies can also result through a variety of mechanisms that include poor bioavailability, interactions with other competing substances, and genetic influences (e.g., polymorphisms that dictate an increased need for given nutrients). Table 24.4 provides a list of mechanisms underlying the development of deficiencies and interactions that will be amplified in each of the sections that follow. Tables 24.5 and 24.6 highlight deficiencies and toxicities in dogs and cats. Note that in many cases, the signs for specific mineral and vitamin deficiencies are similar to those observed in other mammals and common laboratory animals.

24.3 FAT-SOLUBLE VITAMINS

Vitamins A, D, E, and K are unlike the water-soluble vitamins because of their lipid solvent solubility, diverse nonenzymatic functions, sequestration in lipid vacuoles and adipose, and greater risk for toxicity. Like dietary triglycerides, fat-soluble vitamins are solubilized in the duodenal lumen in the presence of bile and pancreatic enzymes. They are then maintained within the lipophilic core of mixed micelles. Next, pancreatic esterases, in the presence of bile salts, catalyze the release of fat-soluble vitamins from their esters. Together with fatty acids derived from triglycerides, fat-soluble vitamins are released from micelles at the enterocyte brush border membrane. At high doses, vitamins A and E can be absorbed directly from water-miscible emulsions. The next steps involve incorporation into chylomicrons for secretion into lymphatics and ultimate uptake by the liver. Intestinal, biliary, and pancreatic diseases that cause decreased dietary lipid absorption may cause a decrease in the absorption of fat-soluble vitamins.

TABLE 24.4
Potential Causes of Vitamin and Mineral Deficiencies

Cause	Mechanism
Food processing	Loss of a nutrient due to isolation and/or refinement of selected food components
Prolonged or inappropriate storage of feed stuffs or components	Exposure to UV light, heat, excessive moisture
Dietary interactions	Competitive interactions between nutrients for transport or chemical modification processes that are in common
Drug interactions	Alterations in metabolism that affect absorption (chelators and structural analogs) and/or excretion (e.g., laxatives, diuretics) redistribution among tissue pools; induction of phase 1 and 2 enzyme systems important to the metabolism of a given vitamin or mineral
Physiological state	Change in requirement due to reproduction, growth, lactation, or aging
Disease	Alterations in metabolism that affect absorption and/or excretion; rates of energy expenditure
Genetic	Polymorphism or alteration in genes important to specific steps in nutrient metabolism and/or transport

TABLE 24.5

Clinical Signs of Nutrient Deficiency and Toxicity, Diagnostic Tests, and Blood Concentrations in Dogs

Nutrient	Clinical Signs of Deficiency	Clinical Signs of Toxicity	Diagnostics for Status Assessment	Blood/Urine or Organ Concentrations ^{a,b}
Fat-Soluble Vitamins				
Vitamin A	Anorexia, weight loss, ataxia, xerophthalmia, conjunctivitis, corneal opacity and ulceration, skin lesions, metaplasia of the bronchiolar epithelium, pneumonitis, and increased susceptibility to infections	Poor bone growth, reluctance to walk, depression, anorexia, gingivitis, fetal malformations	Serum or liver retinol concentrations	Retinol; 642 ± 36 ng/mol (P) (Schweigert et al., 1990) Retinyl palmitate; 609 ± 67 ng/mol (P) (Schweigert et al., 1990) Retinyl stearate; 916 ± 101 ng/mol (P) (Schweigert et al., 1990) Liver retinol; 794–1,129 IU/g retinol (wet tissue) (Goldy et al., 1996)
Vitamin D	Rickets: osteomalacia, orthopedic pain, impaired growth, malformation of long bones	Lethargy, anorexia, vomiting, polydipsia, hypercalcemia	Radiographic imaging of skeletal bones, serum 25-hydroxyvitamin D	Cholecalciferol; 153 ± 50 pmol/L (P) [#] (Gerber et al., 2003)
Vitamin E	Muscle weakness, reproductive failure, nodular adipose tissue (associated with steatitis)	Growth depression, decreased bone growth increased prothrombin time (associated with vitamins D and K antagonism)	Plasma α- tocopherol	α- tocopherol; 7.54 ± 0.4 μg/mL (P) (Schweigert et al., 1990)
Vitamin K	Excessive bleeding, prolonged clotting times	Anemia	Prothrombin times (PT), PIVKA (Proteins induced by vitamin K antagonism)	PT; 11–15 sec (P) (Rozanski et al., 1999) PIVKA; 18–24 sec (P) (Rozanski et al., 1999)
Water-Soluble Vitamins				
Thiamin	Inappetance, weight loss, coprophagia, cardiac hypertrophy, bradycardia, muscle weakness, ataxia, paraparesis, torticollis, circling, tonic-clonic convulsions, death	None reported with oral ingestion in dogs. Intravenous injection can cause a decrease in blood pressure and bradycardia	Plasma concentration of thiamin phosphorylated esters, erythrocyte transketolase saturation	Thiamin; 46–112 ng/mL (WB) (Baker et al., 1986)
Riboflavin	Anorexia, weight loss, periauricular alopecia, epidermal trophy, cataracts	None reported in dogs	Erythrocyte glutathione reductase activity coefficient, urine riboflavin	Riboflavin; 185–420 ng/mL (WB) (Baker et al., 1986)

(Continued)

TABLE 24.5 (Continued)
Clinical Signs of Nutrient Deficiency and Toxicity, Diagnostic Tests, and Blood Concentrations in Dogs

Nutrient	Clinical Signs of Deficiency	Clinical Signs of Toxicity	Diagnostics for Status Assessment	Blood/Urine or Organ Concentrations ^{a,b}
Pyridoxine (vitamin B6)	Anorexia, microcytic hypochromic anemia, convulsions, cardiac dilation, and hypertrophy	Ataxia, muscle weakness, tonic convulsions	Pyridoxal blood concentration, aminotransferase activity, kynureninase activity	Pyridoxine; 40–270 ng/mL (P) (Baker et al., 1986)
Niacin	Black tongue, stomatitis, 4 D's = dermatitis, diarrhea, dementia, and death	High doses reported to cause bloody feces, convulsions, and death in dogs	Nicotinamide loading test: urine N'-methylnicotinamide concentration	Niacin; 2.7–12 µg/mL (WB) (Baker et al., 1986)
Folic acid	Macrocytic hypochromic anemia, poor appetite and weight gain, cleft palates in Boston Terriers	None reported in dogs	Serum folic acid concentration	Folic acid; 4–26 ng/mL (P) (Baker et al., 1986)
Vitamin B12	Macrocytic hypochromic anemia, inappetance, failure to thrive	None reported in dogs	Serum vitamin B12 concentration, serum or urine methylmalonic acid	Vitamin B12; 135–950 pg/mL (WB) (Baker et al., 1986)
Pantothenic acid	Anorexia, diarrhea, locomotive incoordination	None reported in dogs	Urinary output of pantothenate	Pantothenic acid; 104–270 ng/mL (WB) (Baker et al., 1986)
Biotin	Dermatitis	None reported in dogs	Serum biotin concentration, acetyl CoA carboxylase and propionyl CoA carboxylase activities, urine biotin	Biotin; 530–5,000 pg. mL (WB) (Baker et al., 1986)
Vitamin-Like Compounds				
Choline	Weight loss, vomiting, fatty liver	Possible depression in erythropoiesis	Plasma choline and phosphatidylcholine	Choline; 235–800 µg/mL (P) (Baker et al., 1986)
Macro Minerals				
Calcium	Reluctance to move, posterior lameness, uncoordinated gait and painful enlarged joints, osteopenia, rickets, osteoporosis, spontaneous fractures, facial pruritis, agitation, tetany, cardiac arrhythmias, seizures	Inappetance, poor growth	Radiographic imaging of skeleton, parathyroid hormone levels, serum ionized calcium concentration	Calcium; 9.0–11.3 mg/dL (S, P) (Kaneko et al., 2008) Ionized calcium 1.2–1.35 mmol/L (S) (Unterer et al., 2004)

(Continued)

TABLE 24.5 (Continued)

Clinical Signs of Nutrient Deficiency and Toxicity, Diagnostic Tests, and Blood Concentrations in Dogs

Nutrient	Clinical Signs of Deficiency	Clinical Signs of Toxicity	Diagnostics for Status Assessment	Blood/Urine or Organ Concentrations ^{a,b}
Phosphorus	Hemolytic anemia, locomotor disturbances, metabolic acidosis	None reported in dogs, effects appear to be more related to calcium excess rather than phosphorus deficiency	Plasma concentration (not a good assessment of body stores)	Phosphorus; 2.6–6.2 mg/dL (S, P) (Kaneko et al., 2008)
Potassium	Depression, weakness, neck ventroflexion, weight loss	None reported, hypothesized to cause cardiac abnormalities and arrest at very high doses	Plasma concentration (not a good assessment of body stores)	Potassium; 4.35–5.35 mg/dL (S, P) (Kaneko et al., 2008)
Sodium	Inappetance, polyuria/polydypsia, increased hematocrit and hemoglobin concentrations	Vomiting	Increased plasma and urine aldosterone concentration (serum levels not a reliable indicator of nutritional deficiency)	Sodium; 141–152 mmol/L (S, P) (Kaneko et al., 2008)
Chloride	Deficiency leads to excess potassium excretion in the kidneys; therefore, clinical signs of potassium deficiency may occur, metabolic acidosis	None reported in dogs	Plasma concentration (not a good assessment of body stores)	Chloride; 105–115 mmol/L (S, P) (Kaneko et al., 2008)
Magnesium	Tetany, tremors, hyperexcitability, tachycardia, and seizures	None reported in dogs	Ionized serum magnesium concentration	Total magnesium: 1.8–2.4 mg/dL (S) (Kaneko et al., 2008) Ionized magnesium: 0.42–0.58 mmol/L (S) (Unterer et al., 2004)
Trace Minerals				
Iron	Hypochromic, microcytic anemia, lethargy, weakness, weight loss or lack of weight gain, hematuria, melena	Vomiting (acute toxicity)	Total serum iron-binding capacity, serum iron concentration	Iron-binding capacity, total (unbound); 170–222 µg/dL (S) (Kaneko et al., 2008) Total iron-binding capacity; 165–418 µg/dL (S) (Kaneko et al., 2008) Iron; 30–180 µg/dL (S) (Kaneko et al., 2008) Liver; 400–1,200 ppm (dry weight) (Schultheiss et al., 2002)

(Continued)

TABLE 24.5 (Continued)

Clinical Signs of Nutrient Deficiency and Toxicity, Diagnostic Tests, and Blood Concentrations in Dogs

Nutrient	Clinical Signs of Deficiency	Clinical Signs of Toxicity	Diagnostics for Status Assessment	Blood/Urine or Organ Concentrations ^{a,b}
Zinc	Decreased appetite, parakeratosis, reproductive failure, decreased wound healing	Acute gastroenteritis, hemolytic anemia, and lethargy	Plasma or WB zinc concentration (may not be a reliable indicator of zinc stores), liver concentration	Zinc; 1.2–0.4 mg/L (S) [#] (Kazmierski et al., 2001) Liver; 120–300 ppm (dry weight) (Schultheiss et al., 2002)
Manganese	Suspected retarded bone growth, lameness, enlarged joints, poor locomotor function based on studies in other species	None reported in dogs	Manganese lymphocyte concentration	None available
Copper	Neurological signs, anemia, hypochromotricia	Hemolytic anemia, liver disease	Liver concentration, RBC Cu/Zn SOD activity	RBC SOD; 40 ± 6 U/mg Hb [#] (Desilvestro et al., 2005) Copper; 100–200 µg/dL (S) (Kaneko et al., 2008) Liver: 120–400 ppm (dry weight) (Schultheiss et al., 2002)
Iodine	Goiter, alopecia, dry sparse overall hair coat, weight gain	Excessive lacrimation, salivation, nasal discharge, flaky, dry skin, and hair coat	Urine iodine excretion, thyroid hormone	Iodine; 5–20 µg/dL (S) (Kaneko et al., 2008) Thyroxine (T ₄ —RIA); 0.6–3.6 µg/dL (S) (Kaneko et al., 2008) Triiodothyronine (T ₃ —RIA); 82–138 ng/dL (S) (Kaneko et al., 2008)
Selenium	Anorexia, depression, dyspnea, “white muscle disease”	Microcytic, hypochromic anemia, liver necrosis, and cirrhosis	Plasma concentration of Se and activity of glutathione peroxidase (GPx) in plasma	Selenium; 2.29–2.45 µmol/L (S) (Wedekind et al., 2004) GSHpx; 1.25–1.32 nmol/NAPDH (S) (Wedekind et al., 2004)

Note: Serum Se and plasma GSHpx from kittens consuming a diet containing 0.15 mg Se/kg diet.

^a Reference ranges will vary with laboratory, please consult the ranges provided by the lab you are using. In some cases, samples from normal animals may need to be provided to serve as controls. Validation of a given assay for the species in question should be confirmed. In many cases, there are no reference ranges available for the diagnostic tests listed in column 4.

^b GPx = glutathione peroxidase, WB = whole blood, P = plasma, S = serum. Values are expressed as ranges or mean ±SE with the exception that those noted (#) are expressed as mean ±SD.

Nutrient	Clinical Signs of Deficiency	Clinical Signs of Toxicity	Diagnostics for Status Assessment	Blood/Urine or Organ Concentrations ^{a,b}
Fat-Soluble Vitamins				
Vitamin A	Anorexia, weight loss, ataxia, xerophthalmia, conjunctivitis, corneal opacity and ulceration, skin lesions, metaplasia of the bronchiolar epithelium, pneumonitis, and increased susceptibility to infections	Extensive osseocartilagenous hyperplasia of the first three cervical vertebrae, poor bone growth, gingivitis, tooth loss, fetal malformations	Serum or liver retinol concentrations	Retinol; 240 ± 65 ng/mL (P) (Raila et al., 2001) Retinyl palmitate; 275 ± 282 ng/mL (P) (Raila et al., 2001) Retinyl stearate; 433 ± 290 ng/mL (P) (Raila et al., 2001) Liver retinol; 11 ± 4 µg/g retinol (wet tissue) (Raila et al., 2001)
Vitamin D	Rickets: osteomalacia, orthopedic pain, impaired growth, malformation of long bones	Lethargy, anorexia, vomiting, polydipsia, hypercalcemia	Radiographic imaging of skeletal bones, serum 25-hydroxyvitamin D	Cholecalciferol; 36.5 ± 4.8 nmol/L (P) (Sih et al., 2001)
Vitamin E	Muscle weakness, reproductive failure, nodular adipose tissue (associated with steatitis)	Growth depression, degreased bone growth increased prothrombin time (associated with vitamins D and K antagonism)	Plasma α-tocopherol	α-tocopherol; 9.86 ± 1.66 µg/mL (P) (Schweigert et al., 1990)
Vitamin K	Excessive bleeding, prolonged clotting times	None reported in cats	Prothrombin times (PT), PIVKA (Proteins Induced by Vitamin K Antagonism)	PT; <11 sec (P) (Center et al., 2000) PIVKA; 16.6–25.2 sec (P) (Center et al., 2000)
Water-Soluble Vitamins				
Thiamin	Inappetance, weight loss, coprophagia, muscle weakness, ataxia, paraparesis, torticollis, circling, tonic-clonic convulsions, neck ventroflexion, death	None reported in cats	Plasma concentration of thiamin phosphorylated esters, erythrocyte transketolase saturation	Thiamin; 20–90 ng/mL (WB) (Baker et al., 1986)
Riboflavin	Anorexia, weight loss, periauricular alopecia, epidermal trophy, cataracts, fatty liver	None reported in cats	Erythrocyte glutathione reductase activity coefficient, urine riboflavin	Riboflavin; 196–660 ng/mL (WB) (Baker et al., 1986)
Pyridoxine (vitamin B6)	Anorexia, microcytic hypochromic anemia, convulsions, enhanced oxalate excretion	None reported in cats	Pyridoxal blood concentration, aminotransferase activity, kynureninase activity	Pyridoxine; 86–350 ng/mL (P) (Baker et al., 1986)

TABLE 24.6 (Continued)
Clinical Signs of Nutrient Deficiency and Toxicity, Diagnostic Tests, and Blood Concentrations in Cats

Nutrient	Clinical Signs of Deficiency	Clinical Signs of Toxicity	Diagnostics for Status Assessment	Blood/Urine or Organ Concentrations ^{a,b}
Niacin	Black tongue, stomatitis, 4 D's = dermatitis, diarrhea, dementia, and death	None reported in cats	Nicotinamide loading test: urine N'-methylnicotinamide concentration	Niacin; 1.8–5.8 µg/mL (WB) (Baker et al., 1986)
Folic acid	Macrocytic hypochromic anemia	None reported in cats	Serum folic acid concentration	Folic Acid; 3.2–34 ng/mL (P) (Baker et al., 1986)
Vitamin B12	Macrocytic hypochromic anemia	None reported in cats	Serum vitamin B12 concentration, serum, or urine methylmalonic acid	Vitamin B12; 120–1,200 pg/mL (WB) (Baker et al., 1986)
Pantothenic acid	Dermal lesions (dermatitis and alopecia), anorexia, diarrhea, locomotive incoordination, ketoacidosis	None reported in cats	Urinary output of pantothenate	Pantothenic acid; 104–270 ng/mL (WB) (Baker et al., 1986)
Biotin	Alopecia, dermatitis, metabolic acidosis	None reported in cats	Serum biotin concentration, Acetyl CoA carboxylase and propionyl CoA carboxylase activities, urine biotin	Biotin; 1,000–3,000 pg. mL (WB) (Baker et al., 1986)
Vitamin-Like Compounds				
Choline	Fatty liver	None reported in cats	Serum alanine aminotransferase activity (rises approximately 1 week after the feeding a choline-deficient diet), plasma choline, and phosphatidylcholine	Choline; 180–490 µg/mL (P) (Baker et al., 1986)
Macro Minerals				
Calcium	Reluctance to move, posterior lameness, uncoordinated gait and painful enlarge joints, osteopenia, rickets, osteoporosis, spontaneous fractures, agitation, tetany, cardiac arrhythmias, seizures	Inappetance, poor growth	Radiographic imaging of skeleton, parathyroid hormone levels, serum ionized calcium concentration	Calcium; 6.2–10.22 mg/dL (S, P) (Kaneko et al., 2008) Ionized calcium 1.18–1.38 mmol/L (S) (Schenck and Chew, 2010)
Phosphorus	Hemolytic anemia, locomotor disturbances, metabolic acidosis	Depression, dehydration, metabolic acidosis	Plasma concentration (not a good assessment of body stores)	Phosphorus; 4.5–8.1 mg/dL (S, P) (Kaneko et al., 2008)

Clinical Signs of Nutrient Deficiency and Toxicity, Diagnostic Tests, and Blood Concentrations in Cats

Nutrient	Clinical Signs of Deficiency	Clinical Signs of Toxicity	Diagnostics for Status Assessment	Blood/Urine or Organ Concentrations ^{a,b}
Potassium	Depression, weakness, neck ventroflexion, weight loss	None reported in cats, hypothesized to cause cardiac abnormalities and arrest at very high doses	Plasma concentration (not a good assessment of body stores)	Potassium; 4.0–4.5 mg/dL (S, P) (Kaneko et al., 2008)
Sodium	Inappetance, polyuria/polydypsia in kittens	None reported in cats	Increased plasma and urine aldosterone concentration (serum levels not a reliable indicator of nutritional deficiency)	Sodium; 147–156 mmol/L (S, P) (Kaneko et al., 2008)
Chloride	Deficiency leads to excess potassium excretion in the kidneys; therefore, clinical signs of potassium deficiency may occur	None reported in cats	Plasma concentration (not a good assessment of body stores)	Chloride; 117–123 mmol/L (S, P) (Kaneko et al., 2008)
Magnesium	Tetany, tremors, hyperexcitability, tachycardia, and seizures	Struvite urolithiasis	Ionized serum magnesium concentration	Total magnesium; 2–2.59 mg/dL (S) (Shin et al., 2004) Ionized magnesium; 1.1–1.44 mg/dL (S) (Shin et al., 2004)
Trace Minerals				
Iron	Hypochromic, microcytic anemia, lethargy, weakness, weight loss or lack of weight gain, hematuria, melena	Vomiting (acute toxicity)	Total serum iron-binding capacity, serum iron concentration	Iron-binding capacity, total (unbound); 105–205 µg/dL (S) (Kaneko et al., 2008) Total iron-binding capacity; 209 µg/dL (mean) (S) (Kaneko et al., 2008) Iron; 68–215 µg/dL (S) (Kaneko et al., 2008)
Zinc	Decreased appetite, parakeratosis, reproductive failure, decreased wound healing	None reported in cats	Plasma or WB zinc concentration (may not be a reliable indicator of zinc stores), liver concentration	Zinc; 8.2–14.7 µmol/L (P) (Van den Broek et al., 1992)
Manganese	Suspected retarded bone growth, lameness, enlarged joints, poor locomotor function based on studies in other species	None reported in cats	Manganese lymphocyte concentration	None available

Nutrient	Clinical Signs of Deficiency	Clinical Signs of Toxicity	Diagnostics for Status Assessment	Blood/Urine or Organ Concentrations ^{a,b}
Copper	Neurological signs, anemia (kittens), ypochromotricia	None reported in cats	Liver concentration, RBC Cu/Zn SOD activity	RBC SOD; 2.2–11.6 U/mg Hb (Fascetti et al., 2002) Plasma Cu; 8.6–18 μ mol/L (P) (Fascetti et al., 2002) Liver: 0.82 \pm 0.03 μ mol/g (wet weight) (Fascetti et al., 2000)
Iodine	Goiter, alopecia, dry sparse overall hair coat, weight gain	Excessive lacrimation, salivation, nasal discharge, flaky, dry skin, and hair coat	Urine iodine excretion, thyroid hormone	Iodine; 3.23 μ mol/L (U) (Wedekind et al., 2010) Thyroxine (T ₄ -RIA); 0.1–2.5 μ g/dL (S) (Kaneko et al., 2008) Triiodothyronine (T ₃ -RIA); 15–104 ng/dL (S) (Kaneko et al., 2008)
Selenium	Anorexia, depression, dyspnea, “white muscle disease” based on studies in other species	None reported in cats	Plasma concentration of Se and activity of glutathione peroxidase (GPx) in plasma	Selenium; 3.95–8.70 mmol/L (P) (Wedekind et al., 2003) GSHpx; >2 mU/L (P) (Foster et al., 2001)

Notes: Cats were consuming 50 ug/kg diet (DM) cholecalciferol; urinary iodine reported in cats consuming a diet containing 0.47 mg/kg diet (DM) supplied as KI; plasma GSHpx from kittens consuming 0.15 mg Se/kg diet.

^a Reference ranges will vary with laboratory, please consult the ranges provided by the lab you are using. In some cases, samples from normal animals may need to be provided to serve as controls. Validation of a given assay for the species in question should be confirmed. In many cases, there are no reference ranges available for the diagnostic tests listed in column 4.

^b WB = whole blood, P = plasma, S = serum, U = urine. Values are expressed as ranges or mean \pm SE.

24.3.1 VITAMIN A

24.3.1.1 Overview

Vitamin A includes the provitamin dietary carotenoid precursors of retinol and dietary retinol in its esterified form (Figure 24.3). Retinol in the form of retinyl esters is found in liver, eggs, and milk products, while carotenoids are present in oils, fruits, and vegetables. When released, retinol is transported into enterocytes by a specific carrier protein. Carotenoids comprise a group of more than 600 compounds (most often red, yellow, and orange pigments in their isolated states). Carotenoids are split into two classes, xanthophylls (contain oxygen) and carotenes (purely hydrocarbon in nature). A carotenoid must contain a β -ionone structure to act as a provitamin. Of the carotenoids, six are known to be biologically important: α -carotene, lycopene, lutein, zeaxanthin, cryptoxanthin, and β -carotene (Krinsky and Johnson, 2005). Carotenoid pigments in combination with given proteins or fats can produce blue, green, purple, or brown pigments in addition to yellow, orange, and red. Typically, if an animal’s skin or feather color comes from carotenoids, and it is not available in food, some or all of the color fades.

FIGURE 24.3 Absorption and cellular metabolism of carotenoids and retinoids. In the intestinal mucosal cell, some carotenoids are oxidized to both carotenals and retinals. Retinal is reduced by alcohol dehydrogenases (RoldH) to retinol and reesterified by lecithin retinol acyl transferase (LRAT). Retinol and associated esters are incorporated into chylomicrons or into intestinal very low-density lipoprotein particles (not shown), which are released into the lymph. Retinol released from retinyl esters by the action of retinyl ester hydrolase (REH) may also be oxidized to retinal by short-chain dehydrogenases/reductases (SDR). Retinoic acid is formed from retinal by the action of retinal dehydrogenase (RalDH). Retinoic acid-derived products are sufficiently polar that they may be transported directly into blood, whereas carotenoid pigments and retinyl esters are partitioned into chylomicrons for delivery into lymph.

24.3.1.2 Metabolism

The intestinal transport of retinoids is active and saturable at physiological concentrations (Ross and Zolfaghari, 2004; Harrison, 2005). For most monogastric animals, the overall availability of pure β -carotene in oil is about half that of retinol. However, because the average availability of dietary β -carotene is about 8% or less in mixed vegetable and fruit diets after absorption and bio-conversion, 20 μg or more of mixed dietary carotenoids are often required to yield the equivalent of $\sim 1 \mu\text{g}$ of retinol. In nonruminant animals, poor digestion of complex plant organelle structures, such as chloroplasts, where carotenoids are concentrated, can lead to poor digestibility of carotenoid components, even though their concentrations are sufficient to meet requirements. Concerning carnivores, such as cats and ferrets, their digestive systems are best suited for digesting and absorbing nutrients from animal-based proteins and fats, because they are descended from carnivores (Raila et al., 2002). Although early studies were unable to detect significant amounts of β -carotene in the blood of cats given oral doses, more recent studies have found β -carotene absorption to be relatively efficient in cats, which brings into question issues regarding the limits of detection and specificity of earlier methods used for retinoid and carotenoid detection. For example, Schweigert et al. (2002) have reported that cats are able to absorb β -carotene from the diet, but it is not efficiently converted to vitamin A. Unlike most mammals, cats have little capacity to convert carotenoids to vitamin A, because of low levels of β -carotene 15,15'-monooxygenase, an enzyme essential for the conversion of carotenoids to retinol (Figure 24.4). Cats and ferrets should be fed animal sources rich in retinyl ester or vitamin A as retinyl palmitate or acetate in supplements (Lederman et al., 1998; White et al., 1993). Further, it is also noteworthy that cats may potentially serve as a model for the study of β -carotene independent of its role as a vitamin A precursor (e.g., its putative role as an antioxidant or mediator of certain types of immune responses).

24.3.1.3 Absorption and Transport

Efficient entry of carotenoids and retinol in enterocytes is dependent on normal biliary and pancreatic secretion, the presence of dietary lipid, and the formation of intestinal micelles. Sufficient dietary lipid for most animals is achieved if the diet contains more than 10% lipid. The various

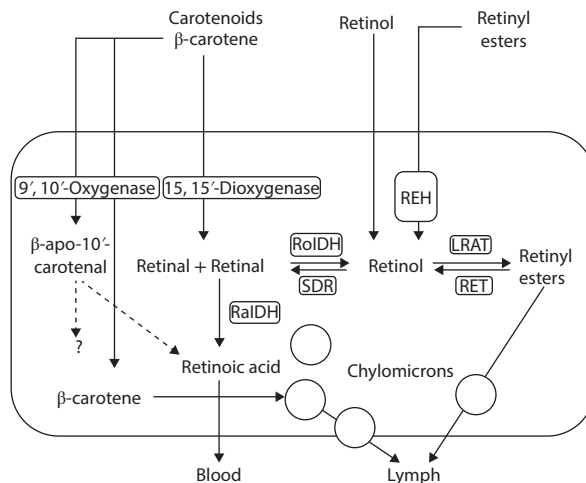

FIGURE 24.4 (a) Structures and relationships for selected retinoids, β -carotene and (b) cholecalciferol. The structures are A, retinol, which can be converted in reversible reactions to B, retinal; retinal can be irreversibly converted to C, all-trans retinoic acid; C can isomerize to D, 11-cis, or E, 13-cis retinoic acids, respectively; F, retinyl palmitate; G, retinoyl glucuronic acid; H, β -carotene. Important interrelationships for the interconversion of retinoids and carotene are also shown. The steps related to the conversion of cholesterol in skin to cholecalciferol are given in (b).

retinoids and carotenoids that enter intestinal cells are transported next by cytosolic retinol-binding proteins (CRBPs) to the smooth endoplasmic reticulum (Ross and Zolfaghari, 2004, Krinsky and Russell, 2001, Wang and Krinsky, 1998, Harrison, 2005). They are next reesterified and incorporated into chylomicrons and very-low-density lipoproteins (VLDLs). Some of the steps are shown in Figure 24.5. Intact carotenoids that reach the liver and other target tissues are converted to retinoids in most animals by tissue β -carotene 15,15'-monooxygenase (EC 1.14.99.36), which catalyzes the chemical reaction:

In liver, there is active exchange of retinyl and other retinoids between stellate (also known as Ito cells) and parenchymal cells. Retinol is converted to retinyl esters to aid in buffering cells from an excess of vitamin A, for which retinyl palmitate is usually the most predominant form of the ester. When vitamin A is needed, retinyl ester in the liver is hydrolyzed and released as retinol bound to retinol-binding protein (RBP), which exists complexed to transthyretin, a thyroxine-binding protein. The purpose of this complex is to protect vitamin A from oxidation, facilitate renal reabsorption, and provide selectivity and delivery to targeted epithelial cells.

Regarding turnover and disposal, liver microsomal CYP2E1 and various phase 2 enzymes enhance catabolism and biliary excretion of hepatic retinoids by converting them to glucuronides or various oxidized forms (Figure 24.5). Drugs that stimulate microsomal and xenobiotic metabolism (e.g., barbiturates) have as a secondary effect the acceleration of retinoid metabolism.

24.3.1.4 Functions

The biologic functions of vitamin A primarily include the maintenance of vision and the orchestration of genes important to immune function, development, and epithelial cell functions (Krinsky and Johnson, 2005). Retinol delivered to the eye helps to sustain rod vision. In rod cells, retinol is converted to retinal, which next binds reversibly via an imine bond to a lysyl moiety in the protein, opsin. Isomerization of 11-cis-retinal into all-trans-retinal by light induces a conformational change in opsin to form rhodopsin (Lamb, 2009). The conformational changes

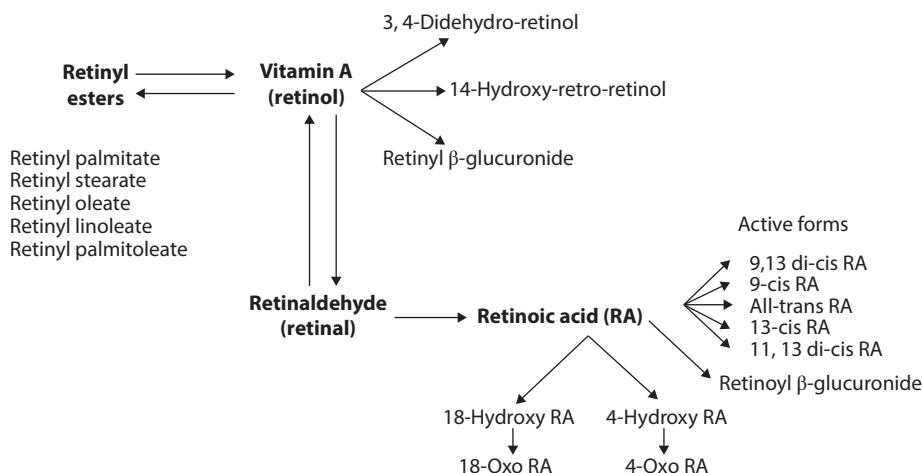

FIGURE 24.5 Retinoid metabolism. Microsomal enzymes (cytochrome P-450 hydroxylases and various transferases) catalyze the conversion of retinyl esters to active cellular forms of vitamin A (the isomers of retinoic acid, RA) or initiate catabolism for eventual excretion by converting them to glucuronides or various oxidized forms.

associated with the transition from opsin to rhodopsin initiate a secondary messenger cascade that alters rod cell membrane potential, which leads to activation of visual signaling via the optic nerve (Figure 24.6).

With regard to control of gene expression, retinoic acid via the retinoic acid receptor influences the process of cell differentiation. Changes in the concentration gradient of retinoic acid along the embryonic anterior–posterior (head–tail) axis, the layers of dermis, and structures containing secretory epithelial cells (e.g., lung, intestine) have been associated with regulation of over 600 genes. Accordingly, the signs of vitamin A deficiency include failure of dark adaptation

FIGURE 24.6 Vitamin A and vision. All-trans retinol is transported to the eye by retinol-binding protein (RBP) and is converted in epithelial cells to all-trans retinyl esters. Next, cleavage of the ester and isomerization to 11-cis retinal occurs. The 11-cis form is either reesterified or transported into rod cells; wherein it combines with opsin to form rhodopsin. The rod cell is designed for highly efficient transfer of energy from photons of light to rhodopsin. The series of events includes structural changes in rhodopsin (e.g., to metarhodopsin and other conformations) with subsequent deprotonation. The deprotonated metarhodopsin interacts with transducin, one of the proteins in the transmembrane G-protein family (depicted as G and G^*) and all-trans-retinal is released for utilization. This interaction causes stimulation of cGMP phosphodiesterase activity (PDE) that results in a decrease in the cGMP formed by guanylyl cyclase (GC) and signal amplification. The local changes in cGMP concentration, in turn, result in cation flux across rod cell membranes to initiate excitation of the optic nerve.

(night blindness), a follicular hyperkeratotic rash of the extremities, and impaired resistance to infections, in addition to congenital ocular malformations in the case of poor maternal vitamin A status.

24.3.1.5 Requirements, Pharmacology, and Toxicity

Cereal grains, with some exceptions (e.g., corn) are minor sources of provitamin A. Among the legume, grains, chickpeas, green, and black beans are the best sources of provitamin A. Because carotenoids are rich in conjugated double bonds and susceptible to oxidation, they are easily destroyed by exposure to intense light, particularly ultraviolet (UV) light. For example, when hay, grasses, and grains are stored for long periods (e.g., months or more), the carotenoid content can be markedly reduced due to chemical or physical (UV light) oxidation. Likewise, retinoid compounds provided as supplements in tablet form or in animal feed are esterified to protect the reactive hydroxyl group; however, this still leaves multiple susceptible double bonds. The esters are further stabilized using various techniques, often with the use of enrobing processes such as antioxidant-containing beadlet coatings.

For any given animal, the requirement for vitamin A depends upon age, sex, rate of growth, and reproductive status. In addition, most carnivores such as cats and ferrets do not efficiently convert carotenoids to vitamin A and require a dietary source of preformed vitamin A (Morris, 2002a, Green et al., 2012). For optimal maintenance, the allowance for many animals in the 10–30 kg body weight range is 100–200 international units per kg of body weight per day (one international unit is equal to 0.3 mg of retinol). However, as noted in the previous section, a more precise method of expressing the vitamin A requirement is on an energetic basis. In animal feeds, 4,000–10,000 international units per kg of feed are considered adequate in the United States to provide vitamin A requirements for most animals. With regard to teratogenic effects, malformations include cleft palate, cranioschisis, foreshortened mandible, stenotic colon, enlarged heart, and agenesis of the spinal cord and small intestine are observed with ingestion of 100,000 RE/kg diet over extended periods (Freytag et al., 2003).

When a single dose of vitamin A (>100 mg) is injected into animals (20–50 kg weight range), symptoms such as nausea, vomiting, increased cerebral spinal fluid pressure, and impaired muscular coordination will result. A lethal dose of vitamin A (100 mg) given to young monkeys has been reported to cause coma, convulsions, and eventual respiratory failure (Macapinlac and Olson, 1981). Chronic toxicity may be induced by intakes of vitamin A in amounts 10 times the normal requirements. Doses of vitamin A in this range can lead to alopecia, ataxia, and bone and muscle pain. Chronic intakes (exceeding 10 times the requirements for given animals) can also be teratogenic. Carotenoids, unlike retinoids, are generally nontoxic, and many animals routinely ingest gram amounts of carotenoids on a daily basis with no deleterious effects.

Vitamin A and various retinoid analogs are used increasingly to treat skin disorders (acne and psoriasis) and certain forms of cancer, because of their role in epithelial cell gene regulation. As an example, vitamin A responsive dermatitis in cocker spaniels is well recognized and described. Retinoyl- β -glucuronide and hydroxyethyl retinamide are commercial preparations of retinoids are sometimes used in treating the dermatitis. In this regard, retinoyl- β -glucuronide and hydroxyethyl retinamide are less toxic than retinoic acid.

24.3.2 VITAMIN D

24.3.2.1 Overview

Vitamin D is the generic term for a group of sterols that regulate calcium absorption and homeostasis (Norman and Henry, 2007). The forms of vitamin D include vitamin D₃ (cholecalciferol), which is the naturally active form of the vitamin, and vitamin D₂ (ergocalciferol), its synthetic form and a form also found in plants, fungi, and yeast. When UV light from the sun interacts with the leaf of

a plant, ergosterol is converted into ergocalciferol or vitamin D₂. Vitamin D₃ is a provitamin that is synthesized in skin from endogenous 7-dehydrocholesterol upon exposure to sunlight and is found in the diet in oily fish, egg yolks, and fortified milk (Figure 24.4). The dietary requirements for the intake of vitamin D are not precise because they depend in part on the degree of exposure to the sun. The differences in the side chains of vitamin D₃ and vitamin D₂ also result in compounds with different potencies.

Most animals can synthesize sufficient quantities of cholecalciferol 7-dehydrocholesterol if they receive adequate exposure to UV light of wavelength 280–320 nm. The skin of dogs and cats and other carnivores (e.g., ferrets), however, contains only small quantities of 7-dehydrocholesterol, which does not permit adequate synthesis of vitamin D or cholecalciferol. As such, both species are solely dependent on the diet for this vitamin (How et al., 1994; Morris et al., 1999; Morris, 1999, 2002b; Hazewinkel and Tryfonidou, 2002). Cats can utilize ergocalciferol to meet these needs with an efficiency of about 70% that of cholecalciferol (Morris, 2002b); research is lacking in dogs but presumably the utilization is at least as high as that of the cat.

With the exception of animal products, most natural foods contain low vitamin D activity. Fish liver oils (mainly sardines, salmon, and herring) contain high amounts of vitamin D. Ergosterol derivatives are present in many plants, some of which have potent vitamin D activities.

24.3.2.2 Metabolism

Like other fat-soluble vitamins, dietary vitamin D is absorbed after micellar solubilization in the upper intestine. It is then incorporated into chylomicrons for entry into the circulation via lymphatics followed by uptake by the liver. Several hydroxylation steps are required for the activation of vitamin D. The product of the hydroxylations is 25-(OH)-D₃. 25-(OH)-D₃ is synthesized in the liver and serves as the precursor for 1 α ,25-(OH)₂-D₃, the active form of the vitamin that is synthesized in response to hypocalcemic states, and 24,25-(OH)₂-D₃, which is synthesized in response to hypercalcemic states. Synthesis of both forms occurs in the proximal renal tubular cells of mammals. The main action of 1 α ,25-(OH)₂-D₃ is to maintain blood calcium levels by aiding in the regulation of calcium absorption from the intestine and by suppressing the release of parathyroid hormone (PTH). 1 α ,25-(OH)₂-D₃ also regulates gene transcription by interacting with vitamin D membrane receptors and nuclear receptors in many different tissues. Alternatively, when calcium regulation is normal, the metabolism of 1-(OH)-D₃ or 1-(OH)-D₂ is diverted to 24,25-(OH)₂-D₃ or 24,25-(OH)₂-D₂ formation, respectively, by the action of a renal 24-hydroxylase (Norman and Henry, 2007). The derivative 24,25-(OH)₂-D₃ metabolite has been shown to be crucial to bone fracture healing. The renal 24-hydroxylase becomes elevated after a fracture, thereby increasing the blood concentrations of 24,25(OH)₂-D₂ or D₃ (Norman and Henry, 2007). Also, more than 20 other hydroxylated intermediates and end products have been identified. Most of these derivatives are routed into elimination pathways, although some may be potentially functional (e.g., 1,24,25-trihydroxycholecalciferol that has some vitamin D activity).

24.3.2.3 Functions

Dietary vitamin D deficiency reduces calcium absorption, secondarily increasing PTH, and the risk for osteopenic bone disorders. The two major sites of action of 1,25-(OH)₂-D₃ (1,25-(OH)₂-cholecalciferol, also called calcitriol) are in bone, where it acts rapidly in concert with PTH in response to hypocalcemia, and at the intestine, where the response time is longer (Xue et al., 2005). Calbindin, a calcium-binding protein, is a major product synthesized in intestinal cells in response to calcitriol. Calbindin influences the movement of calcium across the intestinal cell. Binding of calcium to this protein allows the intracellular concentration of calcium to be elevated. The hormone forms of cholecalciferol also stimulate the production of the calcium, sodium-dependent ATPases, which reside on the luminal surface of the intestinal cell, and facilitate the movement of calcium out into circulation.

Vitamin D receptors (VDRs) have also been found in a large number of cell types, ranging from skeletal muscle to cells important to immune and phagocytic functions, for example, macrophages (Norman and Henry, 2007). In pancreatic β -cells, 1,25-(OH) $_2$ -D $_3$ has also been observed to be important to normal insulin secretion. Vitamin D increases insulin release from isolated perfused pancreatic cells. Moreover, vitamin D metabolites can suppress immunoglobulin production by activated B lymphocytes. T cells are also affected by vitamin D metabolites. 1,25-(OH) $_2$ -D $_3$ exhibits permissive or enhancing effects on T-cell suppressor activity. Naturally occurring deficiencies of vitamin D occur in lambs born to ewes not supplemented prepartum with D $_3$ in northern latitudes during the winter months (Figure 24.7). Vitamin D deficiency also occurs in animals reared in rooms with artificial light (Morris et al., 1999).

FIGURE 24.7 Vitamin D deficient rachitic sheep. (Courtesy of James Morris, School of Veterinary Medicine, UC Davis.)

More recently, Titmarsh et al. (2015a, 2017) demonstrated a negative relationship between serum 25-hydroxyvitamin D concentrations and neutrophil, monocyte, lymphocyte, and eosinophil counts, duodenal histopathology scores, and serum IL-2, IL-6, IL-8, and TNF α concentrations in dogs with histologically confirmed chronic enteropathies. In a related publication, this group also reported that low serum 25-hydroxyvitamin D concentrations at the time of diagnosis were associated with negative outcomes in dogs with chronic enteropathies (Titmarsh et al., 2015b). Also, a study by some of the same authors reported an inverse relationship between serum 25-hydroxyvitamin D and neutrophil counts in hospitalized cats (Titmarsh et al., 2017). They also reported low serum 25-hydroxyvitamin D concentrations in cats with feline immunodeficiency virus (FIV) compared to healthy controls (Titmarsh et al., 2015c). Further research is necessary to determine how vitamin D status influences the immune system and disease outcomes in dogs and cats.

24.3.2.4 Requirements, Pharmacology, and Toxicity

Most adult animals require approximately 7.5 μ g cholecalciferol or more per 1000 kcal of diet. When intake exceeds 10–20 times that amount on a chronic basis, there is a risk of toxicity, characterized by hypercalcemia, hypercalciuria, and soft-tissue calcification, in particular, the blood vessels of the lung, kidney, and heart. Acute doses of vitamin D (>100 times the requirement) can eventually result in a negative calcium balance because bone resorption is accelerated. As noted, some plants (e.g., *Solanum malacoxylon*, *Cestrum diurnum*, and *Trisetum flavescens*) contain compounds with vitamin D activity (mostly glycosylated forms of ergocalciferols), and vitamin D intoxication can follow their ingestion (Norman et al., 2002). Naturally occurring toxicity has occurred in dog and cats given commercial diets containing large amounts of vitamin D or rodenticides (Morita et al., 1995, Studdert, 1990). The viscera of some fish, particularly liver, may contain high amounts of vitamin D. Administration of pamidronate, in the bisphosphonate family, has been used to treat vitamin D toxicosis in dogs (Rumbeiha et al., 1999).

24.3.3 VITAMIN E

24.3.3.1 Overview

Vitamin E comprises eight tocopherols, of which two, α - and γ -tocopherol, appear to be the most significant (Figure 24.8). The predominant natural form of vitamin E is the RRR isomer of α -tocopherol. Compounds with vitamin E activity are found in polyunsaturated vegetable and seed oils. In addition to the tocopherols, tocotrienols are also a part of the family but differ because of the presence of an unsaturated side chain. Tocotrienols occur at lower levels in nature.

Tocopherols act primarily at a chemical level as antioxidants and because of their function in stabilizing cell membranes also have a facilitative role in cell signaling (Mustacich et al., 2009). Compounds with the properties of vitamin E protect unsaturated fatty acids in the phospholipids of cell membranes from oxidation. The quinone moiety of tocopherols is capable of quenching free radicals, such as free radicals of hydrogen (H \bullet), superoxide radicals (O $_2^{\bullet-}$), hydroxyl radicals (OH \bullet), and other lipid-derived radical species (LOO \bullet). Vitamin E, in the course of its action, is sacrificed in acting as a free radical scavenger, although there is evidence that the monomeric forms of the vitamin may be recovered following reduction.

Cell membranes contain vitamin E at a concentration of approximately 1 mg per 5–10 g of lipid membranes. Membrane lipids are constantly engaged in the process of turnover and repair. By prolonging the initiation time, before a free-radical chain reaction occurs (Figure 24.9), vitamin E gives cells time to replace damaged membrane lipids and lipid island domains through the process of normal cell turnover (Rucker, 2015).

FIGURE 24.8 Tocopherol isomers, phyloquinone, and menaquinone.

FIGURE 24.9 Steps in lipid oxidative cascade reactions. Hydrogen atoms associated with nonconjugated double bonds, allylic H atoms ($-\text{C}=\text{C}-\text{HCH}-\text{C}=\text{C}-$) in fatty acids (LH) are particularly susceptible to abstraction. A large amount of oxygen is taken up, leading to the formation of hydroperoxides (LO \cdot), which can decompose into alkoxy and peroxy free radicals, followed by the formation of cross-links and various short-chain cleavage products (malondialdehyde, ethane, and pentane). The process leads to an amplified chain of reactions and cellular damage if the process is not diverted or quenched by an antioxidant.

24.3.3.2 Metabolism

The intestinal absorption of dietary vitamin E (natural and synthetic forms) includes de-esterification of vitamin E esters by pancreatic esterases, followed by bile-dependent incorporation into intraluminal micelles (Traber, 2014). Manufacturers of synthetic vitamin E convert the phenol form of the vitamin to esters (usually as the acetate or succinate), which makes them more stable and easier to use in vitamin supplements. Intraluminal micelle incorporation is followed by the uptake of vitamin E into enterocytes and incorporation into chylomicrons for the eventual transfer to the lymphatics for transport to targeted tissues.

Once the chylomicrons are broken down by lipoprotein lipase, the vitamin E equilibrates with both high-density (HDL) and low-density lipoproteins (LDL) and vitamin E remaining in the chylomicron returns to the liver for reuptake. In this regard, the reuptake and redistribution from the liver to peripheral tissues has some unusual dimensions. The vitamin E returned to circulation from the liver is mostly associated with hepatic VLDL. RRR- α -tocopherol now constitutes over 80% of the vitamin E in the VLDL fraction. The predominance of RRR- α -tocopherol is due to the preference of hepatic alpha-tocopherol transfer protein (ATTP) for RRR- α -tocopherol (Traber, 2007). ATTP is essential for the transfer of vitamin E to VLDL during hepatic VLDL assembly. Following release from the liver and the action of lipoprotein lipase, the VLDL fractions equilibrate to LDL containing RRR- α -tocopherol. Peripheral tissues then take up the LDL by LDL-receptor mediated endocytosis.

24.3.3.3 Functions

Because vitamin E is ubiquitous in most mixed diets, a deficiency occurs primarily with malabsorptive disorders involving the biliary circulation, pancreas, and intestinal mucosa (Traber, 2014). Young animals are more susceptible to a deficiency than older animals. In its most severe forms, vitamin E deficiency results in neurological damage involving the posterior columns, cranial nerves, brainstem, and peripheral nerves. Retinal damage may also occur. Vitamin E deficiency presents clinically with loss of balance, peripheral neuropathy, or possible visual field defects. Deficiency signs also include immune system compromise (including periportal mononuclear infiltration in the liver), dermatitis, cardiomyopathy, and focal interstitial and myositis of muscle.

In horses, neuronal axonal dystrophy, equine degenerative myeloencephalopathy, and equine motor neuron disease are associated with a temporal deficiency of α -tocopherol (Finno et al., 2016). The former two can occur in genetically susceptible horses if α -tocopherol deficiency occurs during the first year of life (Finno et al., 2015). Comparatively, equine motor neuron disease occurs in adult horses after a long period of α -tocopherol deficiency (Mohammed et al., 2007). It is still not clear what role α -tocopherol plays in the pathogenesis of equine degenerative diseases. The major dietary source of α -tocopherol for the horse is grass. It has been speculated that many horses could be deficient in α -tocopherol secondary to reductions in pasture due to drought and urban housing of horses (Finno et al., 2016).

Because vitamin E acts as a defense for lipid oxidation, other compounds capable of residing in lipid membrane may substitute for vitamin E (e.g., various flavonoids). Enzymes such as superoxide dismutase, catalase, glutathione peroxidase (GPx), and related systems for oxidant defense can moderate the absolute need for vitamin E (Figure 24.10; Rucker, 2015).

As noted, vitamin E can also influence cell signal transduction pathways. Changes in the activities of protein kinase C and phosphatidylinositol 3-kinase have been reported and associated with changes in cell proliferation, platelet aggregation, and nicotinamide adenine dinucleotide phosphate (NADPH)-oxidase activation. Vitamin E status also influences genes that are involved in the uptake and degradation of tocopherols and antioxidant defense (e.g., α -tocopherol transfer protein, cytochrome P450-3A, γ -glutamyl-cysteine synthetase heavy subunit, and glutathione-S-transferase), and genes that are involved in the modulation of extracellular matrix proteins, cell adhesion, and inflammation (Traber, 2007, 2014).

FIGURE 24.10 Vitamin E and antioxidant defense. A number of factors can influence the need for tocopherols in cells and its utilization at a cellular level. Vitamin E acts as the last line of defense for lipid oxidation, primarily residing in lipid membranes. Tocopherols quench lipid-derived free radicals (LOO•, see Figure 24.9). Ascorbic acid is capable of regenerating vitamin E as long as ample reduced glutathione (GSH) and glutathione reductase are available to regenerate ascorbic acid. Free radical scavenging enzymes, such as superoxide dismutase (catalyzes super oxide radicals to hydrogen peroxide), catalase (catalyzes hydrogen peroxide to water and oxygen), and glutathione peroxidase (GPx, catalyzes lipid and/or hydrogen peroxides to water or hydroxy fatty acids) assist in the process. Related systems for oxidant defense (generation of reductants, such as NADPH), via the indirect oxidation of glucose (e.g., the hexose monophosphate shunt pathway) and reduced GSH (maintained by glutathione reductase, GR) also play essential roles. Without intracellular control of reactive oxygen species, polyunsaturated lipids are targets for oxidation (see Figure 24.9).

In domestic and laboratory animals, naturally occurring deficiencies of vitamin E do occur. “Brown bowel syndrome” is the condition that has been used to describe inadequate vitamin E intake owing to ulcerative and degenerative changes in intestinal tissue. In addition, the cells of the eyes and testes can be affected. In cats, especially those fed fish diets that are not usually fortified with vitamin E, the condition is sometimes referred to as “yellow fat disease” or pansteatitis. Pansteatitis is often caused by the consumption of high levels of unsaturated fatty acids or the insufficient intake of vitamin E (Niza et al., 2003). Proper handling of fish is essential to prevent the polyunsaturated fatty acids (PUFAs) in fish oil from readily oxidizing following their harvest and processing. Consumption and deposition of oxidized lipids and PUFAs can accelerate tissue oxidation.

24.3.3.4 Requirements, Pharmacology, and Toxicity

The requirement of vitamin E varies with the intake of PUFA, and for most animals is on the order of 25–50 mg per kg dry diet or 4–8 mg per 1000 kcal or 4.184 MJ. A water-soluble form of vitamin E, RRR- α -tocopherol glycol (Aquasol E), is better absorbed than the dietary, fat-soluble natural vitamin, and hence is more useful in the treatment or prevention of vitamin E deficiency in malabsorption diseases. There are few data on vitamin E toxicities (Traber, 2014). In the human clinical literature, there is the concern that pharmacologic doses of vitamin E (gram quantities per day) may displace or interfere with vitamin K metabolism, but very high and sustained intakes are required.

24.3.4 VITAMIN K

24.3.4.1 Overview

Vitamin K is derived from dietary phyloquinone (K₁, from plants) and menaquinones (K₂, synthesized by intestinal bacteria). The primary dietary sources of phyloquinone are green leafy vegetables; dairy products are minor sources. All members of the vitamin K group of vitamins share a

methylated naphthoquinone ring structure (menadione, sometimes designated K_3), but vary in the aliphatic side chain attached at the 3-position of menadione (Figure 24.7). Phylloquinone (vitamin K_1) contains in its side chain four isoprenoid residues, one of which is unsaturated. Menaquinones have side chains composed of a variable number of unsaturated isoprenoid residues and are designated as MK- n , where n specifies the number of isoprenoids. As a class of compounds, vitamin K facilitates the posttranslational γ -carboxylation of proteins involved in blood clotting: prothrombin and factors VII, IX, and X. The presence of γ -carboxyglutamic acid (GLA) residues is essential for calcium binding, as required in blood clotting. Vitamin K also enhances γ -carboxylation of osteocalcin, and vitamin K deficiency contributes to osteoporosis, whereas vitamin K supplementation has been shown to prevent bone fractures (Suttie, 2014).

24.3.4.2 Metabolism

Menaquinone is absorbed from the distal ileum in the presence of bile salts and less efficiently from the colon of most animals. In contrast, phylloquinone undergoes micellar incorporation, after which it is transported into the enterocytes. Comparative studies of the forms of vitamin K in the liver suggest that menaquinone from bacterial synthesis provides substantially less vitamin K than dietary phylloquinone for most monogastric animals. Regarding turnover, unlike other fat-soluble vitamins, the total pool of vitamin K in the body is replaced rapidly within hours to days in contrast to weeks or months (Suttie, 2014).

24.3.4.3 Functions

Although a detailed history related to the discovery of vitamin K is beyond the scope of this section, it is important to note that much of the early progress toward discovery was accelerated when it was demonstrated that hemorrhagic disease in animals could be reversed by extracts of alfalfa. A connection between spoiled clover and grasses that seemed to cause hemorrhagic disorders in animals was also known. It is now appreciated that some compounds in the 1,4-naphthoquinone series possess vitamin K activity, as well as relatively simple compounds, such as menadione. For example, an active “vitamin K” can be synthesized from menadione when combined with isoprenoids from the cholesterol synthesis pathway.

Vitamin K serves as a cofactor for microsomal carboxylases (Stafford, 2005), which are responsible for GLA formation (Figure 24.11). GLA residues serve as calcium binding sites in the pro-forms of proteinases associated with blood coagulation and bone formation. Calcium binding is a requisite for their eventual activation. The vitamin K-dependent (VKD) carboxylase utilizes oxygen and bicarbonate as cosubstrates, and the reaction only occurs if glutamic acid is a part

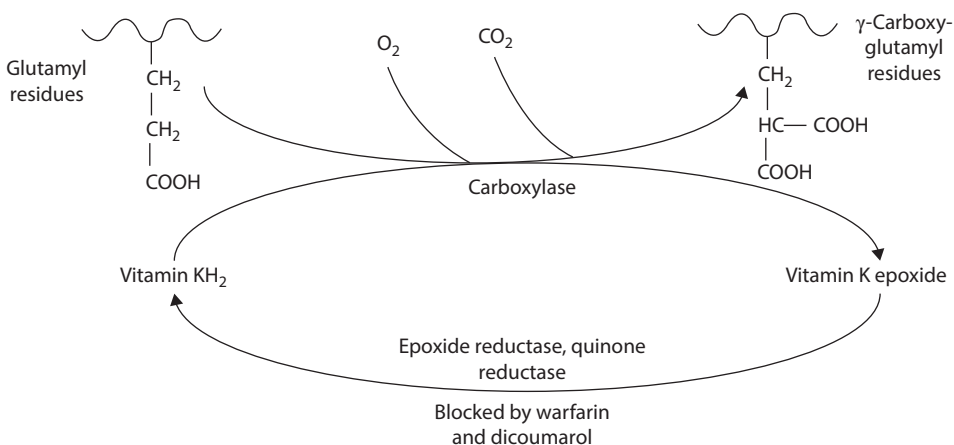

FIGURE 24.11 The role of vitamin K in γ -carboxyglutamyl residue formation.

of a polypeptide. The levels of reduced vitamin K available for the reactions control the rate of carboxylation. Carboxylation requires the abstraction of a proton from the 4-carbon of glutamate by reduced vitamin K and results in the conversion of reduced vitamin K to a vitamin K epoxide, which can be recycled to vitamin K (Stafford, 2005).

Vitamin K regulation is linked to control of blood coagulation owing to its role as a cofactor for the activities of factor X and prothrombin. The system comprises membrane-bound and circulating proteins that assemble into multimolecular complexes on cell surfaces. Vitamin K-dependent protein C also is a key component of the system. VKD protein circulates in blood as a zymogen with potential anticoagulant serine protease activity. It is activated on the surface of endothelial cells by thrombin bound to the membrane protein thrombomodulin; an endothelial protein C receptor further stimulates the protein C activation. Moreover, activated protein C together with another protein, cofactor protein S, can also slow coagulation by degrading FVIIIa and FVa on the surface of negatively charged phospholipid membranes, providing a level of reversible control (Suttie, 2014). Recent interest in vitamin K has also stimulated a search for physiological roles beyond that of coagulation and control of mineralization. Vitamin K and VKD proteins have been suggested to be involved in regulation of energy metabolism and inflammation. However, the evidence for many of these proposed roles in the maintenance of animal health remains equivocal or appears indirectly related to the well-established functions of this vitamin (Booth, 2009).

In bone, GLA-containing proteins (osteocalcins) are involved in the regulation of new bone growth and formation. The presence of GLA protein in bone helps to explain why administration of the vitamin K antagonist at levels that cause hemorrhagic diseases may result in bone defects, particularly in neonates. Vitamin K-related mineralization disorders are characterized by complete fusion of the proximal tibia growth plate and cessation of longitudinal bone growth (Suttie, 2014).

24.3.4.4 Requirements, Pharmacology, and Toxicity

The establishment of the dietary requirement for many animals has been difficult due to vitamin K's short half-life and possible synthesis of vitamin K by intestinal bacteria. The extent to which animal species practice coprophagy is another factor. Birds tend to have relatively high requirements for vitamin K; thus, chickens have been used extensively as experimental animal models in vitamin K-related studies. Recent work suggests that the vitamin K requirement is dependent upon the relative content of vitamin K epoxide reductase activity. A low level of epoxide reductase activity can result in an increased requirement for vitamin K. Ruminant microorganisms synthesize large amounts of vitamin K; thus, ruminants do not need an external source for this reason.

Recent assessments of nutritional requirements suggest that small animals should obtain approximately 500–1000 µg as phylloquinone per kg diet (Table 24.1 and references cited). Oxidized squalene and high intakes of vitamin E may act as vitamin K antagonists. Insufficient vitamin K can also occur with antibiotic treatment, treatment with coccidiostatic drugs, or long-term parenteral hyperalimentation without vitamin K supplements. Few hazards have been attributed to long-term ingestion of vitamin K in amounts of 1–10 mg per kg diet as phylloquinone. However, menadione in amounts corresponding to 10–100 mg per kg of diet may act as a prooxidant, and high dietary concentrations produce hemolysis. Neonatal brain or liver damage has been reported. For humans, the U.S. Food and Drug Administration has banned menadione supplements because of their potential for toxicity; however, low levels of menadione are still used as an inexpensive micronutrient for animals in many countries.

Vitamin K antagonists are utilized in the prevention of thrombosis and emboli formation (Merli and Fink, 2008). Most are effective, but treatment has to be monitored because of interaction with foods and other hemolytic drugs or counteraction by a vitamin K source. The most common vitamin K antagonists are warfarin and coumarin, the latter of which is found naturally in many plants. Warfarin and related coumarins decrease blood coagulation by inhibiting the vitamin K epoxide reductase system. Phylloquinone, rather than menadione, should be used parenterally to treat animals that have ingested warfarin or other anticoagulants. The clinical settings for

vitamin K deficiency include a combination of dietary inadequacy and prolonged antibiotic use, lipid malabsorption syndromes such as cholestatic liver disease (including biliary obstruction), or exposure to vitamin K antagonists.

24.3.5 Fat-Soluble Vitamin Assessment

Vitamin A status can be measured by HPLC methods using plasma or serum samples. Blood levels of RBP can be measured by radial immunodiffusion (Eitenmiller and Landen, 1998, Weinmann et al., 1999). The relative dose–response assay is used in field studies and consists of measuring RBP before and after a standard oral dose of vitamin A. Apo-RBP accumulates in the liver during vitamin A deficiency. Thus, an increase of circulating holo-RBP following treatment is indicative of vitamin A deficiency. Assessment using plasma RBP, however, is complicated when there is accompanying protein–calorie malnutrition, severe infections, or trauma. In particular, malnutrition decreases the expression and release of RBP (Vesterberg, 1994). The content of vitamin A in a liver biopsy is the gold standard for assessment of vitamin A status (Eitenmiller and Landen, 1998).

Reliable assays for the measurement of vitamin D and its calcidiol and calcitriol metabolites in plasma are available (Higashi et al., 2008, 2010). The best index is 25-OH vitamin D, which has a half-life of about 3 weeks and provides a useful index of vitamin D status, making it the measurement of choice. Plasma concentrations of 25-OH vitamin D of 20–150 nmol/L or 8–60 ng/mL cover the normal range of most animals. Specific ranges to support distinctions for sufficiency, insufficiency, and deficiency have recently been advocated in both humans and animals (Holick, 2007; Selting et al., 2014). Calcitriol is present in picomolar concentrations (normal values range from 40 to 150 pmol/L or 16 to 60 pg/mL), and has a half-life of about 4–6 hours in a large (50–100 kg) animal. Concentrations of vitamin D in plasma after oral administration are often a 1000-fold higher in the nanomolar range. Vitamin D has a half-life of 24 hours, so the plasma concentration reflects immediate intake, rather than overall status.

Plasma levels of α -tocopherol are also routinely determined by high-performance liquid chromatography (HPLC) methods (Karppi et al., 2008, Bompadre et al., 2008) and vary according to the total plasma lipid concentration because α -tocopherol is transported mostly in association with LDL particles. While α -tocopherol can readily be separated from other tocopherols, the separation of δ and γ isomers is difficult. For nutritional assessment of vitamin E, the current indices are based on changes in total tocopherol concentrations in plasma and serum. Measurement of tocopherol concentration in erythrocytes or platelets is also a good indicator of vitamin E status. Although the measurement of adipose levels of tocopherols may seem to be a reliable index for assessing vitamin E status, vitamin E partitions primarily into the membrane lipid compartments. Thus, the concentration of vitamin E per adipose tissue mass may increase when there is a loss of nonmembrane-stored triglycerides. As the plasma tocopherol concentration is affected by lipid concentration, an α -tocopherol/total lipid ratio of 0.6–0.8 mg/g of total lipids has been suggested as indicating adequate nutritional status. Functional tests, such as the hemolysis of erythrocytes in the presence of 2% peroxide, are also used to indicate vitamin E status. Malondialdehyde, 8-hydroxy-2'-deoxyguanosine, 4-hydroxy-2-nonenal-modified proteins, and ethane or pentane exhalation (see Figure 24.9) have also been used as indirect measures of vitamin E. Of note, malondialdehyde can be measured as a thiobarbituric acid or 1-methyl-2-phenylindole adduct to yield colored fluorescent derivatives that can be assayed spectrophotometrically.

Vitamin K deficiency can be assessed by a prolonged prothrombin time that responds to parenteral vitamin K administration and by direct measurement of circulating phylloquinone by HPLC methods (Eitenmiller and Landen, 1998, Kamao et al., 2005).

24.4 WATER-SOLUBLE VITAMINS

Most water-soluble vitamins serve as enzymatic cofactors (Rucker and Chowanadisai, 2016). For example, ascorbic acid, niacin, and riboflavin serve primarily as redox cofactors. The roles of

thiamin, pyridoxine (vitamin B-6), and pantothenic acid (as a component of coenzyme A [CoA]) are distinguished because of their importance to carbohydrate, amino acid, and acyl and acetyl transport, respectively. Biotin, folic acid, and vitamin B-12 (cobalamin) have roles in single-carbon metabolism. Regarding functions, the most limiting events that control or regulate function are specific step(s) in cofactor formation, for example, a phosphorylation reaction or adenosine triphosphate (ATP) addition. From a nutrition perspective, the availability of vitamins from foods often requires complex processes and specialized transport mechanisms (Figure 24.12).

24.4.1 VITAMINS INVOLVED IN REDUCTION–OXIDATION

Redox, or reduction–oxidation, reactions describe chemical reactions in which atoms or intermediates in a process have their oxidation number (oxidation state) changed, although the actual transfer of electrons may not always be apparent, such as reactions and processes involving covalent bonds. With the cofactors derived from ascorbic acid, niacin, and riboflavin (Figure 24.13), it is possible for cellular systems to carry out a range of redox reactions utilizing mechanisms that involve ion hydride transfers (via NAD or NADP), radical hydrogen ion transfers (via flavin mononucleotide [FMN] or flavin adenine dinucleotide [FAD] or ascorbic acid), and one electron plus one proton transfers (via FMN or FAD). Enzymes utilizing these vitamins catalyze reactions over a wide range of chemical potentials (Johnston et al., 2014; Kirkland, 2014; McDonnell, 2001; Pinto and Rivlin, 2014; Rucker and Chohanadisai, 2016).

24.4.1.1 Ascorbic Acid

24.4.1.1.1 Overview

Ascorbic acid (vitamin C) is one of the most important redox cofactors in animal systems. Although most animals make sufficient ascorbic acid, for some, ascorbic acid is a true vitamin because of an inability to carry out adequate synthesis or production. This is true for higher primates, a small

FIGURE 24.12 Vitamin absorption. Vitamins in foods are usually present as cofactors or attached to proteins. Pancreatic and intestinal enzymes, nucleosidases, phosphatases, and peptidases are key factors in processing cofactors to vitamins in the intestinal lumen. Transport of given vitamins next occurs by receptor receptor-mediated or pericellular-related processes, passive transport (usually at high luminal concentrations), active transport, or facilitated processes (requiring a transporter or chaperone). (From Rucker et al., In N. Van Alfen (ed.), *Encyclopedia of Agriculture and Food Systems*, San Diego, 2014.)

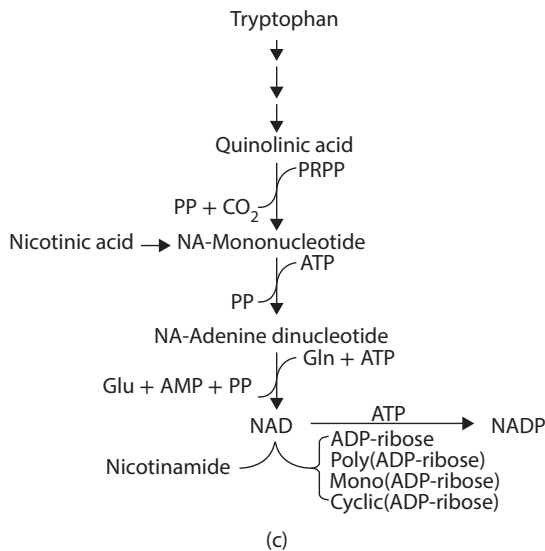

FIGURE 24.13 Vitamins necessary to redox. (a) The relationship between ascorbic acid, dehydroascorbic acid, and various products of ascorbic acid oxidation; (b) the relationship of riboflavin to flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD); (c) the relationship of tryptophan degradation to nicotinic acid, niacin, and NAD production and function.

number of other mammals (e.g., guinea pigs and bats), and some species of birds and fish (Johnston et al., 2014).

Ascorbic acid deficiency causes scurvy. Scurvy in its most severe stages impacts collagen-related supporting structures and can lead to skin lesions and bleeding from the mucous membranes. In most animals, ascorbic acid is derived from the direct oxidation of glucose and galactose. Steps in the reaction are

In animals, a key enzyme in this process is L-gulonolactone oxidase (EC 1.1.3.8), which catalyzes the final step in ascorbic acid synthesis, that is, oxidation of gulono-1,4-lactone to ascorbic acid. In keeping with the evolutionary links to glucose metabolism, L-gulonolactone oxidase resides in the kidney of most birds and reptiles, and during evolution, the enzyme was transferred to the liver of mammals.

In addition to facilitating redox reactions, ascorbic acid can form relatively stable free radical intermediates (Linster and Van Schaftingen, 2007). This ability can significantly delay or prevent free radical-initiated oxidations. Ascorbic acid readily scavenges reactive oxygen and nitrogen species, such as superoxide, hydroperoxyl, peroxyxynitrite, and nitroxide radicals. Ascorbic acid is often associated with the protection of lipid, DNA, and proteins from oxidants. As examples, when peroxy radicals (LOO[•], see Figure 24.10) are generated in plasma, ascorbic acid is consumed faster than other antioxidants, for example, uric acid, bilirubins, and vitamin E. Ascorbic acid is 100 times more reactive than a PUFA in reacting with peroxy radicals. In contrast, ascorbic acid can be viewed as a prooxidant under aerobic conditions when metals capable of redox ($\text{Fe}^{+2} \leftrightarrow \text{Fe}^{+3}$; $\text{Cu}^{+1} \leftrightarrow \text{Cu}^{+2}$) are present. Metals, such as iron and copper in their reduced states, are useful Fenton catalysts (Johnston et al., 2014).

24.4.1.1.2 Metabolism

Specific transport proteins mediate the transport of ascorbic acid across biological membranes. In animals, dehydroascorbic acid uptake can occur by the facilitated-diffusion glucose transporters (GLUT 1, 3, and 4), although under physiological conditions these transporters may play minor roles in the uptake of dehydroascorbic acid due to competition from glucose. In contrast, L-ascorbic acid enters cells via Na⁺-dependent transport systems (e.g., sodium-ascorbate cotransporters (SVCT1 and SVCT2). SVCT2 is involved in ascorbic acid transport in almost every tissue, except red blood cells, which lose SVCT proteins during maturation (Wilson, 2002, 2005).

The bioavailability of dietary ascorbic acid is dose dependent, but absorption can be as high as 70%–80% at physiological concentrations (20–200 mg/kg diet). The ileum and jejunum are major sites of absorption. In circulation, it is not protein bound and is eliminated with a half-life in most animals that may be measured in hours. Some tissues can accumulate as much as 100 times the level of ascorbic acid in blood (e.g., adrenal glands, pituitary, thymus, corpus luteum, and retina). Although tissue concentrations range from micromolar to millimolar amounts, there is also ample evidence that accelerated metabolism occurs after prolonged supplementation at high doses (Wilson, 2005).

Cellular accumulation of ascorbic acid occurs because of cellular dehydroascorbate reduction systems that are capable of rapidly generating reduced ascorbic acid (Wilson, 2002). The ascorbate reduction systems are also important in reducing the ascorbic acid radical. This is important because excess ascorbate radicals may initiate free radical cascade reactions or nonspecific oxidations. The reduction system is dependent on maintaining NADPH and reduced glutathione levels. An aspect of this relationship is given in Figure 24.11 and involves mechanisms in which decreased glutathione levels may stimulate ascorbic acid synthesis in animals that can produce it. During the

postnatal period, animals adapt from a relatively hypoxic to a relatively hyperoxic environment. In this regard, one of the glutathione's many functions is to keep ascorbic acid in a reduced form. In adult animals that make ascorbic acid, a reduction in glutathione levels can lead to a rapid increase in liver dehydroascorbic acid. An adequate ascorbic acid intake is particularly important in newborns and neonates, for which the potential to synthesize ascorbate is less than adults.

Vitamin C homeostasis is also facilitated by the induction of ascorbic acid decarboxylase activity, which initiates degradation of ascorbate to CO₂ and C-4 or C-5 fragments. Significant amounts of ascorbic acid, particularly in fish, may also exist as the 2-sulfate derivative. In rats, about 5% of a labeled dose of ascorbic acid is recovered in urine as 2-O-methyl ascorbic acid. Cellular modification of ascorbic acid is important for compartmentalization or modulation of functional ascorbic acid levels.

24.4.1.1.3 *Functions*

In addition to serving as a general antioxidant and reductant, ascorbic acid also functions as a cofactor in many mono- and dioxygenases to maintain metals (specifically iron and copper) in a reduced state (Rucker, 2015). Important reactions and processes that require ascorbic acid include: (1) norepinephrine synthesis by functioning in dopamine- β -hydroxylase, (2) hormone activation by functioning in peptidyl glycine—amidating monooxygenase, which carries out α -amidation and is found in secretory granules of neuroendocrine cells, (3) carnitine biosynthesis by serving as a cofactor for two of the hydroxylation steps in the pathway of carnitine biosynthesis, γ -butyrobetaine hydroxylase, and ϵ -N-trimethyllysine hydroxylase, and (4) collagen, elastin, C1q complement, and acetylcholine esterase hydroxylations by functioning as a cofactor for prolyl and lysyl hydroxylases. In scurvy, poor wound healing, bruising, and osteopenic abnormalities, impaired lipid metabolism, and behavioral changes occur because of perturbations largely due to the inability to carry out appropriate levels of prolyl and lysyl hydroxylations (Johnston et al., 2014; Linster and Van Schaftingen, 2007).

24.4.1.1.4 *Requirements, Pharmacology, and Toxicity*

To maintain normal functions, most animals generate 10–60 mg of ascorbic acid per 1000 kcal utilized in the course of normal metabolism. The requirement for animals that need dietary sources is in the same range of 30–60 mg per 1000 kcal or 4.2 MJ. Because of the mechanisms in place to homeostatically regulate ascorbic acid, evidence of toxicity, other than gastric upset, is seldom observed (Hathcock et al., 2005). Evidence of toxicity, however, may be manifest when ascorbic acid is consumed in near gram quantities per 1000 kcal. Of interest, ascorbic acid intake in this range can result in decreased histamine production and facilitate reduction of nitrosamines and other putative cancer-promoting agents with similar chemical characteristics. The interaction with nitrosamines occurs primarily in the stomach.

It is also important to reiterate the interaction between ascorbic acid and glutathione (Linster and Van Schaftingen, 2007). Although glutathione's primary function is to reduce disulfide bonds formed within cytoplasmic proteins to cysteinyl residues (by acting as an electron donor), along with ascorbic acid, glutathione is also essential in protecting cells from reactive oxygen species (ROS). Like ascorbic acid, glutathione is found almost exclusively in its reduced form. Indeed, the ratio of reduced glutathione to oxidized glutathione within cells is often used as a measure of cellular toxicity. Also, like ascorbic acid, glutathione is often maintained in the millimolar range in some cells. A deficiency of both ascorbic acid, whether dietary or metabolic, and glutathione (e.g., inhibition by buthionine sulfoximine or acetaminophen) can cause pathologic changes to liver and other organs.

Ascorbic acid is widely distributed in fruits and vegetables; however, it is relatively unstable and easily destroyed during food processing and storage. Ascorbic acid is labile in alkali, heat, intense light, and prolonged exposure to oxygen. The rate of decomposition is accelerated by the presence of metals, especially iron and copper, and by enzymes, such as peroxidases.

24.4.1.2 Niacin

24.4.1.2.1 Overview

Normally, niacin (Figure 24.13) is derived from nicotinamide adenosyl dinucleotide (NAD) and nicotinamide adenosyl phosphodinuclotide (NADP) in food by the action of pancreatic or intestinal nucleosides and phosphatases (Figure 24.12). With the exception of cats and other carnivores, niacin may also be derived from the degradation of tryptophan. Up until the 1930s, niacin deficiency (pellagra) was relatively common and endemic in some human populations. As most mixed diets now contain adequate tryptophan plus available NAD and NADP, niacin deficiency is seldom observed, although it remains a possibility in animals fed monotonous diets containing a limited number of foodstuffs (Kirkland, 2014).

24.4.1.2.2 Metabolism

Following NAD/NADP hydrolysis in the intestinal lumen, niacin is actively taken up by enterocytes. Transporters for subsequent cellular uptake have been identified, but are not as well characterized. About half the niacin present in cells as NAD or NADP is associated with enzymes and the remainder is available as a substrate for mono- and polyribosylation reactions that are important in the regulation of a broad range of enzymes. In the nuclei of cells, polyribosylation of specific histones precedes the normal process of DNA repair. It is this nonredox function of NAD that accounts for the rapid turnover of NAD in cells. Some estimates suggest that as much as 40%–60% of the NAD in cells (Kirkland, 2014; Koch-Nolte et al., 2009) is involved in mono- or polyribosylation reactions (Figure 24.13). When niacin is in excess, most mammals convert it to N-methylnicotinamide, which has a low renal threshold and is excreted (Kirkland, 2014).

24.4.1.2.3 Functions

In 1937, Elvehjem discovered that dogs with “black tongue” responded dramatically both to nicotinic acid and to nicotinamide, which was isolated from liver extracts that had previously been found to have relatively high antipellagra activity. The acid and the amide were tested in humans with pellagra and relief from the irritation of lesions associated with the mucous membrane of the mouth and digestive tract, and the disappearance of acute mental symptoms occurred within a few days.

Virtually, all cells are capable of converting niacin to NAD/NADP. Most enzymes that require NAD are oxidoreductases (dehydrogenases). NAD catalyzes a diverse array of reactions, such as the conversion of alcohols and polyols to aldehydes or ketones. Moreover, cells delegate NAD to enzymes in catabolic pathways, whereas NADP is utilized in synthetic pathways (Kirkland, 2014). An additional and equally important function of NAD is its role as a substrate in mono- and polyribosylation reactions. Mono- and polyribosylation posttranslational chemical modifications are important in many cellular regulatory functions. In the nuclei of cells, polyribosylation of histone precedes the normal process of DNA repair (Koch-Nolte et al., 2008). For example, pellagra-related skin lesions following exposure to sunlight, UV damage of epidermal cell DNA is an underlying mechanism for the dark pigmented lesions associated with pellagra. Lack of niacin and therefore NAD is thought to be a contributing factor to the skin lesions because of the inability of cells to carry out polyribosylation reactions (Koch-Nolte et al., 2008). NAD is also the substrate for cyclic ADP-ribose, which acts as a Ca²⁺ mobilizing second messenger in steps necessary to activating intracellular Ca²⁺ release (Koch-Nolte et al., 2009).

24.4.1.2.4 Requirements, Pharmacology, and Toxicity

Niacin is needed in amounts corresponding to 3–5 mg per 1000 kcal or 4.2 MJ for most monogastric omnivores. The requirement for carnivores is three- to fourfold higher. Carnivores have high protein requirements and appear to have evolved enzyme functions that are less adaptive than in other species (e.g., cats do not downregulate urea cycle enzymes when dietary protein is reduced below requirements). With regard to niacin, the cat also does not decrease

α -amino- β -carboxymuconate- ϵ -semialdehyde decarboxylase (a lyase, which is commonly referred to as picolinic carboxylase) to force tryptophan toward the niacin-synthetic pathway, which in effect makes niacin a dietary essential in carnivores (McDonell, 2001; MacDonald et al., 1884).

Omnivores: Tryptophan \rightarrow L-Kynurenine \rightarrow 3-Hydroxyanthranilic acid \rightarrow Quinolinic acid \rightarrow NAD

Carnivores: Tryptophan \rightarrow L-Kynurenine \rightarrow 3-Hydroxyanthranilic acid \rightarrow 2-aminomuconic acid-6-semialdehyde \rightarrow Picolinic acid or TCA cycle oxidation

Niacin requirements are often expressed as equivalents, where one equivalent corresponds to 1 mg of niacin. In many animals, the conversion of 50–60 mg of tryptophan to niacin produces about 1 mg. Accordingly, a diet containing high-quality protein may contribute as much as 10–15 mg of niacin for NAD/P production. Niacin is found in high levels in animal tissues (chicken, fish, beef—especially liver) and peanuts. Niacin is also present in moderate amounts in whole grains such as wheat and barley, enriched cereal products, mushrooms, and some vegetables such as corn and peas. With regard to pellagra and corn, however, niacin is not highly available unless the corn is finely ground or processed under alkaline conditions, for example, ground in the presence of limestone. Niacin is chemically stable. Thus, treatments such as moderate heat and alkali can result in greater niacin availability.

There are some therapeutic uses for pharmacologic doses of niacin-derived compounds when increased blood flow is desirable. Nicotinic acid can cause vasodilatation. In humans, nicotinic acid in gram quantities per day is an effective lipid-lowering agent (increases HDL).

24.4.1.3 Riboflavin

24.4.1.3.1 Overview

Riboflavin (Figure 24.13) exists in coenzyme forms as FMN and FAD. Riboflavin deficiency is manifested by glossitis, seborrheic dermatitis, and peripheral neuropathies. Riboflavin was one of the first of the B vitamins to be identified. FAD and FMN are cofactors in aerobic processes, usually functioning as cofactors for oxidases, although FAD also can operate in anaerobic environments as a dehydrogenase cofactor (Pinto and Rivlin, 2014).

24.4.1.3.2 Metabolism

FMN and FAD in foods are hydrolyzed in the upper gut to free riboflavin. Riboflavin is absorbed by active processes and is transported in blood to target tissues in association with albumin. The solubility of flavins per se is poor, but the presence of ribose and phosphorylation at the 5 position (riboflavin-5'-phosphate) improves solubility. Riboflavin is chemically stable, although it can be degraded in alkali and by prolonged exposure to UV light.

Enterocytes play a significant role in the rephosphorylation of riboflavin (e.g., the total FMN and FAD prevail over the free form as >50% of the total flavins). Both riboflavin and FMN may be released for utilization by other cells. Because flavin cofactors are tightly bound to the enzymes that they serve, and in some cases even covalently bound, turnover is slower than that for ascorbic acid and niacin (both easily dissociated). The recycling of riboflavin is more a function of the turnover of enzymes that it serves (Mewies et al., 1998) and it does not undergo rapid oxidative destruction (e.g., as is the case for ascorbic acid). Urine is the major route of excretion for riboflavin, although some FAD is excreted in bile. In this regard, riboflavin transport occurs via the bile/arsenite/riboflavin transporter (BART) and putative signaling family of proteins, which includes transporters for bile salts, organic anions, and riboflavin (Mansour et al., 2007).

24.4.1.3.3 Functions

Many flavin-containing proteins are found in the smooth endoplasmic reticulum of cells associated with microsomal phase 1 and 2 processes and xenobiotic metabolism (De Colibus and Mattevi, 2008). Flavoproteins have been discovered that are implicated in a variety of biological processes,

including cell signaling, chromatin remodeling, and cell development. Enzymes containing flavin moieties are distinguished because they are capable of transferring hydrogen directly to molecular oxygen with often the formation of hydrogen peroxide as a product (pinto and Rivlin, 2014; De Colibus and Mattevi, 2008).

Riboflavin deficiency is classically associated with the so-called oral-ocular-genital syndrome. When signs of riboflavin deficiency are observed, they usually include lesions of the oral cavity (cheilitis), inflammation of the tongue (glossitis), and accompanying seborrhea and dermatitis in the genital area. In severe cases of riboflavin deficiency, the filiform papillae are lost, and the tongue changes color from its usual pink to magenta. The ocular lesions include corneal opacity and lenticular cataracts. Riboflavin deficiency also results in lack of growth and failure to thrive. During the deficiency state, dermatitis may develop together with hair loss. One of the more striking signs of riboflavin deficiency in birds is “curled toe syndrome.” Curled toe paralysis has been of economic significance to the broiler industry (McDonnell, 2001). Riboflavin deficiency is rarely found in isolation; it frequently occurs in combination with deficiencies of other water-soluble vitamins.

24.4.1.3.4 *Requirements, Pharmacology, and Toxicity*

Drugs with chemical structures that are similar to riboflavin (e.g., chlorpromazine, imipramine, amitriptyline, penicillin, and theophylline) can displace riboflavin from binding proteins that are important to riboflavin and FMN transport. Flavoproteins are also targets for polymorphic alterations, which can result in higher levels of systemic riboflavin for activation (Shane, 2008). Requirements for riboflavin are lower than those for niacin or ascorbic acid (e.g., 2–6 mg of riboflavin per kg of diet or 0.5–2.0 mg per 1000 kcal). Lean meats, eggs, legumes, nuts, green leafy vegetables, dairy products, and milk are good sources; grains are a poor source of riboflavin. Thus, deficiencies can occur in animals given diets based on primarily cereal grains.

24.4.2 VITAMINS IMPORTANT TO SPECIFIC FEATURES OF CARBOHYDRATE, PROTEIN, AND LIPID METABOLISM

24.4.2.1 Thiamin

24.4.2.1.1 *Overview*

Thiamin, in its active form as thiamin pyrophosphate, is involved in carbohydrate metabolism as a coenzyme for pyruvate dehydrogenase, transketolase reactions, and for the decarboxylation of α -keto acids (Figure 24.14). The five-member (thiazole) ring of thiamin contains an arrangement of atoms ($-N=CH-S-$) called a ylid. The central carbon has carbanion character that acts as an electron-rich center for reactions that are commonly characterized as decarboxylations and transketolations, reactions key to TCA cycle and pentose phosphate pathway regulation.

24.4.2.1.2 *Metabolism*

Thiamin occurs in cells as free thiamin and mono- (TMP), di- (TDP), and triphosphorylated (TTP) derivatives. For example, a thiamine adenine nucleotide has been described (Bettendorff et al., 2007; Makarchikov et al., 2003). As is the case for the other vitamins in their cofactor forms, thiamin is released from foods by the action of phosphatases and pyrophosphatases in the upper small intestine. The active transport of thiamin is greatest in the jejunum and ileum. The majority of thiamin present in the intestine is TDP, but when thiamin is released into circulation, the majority is present as free thiamin. On the serosal side of intestinal cells, egress into plasma is dependent on Na^+ -dependent ATPases.

The majority of thiamin in serum is bound to albumin (Itokawa et al., 1982). Usually, over 80% of total thiamin in blood is found in erythrocytes. A thiamine-binding protein in serum has also been identified and appears to be a hormonally regulated carrier protein. Uptake of thiamin by cells occurs by active transport; about 80% of intracellular thiamin is phosphorylated (Bettendorff and Wins, 2009).

FIGURE 24.14 Chemical structures for (a) thiamin, (b) the vitamers of B-6, pyridoxal, pyridoxine, and pyridoxamine, and (c) the relationship of pantothenic acid to coenzyme A.

24.4.2.1.3 Functions

TDP works as a coenzyme in enzymatic reactions that are involved in oxidative decarboxylations of α -keto acids (Makarchikov et al., 2003). Some examples are given in Table 24.7. These reactions take place in mitochondria and peroxisomes (particularly those involved in the oxidation of branched-chained amino acid and fatty acid-derived products). Also, TDP is also an essential cofactor in transketolase reactions (Figure 24.15). Transketolase reactions (Zhao and Zhong, 2009), in the pentose phosphate pathway, result in the formation of ribose-5-phosphate, which is essential in the production of high-energy ribonucleotides (e.g., synthesis of ATP, GTP, and nucleic acids for DNA and RNA synthesis). An indirect product of such thiamin-related reactions is the production of the coenzyme NADPH, necessary for biosynthetic reactions. A deficiency of thiamin can lead to decreased production of NADPH. In neural tissue, TTP seems to play a role in ion transport (maintenance of Na⁺ and K⁺ gradients). It is evident from the neurological disorders caused by thiamin

TABLE 24.7
Thiamine Pyrophosphate-Related Reactions

Enzyme	Reaction
Pyruvate dehydrogenase complex	Pyruvate → Acetyl CoA + CO ₂
α-Ketoglutarate dehydrogenase complex	α-Ketoglutarate → Succinyl CoA + CO ₂
Pyruvate decarboxylase complex (ethanol fermentation)	Pyruvate → Acetaldehyde + CO ₂ (Acetaldehyde → Ethanol)
Branched-chain amino acid/α-keto acid dehydrogenase complexes	Valine → 2-Ketoisovaleric acid → Isobutyryl CoA + CO ₂ → → Propionyl CoA → Methylmalonyl CoA → Succinyl CoA → TCA cycle
	Leucine → 2-Keto-3-methylvaleric acid → 2 Methylbutyryl CoA + CO ₂ → → Acetyl CoA or [Propionyl CoA → Methylmalonyl CoA → Succinyl CoA] → TCA cycle
	Isoleucine → 2-Ketoisocaproic acid → Isovaleryl CoA + CO ₂ → → Acetyl CoA or Acetoacetate → TCA cycle
2-Hydroxyphytanoyl-CoA lyase	Peroxisomal α-oxidation of phytanoic acid R-CH(-CH ₃)-CH(OH)-C(=O)-SCoA → R-CH(-CH ₃)-C(=O)H + HC=O-SCoA

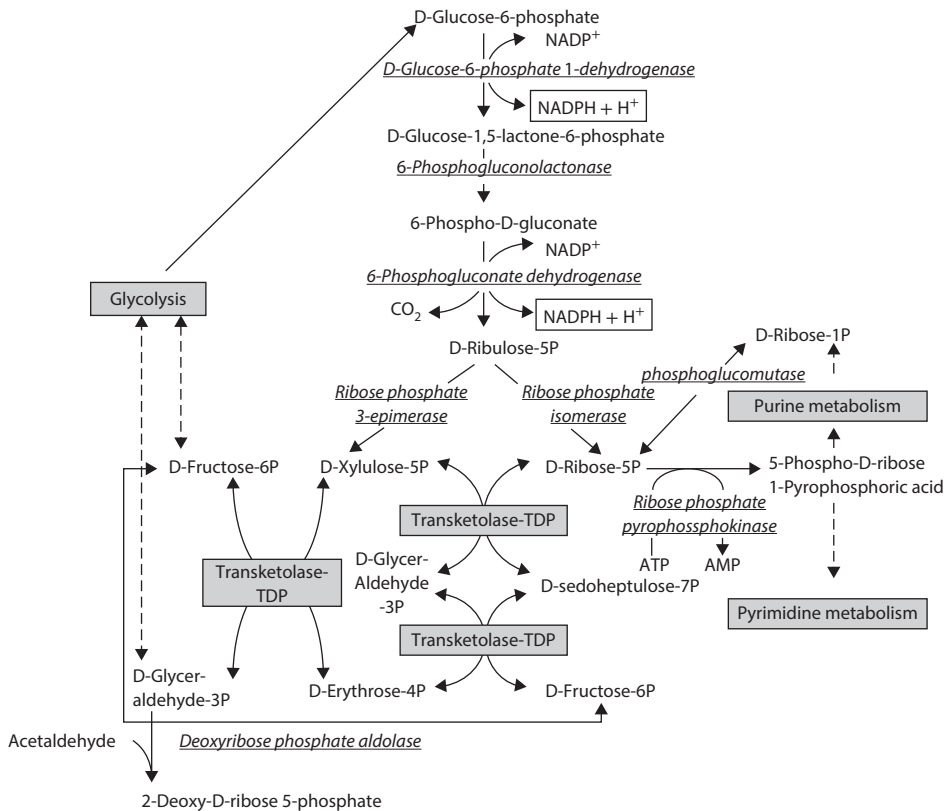

FIGURE 24.15 Transketolation reactions and products. The process is initiated by the direct oxidation of glucose-6-phosphate, which results in the production of NADPH. Next, transketolases are essential to the transformations that take place in the pentose phosphate shunt pathway, which in turn are important to the production of purines and pyrimidines. Transketolation allows for the transfer of aldol and ketol moieties that results in a mix of three, five, and seven carbon sugars.

deficiency that thiamin plays a vital role in nerve function (Makarchikov et al., 2003, Bettendorff, 1994; Bettendorff et al., 1993).

Thiamin deficiency causes the condition beriberi, which is characterized by peripheral neuropathy including abnormal (exaggerated) reflexes, diminished sensations, and cardiac failure (due to impaired oxidative metabolism). Thiamin deficiency is common in animals; poultry are particularly susceptible (McDonnell, 2001; Lanska, 2009). Mature chickens show signs of thiamin deficiency in 3–4 weeks and young chicks after 2 weeks when fed diets deficient in thiamin. Signs include apparent paralysis of the flexor of the toes (similar to that what observed in riboflavin deficiency and avian encephalomyelitis) along with a characteristic head retraction. A therapeutic diagnosis is achieved if the afflicted birds respond in a few hours to thiamin supplementation.

Polioencephalomalacia is the most common thiamin deficiency disorder in young ruminant animals. Diarrhea, listlessness, head retraction, and muscle tremors are symptoms. The most common cause is overgrowth of thiaminase-producing bacteria, ingestion of thiaminases (e.g., in bracken fern), or inhibition of thiamin absorption from diets containing high sulfur. Other examples involving thiaminase exposure include thiamin deficiency in fish-eating birds, seals, and dolphins, and when spoiled or uncooked fish has been routinely fed (Geraci, 1974). Thiaminase activity is strikingly high in fish, particularly in tuna, saminoids, and sardines (Ceh et al., 1964). Idiopathic paralytic disease in wild birds is also associated with thiamin deficiency (Balk et al., 2009; De Roode et al., 2000). The birds have difficulty in keeping their wings folded and loss of their ability to fly. Other examples include foxes fed uncooked fish products and cats fed food in which thiamin has been lost due to excessive processing or preserved by sodium metabisulfite treatment (Okajima et al., 2007). All of the published case reports of thiamin deficiency in cats eating commercially available diets have involved canned foods, which are subjected to relatively high temperatures during processing. Anorexia and vomiting are often reported in these animals, which can exacerbate the thiamine deficiency. Clinical signs in the cat include impaired vision, mydriasis, ataxia, vestibular signs, ventroflexion of the neck, and seizures which progress to coma and death. In both humans and cats, characteristic findings on magnetic resonance imaging (MRI) support a diagnosis of thiamin deficiency; these changes resolve with repletion (White et al., 2005; Palus et al., 2010, Marks et al., 2011, Markovich et al., 2013).

24.4.2.1.4 Requirements, Pharmacology, and Toxicity

The requirement for thiamin is 0.5–1.0 mg per 1000 kcal or 4.2 MJ of diet. As noted above, factors that most often influence the need for thiamin are exposure to antagonists and thiaminases. Antagonists that are used in experimental settings are pyrithiamine and oxythiamine, which act to inhibit the phosphorylation of thiamin. Amprolium is a coccidiostat that can inhibit thiamin absorption. Thiamin is present in most animal and plant foods but is especially prominent in whole grains and organ meats. Similar to other water-soluble vitamins, alkaline conditions, heat, and oxidants can reduce or chemically modify active forms of thiamin. Milling of whole grains to remove the bran reduces the thiamin content. Feedstuffs rich in tannins can bind and facilitate oxidation of thiamin, which leads to reduced availability (Vimokesant et al., 1982).

24.4.2.2 Pyridoxine

24.4.2.2.1 Overview

The family of B-6 vitamers includes pyridoxine, pyridoxal, and pyridoxamine (Figure 24.14). Pyridoxine is most abundant in plants, and pyridoxal and pyridoxamine are most abundant in animal tissues. Each can be converted to the other. The active form of pyridoxal is phosphorylated (e.g., pyridoxal-5-phosphate). Vitamin B-6 is essential for amino acid and sphingolipid metabolism and glycogen hydrolysis (Mooney et al., 2009).

24.4.2.2.2 *Metabolism*

Vitamin B-6 is absorbed in the upper gut by energy-dependent pathways (Said, 2004). As the cofactor forms present in foods, B-6 vitamers are first dephosphorylated by alkaline phosphatases. From the intestine, the bulk of B-6 vitamers is transported to target cells by albumin. Following active cellular uptake, rephosphorylation of the various B-6 vitamers (to corresponding 5'-phosphates) occurs via cellular pyridoxal kinases. The pyridoxine and pyridoxamine forms may then be oxidized, if needed, to pyridoxal phosphate. Muscle, kidney, and liver (the primary sites for amino acid metabolism) are abundant in the B-6 vitamers.

The products of vitamin B-6 metabolism are excreted in the urine, the major product of which is 4-pyridoxic acid (Dakshinamurti and Dakshinamurti, 2014). Other products of vitamin B-6 metabolism that are excreted in the urine include pyridoxal, pyridoxamine, and pyridoxine and their phosphates when high doses (10–20× requirements) are administered.

24.4.2.2.3 *Functions*

The major types of reactions involving amino acids that are catalyzed by vitamin B-6 fall into three categories: (1) transaminase reactions (essential to the interconversion of amino acids to corresponding α -keto acids), (2) decarboxylations, and (3) aldol reactions (electron withdrawal from the α,β -carbons of amino acids). Vitamin B-6 (as pyridoxal 5'-phosphate, PLP) is also a cofactor for glycogen phosphorylase (Palm et al., 1990), which catalyzes the hydrolysis of ether bonds in glycogen to form 6-phosphoglucose (Dakshinamurti and Dakshinamurti, 2014; Mooney et al., 2009; Rucker and Chowanadisai, 2016).

PLP is also an essential component of two enzymes that convert methionine to cysteine, as well as enzymes involved in the metabolism of selenomethionine to selenohomocysteine and selenohomocysteine to hydrogen selenide. Regarding specific amino acid transformations, vitamin B-6 is required for the conversion of tryptophan to niacin. The decarboxylation reactions catalyzed by vitamin B-6 are important to the production of neural signaling compounds such as histidine to histamine, tryptophan to serotonin, glutamate to GABA (γ -aminobutyric acid), and dihydroxyphenylalanine to dopamine (Mooney et al., 2009).

The formation of heme is also vitamin B-6 dependent. The pathway is initiated by the synthesis of δ -aminolevulinic acid (ALA) from glycine and succinyl-CoA. The rate-limiting enzyme responsible for this reaction, ALA synthase, requires vitamin B-6 (Dakshinamurti and Dakshinamurti, 2014). As a final example, vitamin B-6 is an essential component of enzymes that catalyze the formation of sphingolipids; particularly, the synthesis of ceramide via a reaction in which serine is decarboxylated and combined with palmitoyl-CoA (Mooney et al., 2009).

Neurological signs and symptoms occur with vitamin B-6 deficiency as a result of the inability to synthesize important biogenic amines from amino acid precursors (Plecko and Stockler, 2009), and anemia results from decreased heme synthesis. In experimental settings, some animals may show signs of oxaluria with a long-term deficiency.

24.4.2.2.4 *Requirements, Pharmacology, and Toxicity*

Vitamin B-6 deficiency is rarely observed as most diets provide adequate amounts. Typically, the vitamin B-6 requirement is met at about 0.3 mg per 1000 kcal (4.2 MJ) of diet. The richest sources of vitamin B-6 are meats and whole grains. Heat and light negatively affect the stability, and milling to remove bran can result in losses of B-6 from grains.

Drug-induced vitamin B-6 deficiency can also occur following administration of tuberculostatic drugs, such as isoniazid (isonicotinic acid hydrazide). This drug forms hydrazone derivatives with the pyridoxal forms of B-6. Penicillamine (β -dimethylcysteine), a copper chelator, may also interfere with normal B-6 metabolism due to the formation of thiazole derivatives. A naturally occurring antagonist to vitamin B-6, linatine (1-amino-D-proline), is

present in flax seed, which forms a stable product with pyridoxal phosphate (Dakshinamurti and Dakshinamurti, 2014).

24.4.2.3 Pantothenic Acid

24.4.2.3.1 Overview

Although the widespread occurrence of pantothenic acid in food makes a dietary deficiency of pantothenic acid unlikely, the use of experimental animal models and antagonistic analogs has helped to define its functions. Pantothenic acid is composed of pantoic acid linked to β -alanine. Pantothenic acid is one of the components comprising CoA and acyl carrier protein (ACP), important in fatty acid synthesis and metabolism (Figure 24.14). Pure pantothenic acid is water soluble, viscous, and yellow. It is stable at neutral pH but is readily destroyed by acid, alkali, and heat. Calcium pantothenate is the form most often found in commercial vitamin supplements due to greater stability than the pure acid (Rucker and Bauerly, 2014).

24.4.2.3.2 Metabolism

To be absorbed, pantothenic acid in food is released from CoA and ACP by the actions of intestinal phosphatases and nucleosidases (Figure 24.12). In rats, pantothenic acid is absorbed in all sections of the small intestine at high concentrations by simple diffusion; however, at low or physiological levels absorption occurs by saturable, sodium-dependent transport mechanisms, which are used in common by both pantothenic acid and biotin (Said, 2004).

The most important control step in this process is the phosphorylation of pantothenic acid to 4'-phosphopantothenic acid by pantothenic acid kinase. Feedback inhibition of the kinase by CoA or CoA derivatives governs flux and defines the upper threshold for intracellular CoA cofactor levels. Moreover, L-carnitine, important for the transport of fatty acids into mitochondria, is a nonessential activator of pantothenic acid kinase.

24.4.2.3.3 Functions

Pantothenic acid deficiency results in generalized malaise, perturbations in CoA and lipid metabolism, and mitochondrial dysfunction. In animals, a mild pantothenate deficiency in which abnormal weight differences are not observed causes serum triglyceride and free fatty acid levels to be elevated, which is a reflection of reduced CoA levels. In deficient states, pantothenate is reasonably conserved, particularly when there is prior exposure to the vitamin. CoA acts as an acetyl and acyl group carrier and allows pyruvate to enter the tricarboxylic acid (TCA) cycle. CoA also allows α -ketoglutarate to be transformed to succinyl-CoA in the TCA cycle. In addition, ACP is also an important component to both fatty acid and polyketide biosynthetic complexes, where 4'-phosphopantethiene serves as the essential prosthetic group (Rucker and Bauerly, 2009).

Neurological, immunological, hematological, reproductive and gastrointestinal pathologies, and hair loss and graying occur with pantothenic acid deficiency in part related to decreased levels of CoA. For example, acetylcholine synthesis is impaired, which may account for the numbness associated with a deficiency in pantothenic acid. Hypoglycemia and increased sensitivity to insulin may also occur along with adrenal insufficiency.

24.4.2.3.4 Requirements, Pharmacology, and Toxicity

Pantothenic acid deficiency has been induced in animals by administration of the pantothenic acid kinase inhibitor, γ -methyl pantothenate, in combination with a diet low in pantothenic acid. Another pantothenic acid antagonist, calcium hopantenate, has been shown to induce encephalopathy with hepatic steatosis and a Reye-like syndrome in both dogs and humans. The loss of pantothenic acid is 1%–2% of the body pool per day. The requirement is met at about 3–5 mg per 1000 kcal of dietary intake.

24.4.3 VITAMINS INVOLVED IN SINGLE-CARBON TRANSFER REACTIONS

24.4.3.1 Biotin

24.4.3.1.1 Overview

Biotin is a coenzyme in the metabolism of fatty acids and branched-chain amino acids (Figure 24.16). Biotin also plays a significant role in enzymes involved in gluconeogenesis by acting as a catalyst essential to certain types of carboxylation reactions. Biotin is composed of an ureido

FIGURE 24.16 Structures for (a) biotin and biocytin, (b) folic acid, and (c) vitamin B-12/cobalamin.

(tetrahydroimidizalone) ring fused with a tetrahydrothiophene ring. A valeric acid substituent is attached to one of the carbon atoms of the tetrahydrothiophene ring (Zempleni et al., 2008b, 2009b).

24.4.3.1.2 *Metabolism*

Biotin is found in highest concentrations in the liver. In food, biotin is present in relatively high concentrations in cereals including soybeans, rice, barley, oats, corn, and wheat. Bioavailability of biotin from cereals varies widely.

The first steps in absorption involve proteolysis of biotin-containing enzymes to release biocytin (biotin linked to lysine via a peptide bond) and free biotin (Said, 2004). Nutritional problems often arise because biotin and biocytin have affinity for certain proteins, particularly avidin in egg white, which is not easily digested, and as a consequence, biotin is not released in regions of the small intestine where efficient absorption occurs. Inclusion of raw eggs in diets can cause biotin deficiency (Zempleni et al., 2008b). The response in fur-bearing animals to ingestion of significant quantities of raw egg white has been described as “egg white injury.” Native (nondenatured) avidin in eggs causes egg white injury because it binds very tightly to biotin, preventing its absorption (Whitehead, 1981, 1985).

In cells, when biotin-containing carboxylases are degraded, biotin is released as biocytin. Biocytin is an important liver enzyme that catalyzes the cleavage of the peptide linkage between biotin and lysine to release free biotin for utilization. Biotin turnover and requirements can be estimated by concentrations of biotin and metabolites in body fluids, activities of biotin-dependent carboxylases, and the urinary excretion of organic acids that are formed at increased rates in amino acid catabolic pathways if biotin-related carboxylase activities are compromised.

24.4.3.1.3 *Functions*

Biotin serves as a cofactor for three CO₂-fixing enzymes: acetyl-CoA carboxylase, which is essential for fatty acid synthesis; propionyl-CoA carboxylase, which participates in odd chain fatty acid metabolism; and pyruvate carboxylase, which is involved in the formation of oxaloacetate, an important obligatory step in reverse glycolysis and gluconeogenesis (Rucker and Chowanadisai, 2016). Biotin deficiency is rare as intestinal bacteria produce biotin. Symptoms of overt biotin deficiency include hair loss and a red scaly rash around the eyes, nose, mouth, and genital area. Neurological symptoms include lethargy, numbness, and tingling of the extremities. Perosis is observed in the skeleton. Hepatic steatosis also can occur. The biochemical manifestation of biotin deficiency includes ketolactic acidosis, organic aciduria, and hyperammonemia. Mice fed with dried raw egg to induce biotin deficiency during gestation have a high (>80%) incidence of malformations. Biotinylation of histones also occurs and appears to play a role in cell proliferation, gene silencing, and the cellular response to DNA repair (Zempleni et al., 2008a, 2009a, 2009b).

24.4.3.1.4 *Requirements, Pharmacology, and Toxicity*

The relationship of biotin to avidin is important, particularly to industries that utilize fur-bearing animals for profit. It was found that egg white injury could be cured by a liver factor, which was first called protective factor X. Factor X was later determined to be biotin. Because biotin cured the skin disorder of egg white injury, biotin was called vitamin H (for Haut, the German word for skin). For most monogastric animals, 50–100 µg of biotin per 1000 kcal or ~0.2–0.4 mg per kg of diet is probably sufficient.

24.4.3.2 **Folic Acid**

24.4.3.2.1 *Overview*

Knowledge regarding folic acid evolved initially from efforts to understand macrocytic anemias and certain degenerative neurological disorders. By the late 1940s, folic acid was recognized as one of the factors associated with macrocytic anemias, and large-scale efforts by some pharmaceutical companies led to the isolation of folic acid (Goldblith and Joslyn, 1964).

Folic acid is one in a family of compounds with a pteridine moiety associated with aminobenzoic acid and a series of conjugated glutamyl residues. Folic acid along with vitamin B-12 is central to one-carbon transfer reactions (Figure 24.16). The reactions include the generation and utilization of formaldehyde and formimino groups in the synthesis of pyridine nucleotides, interconversion of some amino acids, and eventual reduction of the methylene form of tetrahydrofolic acid (THF) to methyl THF (MTHF) to facilitate the conversion of homocysteine to methionine (Figure 24.17). The formyl, methenyl, and methylene forms are utilized for purine synthesis and steps in thymidylate, that is, DNA-related synthesis (Baily, 2014). These reactions are therefore of obvious importance and are essential to cell division and proliferation. As a final step, 5-MTHF transfers its methyl moiety to vitamin B-12. The resulting product is oxidized folic acid, which must be again reduced to reinitiate the cycle.

24.4.3.2.2 *Metabolism*

The steps in the absorption, transport, and utilization of folic acid (i.e., folacin, the more inclusive term) are more complex than many of those for other water-soluble vitamins. Dietary sources include green leafy vegetables, fruit juices, some grains, and organ meats. Folylpolyglutamates present in the diet are cleaved to folylmonoglutamate by endopeptidases. The various folacins are absorbed in the duodenum and upper jejunum. During the process of intestinal absorption, dietary folylpolyglutamates are hydrolyzed, which is followed by active transport of the folylmonoglutamate derivative, folic acid, which refers to the oxidized monoglutamyl form of the vitamin. Absorption of folic acid is about 85%, compared to 50% or less for the more complex dietary forms of folylpolyglutamates (Baily, 2014).

Two proteins, glutamate γ -carboxypeptidase (formerly designated as folate conjugase) and reduced folate carrier (RFC) protein are essential to the absorption process (Halsted et al., 2002; Villanueva et al., 1998). Following deconjugation or hydrolysis of glutamyl residues, folic acid is taken up by enterocytes and reduced to its THF form. This step is followed by methylation to 5-methyl-THF (Figure 24.17). It is the 5-methyl-THF form that is transported across the intestinal basolateral membrane. RFC protein next carries 5-methyl-THF to target organs, such as the liver.

In the liver, the uptake of 5-methyl-THF by hepatocytes involves carrier-mediated transport. Within the hepatocyte, as well as other cells, 5-methyl-THF uptake is immediately followed by conversion to folylpolyglutamate, which serves to keep the coenzyme inside cells or bound to the appropriate enzymes. The pteridine portion of the coenzyme and the p-aminobenzoic acid portion participate directly in the metabolic reactions of folate. Further, to carry out the transfer of 1-carbon units, NADPH must reduce folic acid two times in the cell. The “rightmost” pyrazine ring of 6-methylpterin is reduced at each of the two N-C double bonds (Baily, 2014).

From 5% to 20% of liver folate undergoes biliary secretion (as 5-methyl-THF) and is subject to enterohepatic recirculation, while most of the remaining passes into the systemic circulation (Tamura and Halsted, 1983). Maintenance of body pools is also dependent on renal filtration and reuptake. About 1% of the total body folate pool is excreted daily in the urine and 0.1% in the feces (Halsted, 1975, 1979, 1980; Halsted et al., 1976, 1977, 1978).

24.4.3.2.3 *Functions*

Folacins serve as substrates or cofactors in the transfer of single-carbon moieties in amino acid metabolism and nucleic acid synthesis. In the methyltransferase pathway, 5-methyl-THF, which is derived from both dietary and endogenous sources, is also the substrate for methionine synthesis (Baily, 2014; Toohey, 2006). Some of the methionine is converted to S-adenosylmethionine (SAM) by methionine adenosyltransferase. A primary function of SAM is methyl transfer reactions. SAM is metabolized to S-adenosylhomocysteine (SAH), which is also generated from homocysteine through the reversible SAH hydrolase reaction (Figure 24.17).

Other functions of SAM include glutathione regulation by up-regulating cystathionine- β -synthase. Further, SAM can provide negative regulatory feedback to the methylene tetrahydrofolate reductase

FIGURE 24.17 Folacin and key steps in single-carbon transfer reactions. Folylpolylglutamates are converted to the monoglutamate by intestinal endopeptidases. In the enterocyte, the oxidized forms of folacin are reduced, and single carbon units derived from formyl groups and formimino groups (from the degradation of L-histidine) are directed to the N10 position of THF. Next, the single carbon is transferred to the N5 position and oxidized to methenyl-THF. Following reduction to N5,N10-methylene-THF, depending on the biosynthetic pathway involved, any of these species can donate the one-carbon group to an acceptor. The methylene form donates its methyl group during the biosynthesis of thymidine nucleotides for DNA synthesis; the methenyl form donates its group as a formyl group during purine biosynthesis, and the methyl form is the donor of the methyl group to sulfur during methionine formation. Intermediates that serve as substrates for transmethylation reactions depend on the continuous synthesis of methionine. S-adenosylmethionine (SAM) is made from L-methionine and adenosine triphosphate (ATP) by methionine adenosyltransferase. Transmethylation, transsulfuration, and aminopropylation are the metabolic pathways that use SAM. These reactions are anabolic and occur throughout the body. More than 40 metabolic reactions involve the transfer of a methyl group from SAM to various substrates such as nucleic acids, proteins, and lipids. The resulting homocysteine is either reutilized for methionine regeneration or converted to cystathionine. It can also be inferred that these processes influence glutathione generation. (From Rucker et al., In N. Van Alfen (ed.), *Encyclopedia of Agriculture and Food Systems*, San Diego, 2014.)

reaction that converts 5,10-methyl-THF to 5-methyl-THF. Thus, adequate SAM ensures sufficient 5,10-methyl-THF as a substrate for thymidylate synthase, which provides the nucleotide balance of deoxyuridine monophosphate and deoxythymidine monophosphate for DNA synthesis (Toohey, 2006; Baily, 2014).

Because folacin is required for maintaining nucleotide balance during DNA synthesis, its deficiency is expressed by increased cell death and in some cases by compensatory increased

proliferation of cells. In bone marrow, megaloblastosis and macrocytosis of enterocytes are a reflection of defective DNA synthesis due to folacin deficiency. There is a production of larger dysfunctional cells that eventually translates into macrocytic anemia, a condition in which the larger red cells are insufficient in number and hemoglobin. Folic acid deficiency can also result in developmental and neural tube defects, and contribute to the development of cardiovascular disease. In one recent study, the incidence of cleft lip/palate was reduced in the offspring of Pugs and Chihuahuas supplemented with 5 or 2.5 mg, respectively, of folic acid from the onset of heat until day 40 of gestation (Domoslawska et al., 2013). For humans, a large body of clinical literature exists noting the connection between folacin intake, hyperhomocysteinemia due to folic acid deficiency, and carotid artery narrowing and occlusive strokes. Ingestion of diets high in folic acid also appears protective against the development of colonic adenomas and related cancers (Depeint et al., 2006; Verhoef, 2007; Verhoef and de Groot, 2005).

24.4.3.2.4 *Requirements, Pharmacology, and Toxicity*

The requirements for folic acid range from 2 to 5 mg per kg of diet or 0.5 to 3 mg per 1000 kcal for most animals. There are some conditions in which the folic acid requirements are conditionally high, for example, when either natural or pharmacological folic acid agonists are present in the diet. The discovery that THF is required for DNA synthesis has led to a number of antimetabolites that function as inhibitors of folic acid reductase and DNA synthesis. The best example is methotrexate (Baily, 2014), which ultimately inhibits the proliferation and regeneration of rapidly replicating cells. Methotrexate irreversibly inhibits dihydrofolate reductase, an enzyme that participates in the tetrahydrofolate synthesis. With insufficient THF, cell division is blocked in the S phase due to impaired DNA synthesis. Drugs such as methotrexate are widely used in treatment of autoimmune disease and cancer chemotherapy, particularly for tumors of the lymphoreticular system (Gangjee et al., 2007, 2008).

24.4.3.3 **Vitamin B-12**

24.4.3.3.1 *Overview*

Vitamin B-12, also called cobalamin, is another water-soluble vitamin that plays a key role in the formation of blood and brain and nervous system (Figure 24.16). Vitamin B-12 helps to link many of the functions of folic acid to the THF-homocysteine transmethylase system (Green and Miller, 2014). Other reactions involving vitamin B-12 utilize the vitamin in the form of the deoxyadenosyl-cobalamine derivative. An example is methylmalonyl-CoA mutase, which catalyzes the conversion of methylmalonic acid to succinyl-CoA for ultimate use as a metabolic fuel. Vitamin B-12 is a class of chemically related compounds, which is structurally more complex than the other vitamins, and novel in that it contains cobalt. Biosynthesis of vitamin B-12 is only accomplished by bacteria, but conversion between different forms of the vitamin can occur in many types of cells.

24.4.3.3.2 *Metabolism*

Vitamin B-12 associated with food is released in the stomach by proteolysis and acid denaturation. In animals with simple stomachs, “R-proteins” (haptocorrins and cobalaphilins) are secreted, which bind to free vitamin B-12 (Festen, 1991, Green and Miller, 2014). Intrinsic factor (IF) is a protein synthesized by the gastric parietal cells of most animals. However, the pancreas can also be a site of synthesis (e.g., in dogs and cats; Vaillant et al. 1990; Fyfe et al., 1991). IF is secreted in response to food consumption and binds vitamin B-12 released in response to gastric digestion. In the small intestine, R-proteins are digested, and B-12 is released. The released vitamin B-12 then binds to IF, to form a B-12-IF complex. B-12 must be attached to IF to be recognized by receptors on the enterocytes in the terminal ileum, where uptake involves endocytotic mechanisms. IF protects B-12 from catabolism by intestinal bacteria. The B-12-IF complex that is recognized by ileal receptors is next transported into the portal circulation where it is transferred to transcobalamin.

Vitamin B-12 is transported in plasma by one of three known transport proteins: transcobalamins I, II, or III (Seetharam and Yammani, 2003). The transcobalamins carry vitamin B-12 to cells where it is again transferred into given cells by endocytotic mechanisms. Interference with R protein or IF production can influence the availability of vitamin B-12. With bacterial overproduction, there is competition between the host and bacteria for vitamin B-12. Many animals obtain vitamin B-12 through coprophagy. In ruminants, vitamin B-12 is synthesized in ample quantities by ruminal bacteria. Within cells, vitamin B-12 is transported by specific chaperons to specific organelles and the locations of vitamin B-12 requiring enzymes (Banerjee, 2006). Once associated with targeted enzymes, the vitamin B-12 in cells is relatively stable. Approximately 0.1% of the pool is lost per day, and bile is the principal route for B-12 excretion (Green and Miller, 2014).

As a final point, malabsorption of B-12 can be a problem in aging animals. Analogous to pernicious anemia in humans, in old animals, autoimmune diseases that affect the gastric parietal cells result in their destruction. Such events can curtail the production of IF and limits absorption. Accordingly, autoimmune diseases should be considered in aging animals with signs of macrocytic or megaloblastic anemia.

24.4.3.3.3 *Functions*

Because methylated folacins and cobalamin are required as substrates and cofactors for the methionine synthase reaction and DNA synthesis, the clinical expression of cobalamin deficiency as megaloblastic anemia or hyperhomocysteinemia is not distinguishable from severe folate deficiency (Figure 24.17). Cobalamin is also required in the methylmalonyl-CoA mutase reaction and methylation of branched-chain fatty acids necessary for neural membrane assembly. The substrate for methylmalonyl-CoA mutase, methylmalonyl-CoA, is primarily derived from propionyl-CoA, a substance formed from the catabolism and digestion of isoleucine, valine, threonine, methionine, thymine, cholesterol, or odd-chain fatty acids (Banerjee, 2006).

As a consequence, prolonged vitamin B-12 deficiency can result in neurologic disorders, for example, degeneration of the myelin sheath, because of the inability to produce complex lipids for membrane assembly. The clinical signs include loss of position and vibratory sensation in the extremities, ataxia, and paresthesia, even in the absence of anemia.

24.4.3.3.4 *Requirements, Pharmacology, and Toxicity*

Vitamin B-12 deficiency should be suspected in macrocytic anemia, particularly when the mean corpuscular red cell volume is elevated. The need for vitamin B-12 for most animals is in the 2–15 µg per kg of diet range. Although deficiencies are uncommon in free-ranging animals, diseases of the proximal duodenum or stomach and ileum and pancreatic insufficiency can decrease vitamin B-12 absorption. Studies have shown low serum cobalamin concentrations are present in most dogs and all cats with exocrine pancreatic insufficiency (Batchelor et al., 2007; Hall et al., 1991; Steiner and Williams, 1995; Thompson et al., 2009). Moreover, cobalt deficiency can result in vitamin B-12 deficiency in ruminants, because of the need for cobalt by rumen microorganisms to synthesize vitamin B-12 (McDonell, 2001).

The daily requirement of cobalamin is very small compared to the body pool size (1–2 mg); therefore, it takes many weeks or months to become deficient from dietary inadequacy alone. Of conditions to note, total gastrectomy in animals places a strain on vitamin B-12 metabolism, because of the loss in IF and R factor production. Autoimmune disorders related to destruction of parietal cells and characterized by the absence of IF and achlorhydria can have a profound effect on vitamin B-12 absorption. Chronic use of antacid medications is also a risk factor for deficiency as release of vitamin B-12 is impaired (Howden, 2000; Andrès et al., 2003). In addition, chronic duodenal hyperacidity may inactivate pancreatic trypsin and prevent the transfer of cobalamin from gastric haptocorrin (R factor) to IF. Further, inflammation of the terminal ileum may impact the receptor-mediated uptake of the IF-B-12 complex. Two drugs, colchicine and p-aminosalicylic acid, may also cause cobalamin deficiency by inhibiting receptor interactions.

Dogs and cats with chronic enteropathies are frequently deficient in cobalamin. Historically, parenteral administration of cobalamin has been recommended in these cases. However, findings of a recent retrospective study suggest that oral cobalamin supplementation is effective in normalizing cobalamin concentrations in dogs with chronic enteropathies (Toresson et al., 2015). However, further studies are needed to compare cobalamin status in dogs receiving oral versus parenteral supplementation before this approach can be widely recommended.

24.4.4 WATER-SOLUBLE VITAMIN ASSESSMENT

Approaches to vitamin assessment may be found in several sources. An excellent series, the *Methods in Enzymology* (particularly volumes: 18, 62, 66, 67, 81, 105, 122, 190, 123, 234, 279, 281, 282, 299) published by Elsevier (<http://www.elsevier.com/>) provide descriptions of numerous approaches for individual water-soluble vitamin determination. HPLC methods using differing detection approaches (e.g., tandem and quadrupole mass spectrometry) are also available. The use of accelerated mass spectrometry constitutes a seminal breakthrough in that physiological concentrations of vitamins (both fat and water soluble) can be detected in the attomolar range (Kim et al., 2009; Ebeler et al., 2005; Ross et al., 2004; Lemke et al., 2003). With approaches currently in use, it is often possible to be noninvasive or carry out multiple sampling on the same subject.

24.5 VITAMIN-LIKE COMPOUNDS

24.5.1 LIPOTROPIC FACTORS

Nutritional requirements exist for a number of compounds at specific periods in development, particularly neonatal development, and periods of rapid growth. These compounds often perform specialized transport functions, particularly in relation to fatty acids. Examples include choline, inositol, carnitine, and taurine (Figure 24.18).

24.5.1.1 Choline

Choline is particularly noteworthy, because it plays a key role in methyl group metabolism, carcinogenesis, and lipid transport as a component of lecithin (Garrow, 2007). Choline is normally

FIGURE 24.18 Chemical structures for choline, inositol, carnitine, and taurine.

produced in sufficient amounts from the transmethylation pathways involving S-adenosyl methionine (Figure 24.17); however, in young growing animals a positive growth response can occur upon addition of choline. Commercially available forms of choline are available as the trimethyl hydroxyethylammonium chloride or as the bitartrate. Choline is generally added to diets to reduce the need for activated methyl groups supplied by methionine. It is more economical to add choline for these methyl groups than to add methionine. The most abundant source of choline in the diet is lecithin.

The primary sign of choline deficiency is fatty liver and cirrhosis. Choline is a component of sphingomyelin and lecithin. Formation of betaine from choline provides another important source of labile methyl groups for transmethylation reactions. In mice and rats, a novel observation is that a prolonged deficiency of choline can result in hepatocellular cancer. This is a unique example of a nutritional deficiency leading to a neoplasm without having to expose the animal to known liver carcinogens or promoters (Zeisel, 1995, 1996). Five hundred to 1000 mg of choline is often added per kg of diet to promote growth and optimize phospholipids production.

24.5.1.2 Inositol

Inositol is synthesized using glucose-6-phosphate as a precursor. Inositol is particularly important in cellular signal transduction and phospholipid assembly. Like choline, a case may be made that it is required to some degree (e.g., to optimize growth in adolescent gerbils and hamsters), although most animals appear able to produce or derive sufficient inositol from dietary sources (Chu and Hegsted, 1980a, 1980b; Holub, 1992). The estimated daily intake of inositol for large animals can be as high as 1 or 2 g per day. It is also noteworthy that a relationship exists between inositol ingestion and its distribution as inositol-6-phosphate in various tissues, and that a depletion of extracellular inositol-6-phosphate occurs at higher rates when inositol-deficient diets are consumed.

24.5.1.3 Carnitine

Carnitine comes both from the diet and synthesis from lysine by a process that is ascorbic acid and iron dependent. Carnitine concentrations in mammalian milk (as carnitine plus acylcarnitine) are in the 100 μ M range. The distribution and levels are affected by a number of factors ranging from changes in the metabolic state (e.g., ketosis) to the stage of lactation (e.g., transition from colostrum to whole milk). These points are important, because carnitine production is not sufficient in newborns, particularly animals that are weaned too early to ill-defined diets. Dogs with the genetic disorder cystinuria may have increased renal excretion of carnitine; monitoring or dietary supplementation is advisable (Sanderson et al., 2001). Carnitine is required for the transport of fatty acids from the cytosol into the mitochondria for the generation of metabolic energy (Kittleson et al., 1997). There is a growing literature in humans that suggests carnitine supplementation may be helpful to improve glucose utilization and fatty acid oxidation (Challem, 1999). Amounts of 100 mg/kg of diet are often suggested, which is similar to the concentration of dried milk or milk solids of most animals (Blanchard et al., 2002; Doberenz et al., 2006; Kidd et al., 2005; Peebles et al., 2007). Much higher doses (2–3 g daily) are advised as a therapy for American Cocker Spaniel dogs with dilated cardiomyopathy, as this has been reported to result in significant improvement in disease parameters, at least when used with taurine (Kittleson et al., 1997).

24.5.1.4 Taurine

Taurine (2-aminoethanesulfonic acid) is derived from cysteine and is one of the few known naturally occurring sulfonic acids. Taurine is present in all animal tissues. Most animals can synthesize taurine; however, some animals, particularly domesticated and wild felids, do not synthesize adequate amounts. In cats and some species of dogs (Kittleson et al., 1997), defective synthesis is a result of low activity of two enzymes in the synthetic pathway: cysteine dioxygenase and cysteine sulfinic acid decarboxylase. Losses occur because of an obligatory requirement for taurine to conjugate bile acids.

An array of clinical signs has been described in taurine-deficient cats including central retinal degeneration, reversible dilated cardiomyopathy, and reproductive failure in queens, teratogenic defects, and abnormal brain development in kittens (Backus et al., 1995; Edgar et al., 1998; Hickman et al., 1990b; Hickman et al., 1992; Kittleson et al., 1997; Pion et al., 1992). Low blood taurine concentrations and dilated cardiomyopathy have been identified in dogs that do not have a genetic predilection to this disease (Backus et al., 2003; Fascetti et al., 2003). Suggested mechanisms for taurine deficiency in these dogs were considered to be (1) insufficient synthesis of taurine, (2) extraordinary loss of taurine or its precursors in urine, (3) extraordinary gastrointestinal loss of taurine in bile acid conjugates (as found in cats), or (4) a reduction in protein digestibility (Morris et al. 1994). Meats, dairy products, and especially seafood in contrast to plant foods are good sources of taurine. Dietary concentrations of taurine that are required to maintain adequate levels in plasma and whole blood in cats are dependent on a function of type of diet, which affects the degree of microbial degradation that occurs during enterohepatic circulation. Plasma and whole blood concentrations of 40 and 300 mM of taurine, respectively, appear to be adequate in cats for reproduction. Intakes of taurine from 1 to 2.5 g taurine/kg of diet may be needed to sustain plasma and blood concentrations in this range.

24.5.2 NOVEL COFACTORS, ELECTRON TRANSPORTERS, BIOFLAVONOIDS, AND POLYPHENOLICS

The following compounds are highlighted because of their known roles as coenzymes in prokaryotes and potential roles as probiotics and growth-promoting substances in higher animals. These compounds include queuosine, coenzyme Q (CoQ), pteridines (other than folic acid), such as bioppterin and the pteridine cofactor for the Mo-Fe flavoproteins (see Section 24.6.4), lipoic acid (LA), pyrroloquinoline quinone (PQQ), and bioflavonoids and related plant pigments (Figure 24.19). Increasing or decreasing dietary exposure to these compounds is known to produce a number of systemic effects, most of which are considered healthful.

24.5.2.1 Queuosine

Queuosine is included because it is a novel product arising from microbe–host interactions. Queuine is a nucleoside base made by bacteria, which is modified to queuosine (Boland et al., 2009; Kang et al., 2009). Germ-free animals seem to survive without a source of queuine or queuosine, yet

FIGURE 24.19 Chemical structures for queuosine, coenzyme Q, lipoic acid, procyanidins catechin, quercetin, hydroxytyrosol, and pyrroloquinoline quinone.

it is found in measurable amounts in animals with a normal intestinal microflora (Farkas, 1980; Reyniers et al., 1981). Queuosine resembles guanidine and is preferentially utilized in some t-RNAs. The importance of this interaction has yet to be fully understood, although it is known that tRNAs of the queuosine-family (Q-tRNA) are completely modified in terminally differentiated somatic cells and that modification of Q-tRNA is associated with cell proliferation, control of aerobic and anaerobic metabolism, and perhaps malignancy.

24.5.2.2 Coenzyme Q

Although claims have been made for a nutritional requirement for CoQ, more work is needed to fully clarify an exact nutritional role for this compound. CoQ, or ubiquinone, is found in mitochondria and is structurally similar to vitamins E and K. As a quinone, CoQ is ideally suited to interact with cytochromes to affect the flow of electrons in the mitochondrial respiratory chain. CoQ can be synthesized and is readily absorbed from the intestine by the same route as other fat-soluble vitamins. CoQ is found mainly in the mitochondrial intermembrane. Although there is no apparent dietary requirement, CoQ is present in food and promoted for various health benefits in which improving the efficiency of oxidative metabolism is a concern. If used therapeutically (based mostly on human and rodent studies), effective doses are one or more g/kg of the dry diet. In dogs, tachycardia-induced cardiac failure is not associated with reduced CoQ levels, but CoQ-treated dogs have less hypertrophy compared with untreated dogs. CoQ that is absorbed from the intestine is transported by the same transport system as vitamin E and vitamin K.

24.5.2.3 Pteridines (Biopterin and the Mo-Fe Pteridine Cofactor)

In animals, tetrahydrobiopterin (commonly abbreviated BH₄) is a redox cofactor, best known for its role at the catalytic site for phenylalanine, tryptophan, and tyrosine hydroxylases, and more recently endothelial NO synthase (Ozkor and Quyyumi, 2008). Tetrahydrobiopterin (BH₄) is synthesized from guanosine triphosphate by GTP cyclohydrolase I, 6-pyruvoyltetrahydropterin synthase (PTS), and sepiapterin reductase (SPD). GTP cyclohydrolase I is the rate-limiting enzyme (Nagatsu and Ichinose, 1999). A related cofactor is the molybdenum cofactor, also in the pterin family, which is a cofactor for xanthine oxidase and aldehyde oxidase (important in purine metabolism) and sulfite oxidase (important in sulfur amino acid metabolism). Dietary intervention with tetrahydrobiopterin may be useful when there are signs of perturbed phenylalanine or tyrosine metabolism that are genetic in origin. The production of the molybdenum cofactor is directly dependent on adequate molybdenum intake (see Section 24.6.4).

24.5.2.4 Lipoic Acid

LA is made in the liver of most animals. This coenzyme is linked by amide linkage to lysyl residues within transacetylases and functions in the transfer of electrons and activated acyl groups as a part of the pyruvate dehydrogenase complex, that is, the initial step important to the regulation and function of the TCA cycle. Reduction of oxidative stress by LA supplementation has been demonstrated in animal models. Mice deficient in LA synthase have been generated. The heterozygotes have significantly reduced erythrocyte glutathione levels, indicating that their endogenous antioxidant capacity is lower than those of wild-type mice (Yi et al., 2009). Homozygous embryos die by day 8–12 of gestation. Of nutritional interest, supplementing the diet of heterozygous mothers with LA during pregnancy fails to prevent the prenatal deaths of homozygous embryos. Apparently, an endogenous LA synthesis is essential for developmental survival and cannot be replaced by LA in maternal tissues and blood via the diet (Yi et al., 2009; Yi and Maeda, 2005). Further, although LA is often supplemented as an antioxidant, toxicity with changes in liver function is more easily observed in felids than in humans and rodents (Hill et al., 2004, 2005). An oral dose of LA produces hepatocellular toxicity in cats when given at 30 mg or more per kg body weight. In dogs, hypoglycemia, acute renal failure, and hepatic injury have also been reported at doses of 1000 mg LA/kg body weight (Hill et al., 2004). The LD 50 for rodents is >2000 mg LA/kg body weight.

24.5.2.5 PQQ, Bioflavonoids, and Dietary Polyphenolic Pigments

Various phytochemicals and biofactors are worth mention, because they are capable of influencing mitochondrial function and oxidative metabolism. Examples include several plant-derived flavonoids (quercetin and the procyanidins, epicatechins, and catechins), and two tyrosine-derived quinones (hydroxytyrosol in olive oil and PQQ). These compounds serve in plants as pigments, phytoalexins, or growth factors. In animals, positive nutritional and physiological attributes have been established for each, especially in the respect to their ability to affect energy metabolism, cell signaling, and mitochondrial function. At least one, PQQ, has been shown to stimulate growth and development in rodents when added to highly purified diets (Akagawa et al., 2015; Chowanadisai et al., 2010; Rucker et al., 2009, 2014; Steinberg et al., 2003; Stites et al., 2006). Regarding possible mechanisms of action, PQQ, quercetin, and hydroxytyrosol have been shown to influence cell signaling and regulators of mitochondrial biogenesis, such as the peroxisome proliferator-activated receptor gamma family of transcriptional coactivators (abbreviated: PGC-1 α , PGC-1 β , and the PGC-related coactivator (Rasbach and Schnellmann, 2008; Davis et al., 2009; Chowanadisai et al., 2010). PGC-1 α is thought to be the principal regulator in this family, although all are important. PGC-1 α helps to regulate many of the genes involved in energy metabolism by interacting with other factors and nuclear receptors. PGC-1 α is an important coactivator of the PPAR family of nuclear receptors, in addition to nuclear respiratory factor 1 and 2. These factors, in turn, are a part of transcriptional complexes that activate other mitochondrial-related transcription factors (Chowanadisai et al., 2010; Tchapanian et al., 2010; Harris et al., 2013; Zhang et al., 2015).

To add to this complex arrangement, another family of factors, silent information regulators or sirtuins (SIRT), function in the nucleus by acting as histone deacetylase and monoribosyltransferases. Histone deacylation and monoribosylation affect DNA and histone organization, making exposure to transcription complexes and related synthesis machinery possible (Zhang et al., 2015). Hydroxytyrosol and quercetin also seem to influence aspects of sirtuin regulation (Shoba et al., 2009; Rasbach and Schnellmann, 2008; Hirschey et al., 2009; Davis et al., 2009; Rucker et al., 2009).

In addition, Akagawa et al. (2016) have demonstrated that some mammalian NAD-dependent dehydrogenases have PQQ-binding domains. For example, in purified rabbit muscle lactate dehydrogenase (LDH), PQQ inhibits the formation of lactate from pyruvate in the presence of NADH and enhances the conversion of lactate to pyruvate in the presence of NAD(+) (Akagawa et al., 2015, 2016). The oxidation of NADH to NAD(+) is attributed to PQQ's redox-cycling activity. PQQ also attenuated cellular lactate release and increased intracellular ATP levels in cells.

The polyphenolics in the catechin family, particularly specific isomers of epigallocatechin-3-gallate, impact on mitochondrial processes appears more related to apoptosis and the expression and regulation of Bcl-2-associated proteins (Keen et al., 2005). The family of Bcl-2 proteins acts as both anti- and proapoptotic regulators. One protein in this family, Bcl-2-associated X or BAX, functions by competing with Bcl-2-proper (another member of the Bcl-2 family of proteins that acts as an antiapoptotic regulator). BAX can also insert itself into organelle membranes, primarily the outer mitochondrial membrane, to induce the opening of voltage-dependent channels, which results in the release of cytochrome c and other proapoptotic factors from the mitochondria. This action eventually leads to activation of caspases, enzymes that are essential to mitochondrial outer membrane permeabilization, as well as other steps important to the initiation of apoptosis and eventual cell death (Rasbach and Schnellmann, 2008).

In addition to the effects on mitochondria, many flavonoids influence endothelial function by activating endothelial nitric oxide synthase. Consumption has also been associated with inhibition of platelet activity, and decreasing blood pressure in animal models and humans because of endothelium-dependent flow-mediated dilation of arteries. Although antioxidant activity is often ascribed as the principal physiological effect of flavonoid and polyphenolic exposure, most

studies indicate that antioxidant capacity of blood seen after the consumption of flavonoid-rich foods is not a direct effect of flavonoids, but rather due to other factors, such as improved mitochondrial function or amplification of other antioxidant processes or factors (e.g., increasing uric acid levels). For the most part, the biological effects of flavonoids appear related more to their ability to modulate cell-signaling pathways than their antioxidant activity (Rasbach and Schnellmann, 2008).

Regarding the intakes that need to be added to diets to obtain physiological effects, quercetin, hydroxytyrosol, and isomers of catechin and epicatechin (e.g., epigallocatechin-3-gallate) are functional in the 20–100 mg/kg diet range. PQQ is effective in promoting growth and reproduction in rodents when fed highly purified diets, if provided at ~0.3 mg or more per kg of diet (Steinberg et al., 2003). Taken together, bioflavonoids, carotenoids, anthocyanins, and other phytochromes are consumed on the order of 2–4 g per kg of conventional diets comprised of whole foods and components. In plants, these compounds provide protective camouflage, facilitate transformation of light into chemical energy, or act as protective chemicals and repellents to predators (e.g., phytoalexins). In animals, plant pigments are also utilized for some of the same purposes, although their importance as absolute nutritional essentials remains unclear.

24.6 TRACE MINERALS

Six elements: cobalt (Co), copper (Cu), manganese (Mn), molybdenum (Mo), selenium (Se), and zinc (Zn) will be used to illustrate concepts relevant to metabolism and function of trace minerals. The importance of iron, calcium, magnesium, sodium, potassium, and other essential minerals is discussed elsewhere in this volume. Discussions of vanadium, chromium, silicon, nickel, and tin are not included because nutritional essentiality remains to be established. If there is a nutritional need for these elements, it is likely to be in the μg per kg of diet range (Reilly, 2004), whereas the relative need for Co, Cu, Mn, Mo, Se, and Zn approach or exceed amounts in the mg per kg of diet range. The essential elements are distinguished because they are usually associated with the functions of specific proteins, peptides, and enzymes. As noted previously, they usually fall into two categories, metalloenzymes and metal–enzyme complexes, depending upon the stability constants that define metal binding. In simple metal complexes, the basicity of the electron donating group and the ability to approach the metal ion (steric effects) are the primary factors that influence stability (Reedijk and Bouwman, 1999, Harris, 2014).

24.6.1 COBALT

24.6.1.1 Overview

Compounds containing Co are stabilized by complex ion formation. In tissues, Co is normally found associated with vitamin B-12 in animals that require preformed vitamin B-12. Co is novel because there is no evidence that any organism needs the Co ion, either in the free form or as a simple protein complex. Plants contain Co, but there is no indication that Co occurs as a cobalamide, that is, vitamin B-12. However, in plants, Co is important because of the symbiotic relationship with nitrogen-fixing Rhizobia in legume nodules (O'Dell and Sunde, 1997).

A somewhat parallel in animals is the role of cobalt in the propagation of microflora cofactors, specifically vitamin B-12, in those animals with reticulorumen pouches (Kennedy et al., 1995, 1997). In ruminants, Co is a primary gluconeogenic precursor for ruminants is propionic acid. Propionyl-CoA cannot enter β -oxidation-related pathways or the TCA cycle unless it is converted to succinyl-CoA via vitamin B-12-dependent steps (Kennedy et al., 1995). A way of thinking about Co from a mechanistic perspective is that as a component of vitamin B-12, it functions as a Grignard reaction catalyst acting as a nucleophile and in the addition of a single carbon moiety to another electrophilic carbon atom to form a new carbon–carbon bond.

24.6.1.2 Metabolism

As noted, Co is most important to ruminant animals, because of the rumen microflora. Ruminants can be fed ionic Co and rumen microbes will synthesize cobalamin for absorption. Nevertheless, the relative inefficiency of vitamin B-12 production in the rumen and poor absorption of B-12 can predispose ruminants to deficiency. Soils comprised of calcareous sands are commonly associated with Co deficiency in grazing animals, and applications of superphosphate have been related to reduced vitamin B-12 concentrations in ruminants. Seasonal variations in Co nutrition may also be significant.

Although roles for Co beyond vitamin B-12 production have not been defined, Co is absorbed and shares the same pathways as iron (Fe) for absorption. High amounts of Fe in the diet can depress Co absorption and vice versa. Co absorption is enhanced in Fe deficiency. Excretion of Co is primarily via the kidneys and bile and is linearly related to the ingested dose (Barceloux, 1999; Lauwerys and Lison, 1994). Other aspects important to the absorption of Co are similar to those described for vitamin B-12.

24.6.1.3 Functions

The signs and biochemical lesions that are manifested in Co deficiency correspond to those of vitamin B-12 deficiency. The pathways that are most severely impaired are those of purine biosynthesis and gluconeogenesis. A primary defect in Co deficiency underlying the above has been attributed to a reduction in the activity of methylmalonyl CoA mutase in ruminants. The hepatic lipidosis observed in Co-deficient animals has been attributed to a reduction in choline biosynthesis caused by a decrease in the activity of homocysteine methyltransferase. Accordingly, Co deficiency eventually leads to a loss of appetite, anemia, decreased fertility, and decreased milk production. Sheep are more susceptible to Co deficiency than cattle (McDonnell, 2001). In this species, there is loss of wool production, and even the accumulation of fat in the liver of vitamin B-12 deficient sheep, but not cattle, may be related to a methyl-group deficiency affecting liver lipid metabolism. Another metabolic anomaly of Co-deficient lambs is the accumulation of homocysteine in the plasma, which leads to an accumulation of oxidation products, depletion of vitamin E, and damage to the mitochondria. Reduction in the ability to produce normal levels of choline (see Sections 24.4.3.2 and 24.4.3.3) can lead to the inability to export triglycerides as a component of VLDL.

24.6.1.4 Requirements, Pharmacology, and Toxicity

Co deficiency in ruminants occurs when pasture Co concentrations are less than 0.10 mg/kg dry edible matter (Ellison, 2002). Toxicity in animals under natural conditions has not been reported. Toxic levels appear to be at least 300–1000 times the requirement in most species.

24.6.2 COPPER

24.6.2.1 Overview

Cu serves as a redox cofactor for a number of oxidases and monooxygenases that are essential for life. Perturbations in the activity of these enzymes are linked to a number of unusual biochemical steps and lesions. Cu deficiency results in reduced rates of growth, impaired reproduction, and defects in skeletal and vascular formation, as well as decreased production of nitric oxide (NO). Impaired immunity, neurological function, and depigmentation may also result from Cu deprivation. Table 24.8 lists processes related to these events.

24.6.2.2 Metabolism

Cu is found in meats, grains, and nuts. Milk and dairy products, however, are low in Cu. Environmental factors, such as soil, water source, fertilizer use, processing, and cooking, may affect the Cu content of food. Cu absorption from diets is relatively efficient, although some dietary constituents can affect bioavailability (Harris, 2014). Cu hydroxides, iodides, glutamates, and citrates are more easily

TABLE 24.8
Physiological Processes Directly Influenced by Dietary Copper Intake

Function	Mechanism
Hematopoiesis	Two copper-containing enzymes, ceruloplasmin (ferroxidase I) and ferroxidase II have the capacity to reduce and oxidize ferrous iron (Fe^{2+}) to ferric iron (Fe^{3+}). Fe^{2+} complexes are two to four orders of magnitude more soluble than Fe^{3+} complexes. Iron mobilization from storage sites is impaired in copper deficiency and microcytic anemia can occur.
Collagen and elastin stability	Copper is a cofactor for lysyl oxidase, an enzyme involved in the intra- and intermolecular cross-linking of collagen and elastin. Defective cross-linking can cause friable skin, bone fragility, and vascular lesions.
Antioxidant defense	Copper functions at the catalytic site of the antioxidant enzyme, superoxide dismutase.
Energy metabolism	The redox potential of ionic copper gives it a role in energy metabolism as a component of the cytochromes that participate in electron transport (e.g., cytochrome <i>c</i> oxidase).
Neurotransmitter production and metabolism	A number of reactions essential to normal function of the brain and nervous system are catalyzed by cuproenzymes. For example, dopamine- β -monooxygenase catalyzes the conversion of dopamine to the neurotransmitter norepinephrine inhibitors as antidepressants.
Pigmentation	The cuproenzyme, tyrosinase, is required for the formation of the pigment melanin important to the pigmentation of hair, skin, and eye.

absorbed than molybdates, sulfates, and phytates. High intakes (100 or more mg/kg of diet) of silver (Ag) and Zn can interfere with intestinal Cu transport. Moreover, the extended use of supplements that contain Fe can negatively affect Cu status. Cu absorption is greater in neonates than in adults. Another interaction involves the relationship between Cu, Mo, and sulfate. In ruminants, dietary sulfate intensifies the harmful effects of Mo on Cu absorption. CuSO_4 and Na_2MoO_4 react to form insoluble thio-molybdate complexes, which render Cu biologically less active and bioavailable (Nederbragt et al., 1984). Dietary reducing agents, such as ascorbic acid, may also lower Cu absorption because the intestinal transfer of divalent cupric ion is substantially greater the monovalent cuprous ion.

Cu absorption occurs by active transport (see Figure 24.20). For most species, absorption takes place in the upper small intestine, but in sheep, considerable absorption also occurs in the large intestine. In many animals, uptake of Cu is about 30%–60% with a net absorption of about 5%–10% owing to the rapid excretion of newly absorbed Cu into the bile (Ammerman et al., 1995). Cu uptake by cells occurs via high- and low-affinity transport systems (La Fontaine et al., 2010). Cupric ion (Cu^{+1}) is the primary substrate for the transport systems that take Cu across plasma membranes.

Recent studies in yeast have shed light on proteins involved in the process of Cu transport. In mammalian cells, the entry of Cu into cells is first orchestrated by the action of a reductase and then contact with a high-affinity Cu transporter, currently designated as Ctr1 and Ctr3 (Ctr2 is a low-affinity transporter). Under Cu-limiting conditions, the transporters and proteins involved in Cu redox are up-regulated. In addition to the transporters, cellular chaperones specific for Cu deliver Cu to specific cellular proteins (La Fontaine et al., 2010). Other important features of Cu regulation include the role for metallothionein, which acts to buffer shifts in the cellular concentrations of Cu (and Zn). Alternatively, Cu egress or transport out of cells is controlled by membrane transporters in the family of P-type ATPases (P-ATPases). Precise control of the regulation of Cu is necessary, in that free cuprous (as well as ferric) ions react readily with hydrogen peroxide to yield harmful hydroxyl radicals. Accordingly, unbound Cu is extremely low in concentration (~one atom/cell). In addition to the transporters, cellular chaperones specific for Cu deliver Cu to specific cellular proteins (La Fontaine et al., 2010). Other important features of Cu regulation include the role of metallothionein, a metal-binding protein for Cu, Zn, and cadmium that acts to buffer abnormal shifts in the cellular concentrations of Cu, and the proteins and transporters involved in the egress of Cu from cells.

Regarding systemic regulation, from the intestine, a case can be made for the transport of Cu on albumin and in the form of low molecular weight complexes (e.g., histidine) to target tissues, particularly the liver. From the liver, ceruloplasmin transports Cu to other tissues. Ceruloplasmin is the predominant Cu containing protein in mammalian serum, a glycosylated multi-Cu ferroxidase that carries >95% of total serum Cu. Although ceruloplasmin may function in Cu transport, the absence of ceruloplasmin has not been shown to alter Cu levels in the peripheral tissues. Such observations come from what is known about individuals and animal models that are aceruloplasminemic, a genetic disorder of ceruloplasmin deficiency (Shim and Harris, 2003; Meyer et al., 2001). Moreover, albuminemic rats do not have significantly impaired Cu metabolism (Vargas et al., 1994). The whole body regulation of Cu is also mediated in part by biliary Cu excretion; about 15% of the Cu excreted in bile is reabsorbed through the enterohepatic circulation. A large animal can contain 50–120 mg (780–1889 μmol) of Cu, about one-third of which is found in the liver and brain. Most nonruminant species have liver Cu concentrations that are between 2 and 10 $\mu\text{g/g}$ liver. Skeletal muscle, although considered low in Cu, represents about one-third of the total body Cu because of its mass.

Ruminants have relatively high levels of liver Cu compared to nonruminants. Typical liver Cu concentrations in sheep and cattle range from 20–150 $\mu\text{g/g}$ liver. Similarly, high liver Cu levels have been reported for ducks and some fish. For most species, liver Cu concentrations are highest in the newborn (Harris, 2014).

FIGURE 24.20 Cellular transport of copper, manganese, zinc, and selenium. (a) Dietary copper is presented to intestinal cells most probably in the form of amino acid complexes. In plasma, Cu is most often associated with albumin and ceruloplasmin. A high-affinity copper transporter (CTR1) is utilized for Cu's entry into cells. It is induced at low copper levels and degraded at high copper levels. Associated with this transporter is a copper reductase that maintains Cu in the +1 state (its most soluble form) while in the vicinity of the transporter. In cells, Cu is next transferred to chaperones whose functions are to carry copper to specific proteins within the cell (e.g., cytochromes, vesicular P-ATPases, or SOD). A novel process accomplishes Cu efflux from cells. There is transport of Cu into secretory vesicles, which occurs coincidentally with efflux of specific apocuproproteins (lysyl oxidase, ceruloplasmin) that are localized to the same vesicles. Two Cu-transporting ATPase enzymes, ATP7A and ATP7B, are responsible for the transfer of Cu to such intracellular vesicles. In response to high levels of cellular Cu, there is a higher rate of recycling of the vesicles to remove copper. Within the vesicles, apocuproproteins can also become activated. Consequently, the amounts of activity of cuproproteins secreted, such as lysyl oxidase (if from connective tissue cells) or ceruloplasmin (if from liver or neural cells), often reflect Cu status or dietary intake. Some evidence also suggests DMT or Nramp transporters essential to iron transport can play a minor role in copper uptake. (b) Intestinal and systemic cellular manganese transport is mediated mostly by divalent metal transporter 1 (DMT1) and is up-regulated in iron deficiency. Within the body, Mn bound to transferrin is taken up by transferrin receptors. Unlike other transition metals, Mn is dissociable; thus less is known currently about specific chaperones for Mn. A Golgi-derived ATPase has been described to facilitate the movement of Mn from and to the nucleus and cis- and trans-Golgi compartments. Given that MnO_4^- anion can be transported into and out of cells, a role for oxyanion transport is indicated. (c) Selenium is delivered to cells via amino acid and oxyanion transporters, and when present in plasma via processes that recognize selenoprotein P. The selenite and selenate forms must first be reduced (via a glutathione reduction system) to HSe^- before Se can be utilized as a cofactor. Selenomethionine, if not incorporated into protein, can also be eventually converted to HSe^- . Next, for incorporation into specific Se-proteins (e.g., GPx, 5'-ID, or Se-protein P), HSe^- is phosphorylated (requires ATP). Next, following transfer to Ser-tRNA_{UGA} to form Se-Cys-tRNA_{UGA} the stage is set for translation of Se-containing proteins. Regarding cellular efflux, Se is lost from cells as secreted Se-proteins, such as selenoprotein P, Se-cystathionine, or as volatile forms of methylated Se (e.g., $\text{CH}_3\text{-Se-CH}_3$). (d) Zinc uptake and cellular translocation are controlled by two large families of metal transporters for which there were over two-dozen variants. More specifically, the two solute-linked carrier (SLC) gene families encode the zinc transporters: ZnT (SLC30) and Zip (SLC39). The ZnT transporters reduce intracellular zinc availability by promoting zinc efflux from cells or into intracellular vesicles, while Zip transporters increase intracellular zinc and promote extracellular zinc uptake. The ZnT and Zip transporter families exhibit unique tissue-specific expression and differential responsiveness to dietary Zn intake and physiologic stimuli. Temporary influxes of Zn are buffered by the induction of metallothionein. DMT1 and other ion channels can play minor roles in Zn transport.

24.6.2.3 Functions

Anemia (microcytic hypochromic or normocytic hypochromic) is probably the most frequent sign associated with chronic Cu deficiency. Cu deficiency results in impaired Fe absorption, mobilization, and utilization due to Cu's role as a redox cofactor in various membrane-associated ferrioxidases that oxidize Fe⁺² and Fe⁺³. ALA dehydrase, critical to the first step in heme synthesis, is also decreased in Cu deficiency. Heinz body anemia caused by ROS is also associated with a significant depression of Cu, Zn superoxide dismutase activity (Hickman et al., 1990a). Neutropenia and myelodysplasia are also associated with Cu deficiency, perhaps related to the importance of adequate Fe to Cu metabolism.

In ruminants, neonatal ataxia (also referred to as enzootic ataxia or swayback) is the most recognized of the naturally occurring Cu deficiency diseases. For example, it is frequently observed in areas of Australia where soil and plant sources of Cu are low. The disorder is characterized by spastic paralysis, especially of the hind limbs, severe incoordination of movement, blindness in some cases, and anemia (Ellison, 2002).

Cardiovascular defects are also associated with Cu deficiency. Cu deficiency can result in degeneration of the myocardium with fibrosis. Cardiac failure may also occur due to decreased cytochrome oxidase activity and abnormalities in elastin and collagen structures. The most severe manifestation of the latter is aortic aneurysms due to decreased elastin and collagen lysine-derived cross-linking, because of reductions in lysyl oxidase activity (Tchaparian et al., 2000; Rucker et al., 1999, 1998; Cui et al., 2004). Moreover, cardiac norepinephrine levels are sensitive to changes in Cu status. Changes in norepinephrine production result in decreased coronary resistance and reduced systolic pressure. Also, skeletal defects have been reported in Cu-deficient dogs, sheep, chicks, cattle, foals, and humans. The primary biochemical lesion is again a reduction in the activity of lysyl oxidase, leading to a reduction in cross-linking of bone collagen.

Increased rates of tissue lipid peroxidation, compromised NO metabolism, and impaired immune response are additional features of Cu deficiency. Lipid peroxidation can occur, because two major components of the cells' antioxidant defense system are affected: Cu, Zn superoxide dismutase, and Se-dependent GPx activities. Because of the increase in various reactive oxidant species resulting from Cu deficiency, NO levels may also be altered (Wu and Meininger, 2002). NO is converted to products, such as peroxynitrite, thus altering NO-dependent cell signaling. Impaired immunity (including defects in neutrophil and lymphocyte function) appears due to the inability to carry out effective oxidative burst reactions and secondary effects, such as the reduced leukocyte trafficking between the blood and tissues. It has been demonstrated that decreased levels of vascular adhesion protein 1 (VAP-1) are associated with deviations in the mucosal immune system (Smith and Vainio, 2007). VAP-1, or semicarbazide-sensitive amine oxidase, is a Cu-containing amine oxidase. VAP-1 alters the expression of molecules involved in the leukocyte extravasation cascade and can prime the vessels for an enhanced inflammatory response. VAP-1 is found in the smooth muscle of blood vessels. Although not all physiological functions of VAP-1 are understood, development of blood vessels, lipolysis regulation, and detoxication are all suggested features.

Moreover, altered insulin secretion and glucose regulation occur during Cu deficiency that can result from peroxidative damage to pancreatic cells. Total cholesterol and free cholesterol levels may also be elevated. A biochemical lesion underlying the hypercholesterolemia is a reduction in hepatic HDL binding. This results in a slower turnover of HDL and leads to an accumulation of apo E-rich HDL. The lipid peroxidation and abnormal lipid transport are important features that can lead to abnormal membrane function.

24.6.2.4 Requirements, Pharmacology, and Toxicity

Most animals meet their requirements if the levels of available Cu exceed 4 mg Cu per kg of diet or 1 mg per 1000 kcal (4.2 MJ) (Doong et al., 1983; Fascetti et al., 2002). Acute Cu toxicity is rare and usually is caused by the consumption of contaminated foods or beverages, or by the accidental or

deliberate ingestion of large quantities of Cu salts (Subcommittee on Mineral Toxicity in Animals and Board on Agriculture and Renewable Resources, 1980). Sheep are more sensitive than cattle, with toxicosis being reported in herds of sheep fed cattle rations or provided water from copper-containing plumbing lines. Clinical signs include gastrointestinal distress followed by hemolytic crises.

Two genetic conditions, Menkes' and Wilson's diseases are worthy of mention because the understanding of each has contributed to the understanding of general Cu transport processes (Harris, 2000). In Menkes' disease, there is poor Cu absorption and Cu transport in mesenchymal cells. In Wilson's disease, there is an increased liver Cu content, leading to severe hepatic damage, followed by increased brain Cu levels and neurological lesions. Menkes' disease results in pathology resembling Cu deficiency, as opposed to the pathology of Wilson's disease, which resembles Cu toxicity. Both the Wilson and Menkes' genes code for one of the P-ATPases involved in Cu egress (Harris, 2000).

In Menkes' disease, the mutation prevents Cu transport across the basal lamina of the intestine. JH Menkes first described this Cu transport disorder in 1962 in a family of English-Irish descent. It was recognized immediately as an X-linked recessive disorder, characterized by retardation, impaired growth, peculiar hair, and focal cerebral and cerebellar degeneration. Oral treatment with Cu is ineffective because the genetic defect is due to altered expression of ATPase A7, the enzyme necessary to Cu egress in mesenchymal-derived cells. The condition is often lethal, with death occurring in the first or second year of life, usually from a vascular accident, that is, aneurysm or stroke. Menkes' patients also show signs of osteopenia (poor bone development) and vascular disease. In cell culture, mesenchymal, epithelial, and neural cells from Menkes' patients abnormally sequester Cu. Moreover, the ability to transfer Cu to some Cu-requiring enzymes, for example, lysyl oxidase, is lacking or abnormal (La Fontaine et al., 2010; Rucker et al., 1998). In humans, the frequency of Menkes' disease is estimated to be about one in 35,000–40,000 live births among those of English-Irish descent. The mottled mouse is an animal model analog for Menkes' disease (Shim and Harris, 2003).

In contrast, Wilson's disease is an inherited, autosomal recessive disorder of Cu accumulation and toxicity that occurs in about one of every 40,000 people (Schilsky, 2009a, 2009b). The responsible gene (P-ATP-7B, a homolog to P-ATP-7A) also codes for a vesicular membrane-bound Cu transport protein, but, unlike the Menkes' gene, it is expressed primarily in the liver. As in Menkes' disease, there are mutations in ATP7B that account for symptoms associated with Wilson's disease. Owing to its location in liver, when ATP7B is altered by mutations, biliary excretion of Cu is impaired. An important detail is that the vesicles to which P-ATPase-7B is localized also appear to transport ceruloplasmin from cells. In cells adjacent to biliary canaliculi, some of the vesicular movement is to the cellular membrane that is exposed to the biliary canaliculus; while in other cells, the movement is to the cell membrane exposed to sinusoids and distensible vascular channels. It has therefore been postulated that the liver "packages" Cu for excretion into the bile by binding Cu to ceruloplasmin for release into bile or plasma. This process accounts for the observations that defects in P-ATPase-7B activity often result in low levels of Cu bound to ceruloplasmin in blood and eventually failure of whole body Cu regulation, due to a hepatic accumulation of Cu.

The analog of this disorder in animals is Cu toxicosis in Bedlington Terriers, which affects 60% of the breed (Haywood, 2006). Dogs homozygous for the gene are characterized by extremely high liver Cu concentrations, often exceeding 500 µg/g (7.87 µmol/g) compared to normal values of less than 75 µg/g (1.180 µmol/g). The associated hepatic injury is thought to be due to free radical damage and lysosomal rupture. Several other breeds, including West Highland White Terriers, Skye Terriers, Dobermans, Dalmatians, Keeshonden, and Labrador Retrievers have also been identified as having Cu-associated liver disease.

The treatment strategies for both Wilson's disease and Cu-associated liver disease in dogs include chelation therapy with drugs such as penicillamine and trientine, or high oral doses of Zn (40–50 mg/d in humans, equivalent to 100–150 mg Zn/kg of typical animal rations). Excess Zn can inhibit Cu absorption (Schilsky, 2009a, 2009b). Recent work in a population of Labrador Retrievers with

subclinical hepatic copper accumulation demonstrated that feeding a copper restricted (1.3 ± 0.3 mg Cu/Mcal), zinc enhanced (64.3 ± 5.9 mg Zn/Mcal) diet reduced hepatic copper concentrations (Fieten et al., 2015). The genetic background of this group of dogs may influence their response to dietary treatment.

In summary, several complex strategies are used to maintain Cu homeostasis at the cellular and organismal level. The complexities are in part related to maintaining Cu in an appropriate redox state and the need to accommodate a diverse array of enzymatic functions. Fortunately, Cu deficiency is a rare occurrence, but genetic polymorphisms involving Cu transporters can occur, which mimic the signs of Cu deficiency and toxicity observed in animal models.

As a final comment, transmissible spongiform encephalopathies (TSEs) are a family of neurodegenerative diseases characterized by their long incubation periods, progressive neurological changes, and spongiform appearance in the brain. There is now evidence that TSEs are caused by an isoform of the normal cellular surface prion protein PrPC. The function of PrPC is still unknown, but it exhibits properties of a cupro-protein, capable of binding Cu ions (Viles et al., 2008; Leach et al., 2006). In sheep, scrapie is one of several forms of TSE and related to bovine spongiform encephalopathy or “mad cow disease.” There are two differing views on Cu’s role in prion diseases. While one view looks at the PrPC Cu binding as the trigger for conversion to PrPSc (the scrapie-associated isoform), the opposing viewpoint suggests it is a lack of PrPC Cu-binding that results in the disease-causing isoform. Moreover, Mn and Zn have also been shown to interact with PrPC; thus, the mechanism remains unresolved.

24.6.3 MANGANESE

24.6.3.1 Overview

Mn is an essential trace element that is required for the activity of enzymes with transferase or hydrolase functions. The mitochondrial form of superoxide dismutase also requires Mn. Maintaining regular Mn status is also important to glucose metabolism, insulin function, and cholesterol regulation. Manifestations of Mn deficiency in domestic animals include impaired growth, skeletal abnormalities, disturbed or depressed reproductive function, ataxia of the newborn, and defects in lipid and carbohydrate metabolism (Aschner et al., 2007).

24.6.3.2 Metabolism

In intestinal cells, the uptake and transport of Mn appear controlled by active transporters (Figure 24.20). The transport characteristics under steady-state conditions at the intestine can exhibit two components that probably reflect transcellular (carrier-mediated) and paracellular (diffusional) pathways. Calcium, calcium antagonists, ATP synthesis inhibitors, and high levels of Fe decrease Mn absorption. Reducing agents, such as ascorbic acid, do not influence uptake. However, compounds that affect solubility (e.g., phytates) decrease Mn absorption (Ammerman et al., 1995). In general, the efficiency of Mn absorption is relatively low. Mn entering portal blood from the gastrointestinal tract can either remain free or rapidly become bound to α -2-macroglobulin and transferrin, particularly as Mn^{+3} . Mn uptake by cells is usually unidirectional and saturable.

The cellular transport of Mn involves transporters in the natural resistance-associated macrophage protein (Nramp) solute carrier family that are involved in proton-coupled divalent metal ion transport (Aschner et al., 2007). The divalent metal transporter-1 (DMT-1) that transports Fe also seems to play a significant role in Mn transport (Fitsanakis et al., 2010). Analogous to the regulation of Zn and Cu transporters, the differential regulation of DMT-1 occurs at the level of protein stability and trafficking through the various secretory pathways. For example, it undergoes regular turnover in cells with sufficient Mn but accumulates in Mn-deficient cells. Moreover, animal models with Fe transporter defects also have impaired Mn transport. For example, homozygous Belgrade rats have hypochromic anemia (due to reduced Fe transport) as well as abnormalities in Mn metabolism (Chua and Morgan, 1997).

Mitochondria have a large capacity for Mn^{+2} uptake and it has been suggested that mitochondrial Mn^{+2} and Ca^{+2} uptakes are linked. Nuclear, cytoskeletal (microsomal), and cytosolic pools of Mn^{+2} also exist. In contrast to Zn, Cu, and Fe for which only a few atoms per cell exist in free form, an easily measurable portion of Mn is dissociable (Reilly, 2004), more analogous to Ca^{+2} and Mg^{+2} .

The metabolic fate of newly absorbed Mn entering the hepatocyte has not been well defined, although several cellular pools of Mn can be identified. The first represents Mn taken up by the lysosomes. Lysosomal uptake of Mn is also considered to be an essential step to egress as it is thought that lysosomes concentrate Mn for delivery to the bile.

Expressed as a percentage of total, skeletal Mn can account for up to 25% of the total body pool. Bone Mn can be raised or lowered by substantially varying dietary Mn, but skeletal pools of Mn exchange slowly; thus they are not thought to constitute a major pool for rapid mobilization. The fetus does not typically accumulate liver Mn before birth, and the levels of Mn in fetal liver are lower than in adult liver, which mainly follows the expression of Mn enzymes such as arginase, pyruvate carboxylase, and Mn-superoxide dismutase.

24.6.3.3 Functions

Mn functions as an enzyme activator and as a constituent of metalloenzymes (Reilly, 2004). For Mn-activated reactions, Mn binds either to a substrate (such as ATP) or to the protein directly, to facilitate subsequent conformational changes. While there are relatively few Mn metalloenzymes, there are a large number of enzymes that can be activated upon Mn additions (e.g., various hydrolases, kinases, decarboxylases, and transferases). Although the extent to which such activation is specifically related to Mn can be questioned (e.g., Mg can replace Mn in many of the reactions), some appear Mn specific (e.g., several glycosyltransferases). For example, it has been suggested that xylosyl transferase is specifically activated by Mn (Liu et al., 1994). Cartilage isolated from Mn-deficient chicks is xylose poor, and fetuses born of Mn-deficient rats have limb deformities that can be related to reduced glycosylation (Liu et al., 1994).

The effects of Mn deficiency on skeletal development have been extensively described (Keen et al., 1999, 2000). Mn deficiency results in limbs that are shortened and thickened, and joints that are swollen and enlarged. The basic biochemical lesion is a reduction in proteoglycan biosynthesis, which is secondary to a decrease in the activities of glycosyltransferases. Ataxia in the offspring of Mn-deficient animals also appears to be related to defects in proteoglycan synthesis. Ataxia is the result of impaired vestibular function caused by abnormal cartilage formation in otoliths present in the utricular and secular maculae.

Further, defects in carbohydrate and lipid metabolism have been observed in Mn-deficient animals due to pancreatic pathology characterized by aplasia or marked hypoplasia of cellular components, including fewer and less intensely granulated pancreatic islet cells than in normal animals. When glucose is given either orally or intravenously to Mn-deficient animals, diabetic-like glucose tolerance curves are observed, which are reversed upon Mn repletion (Keen et al., 1999, 2000). In the pancreas, Mn in islet cells is associated with two pools: a readily exchangeable pool associated with the cell surface, and an intracellular pool. Mn fluxes between these pools can affect insulin release. Accumulation of Mn within the islet cell membrane inhibits insulin release while increases in the intracellular concentration of Mn are associated with a stimulation of insulin synthesis and release. In vivo, Mn deficiency depresses pancreatic insulin synthesis and secretion and enhances intracellular insulin degradation. Also, Mn can activate phosphoenolpyruvate carboxykinase and influence pyruvate carboxylase activity, important to gluconeogenesis (Keen et al., 1999, 2000).

Mn-deficient animals often have excess fat accumulation in the liver. This may be due to alterations in mitochondrial assembly. Mn-deficient animals develop abnormally elongated mitochondria with stacked cristae and decreased capacities to oxidize lipid. Mn is also critical for lipid metabolism as a cofactor in steroid biosynthesis. Mn is thought to be required in farnesyl pyrophosphate synthase, a key step in cholesterol and steroid hormone biosynthesis (Klimis-Tavantzis et al., 1983).

24.6.3.4 Requirements, Pharmacology, and Toxicity

Diets containing less than 1 mg Mn/kg are unable to support normal reproduction. The minimum dietary Mn requirement for poultry for growth and egg production and hatchability is about 40 mg/kg. The concentration of Mn in feedstuffs is dependent on soil conditions and fertilizer practice (Zheljazkov and Warman, 2004). Foods considered high in Mn include nuts, whole cereals, dried fruits, and leafy vegetables. Meats and dairy products are poor sources of Mn. In typical animal feeds, Mn can range from 10 mg/kg in corn and grain-based diets to 100 mg/kg in diets based on ryegrass and clover.

Although excessive Mn can produce toxic effects, it is considered to be among the less toxic of the essential trace elements. For example, chicks, calves, pigs, and sheep can tolerate diets up to 3000, 1000, 500, and 200 mg Mn/kg, respectively. In animals, the primary lesion associated with dietary Mn toxicosis is an induction of Fe deficiency, which is thought to result from Mn and Fe sharing similar transporters (Aschner et al., 2007). In humans working in environments contaminated with Mn, overt signs of toxicity (usually by inhalation) can occur after months of chronic exposure. These signs are characterized by psychiatric disorders that include memory impairment, disorientation, hallucination, speech disturbances, and compulsive behavior and signs of Parkinson-like tremors and gait (Keen et al., 1999). Disturbance in carbohydrate metabolism may also occur. With acute Mn toxicity, there is a rapid uptake of Mn by the pancreas, a sharp reduction in circulating insulin, and an increase in plasma glucose. Thus, similar to Mn deficiency, Mn toxicity can affect insulin production or release from the pancreas (Keen et al., 2000, Harris, 2014). Acute manganese toxicity has been recently reported in a dog that consumed 100 joint supplements containing manganese ascorbate (Borchers et al., 2014). It was determined that the dog consumed 86 mg Mn/kg of body weight. Progression to fulminant liver failure prompted euthanasia in this case.

24.6.4 MOLYBDENUM

24.6.4.1 Overview

The most important function of Mo is as a cofactor for xanthine dehydrogenase/oxidase, aldehyde oxidase, and sulfite oxidase (Brondino et al., 2006). Mo is present in these enzymes as molybdopterin or Mo cofactor (Figure 24.21).

FIGURE 24.21 Molybdenum cofactor. Mo as molybdate enters cells by way of oxyanion transporters. A series of complex condensation and reductive steps (e.g., formation of the pterin precursor from guanidine triphosphate and condensation with Mo) results in the formation of the molybdenum cofactor. The cofactor is essential for the activities of sulfite oxidase, xanthine dehydrogenase, and aldehyde oxidase.

24.6.4.2 Metabolism

Other than thiomolybdates (see Section 24.6.2), Mo is well absorbed by all species. It has been proposed that a carrier-mediated process transports Mo and that sulfate and Mo (as molybdate) compete for the same carrier. Excretion in nonruminants appears to be mostly via the kidney, in contrast to ruminants, wherein fecal and milk losses are more significant.

24.6.4.3 Functions

Mo-containing xanthine dehydrogenase exists in two interconvertible forms, xanthine dehydrogenase and xanthine oxidase. In its dehydrogenase form, xanthine dehydrogenase catalyzes the reaction:

The common substrate (XH) is a purine. Uric acid is a metabolic endpoint (XO). In its oxidase form, the enzyme transfers the reducing equivalent generated by oxidation of substrates to molecular oxygen, with the resultant production of superoxide anion and hydrogen peroxide. For example, during ischemia, reperfusion and/or reoxygenation of an injured tissue can occur, and xanthine dehydrogenase can be converted to xanthine oxidase. In the oxidase form, the reaction sequence is

Given that in such conditions, ATP is usually depleted and there is an increase in the purine pool, increased quantities of superoxide radicals may be released and can be a major source of tissue peroxidation.

Aldehyde oxidase is a related Mo enzyme that catalyzes many of the same reactions as xanthine dehydrogenase. Both of these enzymes are needed in ruminants to catabolize exogenous pyrimidines. The third known Mo enzyme is sulfite oxidase, a mitochondrial enzyme that catalyzes the oxidation of sulfite to sulfate during the degradation of sulfur amino acids.

24.6.4.4 Requirements, Pharmacology, and Toxicity

Deficiencies of Mo are rare. The requirement is no more than 0.15–0.3 mg/kg of diet for most animals. Genetic disorders involving Mo cofactor production are also rare (e.g., 100 cases have been reported in humans). Low levels of the Mo cofactor cause toxic levels of sulfite with accompanying neurological damage (Schwarz and Mendel, 2006).

The clinical signs of Mo toxicity are characterized by achromotrichia, anemia, cartilaginous dysplasia, abnormal endochondrial ossification, subperiosteal ossification, and abnormal fibrogenesis. The clinical signs of molybdenosis also include lameness, weight loss, anorexia, loss of color, and quality of the wool or hair, and in cattle, diarrhea. These lesions are characteristic signs of an induced Cu deficiency.

24.6.5 SELENIUM

24.6.5.1 Overview

A nutritional need for selenium (Se) is now well established, although before 1950 Se was viewed as a potential carcinogen. Se plays an important role in thyroid hormone metabolism, antioxidant defense, and immune function (Foster and Sumar, 1997). Se as selenocysteine is at the active site of a wide range of selenoproteins. Many provocative clinical studies suggest putative roles for Se in cancer protection, ROS protection, and even relationships involving viral exposure.

24.6.5.2 Metabolism

Both organic and inorganic forms of Se can be utilized in the body. The order of uptake is $\text{SeO}_3^{-2} < \text{or} = \text{selenocysteine} < \text{selenomethionine} < \text{SeO}_4^{-2}$. Both amino acid related and anion transporters are involved in Se transport (Figure 24.20). Many of the details, however, have yet to be resolved. The transport of SeO_4^{-2} is inhibited by thiosulfate, but not sulfate. A Na^+ , K^+ -ATPase is probably responsible for energizing the brush-border transport of selenate, where the ileum is the site of absorption. Some inflammatory intestinal diseases and short-bowel syndrome can lead to Se deficiency. In contrast to intestinal cells, selenate, selenite, selenomethionine, and selenocysteine, or selenite injected intravenously is each taken up rapidly and selectively through an anion-exchange carrier or transporter (Burk and Hill, 2009).

Absorption of Se occurs mainly in the duodenum with little evidence of uptake by the rumen, abomasums, stomach, jejunum, or ileum. In monogastric animals, absorption of soluble forms of Se is very high (>80%) and does not appear to be homeostatically controlled (Foster and Sumar, 1997). Absorption of Se in ruminants is lower than in nonruminants (about 40%), presumably because of the reduction of selenite to insoluble forms of Se in the rumen. Elemental Se and Se sulfide are not absorbed to any appreciable degree. After absorption, there appears to be a rapid distribution of water-soluble Se compounds to most organs. Transport in plasma to various organs seems to involve a specific selenoprotein, selenoprotein P. Se is found throughout the body with highest concentrations in the kidney and liver (0.5–1.5 and 0.2–0.8 $\mu\text{g/g}$, respectively). Skeletal muscle has a mean Se concentration of about 0.01–0.2 $\mu\text{g/g}$ and accounts for about 50% of the total body pool (Sunde, 1990).

A novel aspect of Se regulation is that its insertion into protein occurs posttranscriptionally (Lu and Holmgren, 2009). Such occurrence of this element in protein is widespread. The knowledge that Se is incorporated as SeCys has modified our understanding of the genetic code (Lu and Holmgren, 2009). The formation of SeCys with its novel codon expanded to 21 the codon usage for the naturally occurring amino acids. Although it was recognized in the mid-1960s that the codon, AUG, had a dual role of initiating protein synthesis and inserting methionine at protein translation start sites, the possibility that a second codon also had two functions was not considered at the time. It is now known that UGA serves both as a termination and a SeCys codon. SeCys can be attached to tRNACys by cysteinyl-tRNA synthetase and can be incorporated nonspecifically into protein in

TABLE 24.9

Selenium-Containing Proteins

Protein	Function
Glutathione peroxidase (GPx) 1–8	An enzyme family with peroxidase activity lipid hydroperoxides and H_2O_2 is reduced to its corresponding alcohols and water, respectively. GPx1 is the most abundant with H_2O_2 as the preferred substrate. GPx4 has a preference for lipid hydroperoxides. GPx2 is an intestinal and extracellular enzyme. GPx3 is extracellular and abundant in plasma. Four other variants have also been identified.
Iodothyronine deiodinase (ID) 1–3	In the tissues, deiodinase either activates thyroid hormones by converting thyroxine (T4) to the active hormone triiodothyronine (T3) through the removal of an iodine on the outer ring or inactivates by removal of iodine on the inner ring, which converts T3 to the inactive diiodothyroxine (T2). ID 1 is found in liver and kidney, ID 2 in the thyroid and adipose, and ID 3 in fetal tissue and placenta.
Selenoproteins and variants	SEPN1, associated with respiratory distress and muscular dystrophy. SEPP1, a heparin-binding protein that appears to be associated with endothelial cells and has been suggested to function as an antioxidant in the extracellular space and in extracellular transport of selenium to targeted cells. SEPW1, found in skeletal muscle and acts as a methionine sulfoxide reductase. SMCP, sperm mitochondrial-associated cysteine-rich protein.
Thioredoxin reductases 1–3	Thioredoxin reductases catalyze the reduction of thioredoxin using NADPH as a reducing agent.

response to Cys codons, which is the reason why many proteins contain Se at sites other than the Se-containing active sites in selenoenzymes.

The translation of selenoprotein mRNAs requires both cis-acting and trans-acting factors (Lu and Holmgren, 2009; Burk and Hill, 2009). SeCys is inserted into nascent selenopeptides in mammals using a unique amino acid insertion system. Distinct 3'-UTR mRNA structures, designated SECIS elements, function in recruiting SBP2, a SeCys-specific elongation factor, and selenocysteine-tRNA^{Se}, SeCys, into the SeCys insertion complex, designated the selenosome. SeCys tRNA^{Se}, SeCys is used both as the site for SeCys biosynthesis and its incorporation into the active site of specific selenoproteins. Recent work also suggests considerable complexity in the regulation of specific selenoenzymes (Burk and Hill, 2009), for example, transcriptional as well as translational regulatory controls exist for GPx.

24.6.5.3 Functions

Examples of important selenoproteins are noted in Table 24.9. The best defined functionally is GPx. GPx catalyzes the reduction of hydrogen and organic peroxides (ROOH) to their respective alcohols and water (Margis et al., 2008). It is now recognized that there are two different GPx activities in tissues, one that is Se-dependent and a second, which is not. The non-Se-dependent GPx enzymes are referred to as GSH S-transferases, and their activities can increase under conditions of severe Se deficiency. There are several isozymes encoded by different genes that vary in cellular location and substrate specificity. GPx1 is the most abundant and is found in the cytoplasm. Although H₂O₂ is the preferred substrate ($2\text{GSH} + \text{H}_2\text{O}_2 \rightarrow \text{GS-SG} + 2\text{H}_2\text{O}$, where GSH represents reduced monomeric glutathione, and GS-SG represents glutathione disulfide), fatty acid and other lipid peroxides (ROOH) also function as substrates. The product is an acyl moiety wherein the [-OOH] group is converted to a [-OH] group. Mice genetically designed to lack GPx1 are in many respects phenotypically normal, indicating that the enzyme is not critical for life. However, GPx1 belongs to the family of GPxs, which consists of eight known mammalian isoenzymes. Mice lacking GPx4, which differs from the other GPx family members regarding its protein structure and less restricted dependence on glutathione, die during early embryonic development. GPx4 can reduce lipid-hydroperoxides, specifically phospholipids, inside biological membranes (Burk and Hill, 2009).

Another family of selenoproteins is the 1,5'-iodothyronine deiodinases (Beckett and Arthur, 2005). The 5'-monodeiodination of thyroxine, the major secretory product of the thyroid gland, to its active form 3, 3', and 5-triiodothyronine is catalyzed by 1,5'-ID. In Se deficiency, the activity of 1,5'-ID is decreased along with the concentration of thyroxine. Also, a 5'-ID occurs in peripheral tissues (e.g., liver, kidney, and muscle), which can remove the remaining iodine group at the five position.

Moreover, there are also proteins that have been identified that are important to Se transport and delivery to organelles and tissues (Burk and Hill, 2009), for example, the plasma protein; selenoprotein P. Selenoprotein P is an abundant extracellular glycoprotein that is rich in selenocysteine. At least four isoforms of selenoprotein P have been identified. In rats, it has been estimated that 25% of whole-body Se passes through selenoprotein P each day. Selenoprotein P knockout mice have low Se concentrations in the brain, testis, and fetus. Measurement of selenoprotein P in human plasma has shown that it is depressed by Se deficiency and by cirrhosis. Of potential importance, Se supplementation optimizes GPx activity before Se in selenoprotein P is optimized, indicating that plasma selenoprotein P can be a useful index for assessing Se nutritional status (Burk and Hill, 2009).

The primary biochemical lesions that are associated with Se deficiency are low GPx and 5'-ID activities. Excess cellular free radical damage can be the initial lesion underlying the widespread pathologies. Consistent with this idea are the observations that simultaneous deficiencies of other antioxidants (i.e., hypovitaminosis E and A) amplify the signs of Se deficiency when they occur (Foster and Sumar, 1997). Nutritional muscular dystrophy (white muscle disease) is a Se-responsive disorder that can affect farm animals (sheep, cattle, pigs, horses, and poultry). This myopathy is associated with excessive peroxidation of lipids, particularly the mitochondrial lipids, resulting in

degeneration, necrosis, and subsequent fibrosis of myofibers (Lenz and Lens, 2009). Often this is associated with cardiac involvement and, depending on the species, hepatic necrosis. Poultry and swine can be affected by exudative diathesis and edematous conditions that respond to supplemental Se. Testicular degeneration and impaired sperm production and infertility occur with Se deficiency. In humans, Keshan disease is an endemic congestive cardiomyopathy that affects primarily children and women of childbearing age with lesions that are very similar to the characteristic lesions of nutritional cardiomyopathy associated with white muscle disease in animals (Foster and Sumar, 1997).

The study of Keshan disease also led to an association between Se and increased susceptibility to infection with certain enteroviruses. The discovery that the cardiomyopathy of Keshan disease likely had a dual etiology (nutritional and infectious) provided impetus for additional studies of relationships between Se nutritional status and viral infection. It was observed that an amyocarditic strain of coxsackievirus B3, CVB3/0, was converted to a highly virulent strain when it was inoculated into Se-deficient mice. Similar alterations in virulence and genomic composition of CVB3/0 were next observed in GPx knockout mouse models (Beck et al., 2003).

24.6.5.4 Requirements, Pharmacology, and Toxicity

Plants are the primary dietary sources of Se. In general, requirements for Se range from 200 to 400 $\mu\text{g}/\text{kg}$ of diet for most species. Although rare, there is also a health risk of too much Se (selenosis). Symptoms include gastrointestinal irritation, hair loss, changes in hoof and nail texture, and nerve damage (Schrauzer, 2003). Three types of Se toxicity have been identified in livestock: acute and chronic blind staggers and chronic alkali disease. Abnormal movement and posture, breathing difficulties, diarrhea, and rapid death characterize acute Se toxicity. Chronic Se toxicity of the blind staggers type occurs when animals consume Se-toxic accumulator plants (usually over a period of weeks or months).

24.6.6 ZINC

24.6.6.1 Overview

Zn functions at the active site of many enzymes by facilitating strong, but readily exchangeable, substrate or ligand binding (Harris, 2014). Zn is not capable of redox. Thus, it can be used biologically in novel ways at the functional sites of proteins without causing oxidative changes. Zn also plays important structural roles in proteins. One example is the Zn-finger motif, the most common recurring motif in proteins that serve as transcription factors.

24.6.6.2 Metabolism

The primary site of absorption of exogenous Zn is the proximal small bowel, either the distal duodenum or proximal jejunum. Absorption studies in animal models indicate an inverse relationship between the percentage of Zn absorbed and dietary Zn intake (Harris, 2014; O'Dell and Sunde, 1997). In cattle, about one-third of the Zn is absorbed from the abomasum. In most species, the initial absorption of Zn is about 10%–20%. Phytate (myoinositol hexaphosphate), which is found in all plant seeds and most roots and tubers, can significantly inhibit Zn absorption. Moreover, high dietary Fe decreases Zn absorption, although its significance concerning overall Zn balance can be questioned. Several amino acids form Zn complexes with high stability constants and it has been suggested that such complex formation facilitates Zn uptake. Zn absorption is higher in neonates than in adults and is increased in Zn-deficient animals. The physiological state also affects absorption; pregnancy and lactation can enhance absorption.

Plasma Zn is associated with albumin (about 90%) and α -2 macroglobulin (about 10%). Less than 1% is complexed to other plasma components. Zn homeostasis is achieved largely by enterohepatic recirculation. A primary source of Zn in the intestinal lumen is also from pancreatic secretions, because of Zn's importance as a cofactor for pancreatic peptidases, various hydrolases, and proteinases.

As is the case for other essential metals, several transporter systems have been identified for Zn based on corresponding homologs in yeasts (Figure 24.20). Two distinct families of Zn transporters are known: the ZIP family that imports Zn and the ZnT family that functions in releasing Zn or sequestering Zn internally (Lichten and Cousins, 2009). The ZIP transporters are found in the duodenum in the crypts and lower villi and appear available for the uptake of several metal ions, including Zn. Uptake assays demonstrate that Cu^{+1} and Fe^{+2} can be potential substrates, as they inhibit Zn^{+2} uptake, whereas Co^{+2} , Mn^{+2} , Mg^{+2} , and Ni^{+2} have no effect on Zn^{+2} uptake. Given that about 10% of the total proteome has Zn binding domains, the importance of Zn^{+2} transporters and their regulation becomes very clear (Kambe et al., 2015). Such transporters help to regulate processes ranging from proteolytic to neurological functions (Kambe et al., 2015; Chohanadisai et al., 2013).

The ZIP transporters are under transcriptional control based on the observation that one of the family of ZIP transporters, ZRT1, is inversely expressed relative to cellular Zn^{+2} levels; Zn^{+2} depleted cells have 10-fold more ZRT1 mRNA than do Zn^{+2} -repleted cells. There is also evidence for posttranslational regulation. When cellular Zn is elevated, there is degradation of the transporters by vacuolar proteases (Lichten and Cousins, 2009; Kambe et al., 2015).

24.6.6.3 Functions

Specific biochemical changes associated with the clinical features of Zn deficiency are not easy to identify. As a general rule, epithelial cells and cells involved in immune function are most affected by Zn deprivation. The principal biochemical lesion centers on the non-coordination of events critical to the differentiation of cells; perhaps related to the important function that Zn plays in transcription factor integrity and structure (Harris, 2014; Failla, 2003; Keen and Gershwin, 1990). Of interest, there are greater changes in immune responsiveness than in changes in the activities of Zn-requiring enzymes. Zn deficiency can also have a significant impact on the hormonal regulation of cell division, specifically alterations in the pituitary growth hormone (GH) and insulin-like growth factor-I (IGF-I) axes. Changes in the concentrations of GH are observed in Zn deficiency and circulating IGF-I is decreased. Other evidence suggests that Zn deficiency can also alter cell membrane integrity and membrane-signaling systems as well as coordination of intracellular second messengers critical to cell proliferation (Keen and Gershwin, 1990; MacDonald, 2000). Moreover, circulating IGF-I concentrations are decreased.

Zn is essential for the function of more than 200 enzymes. Zn-containing enzymes are found in all of the major metabolic pathways involved in carbohydrate, lipid, protein, and nucleic acid metabolism. Zn functions as a structural component of proteins, as a proton donor at the active site of enzymes, and as a bridging atom between substrates and their enzymes (e.g., carboxypeptidases, alkaline phosphatase, alcohol dehydrogenase, carbonic anhydrase, and superoxide dismutase).

Zn is also involved in stabilizing the structures of RNA, DNA, and ribosomes, wherein Zn facilitates conformational transformations of DNA (e.g., from beta to the Z forms). Further, a large number of nuclear binding proteins (mostly transcription factors) have Zn-binding domains (so-called Zn-binding fingers) (Harris, 2014).

Because of the wide range of functions, Zn deficiency signs are nonspecific and include periorificial (oral, anal, genital) and acral dermatitis, diarrhea, and behavioral and mental changes. Indices of normal immune function are also depressed. An early effect of severe Zn deficiency in many species is anorexia and cyclic feeding. The cyclical food intake patterns of Zn-deficient animals may represent an adaptation of the animal to the Zn-deficient state. During the periods of low food intake, there is muscle catabolism and measurable release of Zn into the plasma pool.

To reiterate, the most striking effect of an acute or marginal prenatal Zn deficiency is on the ontogeny of the immune system. In mice and rhesus monkeys, marginal prenatal Zn deficiency results in impairment in immunoglobulin M production and a decreased sensitivity to specific mitogens. Of interest are the observations that these immune defects can persist well into adulthood despite the introduction of Zn-replete diets at birth. Immune defects associated with postnatal Zn deficiency include reduced thymic hormone production and activity, impaired lymphocyte, natural

killer cell and neutrophil function, and impaired antibody-dependent cell mediated cytotoxicity. Postulated defects include impaired cell replication, gene expression and cell motility, and alterations in cell surface recognition sites.

Genetic disorders of Zn metabolism are rare. However, at least five genetic errors in Zn metabolism that mimic Zn deficiency have been identified in mammals. They are Adema disease (inherited parakeratosis) of cattle (Yuzbasiyan-Gurkan and Bartlett, 2006), chondrodysplasia, congenital Zn deficiency (lethal acrodermatitis) in bull terriers (McEwan et al., 2000), acrodermatitis enteropathica (AE) in humans (MacDonald, 2000), and lethal milk syndrome in mice (Lee et al., 1992). AE responds dramatically to oral Zn supplementation when it occurs in children. AE is autosomal recessive and results from a mutation of the SLC39A4 gene on chromosome 8 q24.3. SLC39A4 encodes for ZIP4 in the family of Zn transporters (Lichten and Cousins, 2009). Bovine hereditary Zn deficiency, Adema disease, is an autosomal recessive disorder that also results in inadequate amounts of Zn being absorbed from the gastrointestinal tract and leads to a number of clinical abnormalities. The first manifestation is diarrhea, followed by skin lesions, poliosis, and a decreased ability to sustain a suckle reflex. It is similar in many respects to AE in humans. The oral administration of Zn acetate causes a reversal of biochemical abnormalities in affected calves. Adema disease occurs predominately in black pied cattle of Friesian descent. An additional sign of the disease is delayed sexual maturation, which is common in many species that are Zn deprived. Mature dwarfs produce spermatozoa with 45% acrosomal defects compared to 5% in controls. Significantly, this defect in spermatozoa is reportedly reversed by dietary Zn supplementation. Lethal milk syndrome is an autosomal recessive disorder caused by a mutant gene in the C57BL/6J(B6) mouse strain (Lee et al., 1992). Offspring which suckle from affected dams exhibit stunted growth, alopecia, dermatitis, immune incompetence, and rarely survive past weaning.

Zn responsive dermatosis is a well-documented disease in dogs. When congenital, it is an autosomal recessive disorder in bull terriers (MacDonald, 2000; McEwan et al., 2000). The phenotypic expression of lethal acrodermatitis in Bull Terriers is very similar to experimental Zn deficiency in dogs. A similar disorder has also been reported in northern-breed dogs (Alaskan Malamute, Samoyed, and Siberian Husky). Although these dogs are consuming Zn-adequate diets, they frequently require Zn supplementation, either orally or parenterally, in some cases throughout their entire life span. Chondrodysplasia (short-limbed dwarfism) is a sign related to the phenomenon in Alaskan Malamute.

Fortunately, the risk for Zn toxicity and the likelihood of achieving excessive dietary intakes of Zn are both low. Zn has been characterized as a relatively nontoxic element with a wide margin of safety. One notable exception is consumption of zinc-containing foreign bodies, which has been documented in humans as well as a wide variety of wild and companion animals. Everyday items associated with zinc toxicity include batteries, zinc-containing creams, zippers, screws/nuts (usually from pet carriers), and pennies minted in the United States in 1983 and later. Investigating the potential presence of a gastrointestinal metallic foreign object is prudent in any case of unexplained hemolytic anemia. For more chronic intakes, toxicity is usually not diagnosed until Zn intake exceeds about 700 mg or more per kg of diet (O'Dell and Sunde, 1997; Harris, 2014). Gastrointestinal, renal, hepatic, pancreatic, and pulmonary systems are the most consistently and severely involved.

24.6.7 TRACE MINERAL ASSESSMENT

Good analytical methodology is essential to data interpretation regarding trace mineral nutritional or toxicological status. Similar to the accelerator mass spectrometry approaches used to assess vitamin status (see Section 24.4.4), inductively coupled plasma mass spectrometry, and newer methods

employing atomic absorption or chemical X-ray fluorescence analyses allow determinations that extend to femtomole range (Tranter et al., 2000; Taylor, 2001; Todoli and Mermet, 2008). It is no longer tolerable to base judgments using methods that introduced error so that values vary substantially from experiment to experiment. As an example, this was the case for chromium measurements during the first two decades of work that was used to define its putative importance, during which errors of two orders of magnitude were tolerated (Mertz, 1993).

Regarding approaches to assessment, tissue concentrations of given minerals can be measured; however, of the six metals discussed only selenium plasma or serum levels reflect prior dietary history with any reliability (Burk and Hill, 2009). Tissue and cellular compartments may also be used. For given well-defined studies, the levels of metals in leukocyte, lymphocyte, and neutrophil compartments may have value for assessment, although as general biomarkers there is currently inadequate validation (Hambidge, 2003). For example, erythrocyte-membrane zinc has been found to be sensitive to dietary zinc restriction, although there are exceptions that have been reported. Moreover, the use of urine or fecal metal concentrations as a biomarker requires a good understanding of the homeostatic mechanisms related to absorption transport and elimination of the given mineral. In some cases, the activity of a metalloenzyme or serum level of a metalloprotein can be used, but again as markers, they may be only specific in the context of well-defined guidelines. The measurement of ceruloplasmin or lysyl oxidase activities for the assessment of copper is an example. Both proteins bind more copper than is needed for optimal activity (Harris, 2000; Rucker et al., 1998). In certain conditions, such as Wilson's disease in which copper is sequestered in cells, the activity of the enzyme in plasma or serum may be quite variable. Likewise, the insensitivity of plasma zinc to reductions in dietary zinc reflects the capacity of the organism to conserve tissue zinc by reductions in zinc excretion, reductions in the rate of growth, or utilization of zinc from sequestration sites (e.g., bone). Accordingly, metallothionein plasma concentrations have been used to reflect hepatic Zn concentrations analogous to the use of ferritin levels, the degree of transferrin iron saturation, or transferrin receptors levels as indirect measures of iron status. For metallothionein, however, the caveats are that its plasma levels change in response to stress, infection, and other metabolic conditions (Hambidge, 2003). Similarly, lymphocyte metallothionein or changes in metallothionein lymphocyte mRNA levels have been suggested as a marker for zinc status (Hambidge, 2003), however, there are examples wherein lymphocyte metallothionein mRNA concentrations do not reflect the differences in dietary zinc supplementation (Carlson et al., 2007).

24.7 CONCLUDING COMMENTS

As is the case for all substances that are relevant to given biological functions, a limitation or excess of an essential vitamin or mineral can result in specific pathological signs and symptoms. That applies particularly to any given vitamin, dietary growth factor, or mineral when there is a loss due to processing, storage, or as often is the case, the consumption of monotonous or nutritionally limiting diet. Concerning each of the nutrients described in this chapter, it may be inferred that fundamental evolutionary processes have led to a physiological need that for most animals are similar on a metabolic basis. Usually, dietary requirements differ depending on the animal's ability to produce the substance. Indeed, there is usually a good biological question to be asked when an organism deviates markedly from an allometric scale that defines metabolic or physiological need. New analytical tools have increased sensitivity in some cases to the attomole to femtomole range along with the ability to carry out high-throughput assays. There is no doubt that the next decades will allow expansion of our current understanding of vitamin and mineral function, particularly in areas such as epigenetics, cell signaling, nuclear organization and regulation, and species systematics.

25.1 DEFINITION OF “BIOMARKER” AS IT APPLIES TO LABORATORY ANIMAL CLINICAL CHEMISTRY

In 2001, the Biomarkers Definitions Working Group convened by the National Institutes of Health defined a biomarker as “a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention” (Atkinson et al., 2001; see Table 25.1). Although this has become a very popular area of research in recent years, the modern notion of biomarkers essentially evolved from the field of clinical chemistry. Clinical chemistry parameters—biomarkers—that are very familiar to veterinary clinical pathologists and laboratory animal clinicians, such as serum alanine aminotransferase (ALT) activity, urine specific gravity, and plasma glucose, have been utilized for decades to diagnose and prognosticate disease, determine responses to experimental conditions, monitor health status, and define phenotypic characteristics. Clinical chemistry tests are now just one facet of the field of biomarkers that encompasses not only biochemical measurements (e.g., proteins, enzymatic activity, nucleic acids, metabolic products), but also structural (e.g., organ weights), anatomical, (e.g., ventricular wall thickness), physicochemical (e.g., bone densitometry), and functional endpoints (e.g., arterial blood pressure).

Innovation in laboratory technology is, and will continue to be, one of the strongest drivers in biomarker development. In the past half century, clinical chemistry methods have transformed from predominantly manual bench-top chemistry testing to high throughput, fully automated analyses. Technological tools derived from immunology, genomics, protein biochemistry, and metabolomics have significantly contributed to expanding the range of possible measurements. In some cases, these technologies have broadened our understanding of traditional biomarkers. For example, ALT is typically measured in terms of serum activity based on an enzymatic reaction. However, there are now experimental methods for measuring specific ALT isoenzyme proteins, ALT1 and ALT2 in serum by immunoassay and isoenzyme messenger RNA in tissues that are enhancing our understanding of the fundamental biology of this enzyme in animals and humans (Lindblom et al., 2007; Miyazaki et al., 2009; Rajamohan et al., 2006).

In the context of laboratory animal clinical chemistry, biomarkers usually represent endpoints measured in serum, plasma, urine, and other body fluids. Advances in assay and technology miniaturization and in sample collection have broadened the range of biomarker alternatives for laboratory animal species in which body fluids may be limited in volume or accessibility. For example, glucose monitoring has historically required repeated collection of serum by venipuncture, but now can be accomplished by continuous microsampling of interstitial tissue fluid with portable miniature analyzers (Woderer et al., 2007). Availability of assays for glycosylated proteins,

such as hemoglobin A1c and fructosamine, supports that serial blood glucose testing no longer remains the only or necessarily the optimal measure of glucose status depending on species and application.

25.2 GENERAL PRINCIPLES OF AN “OPTIMAL” BIOMARKER

Characterizing an optimal biomarker requires clearly defining its intended purpose and use. For example, of the circulating cardiac biomarkers currently available, troponin I is a highly sensitive and specific marker of acute myocardial cell necrosis in multiple species, but it has more limited value in heart conditions that are not associated with myocardial cell disruption, such as non-ischemic ventricular dysfunction (Nishijima et al., 2005). Conversely, natriuretic peptides, which respond to changes in ventricular stretch, may have less value in assessing cardiac injury that is not accompanied by altered cardiac afterload (Oyama et al., 2007). In some cases, diagnostic utility may be optimized with a panel of biomarkers, a common approach in evaluating derangements of systems such as the hepatobiliary and renal systems. In any case, the more diverse and complex the process being evaluated, the more complicated and time consuming are the validation and qualification efforts required.

To this end, Lee et al. (2006) proposed that rational biomarker development should be “fit for purpose” (Table 25.1). Specifically, assay validation should be tailored to meet the intended purpose of the biomarker with a level of rigor commensurate with the intended use of the results. Thus, the most important step in biomarker evaluation is to clarify the purpose of the proposed data and to understand the impact on subsequent decision-making. This shapes the validation and qualification process and ultimately guides determination of the best candidate. As an example, the study design, test groups and outcome measures needed to evaluate a biomarker intended to diagnose osteoarthritis in an experimental mouse model may differ from those needed to evaluate a marker intended to predict efficacy of a novel osteoarthritis treatment, or of a prognostic biomarker intended to predict the course of injury in this model (Bauer et al., 2006; Soreide, 2009). In addition, an optimal “fit-for-purpose” biomarker must be technically feasible, technically sound, and meet the established biologic criteria appropriate to the use of the biomarker.

There are a number of scientific and practical considerations when determining whether an assay is appropriate for a given disease or toxicity and is technically feasible for a given laboratory (Table 25.2). It is important to understand as much as possible about the biology of the biomarker and the process of the disease or toxicity to be evaluated, although valuable biomarkers (such as kidney injury molecule-1 [KIM-1], renal papillary antigen-1, and even ALT) were identified in the

TABLE 25.1
Definitions

Term	Definition	Reference
Biomarker	A characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention.	Atkinson et al. (2001)
Fit for purpose	Assay validation that is tailored to meet the intended purpose of the biomarker with a level of rigor commensurate with the intended use of the data.	Lee et al. (2006)
Validation	The process of assessing the assays and its measurement performance characteristics, and determining the range of conditions under which the assay will give reproducible and accurate data.	Wagner et al. (2008)
Qualification	The evidentiary process of linking a biomarker with biological processes and clinical end points.	Wagner (2002, 2008)

TABLE 25.2
Factors in Assessing the Technical Feasibility of a Proposed Biomarker for Laboratory Animals**Biological and Species Rationale**

- What is the biological rationale for the biomarker?
- Is the analyte appropriate/measurable in the species of interest?

Assay Availability

- Is an assay available?
- Are reagents and instrumentation available?
- Is the assay validated for the species of interest?
- Is the vendor likely to discontinue the assay?

Technology Availability

- Does it require specialized training?
- Does it require special facilities or capabilities?

Cost Effectiveness

- What is the assay cost?
- How much is the labor cost to perform the analysis?

Sample Collection

- Can it be measured in a body fluid?
 - How much volume is required?
 - How invasive is sample collection?
 - Is it sufficiently stable in the matrix of interest?
-

absence of detailed mechanistic information. In veterinary species, an obvious limitation may be whether the analyte is even measurable in the species of interest. For example, circulating cortisol can be assayed in humans, monkeys, dogs, and other species, but it is not appropriate in rats or mice in which the primary glucocorticoid is corticosterone.

Availability of species-appropriate assays can be challenging for laboratory animal species. Commercial tests are often designed for human samples and may or may not be applicable in veterinary species, and assays developed for one animal species may not be valid in another species. This is especially true for immunoassays in which cross-reactivity of antibody reagents must be demonstrated for the species of interest. A good example of the variability in assay performance that can be observed when analyzing animal specimens with human commercial reagents was provided by Apple et al. (2008) who found considerable differences across multiple cardiac troponin platforms tested with rat, dog, and monkey samples. Because the veterinary market is relatively small, assay availability may be hampered by vendor decisions to alter or discontinue assays, irrespective of veterinary customer needs.

An optimal biomarker assay must meet the resource capabilities of a given laboratory: the assay, reagents, instrumentation, and labor requirements should be affordable. Some methods require special facilities or training, such as those using radioactive materials (e.g., radioimmunoassays) or hazardous substances (e.g., paraoxon reagent for measuring serum paraoxonase-1 activity). Proprietary intellectual property restrictions may also restrict availability of unique assay materials.

Sample requirements must be reasonable and attainable for laboratory animal species. For example, methods requiring serum volumes of 2 mL and greater are not practical in mice, but are reasonable for dogs, pigs, monkeys, and other larger species. Many diagnostic applications in laboratory animals are best suited to minimally invasive procedures. Thus, assays that can be performed with peripheral blood, urine, or saliva are advantageous. It is important to confirm that a new assay is appropriate with the matrix of interest. For example, ethylenediaminetetraacetic acid (EDTA)

plasma may not be suitable for a test developed with heparinized plasma, and a serum assay may not work with urine samples. Species differences may also be present across the same sample type. For instance, unless a species-specific calibrator is used, serum albumin as measured by the bromocresol green method may be inaccurate in the rabbit and other species due to inherent differences in protein binding affinity of this dye (Stokol et al., 2001). Stability of the analyte in the matrix of interest must also be confirmed. For example, some urine analytes require overnight collection at low temperature and/or addition of preservatives. If potential interfering conditions, such as hemolysis and lipemia are likely in the test system, then effects of these preanalytical variables on assay results should also be evaluated (Jacobs et al., 1992).

Once there is sufficient technical support and justification to implement a biomarker assay, it must be shown to be technically sound. The term “biomarker validation” has been used interchangeably with terms such as biomarker development, correlation, and evaluation. However, in its guidance on bioanalytical method validation, the Food and Drug Administration (FDA) (2001) defined validation specifically as the procedures that demonstrate that a particular method used for quantitative measurement of analytes in a biological matrix is reliable and reproducible for the intended use. For drug development applications, Wagner (2008) expanded this slightly by describing validation as the process of assessing the assay and its measurement performance characteristics, and determining the range of conditions under which the assay will provide reproducible and accurate data to meet the individual study objectives (Table 25.1).

The assay performance characteristics most commonly evaluated are listed in Table 25.3 and are further discussed in Chapter 26 and by Lee et al. (2005, 2006). Assay performance characteristics should be tailored to the type of analytical method and endpoints. For example, analytical accuracy and dilutional linearity can be assessed in quantitative assays which have reference standards and continuous numeric units (e.g., serum glucose or plasma fibrinogen), but cannot be evaluated for semiquantitative or qualitative methods that lack reference standards and may be reported in discontinuous (discrete) units (e.g., urine protein as measured by reagent pad). Also, immunoassays are inherently nonlinear and may be less precise when compared with an analytical method, such as liquid chromatography/mass spectrometry (LC/MS), necessitating different approaches to validation and acceptance criteria (Findlay et al., 2000; FDA, 2001).

25.3 PROCESS OF IDENTIFYING POTENTIAL BIOMARKERS

Once the biologic, pathologic, or therapeutic process of interest has been defined and an objective criterion or “gold standard” benchmark has been agreed, there are many avenues for identifying potential clinical chemistry biomarkers. Some analytes like HbA1c have been identified as a result of elucidating specific pathobiological effects of the disease (Bunn et al., 1975). Other biomarkers like lipocalin-2, a general marker of inflammation (Devarajan, 2008; Hoo et al., 2008), have been identified by comparing constituents in biological samples from healthy and diseased individuals using technologies that can generate hundreds and even thousands of possible candidates. Such platforms may employ proteomic (analysis of global protein profiles, i.e., using MS or electrophoretic-based methods), genomic (analysis of gene expression profiles, i.e., using DNA or oligonucleotide microarrays), or metabolomic (analysis of endogenous metabolites, i.e., using LC/MS) methods (Marrer and Dieterle, 2007). Emerging techniques using peptidomics (identifying and quantifying peptide fragments, as opposed to proteins), histomics (raising antibodies against peripheral body fluids of diseased or treated subjects and using them to stain tissues of interest), and epigenetics (reversible, heritable changes in gene regulation which occur without a change in DNA sequence) are also under investigation (Marrer and Dieterle, 2007). With the evolution of these high-throughput technologies, multivariate data sets are becoming more widely available in the public arena, facilitating a growing number of *in silico* avenues for potential biomarker identification based on data mining and biostatistical computations (Klee, 2008).

TABLE 25.3
Performance Characteristics in the Technical Validation of a Biomarker

Performance Characteristic	Definition	Quantitative Method	Semiquantitative or Qualitative Method
Analytical accuracy	The closeness of mean test results to the true amount of the analyte.	√ ^a	–
Precision (within run and between run)	The closeness of individual measures of an analyte when the procedure is applied repeatedly to multiple aliquots of a single homogenous volume of sample.	√	√/–
Analytical sensitivity	The lowest analyte concentration detectable with acceptable precision and accuracy.	√ (LLOQ ^b)	√
Assay specificity	Ability of the assay to unequivocally distinguish the analyte from other substances in the sample.	√	√
Dilutional linearity	Ability to dilute samples originally above upper limit of quantification with acceptable precision and accuracy.	√	–
Working range (linearity)	The range of values over which the analyte is measurable with acceptable levels of precision and accuracy.	√ (LLOQ and ULOQ ^c)	√
Analyte stability	Stability should be assessed for storage time and temperature conditions relevant to intended use. May also need to include freeze–thaw cycles.	√	√
Limit of detection	The minimum concentration that can be distinguished from background.	√	√
Cross-validation (inter-method or inter-laboratory)	Comparison of validation characteristics when two or more methods or two or more labs are used to generate the same endpoint.	√	√
Interference	Characterize negative or positive effects of common interfering substances, such as hemoglobin, lipid, or bilirubin.	√	√

^a √ required.

^b LLOQ, lower limit of quantification: the lowest measurable concentration with acceptable precision and accuracy.

^c ULOQ, upper limit of quantification: the highest measurable concentration with acceptable precision and accuracy.

A common approach with these types of broad-based molecular profiling tools is to generate a reference data set from animals with known positive conditions (i.e., exposed to known toxicants or expressing a well-characterized disease, etc.). The specificity and reproducibility of these results are further refined by comparing these responses to responses from animals with known negative conditions (i.e., healthy animals as well as animals with unrelated conditions) and to responses from an independent set of animals with the condition of interest (a validation set). Subsequently, results from animals with unknown conditions can be queried against the defined pattern or “signature” for that condition. Molecular profiling has been used to identify biomarker candidates especially in the areas of cancer staging, classification, and prognosis and in toxicology and drug development (Bailey and Ulrich 2004; Marrer and Dieterle, 2007).

Although “-omics” methods offer the advantages of speed, high throughput, and generation of large numbers of possible candidates, they require appropriate analytical and statistical

expertise and can be expensive. The reproducibility and generalizability of molecular profiling methods can be hampered by poor study design. Common mistakes include experimental bias, use of validation sets that are too small, and validation sets that lack independence from the training set (Ransohoff, 2004, 2007). Discriminating changes due to factors unrelated to the biologic process of interest, such as interindividual variation (e.g., due to hormonal status), unique experimental factors (e.g., effects of fasting), posttranslational modifications, and artifacts continues to be challenging (Sinhaa et al., 2007). Due to this inherent biological and technical variability, “false positives” are common with these “shotgun” approaches and can complicate efforts to produce scientifically robust markers in a timely and efficient manner (Carr, 2008; Ransohoff, 2007). “False negatives” may occur with assays that lack sufficient dynamic range and fail to identify constituents that are present at very high or very low concentrations. The relevance of changes in a new marker must be fully evaluated in relation to changes in the specified gold standard (i.e., functional endpoint, histomorphologic change, disease condition, etc.), as well as normal biological variability of the marker in the population of interest.

One example of a successful biomarker is KIM-1 (Bonventre, 2008, 2009) (Table 25.4). This renal injury marker, also known as TIM-1 or T-cell immunoglobulin and mucin-containing molecule, was first identified through a polymerase chain reaction technique comparing gene expression in renal tissue from healthy and postschemic rats. This was followed by tissue localization with *in situ* hybridization and immunohistochemistry (Ichimura et al., 1998). The gene encoding this type 1 transmembrane protein was an optimal choice to pursue as a renal injury marker as it is present in very low levels in healthy kidney and is strongly upregulated in proximal tubular epithelial cells after ischemia or toxic injury. In addition, the KIM-1 ectodomain is cleaved and the protein can be detected in urine using immunoassay-based methods (Zhou et al., 2008). Subsequent work has shown that urinary KIM-1 is elevated in rodents and humans with a variety of renal pathologies, but not in healthy individuals nor in individuals with other types of injury (Sabbiseti et al., 2013; Bonventre, 2008; Vaidya et al., 2010).

TABLE 25.4
Example of Progression of Novel Biomarker Development

Step	KIM-1 Example
Define need	Biomarker needed for early diagnosis of acute kidney injury and for monitoring proximal tubular injury
Identify a novel biomarker	A PCR method using representational difference analysis identified highly upregulated renal mRNA for KIM-1 in rats with renal ischemia compared with normal rats
Develop and optimize detection method(s) for technical feasibility and soundness	Gene cloned and antibody generated for detection of KIM-1 protein in tissues by immunohistochemistry and in urine by ELISA. Technical attributes of ELISA assessed as noninvasive application
Define biological attributes in healthy and diseased subjects and in species of interest	Assess tissue, cellular localization by <i>in situ</i> methods Evaluate in human specimens as well as animal
Test against current gold standard, other markers in known positive and negative conditions and perform appropriate statistical testing [e.g., Received Operator Curves (ROC) analysis, likelihood ratios].	Test in animals given well-characterized nephrotoxicants and compare with renal histology, serum urea, and creatinine Test as a diagnostic and prognostic marker in cross-sectional and longitudinal studies in healthy volunteers and in human patients with ischemic and acute kidney injury documented by biopsy. Evaluate as a prognostic marker in patients with renal graft rejection

25.4 BIOLOGICAL QUALIFICATION

After a biomarker assay has been optimized analytically, it must be “qualified” for the purposes intended. In contrast to validation which is the evaluation of assay technical performance, assay qualification is “the evidentiary process linking a biomarker with the intended biological processes or clinical endpoint” (Wagner, 2008) (see Table 25.1). Like validation, assay qualification must be tailored to each biomarker application, but in general requires characterizing attributes of the analyte in healthy animals, in animals with the injury or disease of interest, and in animals with unrelated conditions.

Most clinical chemistry biomarker applications in laboratory animals require an understanding of the range of analyte values within normal, healthy individuals (see Table 25.5). The analyte should be measured in a sufficient number of individuals to provide a working reference interval that can be refined as experience with the marker grows. Reference intervals can be stratified as needed to best represent the population of interest, that is, by gender, strain, age, and so on. It is important to also include characterization of the variability of the analyte within the same individual over time (e.g., over 24 hours, over a week, or over the life span of the animal as needed), as this can be substantial for some constituents (e.g., reproductive and adrenocortical hormones). It may also be important to assess effects of external variables, such as environmental conditions, diet, housing, social influences, sample collection site, and sample handling, depending on the range of intended applications for the biomarker.

To fully understand their specificity, sensitivity, and predictive value, new biomarker assays must be evaluated in animals that have the condition (injury, disease, toxicity, etc.) of interest as well as in animals without the condition. To accomplish this, it is essential to evaluate the biomarker against an agreed objective “gold standard” as stated earlier (e.g., histopathology, a measurable functional change, or a physiological endpoint). To demonstrate that changes in a novel marker correlate with the magnitude of a response (i.e., severity of injury), validation studies should be designed to generate a wide range of responses (i.e., minimal to severe injury). For predictive markers that are expected to demonstrate changes that precede changes in the gold standard, longitudinal studies with serial sampling are required. As an example, Zhou et al. (2008) found very good correlation between the magnitude of increase in urinary KIM-1 levels and renal histopathology severity scores by studying rats exposed to several well-characterized rodent nephrotoxicants administered across multiple doses. To provide evidence that KIM-1 is specific for renal injury, rats were also exposed to a known hepatotoxicant with no renal effects (negative treatment control) and no change in urinary KIM-1 was detected. The reversibility of KIM-1 responses was evaluated in a longitudinal study in rats with adriamycin-induced chronic nephropathy. Renoprotective treatment lowered urine KIM-1 levels which was correlated with improved renal morphologic measures (Kramer et al., 2009). As a

TABLE 25.5

Biological Qualification: Characterization in Healthy Animals

Determine Reference Ranges for Population of Interest

- Assess intra-animal variability
- Assess inter-animal variability

Evaluate potential preanalytic effects of interest

- Gender, age, strain
 - Physiologic effects: stress, handling, diurnal or seasonal variation
 - Dietary effects: fasting, nonfasting
 - Environmental effects: housing, light, social structure, etc.
 - Sampling site: tail vein, cardiac puncture, abdominal vessel, etc.
 - Sample handling: anticoagulant, temperature, preservatives, etc.
 - Anesthesia: isoflurane, ketamine, etc.
-

potential predictive application, urinary KIM-1 has also been demonstrated to independently predict graft loss in a prospective study of renal transplant patients (van Timmeren et al., 2007).

Developing a biomarker for acceptance by the wider scientific or medical community requires a rigorous iterative evidentiary process of testing the biomarker in multiple studies across multiple laboratories. Because this is very time consuming and resource intensive, there is a growing number of collaborative initiatives in laboratory animal and human biomarker development (Wagner, 2008). For instance, KIM-1 is one of several nephrotoxicity markers that have been evaluated by the Nephrotoxicity Working Group of the Predictive Safety Testing Consortium established by the FDA and the Critical Path Institute in collaboration with the pharmaceutical industry (Goodsaid et al., 2008, Mendrick, 2008). Whether accomplished through the focused efforts of a consortium or via an unstructured process of repeated testing in diverse independent laboratories, biological qualification of an assay requires generating sufficient positive and negative data to fully evaluate its diagnostic attributes (Table 25.6). Sensitivity (“positivity in disease”) is the proportion of animals with the condition that have positive results. Specificity (“negativity in health”) is the proportion of animals without the condition that have negative results. Thus, a highly sensitive assay is an ideal “rule-out” test and a highly specific test is an ideal “rule-in” test (Florkowski, 2008). Predictive values can also be calculated, though they vary with the prevalence of the condition in the particular population being studied. Positive predictive value is the proportion of positive results that are true positives, while negative predictive value is the proportion of negative results that are true negatives.

Because this type of assay evaluation requires a dichotomous outcome (the animal does or does not have the condition), a cut-off value must be selected for assays that generate continuous data (as do most clinical chemistry assays). Sensitivity and specificity will necessarily vary with the specific threshold chosen. For example, when a 1350 fmol/mL cut-off value for a proANP ELISA is used to screen dogs for the presence of congestive heart failure (in which the theoretical prevalence is 10%), only 38% of positive results represent true cases, though 99% of negative results are correct. Raising the cut-off value to 1750 fmol/mL results in 79% correct positive results and 98% correct negative results (Boswood et al., 2003).

Receiver operator curves (ROCs) are an accepted method for describing and comparing the accuracy of diagnostic assays for each possible cut-off value (Metz, 1978; Zou et al., 2007; Soreide, 2009). Their use in veterinary clinical pathology is growing (Gardner and Greiner, 2006). A ROC curve is a graphical display of the sensitivity (true positive rate) of a diagnostic test over all possible false-positive rates (1 – specificity; false detection of the condition) (see hypothetical ROC curve in Zou et al., 2007). The area under the curve (AUC) is a summary statistic of test accuracy also known as the c-statistic or c-index wherein an AUC of 0.50 indicates that the test has no ability to discriminate animals with the condition from those without the condition, while an AUC of 1.00

TABLE 25.6
Diagnostic Test Attributes Table

	Gold Standard		Total	
	Condition Present	Condition Absent		
Assay Result Positive	True Positive (TP)	False Positive (FP)	TP + FP	Positive Predictive Value = TP / (TP + FP)
Assay Result Negative	False Negative (FN)	True Negative (TN)	TN + FN	Negative Predictive Value = TN / (TN + FN)
Total	TP + FN	TN + FP	–	–
–	Sensitivity = TP / (TP + FN)	Specificity = TN / (TN + FP)	–	Prevalence = TP + FN / TP + FP + TN + FN

Source: Modified from Florkowski, C.M., *Clin Biochem Rev*, 29, S83–S87, 2008.

perfectly discriminates. Tests considered to have moderate to high discrimination have an AUC in the range of 0.80–0.90 (Gardner and Greiner, 2006).

The ROC curve and the measures of accuracy derived from it have several advantages over other measures of diagnostic performance: (1) they are independent of the prevalence of the condition; (2) both components of accuracy, that is, sensitivity and specificity, are incorporated into an AUC as a single measure of accuracy, and (3) two or more diagnostic assays can be compared (Obuchowski et al., 2004). Results from ROC analysis that are typically reported in addition to the AUC include confidence intervals (CIs) for the AUC, and the sensitivity and specificity at selected cut-off points.

Study design that minimizes bias and ensures proper patient selection and classification is essential for optimal ROC analysis (Gardner and Greiner, 2006; Zweig and Campbell 1993). Sample size is a key factor affecting the precision of estimation of AUC for a single assay and the ability to identify differences between AUCs for multiple tests (Gardner and Greiner, 2006). For example, at least 33 control animals and 33 animals with the condition of interest are needed if a given diagnostic test is expected to have fair accuracy (e.g., AUC = 0.70) (Obuchowski 2004). Sample sizes that are too small may result in overly optimistic measures of accuracy (Leefflang et al., 2008). Specific recommendations for sample size calculation for ROC analysis have been published (Obuchowski and McClish, 1997; Obuchowski et al., 2004).

For clinical biomarkers that are specifically intended to be used to diagnose a condition in an individual animal, defining a likelihood ratio (LR) may be helpful (Gardner and Greiner, 2006; Kim and Pak, 2008). This ratio is an index of diagnostic utility that incorporates sensitivity and specificity and provides the diagnostician an estimate of how much a test result will change the odds that the individual has the condition. LRs can be calculated for a positive (LR+) and for a negative (LR–) test result. LR+ is sensitivity/(1 – specificity) and ranges from 1 to infinity. It conveys how much the odds of having the condition increase when the test is positive. LR– is (1 – sensitivity)/specificity and ranges from 0 to 1. It conveys how much the odds of having the condition decrease when a test is negative. The LR can then be used to inform clinical decision-making by providing an estimate of the “posttest” odds that the individual animal has the condition by multiplying the LR by the “pretest” odds. Pretest odds have some level of uncertainty, but can be estimated based on the prevalence of the condition, patient risk factors, and the clinician’s assessment of that individual patient’s status. Examples of applications of likelihood ratios can be found in Gardner and Greiner (2006), Glas et al. (2003), and Parikh et al. (2009).

When multiple biomarkers are compared or a novel biomarker is developed to address limitations of a traditional marker, verifying improved accuracy, sensitivity, and specificity is a key, but not the only consideration in qualification. Additional advantages of a potentially superior candidate might include a greater dynamic range of response, improved correlation with the course injury (e.g., more closely follows changes from baseline, peak, and recovery of the condition of interest), exhibits more consistent premonitory changes prior to manifestation of the condition of interest (e.g., for a predictive biomarker), improved correlation between the magnitude of change in the analyte and the severity of injury, and/or a distinct dose relationship (e.g., for pharmaceutical studies). When urinary KIM-1 was compared to serum urea nitrogen and creatinine in rats with renal toxicity, the traditional markers were less sensitive, exhibited smaller dynamic ranges, and demonstrated less consistent correlation with the course of injury providing support for the practical utility and biological superiority of the new marker (Zhou et al., 2008).

25.5 SUMMARY

Biomarker research is a dynamic interdisciplinary field driven by novel technologies and by advances in basic biological science and comparative medicine. Development of a successful biomarker in laboratory animals can lead to applications in humans and vice versa. Such “bridging” biomarkers must undergo rigorous technical validation and qualification efforts tailored

to the intended use in the species of interest. Markers that progress from research to clinical settings are often described as translational markers. Examples of these types of biomarkers in recent years include KIM-1, troponin I, and natriuretic peptides. Whatever the specific application may be, the key attributes of an optimal biomarker assay are that it is fit for purpose, e.g., technically feasible, technically sound, and meet the established biologic criteria appropriate to the use of the assay.

Clinical chemistry assays produce either quantitative or qualitative results. Because most statistical issues involve quantitative results, this chapter primarily focuses on quantitative assays; however, where applicable, statistical treatment of qualitative assays will also be described.

26.1 STATISTICS FOR EVALUATION OF ANALYTICAL METHODS

26.1.1 QUANTITATIVE ASSAYS

To best understand quantitative assay results, it is helpful to review the numerical development of the assay. Typically, a range of known quantities of the analyte is processed and the assay instrumentation produces numeric results (analytic values or analytic signals). A plot of the analytic values versus the known quantities of the analyte is the calibration or standard curve (Figure 26.1a). While some standard curves are based on as few as six distinct known concentrations, more are recommended, especially if the standard curve departs from linearity (FDA, 2001). In addition to known concentrations, samples lacking the analyte, or blanks, are also included to determine the lower limit of detection (LOD). Once the standard curve is established, unknown concentrations can be determined from analytic values as shown in Figure 26.1b. Standard curves are highly dependent on the assay methodology and laboratory, so each laboratory develops its own standard curve for each assay.

The accuracy of an assay refers to its ability to produce correct values, while the precision refers to its ability to produce consistent, reproducible values. A good assay is both accurate and precise. While it may be reassuring to get similar numbers from different runs on the same sample, these numbers are not useful if they are incorrect. Likewise, if an assay produces correct results, on average, but any given measurement greatly varies around the average, the assay results are also not useful. The precision of an assay is commonly expressed as a coefficient of variation, CV, which is the standard deviation (SD) divided by the mean (\bar{x}), expressed as a percentage.

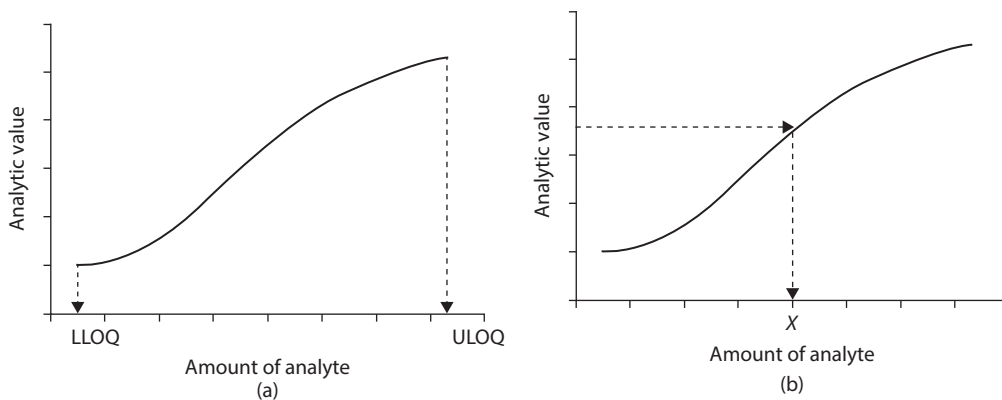

FIGURE 26.1 Standard curve or calibration curve. (a) Using a range of known concentrations of the analyte, the standard curve is a plot of the instrumentation's analytic value versus the amount of the analyte. The standard curve is valid for analyte amounts between the lower limit of quantitation (LLOQ) and the upper limit of quantitation (ULOQ). (b) Once the standard curve is generated, the amount of analyte in a new sample, X , can be determined from the analytic value by following the analytic value horizontally to the curve, then reading down to the analyte axis.

$$CV = \frac{SD}{\bar{x}} \times 100\%$$

Coefficients of variation for quantitative assays should be small, ideally, less than 10%–15%. CVs are useful for quantifying both intra- and interassay variability. Intra-assay variability is assessed from technical replicates (e.g., aliquots from the same sample) that are run simultaneously; interassay variability is assessed from technical replicates that are run sequentially over time. For establishing both intra- and interassay variability, the technical replicates are drawn from samples having known concentrations that span the range of the assay, and runs are repeated several times.

Over time, analytic values may drift due to instrumentation idiosyncrasies and/or local environmental conditions. Therefore, laboratories routinely include calibration runs periodically to check for drift. In these runs, known concentrations of the analyte are processed to verify that they still fall along the standard curve. If the readings are found to be out of calibration, adjustments are made either to the assay or to the standard curve. To minimize potential drift, it is common during assay development to identify factors that affect the readings so that these can be controlled to the extent possible (e.g., temperature, humidity, etc.).

The standard curve is monotonic increasing (or decreasing) for which a one-to-one correspondence exists between analytic values and analyte concentrations. A linear standard curve indicates that analyte concentrations are proportional to the assay's measured values; this contributes to greater assay accuracy. Furthermore, linear standard curves may be converted to formulas that are less prone to error than concentrations read from a plot. Because of the quantitation advantages of linear standard curves, authoritative guidelines describe methods of assuring linearity (EMEA, 1995; FDA, 1998).

All quantitative assays have a specific range within which they provide analytic values. The limits of this range are laboratory-specific and will be determined during the development of the standard curve. In most assays, a blank (absence of the analyte) will still produce a measurement, and if blanks are run repeatedly, these measurements will exhibit variability (e.g., standard deviation of blanks, SD_{blanks}) around a mean (\bar{x}_{blanks}). The LOD is defined as the smallest concentration of the analyte that will produce measurements that are statistically significantly higher than the blank and it is determined from the distribution of blanks measurements. The LOD is calculated as t SDs above the mean of the blanks.

$$\text{LOD} = \bar{x}_{\text{blanks}} + t \times \text{SD}_{\text{blanks}}$$

There are various recommendations about how to determine t . Some authors recommend selecting t from the Student's t -distribution at the 0.01 level of significance, while others set t to a specific number such as 6 or 8 (e.g., see discussions in ACS, 1980; Long and Winefordner, 1983). The lower limit of quantitation (LLOQ) is the lowest concentration that can be reliably measured, while the upper limit of quantitation (ULOQ) is the highest concentration that can be reliably measured. These limits of quantitation are determined during the development of the standard curve and may be laboratory dependent. The interval between the LLOQ and the ULOQ is the dynamic range of the assay.

In research studies, analyte concentrations that are determined to be below the LLOQ or LOD or above the ULOQ present a challenge because numeric values are not immediately available for calculations. These measurements should not be discarded; they indicate that the amount of analyte is very low or very high even if it cannot be reliably quantified. For concentrations below the LLOQ, a usual practice is to substitute LLOQ/2 or LLOQ/ $\sqrt{2}$ (EPA, 2000; Croghan and Egeghy, 2003; Clayton et al., 2003). Substitution is reasonable as long as not more than 10%–15% of the values are below LLOQ. If more than 15% are below the LLOQ, substitution will artificially reduce the variability of the sample, and other methods should be considered. An alternative to substitution is to use likelihood methods, such as profile likelihood estimation. These methods are also applicable when measurements exceed the ULOQ. Likelihood methods rely on specifying the shape of the distribution of measurements (such as log-normal) and using the observed values along with the numbers of values below the LLOQ and above the ULOQ to estimate the mean and standard deviation of the group (Helsel, 1990; EPA, 2000; Koo et al., 2002).

During the development and distribution of a new assay, a round-robin test is often conducted for which a common set of samples are sent to several laboratories to determine the extent to which measurements agree across different laboratories (Youden, 1963). These tests may require that the same assay is used at each laboratory, or they may allow each laboratory to select the assay to use. In either case, the goal is to determine the validity and reproducibility of determining analyte concentrations in a variety of settings.

26.1.2 QUALITATIVE ASSAYS

Qualitative assays, such as dipstick assays, usually indicate the presence or absence of an analyte. For these assays, sensitivity and specificity are of primary importance. Sensitivity of the assay is the proportion of tests that are positive when the analyte is present; specificity is the proportion of tests that are negative when the analyte is absent. An informative assay should be both sensitive and specific. Three additional measures of qualitative assay performance are positive predictive value, negative predictive value, and accuracy. The positive predictive value is the proportion of positive tests that correctly determined that the analyte is present; the negative predictive value is the proportion of negative tests that correctly determined that the analyte is absent. The accuracy is the proportion of all tests that correctly determined that the analyte is present or absent. These measures are summarized in Table 26.1.

26.2 ESTABLISHMENT OF REFERENCE VALUES

A clinician or researcher who obtains an assay value on an animal will usually want to interpret that value in the context of what is typical. There are several ways to determine this. Many diagnostic laboratories maintain reference values (or reference ranges) of “normal” or “control” animals. Research facilities may establish historical control databases in which data from control animals are recorded. These values are species-, sex-, and strain-specific, and they may also depend on a

TABLE 26.1
Sensitivity, Specificity, Positive Predictive Value, Negative Predictive Value, and Accuracy of Qualitative Assays Having Binary Outcomes

Assay Result	In Reality		Total
	Analyte Is Present	Analyte Is Absent	
Positive	n_{p+}	n_{A+}	n_+
Negative	n_{p-}	n_{A-}	n_-
Total	n_p	n_A	n

n_{p+} is the number of samples for which the analyte is present and the assay is positive.

n_{A+} is the number of samples for which the analyte is absent and the assay is positive.

n_{p-} is the number of samples for which the analyte is present and the assay is negative.

n_{A-} is the number of samples for which the analyte is absent and the assay is negative.

n_p is the number of samples for which the analyte is present; it is also called the number of “true positives.”

n_A is the number of samples for which the analyte is absent; it is also called the number of “true negatives.”

n_+ is the number of samples for which the assay is positive.

n_- is the number of samples for which the assay is negative.

n is the number of samples assayed.

Sensitivity = n_{p+}/n_p .

Specificity = n_{A-}/n_A .

Positive Predictive Value (PPV) = n_{p+}/n_+ .

Negative Predictive Value (NPV) = n_{A-}/n_- .

Accuracy = $(n_{p+} + n_{A-})/n$.

multitude of factors including age, diet, route of exposure, housing arrangements, animal husbandry practices, season, and year. Therefore, these factors, and any other potential influences, should be examined and accounted for when compiling reference ranges.

In the past, the range of typical values has been referred to as “normal values” or the “normal range”; this terminology may be somewhat confusing in that it seems to imply that these are ranges for healthy individuals, or possibly that they follow the statistical normal distribution (e.g., see Sunderman, 1975 and its references). A better term is “reference values” or “reference range.” The reference values are obtained from a well-defined set of individuals (the reference sample) in terms of age, sex, species/strain, condition of health, and so on. Furthermore, these values may be specific to a particular laboratory and the analytical instrumentation that they use. Reference ranges should be periodically verified with new data and updated to adjust for unanticipated drift.

The reference range spans the middle 95% of values obtained from the reference sample; this is sometimes referred to as a “tolerance interval” (Wald and Wolfowitz, 1946; Proschan, 1953). Determination of the endpoints of the reference range depends on the shape of the distribution of measurements in the reference sample. Many biological measurements have a normal or Gaussian distribution. Normal distributions are characterized by their mean, μ , and standard deviation, σ , and by their bell-curve shape (see Figure 26.2a). When $\mu = 0$ and $\sigma = 1$, the distribution is known as the standard normal distribution. The normal distribution has been well studied and its properties are also useful in parametric statistical testing, as described later in this chapter. A useful property of the family of normal distributions is that approximately 68% of the distribution lies within one standard deviation of the mean; approximately 95% lies within two standard deviations of the mean; and over 99% lies within three standard deviations of the mean. Thus, if reference sample measurements are normally distributed, as in Figure 26.2a, the upper and lower reference values are 1.96 (or 2) standard deviations above and below the mean

$$\bar{x} \pm 1.96 \times SD$$

This will encompass the middle 95% of values. One should keep in mind that 5% of the reference sample values will be outside of this range.

More typically for clinical chemistry, measurements from the reference sample are not normally distributed, so other methods for determining the reference range must be considered. Often, analyte concentrations are skewed to the right (skewed upward) and the logarithm of the concentrations are normally distributed. In this case, the concentrations are log-normally distributed (Figure 26.2b). Reference values of the log-transformed distribution (i.e., a normal distribution) can be found as described above, then antilog transformed to return to the original unit of measure. If the reference sample values do not reasonably fit a normal or log-normal distribution, the 2.5th and 97.5th percentiles can still be determined, provided that the sample is large enough (Figure 26.2c).

The number of individuals needed to establish the reference range will depend on the nature of the distribution of values. Reed et al. (1971) suggested that data from 120 individuals is usually adequate for establishing reference values. If the values are strongly skewed, however, 120 will not be sufficient to precisely capture the extreme percentiles (Reed et al., 1971; Miller et al., 1984).

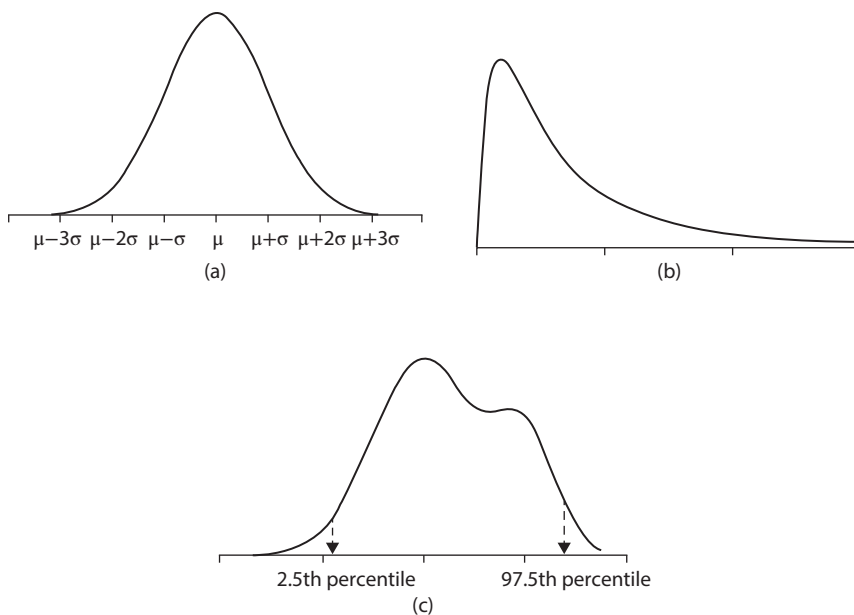

FIGURE 26.2 Examples of analyte distributions. (a) The normal distribution is symmetric and unimodal. It is centered around the mean, μ , and variability is described by the standard deviation, σ . Approximately 68% of the distribution is within 1σ of the mean; 95% is within 2σ of the mean; and over 99% is within 3σ of the mean. (b) The log-normal distribution is skewed to the right. It is a common distribution for clinical chemistry endpoints. (c) This non-normal distribution has two modes, which may suggest that two populations are present. The 95% tolerance interval extends from the 2.5th to the 97.5th percentile.

26.3 METHODS FOR EVALUATING STUDY DATA

Research studies on laboratory animals often involve clinical chemistry endpoints. The statistical methods selected for evaluation of study data will depend on a number of factors including the study design, the hypotheses, the data type (quantitative or qualitative), the sample size, and the shape of the distribution of values. For this discussion, the term, sample, refers to the collection of values obtained from an assay, rather than the biological material that is assayed.

26.3.1 DESCRIPTIVE STATISTICS

The initial step in any statistical analysis is to summarize the data. Three characteristics of the data are of primary interest: central or typical value, variability relative to the center, and shape of the distribution of values. The most appropriate methods for summarizing center and variability depend on the shape of the distribution, so that will be the first topic.

26.3.1.1 Shape of the Distribution

Graphical statistical tools are useful for characterizing the shape of the distribution of an endpoint. These tools include histograms, bar charts, and boxplots. Boxplots convey several important features of a distribution. The box indicates the range of the middle 50% of the values, with endpoints ranging from the 25th to the 75th percentiles (Figure 26.3). The magnitude of this middle 50% is the interquartile range (IQR) and is sometimes used as a measure of variability. Within the box, the median is indicated by a horizontal line. The mean is indicated with a special symbol, usually a plus sign (+). The upper and lower fences are, respectively, 1.5 IQRs above and below the box. A line above the box (also known as a whisker) extends to the value closest to, and less than, the upper fence or to the maximum, whichever is reached first; the line below the box extends to the value closest to, and greater than the lower fence, or to the minimum, whichever is reached first. Any values beyond the whiskers are indicated by individual special symbols, such as asterisks or circles, and may be considered unusual values. The shape of the distribution can be discerned from boxplots by examining the symmetry of the box around the median and mean, as well as the symmetry of the whiskers around the box.

The symmetry (or lack thereof) of a distribution of values has implications for what statistical methods will be appropriate for analyzing such data. A symmetric distribution is one for which the left half is a mirror image of the right half; the normal distribution is an example of a symmetric distribution (Figure 26.2a). A skewed distribution is one for which values in one half extend farther along the scale than in the other half; right or upward skewness indicates that the right-hand tail of the distribution extends farther than the left, whereas left or downward skewness indicates that the left-hand tail of the distribution extends farther than the right (Figure 26.2b). Right-skewed distributions, and in particular, log-normal distributions, are common for clinical chemistry endpoints.

Another important feature of a distribution is the number of modes that are present. The mode, or most commonly occurring set of values, can be identified from a histogram. Unimodal distributions, such as the normal and log-normal distributions, have one mode. Bimodal distributions have two modes and may reflect a mixture of two populations; multimodal distributions also may reflect

FIGURE 26.3 Example of a boxplot. Boxplots are useful graphical tools for illustrating several characteristics of a distribution. The box extends from the 25th to the 75th percentiles, capturing the middle 50% of the data; the length of the box is the interquartile range (IQR). The median and mean are indicated by a horizontal line and a plus sign (+), respectively. Whiskers extend from the box to indicate the range of values within 1.5 IQRs. Values beyond 1.5 IQRs of the box are indicated by special symbols, such as a dot, and may be considered outliers.

a mixture of populations. Samples having bimodal or multimodal distributions may be difficult to interpret in experimental investigations without intensive statistical treatment.

As previously mentioned, the normal distribution is commonly observed in biological systems. It is a unimodal, symmetric distribution that has sometimes been characterized as a bell curve. Because many parametric statistical methods rely on properties of the normal distribution, statistical researchers have developed a number of formal tests for normality. These include the chi-square goodness-of-fit test (Cochran, 1952), Kolmogorov–Smirnov test (Massey, 1951), Lilliefors test (Lilliefors, 1967), Shapiro–Wilk test (Shapiro and Wilk, 1965), among others. In addition, graphical methods such as Q–Q plots are helpful in establishing normality (Samuels and Witmer, 2002). In these plots, the sample percentiles are plotted against theoretical percentiles that would result if the data were normally distributed. If the points fall on or near a straight line at a 45° angle, the data are considered normally distributed.

Another concern about the distribution of an endpoint is the presence of outliers. There are a number of methods for detecting outliers (e.g., see Barnett and Lewis, 1994). As described above for boxplots, values that are more than 1.5 IQRs beyond the 25th and 75th percentiles are unusual and may be considered possible outliers. Formal statistical outlier tests are based on distances between the potential outlier and the rest of the data. For example, if the maximum is suspected to be an outlier, Dixon’s Q test is based on the ratio of the gap between the highest and next highest values and the range.

$$\frac{\text{Maximum} - \text{Next Highest Value}}{\text{Maximum} - \text{Minimum}}$$

If this difference exceeds tabled values, the maximum is declared an outlier (Dean and Dixon, 1951; Dixon, 1953). Other outlier tests are based on properties of the normal distribution, such as Grubbs’ test (Grubbs, 1969). If the maximum is the suspected outlier, the quantity

$$\frac{\text{Maximum} - \bar{x}}{s}$$

is calculated and compared to tabled critical values (Grubbs, 1969). If the minimum is the suspected outlier, it replaces the maximum in the above formula.

When an outlier is found, it is natural to consider whether to retain the value for further statistical analyses. Generally, an outlier should be removed only if there is evidence that it is a result of an error in the execution of the study. These errors may include instrumentation problems, record-keeping errors, insufficient sampling, implausible values, and serious deviations from protocol. Outliers that are likely due to biological variation may be informative to the study and should not be discarded.

26.3.1.2 Measures of the Center

For notational ease, suppose that there are n values, labeled x_1, x_2, \dots, x_n . When the distribution of values is symmetric and unimodal, the mean (or arithmetic average) is the preferred measure of the center of the data:

$$\bar{x} = \frac{\sum_{i=1}^n x_i}{n}$$

If, however, the distribution is skewed to the right (left), the mean will be unduly influenced by the higher (lower) values and will not be a good representative of the center. In this case, the median is preferred. The median is the value for which half of the measurements are higher and half are lower. This middle value is said to be a “resistant” measure of center because it is not influenced

by outliers or skewness. For bimodal and multimodal distributions, the mode(s) will be the most appropriate measure of center.

The geometric mean is used for data that have a log-normal distribution. By definition, the geometric mean is the n th root of the product of the values, and it is easily calculated as the exponential of the mean of the log-transformed values:

$$x_{\text{geo}} = \sqrt[n]{\prod_{i=1}^n x_i}$$

$$= \exp\left(\frac{\sum_{i=1}^n \log_e(x_i)}{n}\right)$$

26.3.1.3 Measures of Variability

Measures of variability are generally paired with a measure of center. The standard deviation and standard error of the mean are typically associated with the mean, while the range and IQR are associated with the median. The modal percentage, or percentage of the sample belonging to the modal set, describes the variability associated with the mode(s).

The standard deviation (SD) describes an average deviation of individual values around the mean:

$$SD = \sqrt{\frac{\sum_{i=1}^n (x_i - \bar{x})^2}{n - 1}}$$

The denominator, $n - 1$, is referred to as the degrees of freedom or *df*. As previously described, normally distributed endpoints have very predictable properties; in that ~68% of the values will be between $\bar{x} - SD$ and $\bar{x} + SD$; ~95% will be between $\bar{x} - 2 \times SD$ and $\bar{x} + 2 \times SD$; and nearly all of the distribution will be between $\bar{x} - 3 \times SD$ and $\bar{x} + 3 \times SD$. Endpoints that are not normally distributed do not follow this 68%–95%–99% rule.

The standard error of the mean (SEM or SE) originates from the properties of the mean, \bar{x} . Hypothetically, if one were to repeat an experiment infinitely many times and calculate the mean each time, the set of means would vary around a true mean. The standard deviation of these infinitely many means is the standard error of the mean. Thus, the SEM quantifies the variation in the sample mean that we would expect to see if we were to repeat the experiment many times. For normally distributed endpoints

$$SEM = \frac{SD}{\sqrt{n}}$$

Whether to use the SD or the SEM in a given situation will depend on the purpose of the numerical summary. If the purpose is to describe how individuals vary, the SD should be selected. For example, for normally distributed endpoints, the SD is used to derive reference values used to interpret individual measurements. On the other hand, if a goal of the study is to describe the mean of a group and how it might differ from other groups, the SEM should be selected.

For log-normally distributed endpoints, use of the SEM is not entirely straightforward. The SEM of the log-transformed data can be calculated using the formula above, but taking the antilog to return to the original unit of measure will give a value that has no context with the log-normal distribution. Instead, calculations using the SEM of the log-transformed data, such as confidence interval construction described below, should be carried out before the result is antilog transformed (Bland and Altman, 1996).

Statistical calculations should always use the original, unrounded data to avoid round-off errors. The final result, however, should be rounded off to reflect the accuracy of the measurements. There is no standard rule for how much to round off. However, some considerations in deciding how much to round off include the precision of the measurements and the sample size.

26.4 CONFIDENCE INTERVALS

Confidence intervals are a useful inferential tool to describe a likely range within which a parameter is likely to belong. The idea behind confidence intervals is very similar to that of the SEM. If an experiment were to be repeated infinitely many times, and a parameter (e.g., mean, area under the curve, proportion) is estimated each time, the parameter estimates would vary and their distribution could be determined. In reality, the experiment is conducted only once and the parameter is estimated only once. By statistical theory, we can predict the distribution of values and construct a confidence interval that will have a prescribed probability of capturing the true parameter value. Generally, this probability is high, such as 95% or 99%. For example, the mean of n normally distributed values has a 95% confidence interval of the form

$$\bar{x} \pm t_{n-1} \times \text{SEM}$$

where t_{n-1} is a critical value from the student's t -distribution having $n-1$ df and probability 0.025 to the right. While this confidence interval is symmetric around \bar{x} , confidence intervals, such as those for the standard deviation or for the geometric mean, may be asymmetric. To construct a 95% confidence interval for the geometric mean, we first construct a confidence interval for the log-transformed mean, using the same critical t_{n-1} value as before. For notational ease, let $z_i = \log_e(x_i)$:

$$\bar{z} \pm t_{n-1} \sqrt{\frac{\sum_{i=1}^n (z_i - \bar{z})^2}{n-1}}$$

Labeling the lower limit of this interval as z_L and the upper limit as z_U , the 95% confidence interval for the geometric mean will be

$$(\exp(z_L), \exp(z_U))$$

Confidence intervals can also be useful for qualitative endpoints, such as for the proportion showing a positive response. Within a homogeneous group, statistical theory predicts that the number of positive responders has a binomial distribution, so the formula for the 95% confidence interval reflects this underlying distribution.

$$\hat{p} \pm z \times \sqrt{\frac{\hat{p}(1-\hat{p})}{n}}$$

Here, \hat{p} is the proportion of responders in the sample, n is the total number of individuals in the sample, and z is a critical value from the standard normal distribution having probability 0.025 to the right. For 95% confidence, $z = 1.96$. The square-root quantity is the standard error of the proportion.

26.5 HYPOTHESIS TESTING

Many excellent introductory statistics texts describe hypothesis testing (Sokal and Rohlf, 1995; Moore and McCabe, 2002; Samuels and Witmer, 2002), so only a brief summary is given here. In

statistical hypothesis testing, two hypotheses (statements) are under consideration: the null hypothesis, H_0 , and the alternative hypothesis, H_1 . H_0 states that there is no difference or no effect, while H_1 is usually the research hypothesis and states that there is a difference or effect and may even specify the nature of the difference (e.g., an increase). It is always the null hypothesis that is tested, in the spirit of assuming no effect unless there is adequate evidence to the contrary. The test statistic is a number calculated from the data, assuming that H_0 is true. In most situations, the distribution of this test statistic when H_0 is true is known, so that the probability of the observed value or a value more extreme when H_0 is true (i.e., the p -value) can be easily found. If the p -value is large, it indicates that the observed test statistic value or something more extreme was likely when H_0 is true; thus, the data are consistent with H_0 , and H_0 is accepted. On the other hand, if the p -value is small, the observed test statistic value or something more extreme is unlikely when H_0 is true, the data are not very consistent with H_0 and, therefore, H_0 is rejected in favor of H_1 .

The level of significance of the test, α , serves as the cutpoint between “small” and “large,” and is usually set at 0.05, or sometimes, 0.01. Researchers should keep in mind, however, that this choice is arbitrary, especially when p only slightly exceeds α . In some instances, the researcher is fairly certain of being able to predict the direction of the effect. Thus, H_1 is directional, in the sense that it specifies an increase (or a decrease). When this is the case, the p -value should be one-sided in the direction that the test statistic would go in the event of an increase (decrease). Directional alternatives should be used with care, however, because if an increase is expected, but the data showed a dramatic decrease, a one-sided p -value (in the “wrong” direction) would lead to acceptance of the null hypothesis of no difference. If the researcher is not fairly certain of the direction of the outcome, a two-sided p -value should be used.

The statistical decision to accept or reject H_0 is based on probabilities of making the correct decision. In reality, the truth of H_0 is never completely known. If H_0 is rejected, there is still the possibility that H_0 is actually true. Rejection of a true H_0 is a Type I error or a false positive. On the other hand, if H_0 is accepted, it is possible that H_0 is actually false. Acceptance of a false H_0 is a Type II error or a false negative. Using statistical theory, it is possible to quantify the probabilities of Type I and Type II errors, and by careful study design, minimize them. As shown in Table 26.2, the probability of a Type I error is the significance level of the test, α , and is usually set by the researcher to be a small number such as 0.05 or 0.01. When H_0 is actually false, the probability of making a Type II error is β and the probability of making a correct decision to reject H_0 is the power of the test, $1 - \beta$.

TABLE 26.2
Hypothesis Testing Outcomes

Statistical Decision	In Reality:	
	H_0 Is True	H_0 Is False
Accept H_0	Correct decision	Type II error False negative, β
Reject H_0	Type I error False positive, α	Correct decision Power = $1 - \beta$

Note: The null hypothesis, H_0 , may be true or it may be false. The statistical decision based on evidence from an experiment will be to Accept H_0 or to Reject H_0 . While the truth of H_0 is not known with certainty, the probability of making an incorrect decision can be controlled to a low level. The significance level of the test, α , is the probability of rejecting H_0 when it is actually true, i.e., the probability of a false positive result. β is the probability of accepting H_0 when it is actually false, i.e., the probability of a false negative result. The power of the test is $1 - \beta$, the probability of correctly rejecting H_0 when it is false; the power is usually controlled by the sample size and study design, and should be high.

The goal of a good experimental design is to maintain both the Type I and Type II probabilities low, in other words, to maintain the probabilities of a false positive and of a false negative low. When the probability of a false negative is low, the power is high. Holding everything else constant, the Type I and Type II error probabilities are inversely related; that is, if α is decreased, β will increase and if β is decreased, α will increase. Because of interrelationships among α , β , σ (the variability of the endpoint), n (the sample size), and D (the difference to be detected), however, there are several approaches to reduce β and thus increase power, while keeping α small. The exact interrelationship will depend on the experimental design and the statistical test to be used, but generally, the power will increase with increasing n and with decreasing variation in the endpoint. Therefore, strategies to reduce false positives and increase statistical power will include having a relatively large sample size and removing as much extraneous variability from each endpoint as possible. Furthermore, the size of the effect to be detected, D , should be an amount that is biologically meaningful. With a sufficiently large sample size, it is possible to declare that even small differences are statistically significant. However, if these small differences are not biologically meaningful, time and resources will have been wasted in conducting such a large study. On the other hand, if the sample size is too small, it is possible to observe a meaningful biological effect that does not reach statistical significance. Again, time and resources will have been wasted in conducting an underpowered study. Therefore, when designing an experiment, it is critical to investigate the statistical power and required sample sizes, as well as control extraneous sources of variability so that effects of biological significance will also be statistically significant.

26.5.1 QUANTITATIVE ENDPOINTS

The statistical test applied to data in any given situation will depend on the experimental design, the hypotheses, and the distribution of the endpoint. Suppose that administration of Compound X to an animal is suspected to change the mean level of analyte A. A study might be designed in which animals are randomly assigned to either receive Compound X or to receive a placebo/control (Figure 26.4a). If A is normally distributed, a two-sample t -test is the test of choice. Alternatively, suppose that the design calls for A to be measured on all animals, then Compound X is administered to all animals, then A is measured again on all animals (Figure 26.4b). In this design, the pretreatment and posttreatment measurements on each animal are statistically treated as a pair, and a paired t -test is the preferred test. More complicated designs, such as a cross-over design, would require more complicated statistical tests.

If A is not normally distributed, either the data may be transformed or a nonparametric method may be used. Mathematical transformations, such as taking the logarithm (natural or common) of each value, may result in a distribution that is approximately normal so that parametric tests, such as t -tests, can be applied. Log-transformations reduce upward skewness and pull high outliers closer to the center of the data. The log-transformation not only tends to improve normality of an endpoint, but it may also equalize variances across groups. The Box–Cox family of power transformations may be useful as they estimate the most effective transformation directly from the data (Box and Cox, 1964). However, there are certainly cases in which even the best transformation does not sufficiently improve normality and other approaches must be considered.

Nonparametric statistical methods, sometimes known as distribution-free methods, include a broad collection of methods and approaches (e.g., see Conover, 1998; Hollander and Wolfe, 1999). Some methods, such as the Mann–Whitney test (Mann and Whitney, 1947) and the Kruskal–Wallis analysis of variance (Kruskal and Wallis, 1952), are based on ranks of the data, while other methods are based on resampling techniques, such as randomization t -tests and permutation tests (Conover, 1998). Recent ease of computing has also led to computing-intensive resampling methods, such as bootstrapping, jackknifing, and Monte Carlo sampling (Efron, 1979, 1981; Efron and Tibshirani, 1993).

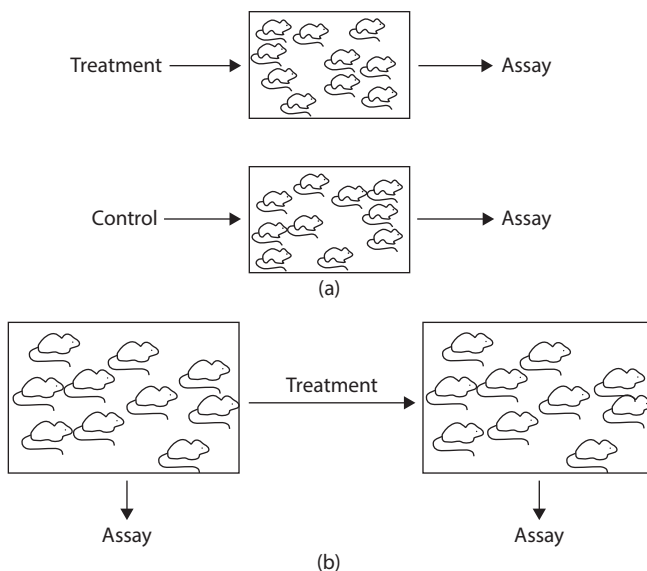

FIGURE 26.4 Illustration of two study designs. (a) Animals are randomly assigned to two independent groups. One group receives a treatment while the other group receives a placebo or control. At some time after treatment, all animals in both groups are assayed. (b) In this pretreatment, posttreatment design, a single group of animals are assayed before treatment. Then, the treatment is applied. After treatment, the animals are assayed again. Because the same animals were measured twice, their pretreatment and posttreatment values are paired and the statistical analysis should acknowledge this pairing.

For non-normally distributed data obtained from the design in Figure 26.4a, the Mann–Whitney test is a nonparametric analog of the two-sample t -test (Mann and Whitney, 1947). Because this test statistic is based on the ranks of the data values rather than on the data values, themselves, it is less influenced by skewness and outliers. For the paired design (Figure 26.4b), the Wilcoxon signed-ranks test, a nonparametric analog of the paired t -test, is a reasonable choice for a non-normally distributed endpoint. Alternatively, a resampling-based test could be applied to data from either experimental design.

Regardless of whether a parametric or nonparametric test is selected in the examples above, the p -value would be two-tailed because Compound X is expected to change A, but the change is not specified as an increase or a decrease. If, on the other hand, Compound X is expected to *increase* A, a one-tailed p -value should be used. Likewise, if Compound X is expected to *decrease* A, a one-tailed p -value should be used.

A common experimental design is the dose–response study. This design includes a placebo or control group along with two or more groups, each receiving a specified dose of Compound X. Animals are randomized to these groups. Moreover, a reasonable alternative hypothesis may be that analyte A increases with dose versus the null hypothesis that A does not change with dose. In this case, a trend statistic should be used to test H_0 . If the data are normally distributed, linear regression or Pearson’s correlation coefficient (Neter et al., 1996) are reasonable choices. If the data are not normally distributed, nonparametric tests of trend, such as Jonckheere’s test (Jonckheere, 1954) or Spearman’s rho (Spearman, 1904) would be more appropriate. If H_0 is rejected, a logical next step is to determine which dose group or groups differ from the control group. Dose groups are then statistically compared, pairwise with the control group. Because this involves testing multiple hypotheses, an adjustment for doing multiple comparisons is usually employed. Such adjustments ensure that the Type I error rate (false positive rate) is controlled; without control, the false positive rate grows with the number of comparisons, possibly approaching certainty. For normally

distributed data, Williams’ test (Williams, 1971, 1972) and Dunnett’s test (Dunnett, 1955, 1964) are good approaches to multiple comparisons with the control group. If other pairs of dosed groups are to be compared, other multiple comparisons procedures are preferable, for example, Tukey’s honestly significant difference (HSD) test (see Neter et al., 1996). For multiple pairwise comparisons with the control group with non-normally distributed data, Shirley’s test (Shirley, 1977; Williams, 1986) and Dunn’s test (Dunn, 1964) are commonly used.

Table 26.3 provides some guidance about selecting test statistics for specific experimental designs and hypotheses.

26.5.2 QUALITATIVE ENDPOINTS

The same hypothesis testing framework extends to qualitative assay data (e.g., present/absent, yes/no). The null and alternative hypotheses are specified, a test statistic is calculated from the data, a *p*-value is derived, and a decision about acceptance or rejection of H_0 is made. For qualitative data, the most common tests used are Fisher’s exact test and chi-square tests (Fisher, 1922, 1954). As with quantitative measurements, the study design and hypotheses are integral to selecting which statistical test should be used.

In dose–response studies, dose-related trends in proportions of positives, for example, can be tested. The Cochran–Armitage trend test (Armitage, 1955) is usually a good choice in this setting. If a significant trend is detected, Fisher’s exact test or chi-square statistics may be used to individually compare each dose group to the control group. To control the false positive rate for multiple comparisons, the Bonferroni correction of dividing α by the number of tests performed may be used to set the significance level for each individual pairwise comparison.

TABLE 26.3
Recommended Statistical Methods for Specific Experimental Designs

	Distribution of the Endpoint		
	Normally Distributed	Not Normally Distributed	Categorical
Two independent groups	Two-sample <i>t</i> -test	Mann–Whitney test, Resampling methods	Chi-square test, Fisher’s exact test
Two related groups (e.g., pre–post treatment)	Paired <i>t</i> -test	Wilcoxon signed ranks test, Resampling methods	McNemar’s chi-square test
Three or more independent groups	Analysis of variance (ANOVA)	Kruskal–Wallis ANOVA, Resampling methods	Chi-square test
Dose–response with three or more groups	Linear regression, Correlation	Jonckheere–Terpstra test, Spearman’s correlation, Resampling methods	Cochran–Armitage trend test
Cross-over design	Repeated measures ANOVA	a	a
Multiple pairwise comparisons with a control group	Dunnett’s test if no trend, Williams’ test if there is a trend	Dunn’s test if no trend, Shirley’s test if there is a trend	Categorical data analysis ^a

^a Seek advice from a statistician.

Note: Most of these statistical tests are widely available in standard statistical software. For non-normally distributed data, resampling methods are also very useful and may take the form of permutation tests, randomization tests, bootstrapping, or Monte Carlo tests; these tests require specialized software.

26.6 SUMMARY

The statistical analysis of clinical chemistry endpoints benefits from an understanding of how analytic measurements are made and translated to analyte concentrations. A good assay determines these concentrations with accuracy and precision. When the assay is performed on a large, well-defined set of animals, reference ranges can be determined to describe typical values and how much variation might be expected for that population. Reference ranges are useful in interpreting the results from assays on individuals and must be updated as characteristics of the population of interest or the assay change. Assay results are also used in research studies. The appropriate statistical methods to be selected for a study will depend on the experimental design, the hypotheses, and the shape of the distribution of analyte concentrations. For complex studies, it is always advisable to involve a statistician, starting from the beginning of the planning stages.
