1.1 INTRODUCTION

The origin of the laboratory mouse lies in pet mice bred by mouse fanciers in Europe throughout the 1800s. These "fancy mice" in turn, were derived from several wild Asian mice species that were selected and mated for desirable traits in Asia before the seventeenth century. Although not appreciated initially, several desirable traits of these so-called "fancy-mice" were genetic in origin. In the early 1900s, biologists conducted Mendelian genetic experiments with fancy-mice (Rader, 2004; Paigen, 2003a). By 1909, the first inbred strain, the *dba* (DBA/2) mouse, was created by selecting for homozygosity of three recessive coat color alleles: *d* dilute, *b* brown, *a* nonagouti (Paigen, 2003a). By the 1970s, more than 250 strains of inbred mice had been created and used extensively in various fields of biomedical research, including cancer, biology, immunology, and genetics. Their use has expanded further with the advent of transgenic technologies in the 1980s (Paigen, 2003a). Outbred mice, especially the "Swiss" stocks, also have been extensively used for diverse research applications.

Practical and scientific advantages of mice in research include small size, ease of handling, low housing costs, short generation time, fecundity, short time to maturation, genetically homogeneous populations (inbred strains) with well-defined traits, 95% genetic homology with humans, and genetic and phenotypic disease homologies between mice and humans (Paigen, 2003b).

Currently, more than 450 major inbred mouse strains and 13,000 unique strains of genetically engineered mice are available for research (National Center for Research Resources, 2004), and mouse gene knockout initiatives ongoing in several countries can be anticipated to increase the numbers further. However, common strains and stocks will be emphasized in this chapter. Further, online resources and information on inbred and genetically engineered mice (and their use as models for disease) not mentioned in this chapter are available to the biomedical researcher, including (but not limited to) the following:

- Mouse Phenome Database (The Jackson Laboratory, Bar Harbor, ME; <http://phenome.jax.org/>)
- Mouse Genome Informatics (The Jackson Laboratory, Bar Harbor, ME; <http://www.informatics.jax.org/>)
- Knockout Mouse Project (<http://www.knockoutmouse.org/>)
- Mutant Mouse Regional Resource Centers (MMRRC Informatics, Coordination and Service Center, Bar Harbor, ME; <http://www.mmrrc.org/>)
- National Toxicology Program (<http://ntp.niehs.nih.gov/>)
- Europhenome Mouse Phenotyping Resource (<http://www.europhenome.org/databrowser/viewer.jsp>)
- Charles River Laboratories (<http://www.criver.com/find-a-model>)

There are many indications for performing clinical chemistry (along with other clinical and anatomic pathology testing) in laboratory mice. First, clinical chemistry may help with the characterization or validation of a disease and/or disease model in mice. Second, clinical chemistry is a critical component during phenotypic assessment of genetically engineered mice and new strains of inbred mice. Finally, clinical chemistry is strongly recommended for nonclinical toxicity and safety studies, and in fact, may be mandated by Federal Drug Administration (FDA) or other regulatory bodies (Weingand et al., 1992).

Clinical chemistry capabilities applicable to laboratory mice have expanded recently from about 20 tests on serum, plasma, and urine, to hundreds of biomarkers that can be quantified in increasingly smaller specimen sample sizes. Certainly, these assays will increase in significance and utility in the foreseeable future. However, the aim of this chapter is to provide information and resources regarding the more traditional bioanalytes assessed in the laboratory mouse.

1.2 UNIQUE PHYSIOLOGICAL CHARACTERISTICS OF THE LABORATORY MOUSE

The main physiological characteristic of laboratory mice relevant to clinical chemistry is their size, which in turn affects the sample volume, sampling frequency, and sample collection of both blood and urine, and potentially limits the number of bioanalytes that can be analyzed per sample and over time.

The metabolism of mice is also relatively high (961 kJ/kg bodyweight), compared to other larger mammalian research species (Terpstra, 2001). Their high metabolism and nocturnal feeding makes *ad libitum* access to food and water, the preferred method for mice. Most mouse activity (e.g., eating, drinking, and locomotion) occurs during darkness, even among blind mice that completely lack photoreceptors (Foster et al., 1991; Foster and Hankins, 2002). Circadian and ultradian variations in some blood and urine bioanalytes (e.g., glucose, lactate, lipids, and proteins) have been identified (discussed further in the following section). Thus, time of day should be considered when scheduling blood collections. In general, nonfasting levels of bioanalytes are routinely used for the assessment of blood and urine of laboratory mice. Depending on study requirements, withholding food for 4–18 hours has been recommended for the examination of fasting levels of certain bioanalytes (e.g., glucose, triglycerides, nonesterified fatty acids, total cholesterol, and insulin; Clapham et al., 2000). Regarding animal health and welfare, it must be stressed, however, that withholding food or water from mice for more than 18 hours is not advisable. Indeed, approval from Institutional Animal Care and Use Committee (IACUC) or Ethics Committees is usually required to pursue studies involving food and water deprivation or restriction.

Corticosterone is the predominant circulating glucocorticoid in laboratory mice (Spackman and Riley, 1978). It is their primary glucocorticoid regulator of carbohydrate, protein, and fat metabolism and modifies the host response to stress and immune response. In contrast, the main role of corticosterone in humans is as an intermediate metabolite in aldosterone biosynthesis, with corticosterone having only weak glucocorticoid and mineralocorticoid activity.

Lipid metabolism in laboratory mice has some significant differences compared to that of humans. In contrast to humans, laboratory mice carry most of their cholesterol as high-density lipoproteins (HDL), and lack cholesteryl ester transfer protein (CETP), which in other species (e.g., humans), is responsible for exchange of triglycerides for cholesteryl esters from very-low-density lipoproteins (VLDL) and low-density lipoproteins (LDL) to HDL, and vice versa (Lusis, 2000; Fernandez and Volek, 2006). Similar to humans, mice synthesize B apolipoproteins (apoB-100 and apoB-48) in the liver and small intestine; they are essential components for the transport of lipids in plasma. Both apoB-100 and apoB-48 are derived from a common structural gene, and apoB-48 results from an enzymatic editing of a single codon of the apoB mRNA. In mammals, due to the abundance of apolipoprotein B mRNA editing enzyme gene expression in the small intestine, effectively all B apolipoproteins produced at this location is apoB-48 (essential for production of chylomicrons). In humans, the liver is missing apolipoprotein B mRNA editing enzyme, and only apoB-100 is produced (needed for hepatic production of VLDL). In murine liver, however, there is a significant editing of apoB mRNA transcripts; thus, hepatic secretion of both apoB-100 and apoB-48 occurs. The reader is referred to the review of Kim and Young (1998) for more detail regarding mouse B apolipoproteins.

Bile acid metabolism in laboratory mice and humans also differ. Bile acids consist of a heterogeneous group of structurally different, hepatic-derived molecules that are the metabolic

breakdown products of cholesterol. In humans, the primary bile acids are cholic acid (CA), chenodeoxycholic acid (CDCA), deoxycholic acid (DCA), and lithocholic acid (LCA), along with their glycine and taurine conjugates (Argmann et al., 2006b). However, in mice, the primary bile acids are CA and CDCA-derived muricholic acid (MCA), along with their taurine conjugates but a virtual absence of glycine bile acid conjugates.

1.3 METHODOLOGY FOR SAMPLE COLLECTION

1.3.1 BLOOD COLLECTION

1.3.1.1 Collection Volume Limits and Frequency of Collection

Blood collection is the most common experimental procedure performed in the laboratory mouse, and often an essential component of most biomedical research. However, the major limiting factor in blood collection in the laboratory mouse is their size, which limits the total amount of blood that can be collected, as well as the frequency at which the blood is collected. Diehl et al. (2001) and Donovan and Brown (2005) provide good reviews of the amount of blood and the frequency of collection that can be obtained from live, healthy adult mice.

The circulating blood volume in a healthy, adult mouse is approximately 63–80 mL/kg (average 72 mL/kg). For single sampling purposes, not more than 15% of circulating blood volume can be sampled at any one time (allowing for a 4-week postcollection rest period) without any long-term adverse effects on health and physiology (such as hypovolemic shock and anemia) and allowing for adequate tissue repair at the site of collection (Diehl et al., 2001; Donovan and Brown, 2005). Additionally, not more than 20% of circulating blood volume can be removed over 24-hour period without any lasting adverse health and pathophysiologic effects, as well as effects on the concentration of bioanalytes and/or half-life other biomarkers being examined (allowing for a 3-week postcollection rest period) (Diehl et al., 2001; Donovan and Brown, 2005). Table 1.1 provides a summary of the circulating blood volume of healthy adult laboratory mice of different weights. Table 1.2 outlines the recommended maximum blood sample volume limits (as a percentage of circulating blood volume) and postcollection recovery periods in healthy adult laboratory mice, based on sampling frequency over a 24-hour period. Table 1.3 details the recommended maximum blood sample volumes from healthy adult mice of different weights, based on the blood sample volume limits presented in Table 1.2. Repeated blood sampling, especially over a short period of time (e.g., 24 hours) can result in alterations in the concentration of certain bioanalytes. While the volumes described above and in Table 1.2 list the maximum acceptable volumes published in the literature, individuals should check with their IACUC or Ethics Committee on limits to survival blood collection.

The limits that the size of laboratory mice has on blood volume collection can be somewhat overcome by collecting terminal blood samples (Donovan and Brown, 2005). At least half (50%) of the circulating blood volume can be obtained terminally via cardiocentesis (often termed cardiac puncture) by a trained individual (technique discussed in the following section), which is summarized in Table 1.3.

There are several factors, however, that must be considered when deciding how much blood should be collected for clinical chemistry from a live laboratory mouse, given the overall low blood volume collection limits. First, most bioanalytes and biomarkers are performed on serum or plasma samples. Given that the normal hematocrit of the laboratory mouse has a conservative reference range of 35%–50%, the serum or plasma collection limit may be a little as 50% and at the most 65% of the total blood volume collected in the healthy adult mouse. Second, blood is often collected from a single mouse for competing purposes beyond clinical chemistry, such as hematology, serology, immunology, and pharmacotoxicology. For example, Table 1.4 summarizes the volume of serum or plasma that is required to run certain clinical chemistry bioanalytes using a Siemens (Dade Behring) Xpand Integrated Chemistry System (Deerfield, Illinois) at the Diagnostic Laboratory of the Veterinary Services Center at Stanford University, Stanford, California (please note that these values are specific for this analyzing system and therefore may differ from other analyzing systems

TABLE 1.1
Summary of the Circulating Blood Volume of Healthy Adult
Laboratory Mice of Different Weights

Weight (g)	Circulating Blood Volume (mL)		
	Minimum	Mean	Maximum
10	0.63	0.72	0.80

in other reference laboratories; please check with the reference laboratory that will be used to obtain more specific information regarding the exact amounts of serum or plasma amounts required for their analyzing systems). A quick perusal of this reveals that a significant amount of serum (and therefore the amount of whole blood) that is required just for clinical chemistry purposes only. Third, the amount of actual serum required is greatly influenced by laboratory equipment and procedural methodology. For example, smaller amounts of serum are required for clinical chemistry analyzers that are based on microfluorescent immunoassays (MFIAs) technologies. Conversely, all chemistry analyzers require slightly more serum than required for proper bioanalyte analysis due to the issue of dead volume, which is the amount of serum that is not recoverable due to handling and processing

TABLE 1.2
Recommended Maximum Blood Sample Volume Limits (As a Percentage of Circulating Blood Volume) and Post-Collection Recovery Periods in Healthy Adult Laboratory Mice, Based on Sampling Frequency within a 24-h Period

Sampling Frequency within 24 Hours	Blood Sample Volume Limits (% of Circulating Blood Volume)	Approximate Recovery Period

(in container reservoirs such as pipettes, serum tubes, and wells). Additionally, the amount of serum required might be increased if repeated testing or re-validation is required for any particular sample. Fourth, blood is often collected from mice with disease, and the disease state in turn may decrease the total circulating blood volume (e.g., via dehydration). Finally, the site of blood collection may influence the amount of blood that can be collected (discussed in the following section). All of these factors may therefore decrease blood volume available (or conversely, increase the blood volume that must be collected) for clinical chemistry. Therefore, the biomedical researcher wishing to perform clinical chemistry on laboratory mice must plan ahead to optimize the blood collection volume required, based on the factors just discussed. For example, the researcher might have to limit the number of bioanalytes that are assessed when dealing with smaller mice or diseased mice, or with mice that require simultaneous analysis of certain bioanalytes and other tests (such as serology).

1.3.1.2 Primary Sites for Collection and Restraint

There are four primary sites for routine blood collection in the adult laboratory mouse: the retro-orbital sinus, the tail vein, the superficial temporal vein (often called the submandibular or facial vein), and cardiocentesis (Argmann and Auwerx, 2006a; Diehl et al., 2001; Donovan and Brown, 2005). The choice of which blood collection site to be used will depend on the quantity of blood required, the frequency of blood collection, animal welfare and/or protocol restrictions, and (in this author's experience) the skill of collector. Most sites require some sort of physical and/or anesthetic restraint. Table 1.5 provides a summary of these four sites, whereas Tables 1.6 and 1.7 provide an outline of recommended injectable and inhalational anesthetic agents, respectively, that can be used for blood collection. Investigations into other blood collections sites (such as saphenous vein, tail clip, tail vein cut) have been recently described (Abaton et al., 2008; Argmann and Auwerx, 2006a), but these have not been reviewed here.

Regardless of the bleeding site and general anesthetic used, the author strongly recommends that individuals seek training in collection techniques and proper anesthesia from experienced laboratory animal care and technical staff, as to minimize any adverse effects on the welfare and health of the mice used for bleeding. Indeed, at some institutions, mandatory training for bleeding and anesthesia of laboratory mice might be a regulatory requirement, so consultation with animal care and technical staff is advised in any case. Additionally, regardless of site used, aseptic technique should be used. For survival procedures, the animal should also be assessed for adequate hemostasis, 30–60 minutes after blood collection (Donovan and Brown, 2005). Finally, the use of anticoagulants should be considered when plasma is required, with the choice of anticoagulant based on the clinical chemistry bioanalytes being performed (see the following section).

Total serum or plasma yield is expected to be not more than 50%-65% of these values.

Blood collection from a newborn mouse is much more challenging, but can be accomplished by administering two units of heparin subcutaneously before decapitation (Loeb, 1998). Subsequently, up to 40 μ L of blood (approximately 20 μ L of plasma) can then be collected from the decapitation site. However, blood collected by decapitation is subject to contamination (e.g., with particulate matter, cerebrospinal fluid (CSF) fluid, ingesta, and infectious agents), which may interfere with or invalidate any bioanalyte results acquired.

TABLE 1.4
Minimum Volume of Serum or Plasma Required for Individual Clinical Chemistry Bioanalytes Using a Siemens (Dade Behring) Xpand Integrated Chemistry System (Deerfield, Illinois) at the Diagnostic Laboratory of the Veterinary Services Center at Stanford University, Stanford, CA

Bioanalyte	Sample Volume (μL)—Plasma or Serum
Dead volume	30
Albumin	5
Alkaline phosphatase	7
Amylase	14
Alanine aminotransferase	35
Aspartate aminotransferase	40
Blood urea nitrogen	3
Calcium	5
Cholesterol	3

High-density lipoprotein	3
Hemoglobin (A1C)	3
Immunoglobulin (indirect)	Calculation (total protein – albumin)
Iron (total)	50
Iron (binding capacity)	25
Lactate	4
Lactate dehydrogenase	14
Low-density lipoprotein	3
Lipase	4
Phosphorus	3
Total protein	15
Triglycerides	5
Troponin I	50
Uric acid	5

These values are in addition to the dead volume of the system (30 μL). *These values are specific for this instrument* and should be expected to differ from requirements for other reference laboratories.

Always check with the reference laboratory regarding volume requirements and submission recommendations for their analyzing systems.

1.3.1.3 Handling and Storage

Proper handling and storage of the blood sample is imperative, not only for producing suitable and reliable data, but also for maximizing the amount of suitable blood that can be used for clinical chemistry and other purposes. Regardless of whether serum or plasma is to be used, it is best to process any blood for clinical chemistry within the first 2 hours after collection. The following

TABLE 1.5
Primary Sites for Routine Blood Collection in Adult Laboratory Mouse

If used with nitrous oxide (N₂O), reduction of the induction and maintenance percentage of the inhalational agent is required. Any inhalational agent should be used with a precision vaporizer and an adequate gaseous scavenging system

recommendations are adapted from the Diagnostic Laboratory of the Veterinary Services Center at Stanford University, Stanford, CA. For the interested biomedical researcher, Henry et al. (2001) provides more comprehensive discussions and guidelines for blood handling and storage.

1.3.1.4 Serum

Immediately after blood collection, place the blood in a 1 mL blood centrifuge tube (without any anticoagulants or preservatives). Allow the blood to clot for 30–60 minutes at ambient room temperature. Centrifuge the clotted blood sample for 10–15 minutes at a relative centrifugal force (RCF) of 14,000 *g*. Pipette the separated serum and transfer to a clean blood centrifuge tube. Recentrifuge the serum sample for another 2–3 minutes at 14,000 *g* to separate any remaining red blood cells. Pipette the clean serum and transfer to a clean blood centrifuge tube, and cap the tube tightly to prevent evaporation.

1.3.1.5 Plasma

Blood must be thoroughly mixed with an anticoagulant at the time of blood collection or immediately after blood collection. For the former, the sterile 1 mL syringe used for blood collection may be “primed” with the anticoagulant prior to blood collection by sterily drawing 1 mL of the anticoagulant from the vial into the syringe, and then reinstilling the entire amount of the anticoagulant back

into the vial. For the latter, add not more than 150 μL of anticoagulant to the 1 mL blood centrifuge tube used for blood collection. In either case, ensure that the blood is thoroughly mixed with the anticoagulant after the blood has been collected and introduced to the anticoagulant. Centrifuge the blood sample for 10–15 minutes at a RCF of 14,000 g . Pipette the separated plasma and transfer to a clean blood centrifuge tube. Recentrifuge the plasma sample for another 2–3 minutes at 14,000 g to separate out any remaining red blood cells. Pipette the clean plasma and transfer to a clean blood centrifuge tube, and cap the tube tightly to prevent evaporation.

1.3.1.6 Choice of Anticoagulant

The choice of anticoagulant will depend on the bioanalyte being analyzed and/or the preferences of the laboratory in which the clinical chemistry is run. Additionally, the choice of anticoagulant may be influenced if other concurrent tests beyond clinical chemistry are required (such as hematology and serology). Therefore, the biomedical researcher is strongly encouraged to contact the laboratory used prior to blood collection to ensure that the blood collected is introduced with the correct anticoagulant (if required). A common anticoagulant used for clinical chemistry is lithium heparin, which in general, has little effect on the values of most bioanalytes (Wiedmeyer et al., 2007). However, a main disadvantage of using lithium heparin is that it does not contain cell preservatives, which precludes analysis for hematology (if concurrently required) unless blood smears are performed immediately after blood collection (Wiedmeyer et al., 2007). Another common anticoagulant used in the laboratory setting is ethylenediaminetetraacetic acid (EDTA). Although it is used extensively for hematology, it is not generally a suitable anticoagulant for clinical chemistry because its strong chelation properties interfere with calcium-dependent enzyme reactions of several bioanalytes (e.g., alkaline phosphatase) and the values of certain electrolytes (such as sodium or potassium). Similarly, the anticoagulant sodium citrate also strongly chelates with calcium, which makes it useful for analyzing clotting factor levels but not for general clinical chemistry.

1.3.1.7 Storage

Most bioanalytes are best analyzed at ambient room temperatures within the first 2 hours of collection. If the serum or plasma sample cannot be processed for clinical chemistry within this 2-hour time period, then place the sample (in its capped tube) into a refrigerator at 4°C for short-term storage (<1 week) or into a non-frost-free freezer at –20°C or colder for long-term storage (1 week to 6 months). There are some exceptions to these storage recommendations. For example, unless ammonia, lactate, and the bioanalytes of blood gas are analyzed immediately after collection, the serum or plasma samples should be stored in ice baths or –4°C to maintain accurate levels of these bioanalytes. Additionally, bilirubin will degrade upon exposure to direct light. Therefore, blood destined for bilirubin analysis should be stored via a lightproof method (e.g., wrapping the blood sample container with aluminum foil). Furthermore, if lactate dehydrogenase is the bioanalyte of interest, storage at room temperature is recommended.

1.3.2 URINE COLLECTION AND STORAGE

The body size and physiology of the laboratory mouse limits the total amount of urine that can be collected, as well as the frequency at which the urine is collected. The total urinary bladder volume of an adult mouse is normally less than 0.5 mL, and the total urinary output per day is less than 1.5–2 mL (Jung et al., 2003). The laboratory mouse also urinates frequently in small amounts, usually 0.1–0.3 mL per urination. All of these factors limit the amount of urine that can be collected at any one time, and therefore the number of bioanalytes that can be assessed from any one urine sample.

Table 1.8 outlines the different methods of collecting urine from the laboratory mouse (Cohen et al., 2007). The mouse should not be fasted prior to urine collection, in order to minimize any

TABLE 1.8
Methods for Collecting Fresh Voided Urine in Laboratory Mouse. The Mouse Should Not Be Fasted Prior to Collection

Method	Procedure	Advantages	Disadvantages
Routine collection of fresh voided urine	<ul style="list-style-type: none"> Secure a large piece of clean parafilm to a solid surface with a raised edge Pick the mouse up by gently squeezing the skin behind the ears to secure the head Place the mouse on the parafilm allowing the mouse to grab the raised edge with the front feet With the free hand, gently massage the lateral abdomen of the mouse just cranial to the pelvis to induce the mouse to void Pipette up the voided urine and place in a small centrifuge tube 	<ul style="list-style-type: none"> Survival procedure Relatively stress-free for mouse Relatively easy procedure Relatively clean urine sample collected 	<ul style="list-style-type: none"> Small volume of urine collected (0.1-0.3 mL)
Collection in metabolism cage	<ul style="list-style-type: none"> Acclimatize mouse to the metabolism cages for at least 48 hours (ensure provision of food and water) Collect urine after desired time period (2-24 hours) For collections greater than 4 hours, ice and/or antimicrobial agents may be required in the collection point 	<ul style="list-style-type: none"> Relatively large volume of urine collected (1.0-2.0 mL) 	<ul style="list-style-type: none"> Ice used for preserving urine may dilute out urine bioanalytes and change solubility characteristics of sediments and other constituents Urine contamination high Requires use of antimicrobials to minimize urine contamination
Collection after euthanasia	<ul style="list-style-type: none"> Humanely euthanize mouse via carbon dioxide asphyxiation Using aseptic techniques, expose the urinary bladder by incising through the abdominal skin and body wall along the ventral midline Aspirate urine directly from the urinary bladder via a 25 g needle attached to a 1.0 mL syringe 	<ul style="list-style-type: none"> Sterile urine collected 	<ul style="list-style-type: none"> Non-survival procedure Mouse may involuntarily void urine at time of euthanasia Small volume of urine collected (0.1-0.5 mL)

Source: Reprinted from Cohen, A.M. et al., *Toxicol Pathol.*, 35, 339-340, 2007. Copyright © 2007 SAGE Publications. With permission of SAGE Publications.

changes to urine bioanalyte and sediment content. Furthermore, the urine is best collected at night or in the first 2 hours of the light cycle if possible. Ideally, urinalysis should be performed immediately after urine collection. If immediate urinalysis is not possible, storing urine samples in an airtight container (e.g., an Eppendorf tube) to prevent evaporation, and in a refrigerator at 4°C (to limit bacterial growth) is recommended.

To mitigate the small urine volume limitations associated with mouse urinalysis, the dilution of urine samples can be performed to effectively increase the volume size. However, this may (and often does) introduce errors in the accuracy of any results generated for urinalysis. Pooling urine

samples from multiple mice from single research group can also increase the total amount of urine collected. The main disadvantage of this technique is that it does not allow specific results to be related back to specific individuals from that group.

1.4 PREANALYTICAL SOURCES OF VARIATION

1.4.1 SEX

While variations in the levels of sex hormones are expected in most mammalian species, other less obvious yet significant variances in bioanalytes in the laboratory mouse have been attributed to sex. Corticosterone levels are reported to be higher in female mice than in male mice (Ottenweller et al., 1979; Scheving et al., 1983). Male mice have a well-defined diurnal concentration pattern, with a maximum concentration of 9 µg/dL at the start of the dark cycle and a minimum concentration of 5 µg/dL shortly before the end of the dark cycle (Ottenweller et al., 1979). In contrast, female mice have a minimum concentration of 13.5 µg/dL at the beginning of the dark cycle and a maximum of 40 µg/dL well into the dark period (Scheving et al., 1983). More recently, Laviola et al. (2002) confirmed this trend of sex differences in corticosterone levels in laboratory mice, with female adult mice having higher overall levels of corticosterone than males, although the significant sex differences were not noted between younger mice, 30–45 day old male and female mice.

Pickering and Pickering (1984) demonstrated that serum alkaline phosphatase activity is lower in males than in females, whereas serum alanine aminotransferase and aspartate aminotransferase activity is higher in males. Lactate dehydrogenase levels have been shown to be higher in males compared to females of the BALB/c strain (Frith et al., 1980). Male C57BL/6 mice exhibited higher glomerular filtration rate than female mice, as determined by a greater fluorescein isothiocyanate (FITC)-labeled inulin clearance rate (Qi et al., 2004).

Additional reviews and resources that document sex-related differences in bioanalytes include Loeb et al. (1996); Serfilippi et al. (2003), the Mouse Phenome Database (The Jackson Laboratory, Bar Harbor, ME; <http://phenome.jax.org/>), the National Toxicology Program (<http://ntp.niehs.nih.gov/>), the Europhenome Mouse Phenotyping Resource (<http://www.europhenome.org/databrowser/viewer.jsp>); and Charles River (<http://www.criver.com/find-a-model>).

1.4.2 AGE

Loeb et al. (1996) reviews effects of age on clinical chemistry values in five inbred strains and two F1 hybrids. Glucose levels demonstrated the most dramatic changes, decreasing throughout life at an approximate rate of 2 mg/dL per month in both sexes of DBA, B6C3F1, C57BL/6J, and CBA/J mice, and in male BALB/cByJ and DBA/2J mice. Scrofano et al. (1998) found similar decreases in glucose as a function of age in a cohort of Emory mice. Other bioanalytes that decreased with age included: alkaline phosphatase activity in both sexes of BALB/c and C57BL/6, triglycerides in male and female C57BL/6, DBA, B6C3F1, B6D2F1 mice. Bioanalytes that increased with age included phosphorus in both sexes of BALB/c and C57BL/6; aspartate aminotransferase and alanine aminotransferase activities in both sexes of BALB/c and C57BL/6, and in female DBA and male B6D2F1 mice; total protein and gamma-globulins levels in both sexes of BALB/c and C57BL/6 (Loeb et al., 1996). More recently, Laviola et al. (2002) showed that younger 30–45-day-old mice have higher levels of corticosterone compared to older adult mice.

Additional reviews and resources that document sex-related differences in bioanalytes include the Mouse Phenome Database (The Jackson Laboratory, Bar Harbor, ME; <http://phenome.jax.org/>), the

National Toxicology Program (<http://ntp.niehs.nih.gov/>), and the Europhenome Mouse Phenotyping Resource (<http://www.europhenome.org/databrowser/viewer.jsp>).

1.4.3 GENETICS

Genetic-associated variations (including those related to strain) have been noted for diverse clinical pathology bioanalytes and continue to be identified as mouse genome and phenome projects progress, and as genetically engineered mice and their background “control” strains are analyzed further. At least 14 inbred strains (including AKR/J, DBA/2J, FVB/N, some A strains, non-obese diabetic (NOD) strains and many BXD recombinant inbred strains) lack the fifth complement component, C5 (hemolytic complement) (Goldman and Goldman, 1976; Lake, 2009). Strain-associated variations in serum cholesterol (Dunnington et al., 1981; Maier et al., 2007; Meade and Gore, 1982); serum testosterone (Ivanyi et al., 1972); serum cortisol-binding protein (Goldman et al., 1977); serum protein (Borovkov and Sviridov, 1975; Loeb, 1997); and urine albumin excretion (Maier et al., 2007) are documented. Male Swiss-Webster mice possess a higher glomerular filtration rate than male C57BL/6 mice, as determined by a greater FITC-labeled inulin clearance rate (Qi et al., 2004).

Additional reviews and resources that document genetic- and strain-related differences in bioanalytes include Loeb et al. (1996); Serfilippi et al. (2003), the Mouse Phenome Database (The Jackson Laboratory, Bar Harbor, ME; <http://phenome.jax.org/>), the National Toxicology Program (<http://ntp.niehs.nih.gov/>), the Europhenome Mouse Phenotyping Resource (<http://www.europhenome.org/databrowser/viewer.jsp>); and Charles River (<http://www.criver.com/find-a-model>).

1.4.4 HEALTH STATUS

It is beyond the scope of this material to discuss bioanalyte variability related to specific pathologic conditions that affect the health status of laboratory mice. In general, however, many diseases may induce similar nonspecific clinical signs of ill-health (e.g., dehydration, infection, and inanition due to illness, inability to access food, experimental protocol, or other causes) that may in turn alter bioanalytes. Furthermore, specific treatment for diseases conditions (such as antimicrobials, anti-inflammatory drugs, and immunomodulatory drugs) may furthermore introduce variability in bioanalyte levels.

Dehydration will in general cause concentration of proteins in the blood, resulting in hyperproteinemia in an otherwise healthy laboratory mouse. Generalized acute systemic inflammation (such as with acute, recent infection by a micro-organism or elements of micro-organisms, such as endotoxin/lipopolysaccharide; or with acute, recent administration of biologics or small molecules that may modulate the immune system) manifest with transient or sustained elevations in acute-phase proteins (mainly increases in serum amyloid A, with moderate or minor increased in α 1-acid glycoprotein, haptoglobin, fibrinogen, and α 2-macroglobulin) (Watterson et al., 2009). The effects of nutrition on the health status of laboratory mice are discussed in the following section.

Of particular note to laboratory mice is infection by lactate dehydrogenase-elevating virus (LDEV). This is a murine-specific arterivirus that may rarely cause clinical disease in susceptible mouse strains (immunosuppressed C58 and AKR) under specific conditions (Percy and Barthold, 2007). Regardless of strain and the manifestation of clinical disease, however, LDEV infection in laboratory mice is associated with a persistent elevation in lactate dehydrogenase (LDH) activity (and to a lesser degree, other enzyme-based bioanalytes such as isocitrate dehydrogenase, malate dehydrogenase, phosphoglucose isomerase, glutathione reductase, aspartate transaminase, glutamate oxaloacetate transaminase, and alanine transaminase) in plasma or serum. This persistent elevation of enzymes is caused by viral infection and destruction of a nonessential population of murine macrophages that normally clear these enzymes (Riley et al., 1978; Plagemann et al., 1995).

Therefore, infections by LDEV in a mouse colony with subclinical infections may introduce variability into clinical chemistry results that are obtained.

1.4.5 NUTRITIONAL STATUS

1.4.5.1 Diet

Diet is known to influence the blood levels of many bioanalytes. Perhaps the best studied of these is the effect of atherogenic diets on serum cholesterol (Morrisett et al., 1982). Similarly, significant differences in both serum cholesterol and blood urea nitrogen are seen in mice maintained on a semipurified (AIN-76) diet (Greenman et al., 1982). Also, Cederroth et al. (2008) recently demonstrated that soy-fed mice showed reduced serum insulin levels (related to reduce pancreatic insulin content).

Immunocompromised mice are often administered antimicrobial-supplemented feed or water as a prophylactic treatment for *Pneumocystis murina* pneumonia. Recently, Altholtz et al. (2006) demonstrated that certain trimethoprim-sulfamethoxazole-medicated feeds may cause dose-dependent hypothyroidism in C57BL/6 mice, with significant decreases in plasma thyroxine (T₄) levels and increases in thyroid-stimulating hormone (TSH) levels. The mouse is unique among mammals because its muscles do not contain carnosine or anserine (Brewer, 1986). Carnosine serves as a source of histidine when its dietary intake is low, and mice on histidine-free diets show signs of histidine deficiency (Parker et al., 1985).

1.4.5.2 Fasting

Mice and rats are generally nocturnal. Overnight fasting impacts their period of greatest activity and may constitute a different or greater stressor compared to overnight fasting of diurnal species. Overnight fasting in BALB/c mice has been reported to decrease plasma glucose and plasma lactate levels (Young, 2005). Muglia et al. (2001) demonstrated that stressing healthy mice via fasting resulted in robust corticosterone production. Lipid metabolism is also altered by fasting of mice with longer periods of fasting (8–16 hours) resulting in higher circulating levels of free fatty acids and triglycerides than short periods of fasting (2 hours) (Argmann et al., 2006b). Similarly, bile acids are lower in fasted mice (Argmann et al., 2006b).

1.4.5.3 Caloric Restriction

Energy (or caloric) restricted diets can significantly change the clinical chemistry profile of laboratory mice. In one large study of 100 mice (Williams et al., 2007), a 30% energy restriction in C57BL/6 mice resulted in significant decreases in glucose, triglycerides, and cholesterol. Scrofano et al. (1998) found similar result in a cohort of Emory mice on long term, 50% caloric restriction, with decreases in glucose and cholesterol as well.

1.4.6 ENVIRONMENT

Environmental factors have been recognized as early as the 1940s to affect the results of scientific studies using laboratory mice. In one early study by Chance (1947), the degree of hydration, exposure to noise, degree of confinement, and environmental temperatures was shown to affect the metabolism and toxicity of drugs in mice. Subsequently, these same housing environmental factors have also been shown to influence bioanalyte values (Besch, 1985; Boyd, 1983; Jensen and Rasmussen, 1963; Laber et al., 2008; Lindsey et al., 1978; Serrano, 1971). For example, in one recent study, Laber et al. (2008) demonstrated that housing density influences stress and immune parameters in BALB/c and C57BL/6. Specifically, BALB/c and C57BL/6

mice housed at 10 animals per cage (compared to 2 or 5 animals per cage) demonstrated significant negative effects on stress (increased corticosterone levels) and immune parameters (decreased helper T-cell levels). Lower testosterone levels were noted in male mice in overcrowded (9 mice per cage) cages when compared to noncrowded (3 mice per cage) cages (Laviola et al., 2001).

1.4.7 CIRCADIAN RHYTHM

Cyclic biorhythms, whether circadian or ultradian, influence blood levels of various bioanalytes in laboratory mice, with the most extensively researched being the hormone of hypothalamic-pituitary-adrenal gland axis. Blood levels of corticotrophin-releasing hormone (CRH), adrenocorticotrophic hormone (ACTH), corticosterone, growth hormone (GH), and luteinizing hormone (LH) may peak one or more times daily (Loeb, 1997; Muglia et al., 2001). ACTH release is episodic (not at fixed intervals) and does not involve steroid feedback, and to visualize episodic cycling; samples must be collected at 5–30-minute intervals (Edwardson and Hough, 1975; Woodman, 1997). ACTH concentration peaks in the early evening in mice and can be reversed by reversing the light cycle (Halberg et al., 1965; Krieger, 1979). In terms of corticosterone, female mice have a minimum concentration of 13.5 µg/dL at the beginning of the dark cycle and a maximum of 40 µg/dL well into the dark period (Scheving et al., 1983). In contrast, male mice have a maximum concentration of 9 µg/dL at the start of the dark cycle and a minimum concentration of 5 µg/dL shortly before the end of the dark cycle (Ottenweller et al., 1979). These findings illustrate the importance that must be given to the timing of sample collection in laboratory mice.

1.4.8 PREGNANCY

Holinka et al. (1979) found that estradiol levels significantly increased after day 17 of gestation in younger pregnant mice (3–7 months of age) when compared to older pregnant mice (11–12 months of age), attributing this difference to longer gestation time in the older mice.

1.4.9 STRESS

Stress may result in alterations in clinicopathologic parameters can be attributed to stress in mice. Landi et al. (1982, 1985) found that plasma corticosterone concentrations in mice tested on arrival, or 24 or 48 hours after arrival (by plane or truck transport) were significantly higher than those of control mice. Muglia et al. (2001) reinforce these findings by demonstrating that stressing healthy mice via physical restraint for 20 minutes or acute, overnight fasting resulting in robust corticosterone production. Even handling prior to blood collection can profoundly alter serum corticosterone levels (MacLeod and Shapiro, 1988).

1.4.10 ANESTHESIA

Variations associated with the anesthesia have been described by Chuang and Luo (1997). In these studies, higher glucose levels were reported with tail vein blood collection in laboratory mice anesthetized with pentobarbital or methoxyflurane (compared with conscious mice); and after collection from the orbital plexus after pentobarbital or proparacaine hydrochloride administration. However, methoxyflurane had no glucose-elevating effect on samples collected from the orbital plexus. Ether inhalation has also been demonstrated to cause increased corticosterone production in healthy mice (Muglia et al., 2001).

1.4.11 SPECIMEN COLLECTION AND HANDLING

1.4.11.1 Interfering Constituents

The effect of sample storage at various temperatures and for varying periods has been described. Falk et al. (1981) evaluated the effect of storage time (after freezing) on 20 serum bioanalytes in 6 laboratory species, and found that in the mouse, only creatine kinase activity changed significantly with storage up to 28 days.

Hemolysis is a common problem during blood collection in mice. Hemolyzed samples are associated with changes in various enzymes, such as increased total protein, alanine aminotransferase, aspartate aminotransferase, lactate dehydrogenase, potassium, and creatine kinase levels, and decreased phosphorus and lipase levels (Latimer et al., 2003). The effect of lipemia on clinical chemistry values has been reviewed for domestic animals (Latimer et al., 2003), which include increased glucose, calcium, phosphorus, and total bilirubin values, and decreased total protein, albumin, sodium, and potassium values.

1.4.11.2 Site of Sampling

Patrick et al. (1983) found that terminal cardiac puncture was associated with higher glucose and lower creatine kinase levels. O'Brien et al. (1997) demonstrated higher cardiac troponin levels in mice after terminal cardiocentesis as well. Increased alanine aminotransferase and aspartate aminotransferase levels are observed with terminal cardiac puncture in mice as well (Luong, 2009).

1.5 BASIC METHODOLOGY FOR COMMON PROCEDURES

1.5.1 ADRENOCORTICOTROPIN HORMONE STIMULATION TEST

Purpose of test: To assess adrenal gland corticosteroid-production function by measuring the corticosteroid response to exogenous adrenocorticotropin hormone administration.

Procedure:

1. Obtain 50 μL of plasma. Label sample as "baseline plasma."
2. Inject adrenocorticotropin (10 $\mu\text{g}/\text{kg}$ body weight) intraperitoneally.
3. Obtain 50 μL of plasma 1 hour after adrenocorticotropin injection. Label sample with the appropriate time point.
4. Submit plasma samples for corticosterone and/or aldosterone analysis.

Source: Muglia et al. (2000).

1.5.2 WATER DEPRIVATION

Purpose of test: To differentiate between the causes of polydipsia, including: primary polydipsia, neurogenic diabetes insipidus, and nephrogenic diabetes insipidus.

Procedure:

Note: Obtain approval from institutional animal care and use committee/welfare and ethics committee BEFORE carrying out any water deprivation studies on mice.

1. Maintain mouse with normal access to food and water for a predetermined time (e.g., 1 week).
2. Obtain 10 μL of plasma. Ensure proper labeling of sample as "baseline plasma."
3. Immediately deprive mouse of water for a predetermined length of time (e.g., 6, 12, 24, 36, or 48 hours). Allow normal access to food during this period.

4. Obtain 10 μL of plasma at the end of the water deprivation period. Ensure proper labeling of sample with the appropriate time point.
5. Submit plasma samples for plasma osmolality and/or antidiuretic hormone (arginine vasopressin) analysis.

Sources: Kessler et al. (2007) and Tsunematsu et al. (2008).

1.5.3 AMMONIA TOLERANCE TEST

Purpose of test: To assess liver function, specifically hepatic functional mass and integrity of the enterohepatic circulation.

Procedure:

1. Fast mouse for 8–12 hours.
2. Administer a 5% ammonium chloride solution (100 mg/kg body weight) orally via oral gavage.
3. Obtain 20 μL of blood at predetermined time points after ammonium chloride administration (e.g., 5, 10, 15, 20, and 30 minutes). Immediately separate blood for plasma separation (place blood sample on ice if there is even the slightest delay between collection and plasma separation). Ensure proper labeling of samples with appropriate time points.
4. Submit plasma samples for ammonia level analysis.

Source: Hiroyama et al. (2007).

1.5.4 INDOCYANINE GREEN ELIMINATION TEST

Purpose of test: To assess liver function, specifically hepatic functional mass and integrity of the enterohepatic circulation.

Procedure:

1. Dissolve indocyanine green (ICG) dye in a minimum volume of water, and then dilute the dissolved ICG dye with Phosphate Buffered Saline (PBS) at 0.1 mg/mL.
2. Fast mouse for 8–12 hours.
3. Inject the ICG solution (0.5 mg/kg body weight) intravenously into the tail vein.
4. Obtain 20 μL of plasma at predetermined time points after ICG solution injection (e.g., 5, 10, and 15 minutes). Ensure proper labeling of samples with appropriate time points.
5. Submit plasma samples for ICG elimination rate analysis.

Source: Hiroyama et al. (2007).

1.5.5 BILE ACIDS—PRE- AND POSTPRANDIAL

Purpose of test: To assess liver function, specifically biliary system function, hepatic functional mass and integrity of the enterohepatic circulation.

Procedure:

1. Fast mouse for 8–12 hours.
2. Obtain 20 μL of plasma. Ensure proper labeling of sample as “preprandial plasma.”
3. Feed mouse.
4. Obtain 20 μL of plasma at predetermined time points after feeding (e.g., 15 and 30 minutes). Ensure proper labeling of sample as “postprandial plasma.”
5. Submit plasma samples for bile acid analysis.

Source: Argmann et al. (2006b).

1.5.6 BROMOSULPHTHALEIN CLEARANCE

Purpose of test: To assess liver function, specifically hepatic functional mass and integrity of the enterohepatic circulation.

Procedure:

1. Inject bromosulphthalein (BSP) (125 mg/kg body weight) intravenously into the tail vein.
2. Obtain 20 μL of plasma at predetermined time points after BSP injection (e.g., 10, 20, and 30 minutes). Ensure proper labeling of samples with appropriate time points.
3. Submit plasma samples for BSP clearance analysis.

Source: Hurwitz et al. (1985).

1.5.7 LOW-DOSE DEXAMETHASONE SUPPRESSION TEST

Purpose of test: In conjunction with other tests (such as the high-dose dexamethasone suppression test), to differentiate between the causes of hyperadrenocorticism, including primary hyperadrenocorticism (Cushing's syndrome), and secondary hyperadrenocorticism (Cushing's disease, ectopic adrenocorticotropin hormone syndrome).

Procedure:

1. Obtain 50 μL of plasma. Ensure proper labeling of sample as "baseline plasma."
2. Inject dexamethasone (0.03 $\mu\text{g}/\text{kg}$ body weight) intraperitoneally.
3. Obtain 50 μL of plasma 6 hours after dexamethasone injection. Ensure proper labeling of sample with the appropriate time point.
4. Submit plasma samples for corticosterone analysis.

Source: Ridder et al. (2005).

1.5.8 HIGH-DOSE DEXAMETHASONE SUPPRESSION TEST

Purpose of test: In conjunction with other tests (such as the low-dose dexamethasone suppression test), to differentiate between the causes of hyperadrenocorticism, including primary hyperadrenocorticism (Cushing's syndrome), and secondary hyperadrenocorticism (Cushing's disease, ectopic adrenocorticotropin hormone syndrome).

Procedure:

1. Obtain 50 μL of plasma. Ensure proper labeling of sample as "baseline plasma."
2. Inject dexamethasone (1 mg/kg body weight) intraperitoneally.
3. Obtain 50 μL of plasma 6 hours after dexamethasone injection. Ensure proper labeling of sample with the appropriate time point.
4. Submit plasma samples for corticosterone analysis.

Source: McGill et al. (2005).

1.5.9 INTRAPERITONEAL GLUCOSE TOLERANCE TEST

Purpose of test: To differentiate between the causes of hyperglycemia, including impaired fasting glycemia, impaired glucose tolerance, and diabetes mellitus.

Procedure:

1. Fast mouse for 8–12 hours.
2. Inject a 20% glucose solution (1.5–2.0 g/kg body weight) intraperitoneally.

3. Obtain 5–20 μL of plasma at predetermined time points after glucose solution administration (e.g., 0, 15, 30, 60, 90, and 120 minutes). Ensure proper labeling of samples with appropriate time points.
4. Submit plasma samples for glucose level analysis.

Sources: Heikkinen et al. (2007) and Yamada et al. (1997).

1.5.10 ORAL GLUCOSE TOLERANCE TEST

Purpose of test: To differentiate between the causes of hyperglycemia, including impaired fasting glycemia, impaired glucose tolerance, and diabetes mellitus.

Procedure:

1. Fast mouse for 8–12 hours.
2. Administer a 20% glucose solution (1.5–2.0 g/kg body weight) via oral gavage.
3. Obtain 5–20 μL of plasma at predetermined time points after glucose solution administration (e.g., 0, 15, 30, 60, 90, and 120 minutes). Ensure proper labeling of samples with appropriate time points.
4. Submit plasma samples for glucose level analysis.

Source: Heikkinen et al. (2007).

1.5.11 INULIN CLEARANCE—SINGLE BOLUS INJECTION METHOD

Purpose of test: To assess renal function by determining glomerular filtration rate.

Procedure:

1. Dissolve 5% FITC-labeled inulin in 0.9% NaCl by heating the solution in boiling water.
2. Dialyze the solution in 1000 mL of 0.9% NaCl at room temperature for 24 hours using a 1000-Da cutoff dialysis membrane to remove residual FITC not bound to inulin. Wrap the dialysis bottle with aluminum foil during the procedure. The resulting FITC-labeled inulin concentration is 3%.
3. Sterilize the dialyzed 3% FITC-labeled inulin solution by filtration through a 0.22 μm filter.
4. Inject the dialyzed 3% FITC-labeled inulin solution (3.74 $\mu\text{L/g}$ body weight) intravenously, or retro-orbitally (under light anesthesia of approximately 20 seconds induced using isoflurane).
5. Obtain 10 μL of plasma at predetermined time points after dialyzed 3% FITC-labeled inulin solution administration (e.g., 3, 7, 10, 15, 35, 55, and 75 minutes). Ensure proper labeling of samples with appropriate time points.
6. Obtain as much urine as possible at the mid- and end time-points. Ensure proper labeling of samples with appropriate time points.
7. Submit plasma and urine samples for determination of FITC-labeled inulin clearance analysis.

Source: Qi et al. (2004).

1.5.12 TSH (THYROTROPIN) STIMULATION TEST

Purpose of test: In conjunction with other tests (such as the thyrotropin-releasing hormone stimulation test), to differentiate between the causes of hypothyroidism, including primary hypothyroidism and secondary hypothyroidism.

Procedure:

1. Obtain 50 μ L of serum. Ensure proper labeling of sample as “baseline serum.”
2. Inject bovine TSH /thyrotropin (2.5 units/kg body weight) intraperitoneally.
3. Obtain 50 μ L of serum 120 minutes after TSH /thyrotropin injection. Ensure proper labeling of sample with the appropriate time point.
4. Submit serum samples for triiodothyronine (T₃) analysis.

Source: Yamada et al. (1997).

1.5.13 THYROTROPIN-RELEASING HORMONE STIMULATION TEST

Purpose of test: In conjunction with other tests (such as the TSH stimulation test), to differentiate between the causes of hypothyroidism, including primary hypothyroidism and secondary hypothyroidism.

Procedure:

1. Obtain 50 μ L of serum. Ensure proper labeling of sample as “baseline serum.”
2. Inject thyrotropin-releasing hormone (5 μ g/kg body weight) intraperitoneally.
3. Obtain 50 μ L of serum 30 and 120 minutes after thyrotropin-releasing hormone injection. Ensure proper labeling of sample with appropriate time point.
4. Submit baseline and 30-minute serum samples for thyroid-stimulating hormone analysis, and baseline and 120-minute serum samples for triiodothyronine (T₃) analysis.

Source: Yamada et al. (1997).

1.6 REFERENCE RANGES

Reference ranges refer to the range of a bioanalyte or biomarker in a population that has not been selected for the presence of disease or abnormality, and are used as a comparison to determine the presence or absence of disease or abnormality in a particular individual or group of individuals of diagnostic or research interest. Reference ranges and historical control data can be useful in designing experiments, but should be used with extreme caution in analysis and interpretation of experimental results. Sufficient sample size of concurrent relevant control animals should be included in the experimental design (i.e., baseline reference ranges should be compiled a sufficient sample size of individuals from the population of wild-type mice from which transgenic and knock-out (KO) mice were derived).

Protocol details regarding procurement of reference range or historical control data may have more value than the data itself in terms of obtaining useful or comparable data. As discussed throughout this chapter, collection methods and equipment (e.g., type or volume of anticoagulant, instrumentation, analysis method, or reagents), signalment (including genetic background), diets, housing, handling, and health status, are some of the factors that can influence results. Therefore, it is imperative that when publishing clinical chemistry data, sufficient details should be provided in the materials and methods sections that allow for replication the protocols used.

Tables 1.9 and 1.10 summarize clinical chemistry data in three strains of laboratory mice, whereas Table 1.11 summarizes the clinical urine data in laboratory mice. Moreover, the following resources may provide information on other outbred strains of mice, inbred strains of mice, and genetically modified mice: Loeb et al. (1996); Serfilippi et al. (2003), the Mouse Phenome Database (The Jackson Laboratory, Bar Harbor, ME; <http://phenome.jax.org/>), the National Toxicology Program (<http://ntp.niehs.nih.gov/>), the Europhenome Mouse Phenotyping Resource (<http://www.europhenome.org/databrowser/viewer.jsp>); and Charles River (<http://www.criver.com/find-a-model>).

All values are performed on nonfasting animals and on serum, unless otherwise noted. Site and method of collection unspecified.

TABLE 1.11
Urine Chemistry Data for Several Strains of Laboratory Mice

Bioanalyte	Value	Units
Urine output (Jung et al., 2003; Takahasi et al., 2007; Yang and Bankir et al., 2005)	1.3-2.0	mL/day
pH (Kovacikova et al., 2006)	5.0-6.6	~
Specific gravity (Luong, 2009)	1.022-1.048	~
Osmolality (Takahasi et al., 2007)	1919-2650	mOsm/kgH ₂ O
Creatinine (Qi et al., 2004)	372-462	µg/day
Glucose (Luong, 2007)	0.5-3.2	mg/day
Protein (Luong, 2007)	0.5-2.7	mg/day
Urea (Yang and Bankir, 2005)	130	mmol/day/kg body weight
Sodium (Jung et al., 2003; Yang and Bankir, 2005)	0.15-0.29	mmol/day
Potassium (Jung et al., 2003)	0.34-0.37	mmol/day
Chloride (Jung et al., 2003)	0.28-0.34	mmol/day
Glomerular filtration rate	~	~
Creatinine clearance (Takahasi et al., 2007)	302-346	µL/min
FITC-labeled inulin clearance (Qi et al., 2004)	283-351	µL/min

2.1 INTRODUCTION

The laboratory rat is one of the most extensively used animal models in biomedical research. A recent PubMed search of the National Library of Medicine indicated that more than 36,000 articles concerning rats were published in a single year. Rats are second only to mice in terms of numbers of animals used in biomedical research. Nevertheless, more than 50% scientific articles are published about rats than mice (Hendrich, 2006). Much of the research conducted on rats uses clinical chemistry parameters as important endpoints because they enable correlation of clinical signs and histopathology and are highly translatable to studies conducted in humans. Clinical chemistry endpoints constitute widely accepted and accessible first-tier biomarkers. A selection of important research areas and examples of rat models are listed in Table 2.1. Several recent reviews that include information concerning clinical chemistry of laboratory rats are available (Car et al., 2006; Evans, 2009; Peterino et al., 2006; Gosselin et al., 2009).

Rats have a number of attributes that make them particularly useful as animal models for biomedical research. They are generally healthy and robust research animals, have tolerance to manipulations (e.g., telemetry, implantation, catheterization, cannulation), and are easily trained for use in behavioral, cognitive, and neurological research. Rats are less expensive to maintain than other larger species such as rabbits, dogs, sheep, or pigs, and are more suitable for chronic or aging studies

TABLE 2.1
Important Rat Research Areas Using Clinical Chemistry as Key Endpoints

System	Models or Diseases	Rat Model
Gastrointestinal	Protein losing enteropathy, digestion	Many
Stress	Restraint stress, repeated variable stress, conditional stress	Many
Nutritional	Zucker obese rat, caloric restriction	Zucker Diabetic Fatty (ZDF)
Protein biochemistry	Analbuminemic rats	Nagase albuminemic rats
Hepatology	Toxicity, regeneration	Many
Endocrinology	Type II diabetes	Zucker Diabetic Fatty (ZDF), Cohen diabetic rat, Toto-Kakizaki (GK)
	Type I diabetes	Biomedical Research Models BBDP, BBDP/Wor
	Hypercholesterolemia	EXHC
	Hyperlipemia	FCH
Neurologic	Epilepsy, experimental autoimmune encephalitis	Genetically Epilepsy-Prone Rats (GEPR/3, GEPR-9), WAG/Rij; EAE rats (Lewis, Dark Agouti)
Pulmonary	Asthma	Brown Norway
Renal	Polycystic kidney disease, compensatory renal hyperplasia	CyCy strain of Han:SPRD; CRJ:CD (SD) BR (Japan)
Acid/base	Acid loading, base loading	Many
Inflammation	Interleukin, acute phase, cytokine research	Many
Cardiovascular	Hypertension	Spontaneous hypertension (SHR) Obese spontaneously hypertensive (SHROB) Spontaneous hypertensive heart failure (SHHF) Fawn hooded hypertensive (FHH) Dahl/salt-sensitive (DSS)
	Stroke	SHR/stroke-prone (SHR/SP)
Toxicology	Acute, screening, and long-term toxicity and carcinogenicity	Wistar, Sprague-Dawley (SD) Fischer 344
Oncology	Prostate cancer	Noble (NBL)
	Pituitary tumors	Wistar Furth Rat (WF)
	Leukemia	AKR
Bone biology	Ovariectomized rat for osteoporosis	Many
Aging/gerontology		F344, BN, F344BNF1 hybrid
Immunodeficient	Nude athymic	Nude (NIH-Foxn1)
Ophthalmology	Cornea, lens, and retinal disorders	Many, RCS rat

owing to their shorter lifespan. Compared to mice, the larger size of rats makes them easy to handle, and amenable to surgical procedures and functional studies. In addition, larger volumes of rat blood can be collected on multiple occasions, such that several parameters can be evaluated over time on a single animal. Disadvantages of rats compared to mice include higher expense of husbandry, longer generation time, greater quantities of test article required to achieve an equivalent mg/kg body weight dose, and very limited availability of rats with targeted mutations (e.g., transgenic, knock-in, and knock-out strains).

Rats are classified as outbred stocks and inbred strains. Commonly used outbred stocks include Sprague-Dawley and Wistar rats. Outbred stocks are closed colonies of more or less genetically heterogeneous animals bred to maintain maximum heterozygosity by minimizing inbreeding. Because each animal is genetically unique, outbred stocks more accurately mimic the genetic variability in the human population than inbred strains. In addition, outbred stocks are considered to be more robust than inbred strains, since they tend not to suffer from inbreeding depression that results from increased homozygosity. Examples include differences in life spans, disease resistance, reproductive capacity, growth rate, and size. However, these stocks are also genetically undefined and experimental designs necessitate larger sample sizes than inbred strains due to interindividual genetic variability of outbred stocks.

Rat strains and stocks exhibit drift in physical and physiologic characteristics over time, affecting attributes including weight, growth rate, fertility, and lifespan. This drift occurs in both inbred and outbred rats but is more pronounced in outbred stocks particularly if small populations are maintained as the stock becomes partially inbred with resultant loss of heterozygosity. Effects can be minimized by regularly migrating breed stocks within a given outbred colony. Unless breed stock is regularly migrated among extant colonies of a given stock, drift will occur among various breeding facilities of a given supplier. For example, differences in incidence of chronic progressive nephrosis in Sprague-Dawley rats from different breeders may affect the interpretation of nephrotoxicity (Palm, 1998). Genetic drift, as well as changes in reagent systems and instrumentation, may affect the clinical pathology parameters. Because of the effects of drift in physiologic characteristics and changes in analytic procedures, relevant reference intervals for clinical chemistry parameters should include data collected from animals from a single supplier over a time span within a few years of the data being evaluated.

Inbred strains are genetically uniform strains originating from at least 20 consecutive brother-to-sister matings and maintained by continued brother-to-sister mating. In contrast to outbred stocks, properly maintained inbred strains are genetically uniform. Their defined and uniform genetic background minimizes interindividual variability in results. In addition, the inherent susceptibility or resistance of an inbred strain to a particular disease may make them ideal animal models for a wide variety of diseases. However, inbred strains are more prone to strain-specific phenotypes and lesions due to fixation of homozygous traits. Commonly used inbred strains include Brown Norway, Fischer 344, and Lewis rats. Lines of inbred strains separated for more than 10 generations of brother-to-sister inbreeding will show evidence of drift and are considered to be substrains.

Congenic strains are a type of inbred strain in which the genetic locus or phenotype from one inbred strain is introduced into the genome of another inbred strain by a series of selective backcrosses followed by 20 consecutive brother-to-sister matings. Consomic strains are similar to congenic strains, but an entire chromosome (rather than a fraction of a chromosome) is replaced in the inbred strain's genome. In addition, a few recombinant inbred rat strains have been developed. Related sets of recombinant inbred rat strains are studied in conjunction for identifying the location and linkage of polygenic traits (Hedrich, 2006).

Nomenclature for rat genes, strains, and stocks follows a standardized system, which allows quick recognition of the type of rat under consideration. This system is organized by the Rat Genome and Nomenclature Committee (RGNC) and curated by the Rat Genome Database. For outbred rat stocks, the first part of the name indicates the registered laboratory (e.g., Han, Crl, Hsd, Tac). The laboratory code is followed by a colon and then the specific stock name in uppercase letters. Thus, Crl:SD is the Charles River Sprague-Dawley. For inbred strains, the rules for rats are similar to those for mice. These detailed rules can be found at the website <http://rgd.mcw.edu/nomen/nomen.shtml#StrainNomenclature> (accessed on 9 August 2009). Further explanation about inbred strain nomenclature and extensive lists of rat strains can be found in Suckow et al. (2006), as well as vendor websites and publicly available databases (<http://www.informatics.jax.org/external/festing/rat/STRAINS.shtml>). Selected examples of some common spontaneous mutant or

TABLE 2.2
Examples of Strains and Stocks of Laboratory Rats

Inbred Rats	Outbred Rats	Hybrid Rats	Mutant Rats	Congenic Rats
Brown Norway	Sprague-Dawley	FBNF1/Hsd	Athymic Nude	PVG.DA-RT1 ^{av} 1
Fischer 344	Wistar	LBNF1/Hsd	DPPIV Deficient	PVG.AO-RT1 ^{au}
Lewis	Long-Evans	DALF1/OlaHsd	HIV-1 Zucker	PVG.R8/OlaHsd

Dahl Salt-Sensitive/ Resistant		WAGBUFF1		
Wistar Furth				
Wistar Kyoto				

genetically modified strains are provided in Table 2.1, and examples of common stocks and strains used in laboratory research are provided in Table 2.2.

2.2 HISTORY OF LABORATORY RATS

The modern laboratory rat is considered to be derived from naturally occurring albino mutants of the wild Norway rat (*Rattus norvegicus*), which originated in China but is now found on all continents except Antarctica. Albino Norway rats were bred in the nineteenth century as show animals and eventually became utilized in research laboratories. Brief histories of four commonly used stocks and strains are presented below:

- Wistar rats are outbred rats that originated from albino Norway rats transported from the University of Chicago to the Wistar Institute in Pennsylvania. Currently, Wistar rats contribute to more strains and stocks of rats than other type of rat.
- Sprague-Dawley rats are outbred rats originating from a white Wistar female and a hooded male that is half-white. The male was subsequently bred to females of successive generations of offspring. The colony was the basis on which Sprague-Dawley Inc. was established. The CrI:CD rat was developed in the 1950s from cesarean-derived SD rats.
- Lewis rats are inbred rats that were originated by Dr. Margaret Lewis in her laboratory at the Wistar Institute in the 1920s.
- Fischer 344 or F344 rats are albino inbred rats that originated in the lab of Curtiss and Dunning at the Columbia University Institute for Cancer Research in 1920. The colony eventually was migrated to the National Institutes of Health (NIH) in 1951 (Lindsay and Baker, 2006).

2.3 ANATOMIC AND PHYSIOLOGIC CHARACTERISTICS OF LABORATORY RATS

Laboratory rats, like several rodent species, are nocturnal. Laboratory rats breed throughout the year with a gestation period of approximately 21–23 days. Puberty is highly variable among strains with reports ranging from 40 to 70 days of age. While rats reach full sexual maturity at a young age (approximately 7–10 weeks of age), growth continues past sexual maturity for both males and females (Creasy, 2003; Mitchell and Creasy, 2007). The lifespan of a laboratory rat ranges from 2.5 to 3 years. Rats are social animals and will sleep together with cage mates.

Although wild rats are omnivores, laboratory diets for rats usually contain vegetable protein and no animal protein. Dietary protein exceeding 12%–15% has been associated with chronic nephropathy in rats (Keenan et al., 2000). The use of fish protein in rat chow has declined in Europe but may still occur in Japan.

Anatomic and physiologic features unique to rats must be considered when interpreting clinical chemistry endpoints. While thorough descriptions of these can be observed in textbooks such as *The Laboratory Rat* (Suckow et al., 2006), a short list of some rat peculiarities that influence clinical chemistry results is presented below:

- **Growth/maturation:** Rats have slow bone maturation compared to other mammals, with ossification occurring after 1 year of age. Peak growth rates occur at 7 weeks of age. Androgens, which help to maintain skeletal integrity, decline in aged nongrowing rats, resulting in accelerated bone turnover and osteopenia.
- **External ophthalmic veins:** In contrast to the mouse, which has an orbital venous *sinus* in the retro-orbital space, the rat has an orbital venous *plexus* formed by numerous anastomoses between the dorsal and ventral external ophthalmic veins (Timm, 1979).
- **Stomach:** Rats are unable to vomit owing to a limiting ridge that separates the forestomach from the glandular stomach. Gastric secretions in the rat are limited to pepsinogen C and Cathepsin D and E, in contrast to other species that also secrete pepsinogen A (Senoo, 2000).
- **Alkaline phosphatase (ALP):** In rats, serum ALP activity is composed of activities from liver/bone isoenzymes and intestinal isoenzymes (Hoffmann et al., 1994). The liver and bone isoforms of ALP are products of the same gene (tissue nonspecific ALP isoenzyme) differing by posttranslational modifications. The intestinal and bone isoforms predominate in serum of rats, in contrast to other species, in which the liver isoform of ALP predominates. This results in more prominent effects on ALP due to feeding (intestinal) and body mass or growth (bone).
- **Amylase:** The rat has four salivary and liver amylase isozymes and two pancreatic amylase isozymes (Robinovitch and Sreebny, 1972). Amylase is present at higher concentrations in the salivary gland in rats and mice than that in other laboratory animals. Considerations for an increase in amylase include increases in food consumption and sialadenosis (Arglebe et al., 1978; Nagy et al., 2001; Proctor et al., 1990).
- **Insulin:** The rat has two nonallelic genes coding for insulin, and two proinsulins, whereas other species studied have one (Evans, 2009).
- **Acute phase proteins:** α -2 macroglobulin (A2MG), α -1 acid glycoprotein (AGP or A1AG), and thiostatin (α ₁-major acute protein) are the major acute phase proteins in the rat (Gentry, 1999; Watterson, 2009).
- **Liver:** Gamma-glutamyltransferase (GGT) and total bilirubin concentrations are low to undetectable (depending on methodology) in the rat. Microsomal induction has been associated with decreased and increased serum liver enzymes in rats (Smith et al., 2002). The rat has no gall bladder. Biliary ducts from each hepatic lobe join to form the common bile duct and empty directly into the descending duodenum. Unlike species with gall bladders, the bile of rats is not concentrated and stored during periods of fasting.
- **Lipid profile:** In contrast to humans and nonhuman primates, high-density lipoproteins (HDL) cholesterol predominates over low-density lipoproteins (LDL) cholesterol in rats (Kieft et al., 1991). This may be due to the absence of cholesteryl ester transfer protein (CETP) in the rat (Guyard-Dangremont et al., 1998; Turk and Laughlin, 2004).
- **Corticosteroid:** Corticosterone, as opposed to cortisol, is the predominant form of corticosteroid in the rat and mouse (Rosol et al., 2001).

- **Thyroid hormone:** In the rat (and mouse), thyroxine and triiodothyronine have short half-lives (12–24 hours) because they are not transported bound to globulins (Capen et al., 2002).
- **Urine protein:** Male rats produce alpha 2-microglobulin (~20 kDa), a testosterone-dependent sex-associated protein produced by the liver that is hypothesized to act as the carrier for volatile substances important for pheromonal communication (Dinh et al., 1965; Mancini et al., 1989). Alpha 2-microglobulin is the major urinary protein in male rats in contrast to other laboratory animals and female rats, in which albumin predominates.

2.4 GENETIC CHARACTERISTICS AND BACKGROUND LESIONS

Phenotypic differences between rats of different genetic backgrounds can be quite useful when modeling particular diseases. However, these differences also have a considerable impact on many research endpoints. Genetic background may influence baseline clinical pathology tests in healthy animals (see Table 2.3, Sprague-Dawley vs. Wistar). In addition, there are many genetic differences with respect to organ function (e.g., kidney, liver, immune), xenobiotic metabolism, susceptibility to toxicity, carcinogenesis and spontaneous diseases, and aging diseases (Kacew et al., 1995; Firriolo et al., 1995; Hackbarth et al., 1981; Suckow et al., 2006; Evans, 2009). Therefore, choice of genetic background is an important consideration in experimental design and maintenance of historical control data.

2.5 METHODOLOGY FOR SAMPLE COLLECTION

2.5.1 BLOOD COLLECTION (FOR SERUM OR PLASMA)

Blood collection volume is an important consideration in rats, owing to their relatively small size. This is particularly true when multiple sampling intervals are required. Volume limits for collection of blood from rats vary from institution to institution on the basis of the local Institutional Animal Care and Use Committee (IACUC) or Ethics Committee guidelines. IACUCs or Ethics Committees usually limit blood collection to 10% of total blood volume, with additional collections permitted on a rolling accrual basis. As a general guideline, for a single collection (every 2–3 weeks), 10%–15% of total blood volume may be collected without adverse effects to the animal such as anemia, hypoxia, and hypotension. For repeated collections, 1% of the total blood volume may be collected daily, or no more than a total of 20% over a period of 3 weeks. Rat circulating blood volume is estimated to be 6.4% of body weight, or 57–69 mL/kg (McGuill and Rowan, 1989; Suckow et al., 2006). The maximum volume that can be collected from an adult rat in a terminal procedure depends on the site of collection, anesthetic used, skill of the phlebotomist, size of the animal, and hydration status but can range from 5 to 10 mL. The volume of blood that can be safely withdrawn as a survival procedure is dependent on these same characteristics, as well as IACUC or Ethics Committee requirements.

The preferred site for blood collection from rats depends on the volume and type of blood required (serum, plasma, or whole blood), sampling frequency (single vs. multiple collections), state of consciousness (anesthetized or unanesthetized), timing during experiment (interim or terminal time point), skill of phlebotomist, and IACUC or Ethics Committee requirements. For survival procedures, the chief blood collection sites are retro-orbital, tail vein (using a hypodermic needle or a nick), lateral saphenous vein, and jugular vein, while the sublingual and metatarsal veins are used less commonly. Historically, blood collection from the retro-orbital plexus was used commonly as a survival procedure. Today, its use as a survival procedure is discouraged because collection of blood from this site is associated with greater tissue injury and thus may affect animal welfare. Multiple survival collections are facilitated by pre-placement of a catheter in any one of several vessels (Thrivikraman et al, 2002). The chief sites used for terminal blood collection under

anesthesia are retro-orbital plexus, abdominal aorta, abdominal vena cava, and heart. Specialized studies sometimes require decapitation; this is mostly performed for very young rats or for some hormonal research. When performing multiple collections, it is preferable to consistently collect from the same site owing to the differences between collection sites for a number of clinical pathology parameters (Van Herck et al., 2001; Dameron et al., 1992; Suber et al., 1985; Neptun et al., 1985).

The best method of blood collection is one that is the least stressful and most humane, yet provides a sufficient quantity of a quality blood sample. Major stressors for rats are listed in Table 2.4; several of these stressors are unavoidable during blood collection. While all blood collection methods require training, some methods (most notably jugular collections) must be performed regularly in order to maintain proficiency. Ongoing training for all methods of collection of blood should be conducted to ensure collection of a quality sample with minimal stress to the rat. Table 2.5 provides a list of the major sites of collection and their attributes.

2.5.2 URINE COLLECTION

In rats, urine may be collected by free catch, timed collection into metabolic cages (e.g., Nalgene cages or wire-bottom cages), and cystocentesis, catheterization, or cystotomy at necropsy (Kurien et al., 2004; Cohen et al., 2007). Each method has advantages and disadvantages as detailed below.

Free catch collections are quick and yield clean samples (i.e., without contamination by water, food or feces). However, collected volumes are small (usually <0.5 mL) and may be insufficient for analysis in many animals on a given day. Success in collection of urine samples by free catch may be dependent on genetic background characteristics (Sprague-Dawley rats are easier than Wistar), sex (females are easier than males), time of day (first in the morning is usually most successful), and technique of the collector. In general, free catch is more successful with gentle, slow, and quiet handling of rats (Cohen et al., 2007). Light stimulation around the region of the bladder facilitates collections by promoting micturition. However, this method must not be used repeatedly because it has been shown to lead to necrosis and regenerative hyperplasia of the urothelium when performed several times weekly (Cohen et al., 1996).

In large rat studies, the most common method of urine collection is the timed (e.g., 16–24 hours of overnight collection, daytime collection, or other interval) collection. Urine is freely voided into trays placed beneath cages or into metabolic cages designed to minimize contamination from water, food, and feces. The main advantage of timed collections over other urine collection methods is that volumes are generally sufficient for analysis (approximately 0.5–20 mL depending on elapsed time) from most or all animals. In addition, timed sampling can be coordinated with experimental manipulations or pharmacodynamics of a test article (e.g., 0–4 and 4–24 hours post-dose). To improve accuracy of timed collections, bladders may be completely emptied prior to the start of collection by light stimulation of the region around the bladder to promote micturition. Timed collections minimize effects of diurnal fluctuations on urine constituents, although short timed collections can still show wide variability and analytes must be corrected for volume or creatinine concentrations (Haas et al., 1997). The disadvantages of metabolic cages are requirements for specialized caging and cage changing, delay between sample collection and analysis, and potential contamination of urine with hair, feces, test articles, water, food, and bacterial growth. There is a large variety of specially designed cages for rat urine collections, and each design has advantages and disadvantages. Optimally designed caging serves food and water outside the main collection area. The flooring optimally has pore sizes small enough to catch feces but large enough that urine droplets are not caught in the mesh flooring by capillary action. Placement of rats into wire-bottomed metabolic caging has been shown to be relatively nonstressful for rats (Eriksson et al., 2004).

Urine collected in metabolic cages can be collected at room temperature or cooled depending on the duration of collection (e.g., 5 hours vs. overnight) and stability of parameters to be

analyzed. Water evaporation, solute decomposition, and bacterial growth can be minimized by collecting samples into cooled containers. If urine is collected in a cooled container, care must be taken so that the cooling system does not decrease the ambient temperature, cause stress to the animals housed in the metabolic cages, or cause water condensation within the underlying cage or on the inner surface of the collection container. In addition, collection of urine over ice changes the solubility characteristics of urine and may result in *ex vivo* crystallization or precipitation of solutes. The use of preservatives such as boric acid, thymol, toluene, and Stabilur® is not required and may even interfere with some analyses. For example, sodium azide and thimerosal at concentrations higher than 0.1% inhibit the enzymatic reaction for the detection of microalbumin. Conversely, preservatives and/or stabilizers may be required when control of bacterial contamination is a prerequisite or for detection of urinary enzymes (e.g., urine metabonomics, nuclear magnetic resonance [NMR]) (Evans, 2009).

The main advantage to collecting urine at necropsy is that sample deterioration and contamination are minimized and specialized caging is not required. Disadvantages of this technique are that they yield small volumes (usually <0.5 mL), urine will likely not be collected from all animals, and they may be technically challenging or time-consuming. The ability to collect urine samples at necropsy is dependent on having minimal pre-necropsy procedures and manipulations to minimize voiding prior to necropsy.

There are no specific storage requirements for rat urine compared to other species. Best practices minimize growth of bacterial contaminants. The containers and cleaning products used for urine collection and storage must be nonreactive with urine constituents. Samples should be stored at 2°C–6°C and are generally stable for less than 72 hours. Freezing samples at –20°C may falsely decrease the concentrations or activities of proteins including albumin, beta 2-microglobulin, GGT, and glutathione-S-transferase (GST) (Elving et al., 1989; Brinkman et al., 2005; Evans, 2009).

2.6 SOURCES OF VARIATION

The major preanalytical and analytical sources of variation in clinical chemistry parameters for laboratory rats are listed in Table 2.6. The sources of variability can be divided into those concerning inherent animal properties (e.g., age) and husbandry (e.g., caging), those concerning procedures conducted in conjunction with blood collection (e.g., collection site), and those occurring post-collection in the clinical chemistry laboratory (e.g., storage duration). There is a multitude of variables that can affect laboratory result outcomes including, but not limited to, considerations such as age, sex, strain, route of exposure, diet, caging, overnight fasting, handling, restraint, anesthetic, type of tube (anticoagulant or serum type), the use of anticoagulants, the site of collection,

and sample storage conditions. The following is a description of some of the more prominent concerns when clinical chemistry assessments are to be evaluated.

2.6.1 SEX AND AGE

Clinical chemistry parameters that are consistently higher in males compared to female rats are serum ALP and triglycerides, and urine protein and ketones (Zhang et al., 2004; Charles River, Inc., 1993; Harlan Research Models and Services, 2009).

Male rats between 8 and 60 weeks old show higher serum ALP activity compared to female rats primarily due to the predominance of the bone isoenzyme, with a lesser contribution from the liver isoenzyme (Hoffmann et al., 1994). Male rats have higher triglycerides compared to female rats due to the testosterone-mediated reduction of postheparin-lipoprotein lipase activity in males (Reaven, 1978, Shearer et al., 2000).

Sexually mature male rats show slightly more urine protein compared to female rats. Prior to 100 days of age, this is due to high urinary concentrations of the androgen-dependent rat prostatic protein alpha 2 μ -globulin (Alt et al., 1980; Goldstein et al., 1988). Some nephrotoxicants cause accumulation of this male rat major urinary protein in secondary lysosomes of renal tubules, resulting in a male rat-specific nephrotoxicity (Hard et al., 1993). In addition, male rats are susceptible to the development of age-related nephropathy (Doi et al., 2007). Because of this condition, the primary urinary protein in aging male rats older than 200 days is albumin and is associated with chronic renal disease (Goldstein et al., 1988; Loeb, 1999). Urine from fasted male rats often has trace urine ketones, whereas urine from female rats is negative by the dipstick method.

Clinical chemistry values that decrease with age in rats include phosphorus and ALP (Lillie et al., 1996; Hoffmann et al., 1994; Wolford et al., 1987). Clinical chemistry values that increase and become more variable with age in rats include aspartate aminotransferase (AST), alanine aminotransferase (ALT), glutamate dehydrogenase (GLDH), cholesterol, and triglycerides (Lindena et al., 1980; O'Brien et al., 2000; Waner et al., 1991; Wolford et al., 1987; Charles River Laboratories, Inc., 1993). In general, clinical chemistry values of younger rats (less than 6 months old) exhibit less interindividual variability (lower coefficient of variation (CV)%) compared to older animals (Charles River, Inc., 1993). In older animals, the high degree of heterogeneity due to age-related changes and spontaneous disease may obscure compound effects, making clinical pathology testing less informative.

Young rats tend to have higher ALP owing to higher bone, as well as intestinal and liver ALP isoenzymes; the activity of these isoenzymes decreases during aging, with the biggest decrease in bone ALP. Adult activities are reached by 34 weeks of age in both sexes (Hoffmann et al., 1994).

Urinary protein, especially albumin, increases from about 8 to 14 months of age in both sexes (Robinson and Evans, 1996).

2.6.2 GENETIC INFLUENCE

Undoubtedly, several strain- and stock-related differences occur for clinical chemistry parameters of rats. Unfortunately, there are no published studies comparing full chemistry panels of commonly used rat strains and stocks on a side-to-side basis (within the same lab and at the same time). Some documented strain differences are listed below:

- Multilaboratory genetic background differences have been reported for AST (F344 > SD), ALP (F344 > SD > Wistar), creatinine (F344 > SD or Wistar), and creatine kinase (SD > Wistar or F344) (Matsuzawa et al., 1993).
- Sprague-Dawley rats excrete approximately twice as much urinary protein when compared to Han Wistar rats (Ramaiah et al., 2009). This may relate to Sprague-Dawley's susceptibility to chronic progressive nephropathy. Susceptibility to urolithiasis is also greater in SD rats than that in Wistar, likely due to higher protein and magnesium excretion in SD rats (Brdicka, 1984).
- Bilirubin is higher in mutant strains (e.g., Gunn rat) which cannot convert bilirubin to glucuronide because they lack uridine diphosphate (UDP)-glucuronate glucuronyltransferase activity (Wolf et al., 1979; Robinson, 1971).
- Wistar rats may be more sensitive to anesthesia (ketamine/xylazine followed by 5 hours of isoflurane) than Sprague-Dawley rats. Wistar rats anesthetized with this regimen have decreased blood pH and increased lactate, creatinine, ALT, AST, and lactate dehydrogenase (LDH) compared to similarly treated Sprague-Dawley rats (Siller-Matula and Jilma, 2008).
- Rats from different genetic backgrounds may vary in their stress response to restraint. After a given stressor, Fischer rats tend to exhibit greater changes in stress-related parameters, while SD and Wistar rats are intermediate, and Long-Evans rats exhibit very low stress responses (Dhabhar et al., 1997).

2.6.3 NUTRITIONAL STATUS

Rats are extensively utilized in nutrition research. A thorough review of the effects of dietary manipulation on clinical chemistry parameters is beyond the scope of this chapter. However, a brief discussion of the effects of diet restriction on clinical chemistry is presented below. Effects of fasting are discussed as a part of preanalytical variables impacting clinical chemistry parameters.

In rats, short-term dietary restriction of ≤ 2 weeks can result in decreased globulins and cholesterol, increased bilirubin, and electrolyte disturbances related to the severity of the restriction (Levin et al., 1993). Long-term restriction decreased total protein, albumin, globulin, triglycerides, phosphorus, potassium, and increased ALP, ALT, AST, urea nitrogen, and sodium, and either decreased or increased glucose (Schwartz et al., 1973; Oishi et al., 1979; Boiziau et al., 1996). Urine protein excretion is decreased in diet-restricted rats compared to ad libitum-fed rats (Gumprecht et al., 1993).

2.6.4 CAGING

Housing type (wire-bottom vs. solid-bottom caging) has been shown to exhibit little or only transient effects on clinical chemistry parameters in rats (Sauer et al., 2006). A change in caging causes a transient, 8–10-fold increase in corticosterone. Corticosterone concentrations peak approximately 40 minutes after a rat is placed in a new cage and return to baseline after 2 hours (Fluttert et al., 2000).

2.6.5 CIRCADIAN RHYTHM

Most diurnal variations in clinical chemistry parameters can be attributed to light/dark cycles, hypothalamic–pituitary axis rhythms (circadian and ultradian), and feeding cycles. The nocturnal feeding habits of rats are likely responsible for the circadian rhythms of serum ALP and urine volume, urinary protein excretion, and fractional excretion of phosphorus, sodium, chloride, potassium, and calcium (Ramaiah et al., 2009). Circadian variations in urinary analytes that are independent of feeding habits exist for glomerular filtration rate and renal excretion of potassium, calcium, and phosphorus (Rabinowitz et al., 1987; Ramaiah et al., 2009). In addition, diurnal variations have been reported for tacrolimus-induced nephrotoxicity in rats (Yamauchi et al., 2004). A circadian rhythm of urinary immunoglobulin excretion in rats has been reported following the subcutaneous implantation of a lymphoid tumor that produced immunoglobulin light chains (Nelson et al., 1974).

Diurnal differences in hormone concentrations in rats are well documented. Diurnal rhythms are observed for a wide variety of hormones, including but not limited to melatonin, adrenocorticotrophic hormone (ACTH), corticosterone, aldosterone, thyroxine, intermedin, calcitonin (and calcium), follicle stimulating hormone, thyrotropin, and prolactin (Levinson, 1940; Nathanielsz, 1969; Milhaud et al., 1972; McLean et al., 1977; Kimura and Kawakami, 1980; Szafarczyk et al., 1985; Kant et al., 1986; Laakset al., 1990; Atkinson and Waddell, 1997; Lightman et al., 2000; Evans, 2009). Minor diurnal variations have also been reported for glucose, triglycerides, cholesterol, and amino acids (Kaminsky and Kosenko, 1986; Marrino et al., 1987; Eriksson et al., 1989).

A circadian rhythm has been demonstrated for markers of bone metabolism. Studies using dietary calcium restriction found a circadian rhythm in total calcium concentration (Hirsch and Hagaman, 1982; Lausson et al., 1985). The bone metabolic markers reported to exhibit a circadian rhythm include ALP, procollagen type I C-terminal peptide (PICP), type I C-terminal telopeptide (ICTP), hydroxyproline (HYP), and Ca. These variations appear to be regulated by melatonin and light/dark cycles. In addition, ICTP and Ca concentrations correlate positively with daily fluctuation of insulin-like growth factor-1 (IGF-1) (Ostrowska et al., 2003).

2.6.6 EFFECTS OF ESTROUS CYCLE, PREGNANCY, OR LACTATION

The effect of the rat estrus cycle on routine clinical chemistry parameters has not been described. Effects of the estrus cycle on plasma corticosterone have been documented, with lowest concentrations at estrus and highest concentrations at proestrus. The differences are most pronounced at the peak of the circadian rhythm (Atkinson and Waddell, 1997). Effects of pregnancy on clinical chemistry parameters have been evaluated in several studies with generally concordant results (LaBorde et al., 1999; Papworth and Clubb, 1995a, 1995b; Liberati et al., 2004; de Rijk et al., 2002; Horne and Ferguson, 1972). Most of the changes in the dams occur near term. ALP, glucose, bilirubin, total protein, albumin, sodium, and chloride are fairly consistently reported to be decreased near termination of pregnancy. The mechanism underlying the decreases in the latter four parameters may be the characteristic plasma volume expansion that occurs in pregnancy in many species. The largest magnitude of change occurs for triglycerides (a three- to fourfold increase). Postnatally, most values return to baseline within a short period of time. During lactation, calcium and parathyroid hormone (PTH) concentrations are increased compared to non-lactating controls (Gonen et al., 2005).

2.6.7 FASTING

Fasting of rats prior to measurement of clinical chemistry parameters is a practice with advantages and disadvantages, and the decision to fast or not should be made on a case-by-case basis (Matsuzawa and Sakazume, 1994). The advantages of fasting are that it yields data that is less variable and minimizes changes related to test article effects on food consumption. In contrast, allowing access to food prior to blood collection maintains the normal feeding schedule of rats (e.g., prevents

a nonphysiologic catabolic state that may obfuscate effects). In addition, fasting status can affect the rate of test article absorption and clearance from the stomach. Regardless of fasting status, consistency must be maintained among the treatment of all animals.

In general, fasting of rats for up to 24 hours results in decreased serum ALP, bilirubin, cholesterol, triglycerides, glucose, and total protein. Most parameters recover within 6 hours of refeeding (Maejima and Nagase, 1991; Mitev et al., 1993; Thompson et al., 1989; Matsuzawa and Sakazume, 1994; Waner and Nyska, 1994).

Serum ALP of rats is more influenced by status of food intake than that of other species (Evans, 2009). Fasting decreases serum ALP activities in the rat. Feeding, especially with a high fat meal, results in increased ALP within approximately 7 hours (Eliakim et al., 1991; Hoffmann et al., 1994). The influence of feeding status on ALP in the rat is at least partially due to its longer half-life (54.1–68.3 minutes for the second elimination phase; Young et al., 1984). Intestinal ALP (IAP) of the rat is the product of two separate genes that share only 79% sequence homology (Engle and Alpers, 1992), unlike other species that have different isoforms of intestinal ALP due to posttranslational modifications. The intestinal alkaline phosphatase (IAP)-II isoenzyme is most responsive to feeding of a fat meal (Eliakim et al., 1990).

Fasting of rats also results in an initial fall in water intake coupled with an increase in urine output (Thompson et al., 1987; Apostolou et al., 1976; Pickering and Pickering, 1984). After 24 hours of fasting, rats begin to conserve sodium, unlike other species that exhibit natriuresis (Van Liew et al., 1978).

2.6.8 HANDLING

Entry of a caretaker into an animal room and movement of cages causes increases in plasma protein, glucose, pyruvate, and lactate, along with other indicators of excitement/stress (heart rate, hematocrit, hemoglobin, plasma protein) (Gärtner et al., 1980). Routine cage changing alters behavior and cardiovascular parameters in rats, but clinical chemistry parameters were not investigated (Duke et al., 2001). Anesthetizing rats in their home cages has been shown to be less stressful than removing animals and placing them in an induction chamber, although the effect on standard clinical chemistry parameters was not determined (Fomby et al., 2004). Limited data exists on the effects on clinical chemistry parameters of picking up rats from their home cage. Picking up rats behind the front legs results in twofold higher serum creatine kinase activities compared to picking rats up by the tail, even if rats are handled for 30 seconds or less (Yerroum et al., 1999).

2.6.9 RESTRAINT

Light restraint of rats for 6 hours, allowing movement of limbs but restriction of relocation (vertical 23°C water immersion to the level of the xyphoid process while confined within a firmly fitted stainless mesh cage), results in increases in creatine kinase (CK), AST, ALT, LDH, amylase, lipase, urea nitrogen, creatinine, and glucose; some of the increases are quite dramatic (Arakawa et al., 1997). Recovery for most parameters is partial or complete by 24 hours. These increases in serum enzymes are blocked by pretreatment with β -adrenergic agonists, suggesting that stress associated with restraint, rather than the physical restraint itself, is responsible for these effects. When exposed to repeated consistent handling or mild restraint, rats may become habituated. Habituation results in attenuation of the increase in ACTH, corticosterone, and glucose in some stress models (Márquez et al., 2004).

2.6.10 ANESTHESIA

Some anesthetics have significant effects on clinical chemistry parameters in rats. Inhalation anesthetics have the least effects, and are generally the method of choice for rat anesthesia, provided that

proper protection is afforded the experimenter (e.g., backdraft tables, scavenging systems). Generally speaking, all inhalation anesthetics have some effects on clinical chemistry when compared with unanesthetized rats (Deckardt et al., 2007). Historical publications addressing effects of anesthesia commonly include experiments using ether, an anesthetic that is infrequently used at the present time. Many of these studies also include collection of blood from the retro-orbital plexus as a survival procedure. As noted previously, collection from this site is now limited in some geographical areas to terminal procedures under anesthesia.

Inhalation anesthetics such as isoflurane provide sufficient depth and length of anesthesia for most blood collection procedures. Isoflurane anesthesia for less than 10 minutes has little to no impact on routine clinical chemistry parameters for rats (unpublished observation; Saha et al., 2005). Blood collected from the jugular vein of isoflurane anesthetized non-cannulated rats had similar but slightly higher serum corticosterone and glucose concentrations compared to blood collected from non-anesthetized rats with cannulated jugular veins, suggesting that the anesthetic procedure is slightly stressful (Vachon and Moreau, 2001). Rats rapidly recover from short-term isoflurane without deleterious effects. Ether or halothane/O₂/N₂O anesthesia increase glucose; ether also increases pyruvate and lactate (de Haan et al., 2002; Gärtner et al., 1980). CO₂ or CO₂/O₂ combinations have been used for immobilization of rats for blood collection but are more stressful than isoflurane (Altholtz et al., 2006). Compared to animals exposed only to room air, animals immobilized with CO₂ or CO₂/O₂ mixtures prior to retro-orbital plexus blood collection have higher serum glucose concentrations and lower calcium concentrations and CK and ALT activities (Walter, 1999). CO₂ anesthesia is inappropriate for studies in which blood gas parameters are measured (e.g., Gaspari et al., 2007).

Injectable anesthetics (generally given intramuscularly or intraperitoneally) are also used for rat anesthesia. Intramuscular injection of anesthetics causes alterations in serum activities of muscle enzymes, increasing AST, ALT, CK, and LDH. Other muscle-specific parameters such as skeletal troponin and aldolase would likely also be affected. Xylazine alone or in combination with ketamine increases glucose (Saha et al., 2005; Rodrigues et al., 2006). Intraperitoneal injections of saline cause markedly increased corticosterone, indicating stress; these changes likely occur with intraperitoneal injections of pentobarbital as well (personal observation). Intraperitoneal pentobarbital may also result in hemolysis, with resultant effect on clinical chemistry parameters.

2.6.11 SITE OF BLOOD COLLECTION

Because methods vary widely among the numerous studies examining effects of site of collection on clinical chemistry parameters, consistency among the results is limited (Van Herck et al., 2001; Dameron et al., 1992; Suber et al., 1985; Neptun et al., 1985). In addition, such studies are invariably complicated by differences in anesthesia, collection device, and volume collected among the different sites of blood collection, making interpretation of data even more difficult. These publications, like those evaluating effects of anesthetics (e.g., ether), include data from procedures that, at the current time, are less frequently used or only used in limited geographic areas. The following studies illustrate the differences observed depending on the experimental conditions used.

Comparing heart (H), retro-orbital plexus (O), and tail collection (T), Suber found the following effects for various clinical chemistry parameters: ALP (O>H=T), LDH (H=T>O), AST, ALT, GGT, creatinine (H>O=T), urea nitrogen (H=O=T). Comparing retro-orbital plexus to posterior vena cava, Dameron observed mostly minor effects except for magnesium and phosphorus, which were both higher in the posterior vena cava. Neptun et al. (1985) examined five sites of collection and found that, for most parameters, tail and retro-orbital plexus samples of blood deviated most from the grand mean of all methods, and that exsanguination and small volume collection from the identical site resulted in significantly different results (Neptun et al., 1985). Blood collected from the retro-orbital plexus of rats under ether anesthesia had lower glucose and total bile acid concentrations and higher cholesterol and triglyceride concentrations and sorbitol dehydrogenase (SDH) activity (Khan et al., 1996). Finally, samples collected from two periorbital sites (retro-orbital plexus

and dorsal anastomotic orbital vein), sublingual vein, and abdominal aorta, all under ether anesthesia showed significant increases for creatine kinase, LDH, and AST activities in the peripheral sites, compared to that in the abdominal aorta (Bernardi et al., 1996).

Decapitation has been considered to be essential for stress studies in which ACTH and catecholamine concentrations are measured. However, recent literature in mice and rats suggests that retro-orbital or arterial cannulation (mice) or tail vein collection (rats) are equal or superior to decapitation (Vahl et al., 2005; Grouzmann et al., 2003).

Some sites for blood collection have been reported to be inappropriate for certain parameters. Compared to the blood collected from a tail vein, the blood collected from the retro-orbital plexus or from the heart results in increased creatine kinase activity. Creatine kinase and AST activities are highly increased when blood is repeatedly collected from the retro-orbital plexus compared to that collected from the sublingual vein (Mahl et al., 2000). Blood collection by puncture of heart has been shown to alter cardiac troponin concentrations as well as creatine kinase activities (Bachmaier et al., 1995).

2.6.12 VOLUME OF BLOOD COLLECTED

Although IACUC guidelines allow blood collection volumes that are acceptable in terms of animal welfare, these volumes are considerably sufficient to affect the clinical pathology parameters in subsequent blood draws. In addition, blood collection may potentiate or obfuscate test article effects on hematologic and clinical chemistry parameters (Furuhama et al., 1987). Published data on the effect of repeated blood sampling on clinical chemistry parameters in rats is limited; however, single or repeated phlebotomies may increase serum glucose, regardless of site (Mahl et al., 2000). In addition, clinical chemistry parameters measured when limited blood is collected may differ from those measured in blood collected from the same site during exsanguination (Neptun et al., 1985).

2.6.13 POST-COLLECTION PROCESSING ARTIFACTS

Interferences: As with other species, hemolysis, lipemia, and icterus can influence results of clinical chemistry parameters. The level at which these interferents affect results is dependent on instrumentation and methodology used in the laboratory. Each laboratory should establish its own levels of acceptable hemolysis, lipemia, and icterus; and develop criteria for unacceptable levels of interference. Species-specific interferences that affect rats are effects of hemolysis and platelet counts on potassium concentrations. Hemolysis as an interferent is similar for rats, humans, and other species with similar biochemical RBC composition. Rat red blood cells contain high concentrations of potassium relative to serum such that hemolysis in rats increases serum potassium concentrations (Harvey, 1997). Because rats, like mice, have high numbers of platelets (approximately $900\text{--}1500 \times 10^3/\mu\text{L}$), formation of a clot releases sufficient amounts of potassium to result in substantial differences between plasma (non-clotted) and serum (clotted) potassium concentrations (Sevastos et al., 2008). This effect is exaggerated in rats with increased platelets.

Evaporation during processing and analysis can affect clinical chemistry results due to the small volume of serum/plasma available from rats. Evaporative concentration of analytes usually is most noticeable for sodium and chloride, since these parameters have such a narrow range of values in health. To minimize the effect of evaporation, it is important to keep samples covered, to run samples in a timely fashion, and to randomize or stratify collection and analysis across groups in order to minimize the consequence of evaporation.

Refrigerated and frozen stability for clinical chemistry parameters of the rat has been reported in the literature and is generally similar to the stability for human parameters (Cray et al., 2009). Freezing and storing serum samples at -70°C is preferable to freezing and storing at -20°C . Of the common clinical chemistry parameters measured, CK, CO_2 , and ALT have the lowest stability when rat serum samples are frozen at -70°C . Because stability is dependent on methodology, it is important for each laboratory to establish stability under the conditions in which it operates. For example,

recently, it has been shown that the CK activity of rats can be almost doubled by maintaining the serum sample at room temperature rather than at 4°C prior to analysis (Goicoechea et al., 2008).

2.7 REFERENCE INTERVALS FOR LABORATORY RATS

Reference intervals for clinical chemistry parameters of laboratory rats are available from numerous sources, including this book (Table 2.3), for rats of various ages, strains, and sexes. As mentioned in the previous sections, several preanalytical factors influence the result generated for a given clinical chemistry parameter. In addition to the preanalytical factors described earlier in this chapter, other procedures within a laboratory also affect results, including sample handling, instrumentation, assay methodology, and laboratory data review procedures (Matsuzawa et al., 1997). For these reasons, the most useful clinical chemistry reference intervals are those generated within each laboratory based on routine conditions (Hall, 1997). Reference intervals are useful tools to gauge the magnitude of changes and to determine whether they are adverse or not (Table 2.7). However, they should not be relied upon to determine the relatedness of a change to an experimental treatment. To interpret changes in clinical pathology endpoints, test values must be compared to that from concurrent controls, using reference intervals as supportive data if necessary. A robust change from controls may be within the reference interval but may still be consistent with a treatment-related effect. This is particularly true for stocks/strains of rats (vs. large animals), where the inter-individual homogeneity and more animals per group enables detection of subtle changes.

TABLE 2.7
Quantitative Urinalysis Normative Data for Male Han Wistar—Crl:WI(Han)—Rats Age 11–15 Weeks

Analyte	Units	Mean ± SD	Ref Interval	n
Water intake	mL/hour	1.24 ± 0.75	(0.08–2.45)	192
Volume (20 hours)	mL/hour	1.04 ± 0.61	(0.23–2.23)	192
Osmolality	mOsm/kg H ₂ O	664 ± 593	(205–2118)	191
Free water clearance		−0.33 ± 0.49	(−1.03–0.60)	174
pH		6.6 ± 0.5	(5.8–7.0)	192
Sodium (Na)				
Concentration	mmol/L	43 ± 42	(10–19)	192
Rate of excretion	μmol/hour	30 ± 12	(12–52)	192
Fractional excretion	%	0.12 ± 0.06	(0.05–0.21)	174
Chloride (Cl)				
Concentration	mmol/L	48 ± 60	(20–211)	192
Rate of excretion	μmol/hour	32 ± 18	(14–72)	192
Fractional excretion	%	0.15 ± 0.06	(0.07–0.25)	174
Potassium (K)				
Concentration	mmol/L	90.3 ± 95.9	(23.6–351.2)	192
Rate of excretion	μmol/hour	59 ± 28	(31–130)	192
Fractional excretion	%	8.3 ± 3.2	(3.9–14)	174
Calcium				
Concentration	mmol/L	0.87 ± 0.86	(0.05–2.71)	192
Rate of excretion	μmol/hour	0.6 ± 0.5	(0.1–1.4)	192
Fractional excretion	%	0.12 ± 0.10	(0.02–0.29)	192
Phosphorus				
Concentration	mmol/L	38.6 ± 29.1	(12.0–103.7)	192
Rate of excretion	μmol/hour	27.2 ± 7.2	(16.1–39.0)	192
Fractional excretion	%	7.5 ± 2.8	(3.5–12.4)	174

3.1 USE OF RABBITS IN BIOMEDICAL RESEARCH

Rabbits (*Oryctolagus cuniculus*) have long been used as research animal models. Many of their anatomic and physiologic features make them uniquely suited for use in research. Following centuries of domestication, rabbits thrive in captivity. In addition, their ability to produce large numbers

of offspring at short and predictable intervals not only supports their ready availability but also facilitates their study over multiple generations. The body size of a rabbit is small enough to permit animals to be acquired and housed economically and at high densities. However, they are sufficiently large, especially when compared to mice and rats, for facilitating instrumentation and visualization of anatomic regions as well as collection of sizable tissue samples. Currently, with recent expansions in transgenic technology, numerous strains of rabbits are being developed to more closely model diseases and conditions of interest. Therefore, rabbits are considered valuable experimental animal models.

3.1.1 EXAMPLES OF EXISTING RABBIT MODELS

While many breeds of rabbits have been used in research including the Flemish Giant and the Polish rabbit (Kraus et al., 1984), the two breeds used most commonly are the New Zealand White (NZW) and the smaller Dutch Belted with mature body weights of approximately 5–6 kg and 1.5–2 kg, respectively (Brewer, 2006). Rabbits have been used in the study of a diverse array of scientific areas including cancer, cardiovascular disease, aging, ophthalmology, reproductive physiology, and infectious and parasitic diseases. They are also commonly employed in the production of antibodies and in pharmaceutical and environmental safety testing. Although samples for clinical chemistry analytes may be collected from any experimental model, discussion of rabbit models in this chapter will focus on those most applicable to veterinary clinical chemistry.

Within the field of cancer research, many of the frequently published rabbit models involve tumors known to spontaneously develop in the rabbit *in situ* (e.g., spontaneous endometrial adenocarcinoma [Baba and von Haam, 1972; Elsinghorst et al., 1984]) or as a sequela of a viral infection (e.g., myxomatosis and rabbit papillomavirus) (Suckow et al., 2002). Many models involve the purposeful inoculation of transplantable tumors including the VX-2 carcinoma (Gu et al., 2007; Kreuter et al., 2008), Brown-Pearce carcinoma, and Greene melanoma (Shikishima, 2004). More recently, transgenic rabbits such as the HLA-A2.1 rabbit and rabbits genetically modified to express oncogenes have been produced to closely model human cancer conditions (Hu et al., 2007; Fan and Watanabe, 2003).

Perhaps, the most well-recognized rabbit models are those used in cardiovascular research. Rabbits were the first and are currently one of the most common animal species used to model human atherosclerosis. Initially, rabbits were selected as they were found to quickly develop hypercholesterolemia when fed a high-cholesterol diet and then progress to develop arterial mineralization (Yanni, 2004).

The Watanabe Heritable Hyperlipidemic (WHHL) rabbit is the predominant rabbit strain used as a model of atherosclerosis and is a well-accepted model of human familial hypercholesterolemia. An inbred strain derived from a male mutant Japanese rabbit, the WHHL rabbit possesses a single mutation in the low-density lipoprotein (LDL) receptor gene resulting in reduced LDL catabolism and lipoprotein accumulation in the plasma. As a sequela to their hypercholesterolemia and hypertriglyceridemia, WHHL rabbits consistently develop aortic and coronary atherosclerosis at 4–5 months of age as well as skin xanthomas (Aliev and Burnstock, 1998; Norido et al., 1993). The WHHL rabbit has been used to study characteristics and development of atherosclerosis as well as to assess experimental therapies (Aliev and Burnstock, 1998). The general health characteristics, development of lesions, and biochemical profile of the WHHL rabbit have been described (Aliev and Burnstock, 1998; Norido et al., 1993).

Another well-known, but less frequently used rabbit model of atherosclerosis is the St. Thomas' Mixed Hyperlipidaemic (SMHL) rabbit (previously known as the St. Thomas Hospital rabbit). The SMHL rabbit is used as a model of human familial combined hyperlipidemia (FCHL), a genetic disorder of unknown etiology (de Roos et al., 2005). Similar to the WHHL rabbit, the SMHL rabbit developed as a result of a spontaneous mutation and maintains a combined hyperlipidemia with significantly elevated levels of plasma cholesterol and triglycerides. However, hyperlipidemia

in the SMHL rabbit is attributed not to an LDL receptor defect as in the WHHL rabbit but to an increased production rate of apolipoprotein B (apoB)-containing lipoproteins (de Roos et al., 2005). One disadvantage of many rabbit models, both those induced by high-cholesterol diets and those developed through a spontaneous mutation (e.g., WHHL), is that lesions do not develop in the same locations as in humans. Transgenic strains derived both from NZW and WHHL strains as well as additional experimental techniques are being developed to address this issue and to examine unique aspects of the disease (Moghadasian et al., 2001; Brousseau and Hoeg, 1999; Yanni, 2004).

Rabbits are also commonly used in a wide range of other cardiovascular diseases including myocardial infarction and cardiomyopathy. For instance, the Watanabe Heritable Hyperlipidemic Myocardial Infarct (WHHLMI) strain of rabbit has been developed through selective breeding of WHHL rabbits to spontaneously develop myocardial infarction that is uniquely similar to the human condition (Shiomi et al., 2003). The β -MyHC-Q transgenic rabbit is a valuable model of human familial hypertrophic cardiomyopathy (Marian et al., 1999).

Recently, the rabbit has been increasingly studied as a model of Alzheimer's disease following the observation that cholesterol-fed rabbits develop many of the neuropathologic features of the condition including central accumulation of amyloid-beta in the nervous tissue and development of cognitive deficits (Woodruff-Pak, 2008; Sparks, 2008).

The rabbit has been used as an animal model of several ophthalmologic conditions. It has the advantage over many smaller species (e.g., mice and rats) of a large globe (eye) for which diagnostic and therapeutic interventions developed for use in humans can easily be applied (Shikishima, 2004). The spectrum of ophthalmologic studies utilizing rabbits include contact lens-associated corneal hypoxia (McCanna et al., 2008), dry eye (Schrader et al., 2008), and most notably glaucoma and uveal melanoma. Buphthalmia, or enlargement of the eye (also termed congenital or infantile glaucoma) is one of the most common inherited diseases in domestic rabbits (Brock, 2012). The buphthalmic (*bu/bu*) NZW rabbit had been commonly used as an animal model of glaucoma as the disease frequently occurs spontaneously in this breed (Hanna et al., 1962; Tesluk et al., 1982). Treatments for uveal melanoma have been extensively evaluated (Brock, 2012) following the implantation of a melanoma cell line in the immuno-privileged anterior chamber of a rabbit's eye. The most frequently utilized tumor line in the rabbit model is the Greene melanoma, a tumor line originally derived from a hamster amelanotic melanoma (Shikishima, 2004).

The reproductive physiology of the rabbit has been well studied. Rabbits and humans share many similar hematological and biochemical trends during pregnancy (Wells et al., 1999). The tightly controlled timing of rabbit ovulation and subsequent egg maturation and development have made them useful in studies of egg maturation, fertilization, cleavage, and implantation. The anatomy of a female rabbit's uterus and two cervixes (opening separately into the vagina) prevents the migration of embryos between uterine horns as in most other species allowing separate fetal populations in the same animal (Kozma et al., 1974). Rabbits have also been used extensively to study fetal development and to evaluate the potential teratogenic effects of substances proposed for human administration (Hartman, 1974; Wells et al., 1999). Smaller breeds are often preferred for studies to test novel compounds as a smaller quantity of drug is required when administered on a per body weight basis (Spence, 2003).

Rabbit models continue to fill an important role in the study of infectious and parasitic diseases. Although consistent or expanding in some areas (e.g., tuberculosis and microsporidiosis), the use of rabbits is being largely surpassed by that of transgenic rodent models (Basaraba, 2008; Wasson and Peper, 2000).

Many treatment, diagnostic, and testing modalities incorporate use of purposefully produced monoclonal or polyclonal antibodies. Rabbits have been consistently used for decades in the production of polyclonal antibodies (Suckow et al., 2002). Detailed descriptions of the procedure have been published (Hendriksen and Hau, 2003; Cooper and Patterson, 2008). Rabbits are an almost

ideal species for this purpose as they have readily accessible blood vessels for blood collection, are of significant body size (especially when compared to rodents) to permit frequent collection of large volumes of blood, and often have strong immunologic responses to administered immunogens (Stills, 1994).

Rabbits are regularly utilized in the safety testing of pharmaceuticals, biologic materials, and medical devices. In the past, rabbits were commonly used for evaluating the degree of ocular or dermal irritation induced by substances prior to their approval for human use. Common tests included the Draize rabbit eye and skin irritancy tests. Numerous alternative tests have been developed resulting in a substantial reduction in the number of rabbits used for these types of tests. These include the red blood cell, hemoglobin denaturation, bovine corneal opacity and permeability, isolated chicken eye, isolated rabbit eye, and the chorioallantoic membrane test methods to evaluate eye irritation (NICEATM, 2006). Cell culture systems, transcutaneous electrical resistance assays, and commercially produced *in vitro* tests are among the alternatives used to evaluate skin irritation (Vinardell and Mitjans, 2008). Rabbits were also historically used in an *in vivo* test to evaluate the presence of bacterial endotoxins or other pyrogens in substances produced for human administration. The rabbit pyrogen test has been largely replaced with alternative tests such as the limulus amoebocyte lysate assay (Hartung, 2002). The suitability of these and other alternative tests for safety testing of pharmaceuticals, biologic materials, and medical devices are periodically reviewed for acceptance by the United States, Europe, and other region's regulatory agencies. In some instances, no one test is accepted as a total replacement for an animal-based test. Rather, conduct of a series of alternative tests may be accepted in full or partial replacement of the relevant animal-based test.

3.1.2 MUTANT AND GENETICALLY MODIFIED STRAINS

Inbred strains of rabbits have been developed to decrease the biologic variability present in outbred stocks. However, while inbred animals are genetically uniform, significant experimental variability can be induced through minor environmental alterations (Napier, 1963). On average, the reproductive efficiency of inbred rabbit strains may be lower than that of outbred stocks partially owing to decreased litter size and increased mortality rates (Fox, 1974). As a result of this and an increased susceptibility to disease, it is not uncommon for lines of inbred strains to be lost within the first few generations of inbreeding (Napier, 1963). Although many inbred strains of rabbits (e.g., WHHL, WHHLMI, SMHL) have been developed, few are commercially available. Many stocks and strains have been preserved through cryopreservation (Joly et al., 2012).

Many of the transgenic technologies initially developed in the mouse have been adapted for use in the rabbit. Numerous transgenic rabbit strains have been developed for a wide variety of uses including as specially designed models of disease (e.g., cardiovascular disease and acquired immunodeficiency syndrome [AIDS]) and as live bioreactors for the large-scale production of biologically active recombinant proteins (e.g., human interleukin-2, erythropoietin, and growth hormone) (Fan and Watanabe, 2003). Compared to other species, the rabbit is highly suited to use as a bioreactor owing to its size and reproductive and physiologic characteristics. Colonies of transgenic rabbits expressing human genes can be maintained free of selected diseases and intensively reared within strictly controlled environmental conditions. As a consequence of their highly efficient reproductive physiology, rabbits produce large volumes of protein-rich milk that can be collected and processed to yield recombinant proteins for therapeutic, diagnostic, and research applications at relatively low cost compared to that from larger agricultural species (Fan and Watanabe, 2003).

Numerous spontaneous mutations have been identified and are frequently selected for study in rabbit colonies (Fox, 1974; Lindsey and Fox, 1994). These include buphthalmia (Fox et al., 1969) and mandibular prognathism (Fox and Crary, 1971) in the NZW used as models for human glaucoma and prognathism, respectively, and the Pelger-Huet anomaly (Lindsey and Fox, 1994).

3.2 UNIQUE PHYSIOLOGICAL CHARACTERISTICS OF RABBIT

The rabbit possesses many unusual or unique anatomical and physiological characteristics on which researchers can capitalize when designing scientific studies. Rabbit breeds vary greatly in size and include the large Flemish giant with an adult weight of approximately 9 kg and the Polish rabbit with an adult weight frequently less than 1 kg (Yanni, 2004). In addition, rabbits possess a very light and fragile skeletal system, accounting for only 7%–8% of the total body weight (Suckow and Douglas, 1997; Brewer, 2006). In contrast, they are heavily muscled (approximately 50% body weight) with much of their muscle mass associated with the rear legs (Donnelly, 2003). As a result, rabbits are prone to lumbar back fractures if they are not handled and restrained appropriately (Bergdall and Dysko, 1994). The fasting metabolic rate of the rabbit is high when compared to that of other animals of their size. For instance, the fasting metabolic rate of a 2 kg rabbit is approximately 120 kcal/day or 750 kcal/m² (Brewer, 2006). Lacking sweat glands over the majority of their body, rabbits are most comfortable in cool environmental temperatures. Their pinnae (external ears) represent a large portion of their total body surface, approximately 12% in NZW (Donnelly, 2003). Their ears are utilized in thermoregulation, providing a means to help cool the body, and are vascularized with proportionately large blood vessels facilitating arterial and venous access (Brewer, 2006). Furthermore, the thymus persists into adulthood (Donnelly, 2003). Cortisol is the major plasma glucocorticoid (Lassen, 2004).

Compared to other common laboratory animals, the rabbit has a high number of basophils in its peripheral circulation (Kozma et al., 1974). The rabbit polymorphonuclear leukocyte is referred to as a heterophil not a neutrophil due to the presence of large granules that can be easily visualized on routine bloodstains. The Pelger-Huet anomaly is inherited as a partial dominant trait and is observed in varying frequencies across rabbit strains. In this anomaly, the heterophil is hyposegmented due to the incomplete differentiation of granulocytes (McLaughlin and Fish, 1994). Similar to the mouse and rat, the rabbit is a steroid sensitive species in which lymphopenia is induced through lympholysis following exposure to stressors or exogenous glucocorticoids (Toth and January, 1990).

All rabbit teeth are open-rooted (hypsodontic) and grow continuously throughout life. A normal anatomic feature that distinguishes all lagomorphs is the “peg” teeth, a second set of upper incisors located immediately behind the more visible front upper incisors. Three layers of striated muscle extend the full length of the esophagus and include the cardiac portion of the stomach (Kraus et al., 1984). The gastrointestinal tract and its contents can account for 10%–20% of an animal’s body weight. The stomach of a rabbit is rarely empty even after prolonged fasts and may contain 15% of the intestinal contents. Furthermore, rabbits are not able to vomit due to the anatomic position of their well-developed cardia relative to the other portions of the stomach (Brewer, 2006; Donnelly, 2003).

Compared to other segments of the gastrointestinal tract, the cecum is disproportionately large, accounting for approximately 40% of the total digestive tract (Brewer, 2006) and with a capacity approximately 10 times that of the stomach (Suckow et al., 2002). This large structure plays a vital role in supporting the nutritional health of the animal. It is within the cecum that a high concentration of microorganisms converts substances within the ingesta to highly nutritive components of the cecotrophs.

Coprophagy, the eating of feces, is a normal behavior of rabbits. Produced in the evening, cecotrophs are soft fecal pellets that are high in B-complex vitamins, electrolytes, water, and protein and are low in fiber. In contrast, the firmer fecal pellets produced during the day are composed predominantly of undigested fiber (Suckow and Douglas, 1997; Kraus et al., 1984). Rabbits will consume the cecotrophs as they are passed from the anus. Thus, housing rabbits on raised surfaces, through which fecal pellets can fall, will not prohibit their coprophagic behavior. It is interesting to note that germ-free rabbits do not consume their cecotrophs (Kozma et al., 1974), presumably due to the lack of additional nutrients.

Two distinctive structures composed of gut-associated lymphoid tissue, the sacculus rotundus and the cecal appendix, are present in the rabbit gastrointestinal tract. The sacculus rotundus (also known as the cecal tonsil) is a distinctive structure at the terminal ileum. The cecal appendix is a long, thin structure at the distal end of the cecum (Suckow and Douglas, 1997).

The water consumption rate of rabbits spans a wide range (50–150 mL/kg of body weight/day) and, at its upper end, is higher than that of most other mammals (Cizek, 1961). However, they have a remarkable ability to withstand significant levels of dehydration, up to 48% of their body weight (Brewer, 2006). Rabbits tend to drink copious quantities of water when food is withheld, which is enough to alter their serum electrolyte balance (Cizek, 1961). If water is withheld, food consumption decreases (Cizek, 1961).

As indicated in Table 3.1, many of the enzymes traditionally assessed to evaluate liver function are produced by multiple tissues in the rabbit, as is true in many mammal species. Therefore, it is important to recognize all sources of an enzyme when interpreting clinical chemistry data (Benson and Paul-Murphy, 1999; McLaughlin and Fish, 1994).

Additional factors that must be considered when interpreting enzyme levels in the rabbit and other species include the means by which the enzyme is released into the blood (e.g., leakage from the extracellular space following cell injury or following increased production); the duration of enzyme activity once in the blood; tissue specificity of the enzyme; and the methods used to collect, store, and analyze the blood sample (Lassen, 2004). It is also important to consider the degree of muscle trauma induced during blood collection through such procedures as restraint, administration of injections, decapitation, or surgical incisions as they may result in significant elevation of enzymes present in both the liver and the muscle, thereby making evaluation of liver function difficult.

On a per weight basis, rabbits produce a relatively high volume of bile. The components of bile acid differ significantly in the rabbit when compared to other mammals. For instance, over 80% of rabbit bile acid is composed of deoxycholic acid while it is composed of limited chenodeoxycholic acid, the primary bile acid in several mammals (Taylor et al., 1981). Rabbits possess a gallbladder

TABLE 3.1
Tissue Origin of Enzymes Commonly Measured in Blood

Enzyme	Tissue Source of Enzyme
Alanine aminotransferase (ALT)	Liver, cardiac muscle
Aspartate aminotransferase (AST)	Liver, cardiac and skeletal muscle, kidney, pancreas
Creatine kinase (CK)	Cardiac, skeletal, and smooth muscle; brain
Gamma glutamyltransferase (GGT)	Liver including bile duct epithelial cells (the major source of the enzyme), renal epithelium
Alkaline phosphatase (ALP)	Several tissues including osteoblasts, renal tubular epithelium, intestinal epithelium, liver, and placenta. Rabbits are unique in having three ALP isoenzymes (one intestinal and two liver/kidney forms) as opposed to the two isoenzymes (intestinal and liver/kidney/bone forms) of most other mammals.
Glutamate dehydrogenase (GD)	Liver, cardiac and skeletal muscle, kidney, brain, leukocytes
Lactate dehydrogenase (LDH)	Cytoplasm of almost all cells of the body. The rabbit has multiple isoenzymes of LDH that correspond with isoenzymes 1–5 of humans.
Alpha-amylase	Pancreas, salivary glands, liver

and the common bile duct enters the duodenum separately from the pancreatic duct thereby making it relatively easy to cannulate (Brewer, 2006). Unlike most other mammals where bilirubin is the only heme end product excreted in bile, rabbits excrete both biliverdin (70%) and bilirubin (30%) in the bile. Bilirubin found in the bile and in plasma is most frequently in its conjugated form (McLaughlin and Fish, 1994). Biliverdin is not normally present in the plasma (Lassen, 2004). Some rabbits produce a liver enzyme, atropinesterase, which allows them to quickly and efficiently metabolize the antimuscarinic agent atropine (Sawin and Glick, 1943; van Zutphen, 1974) that may be administered to control respiratory tract secretions and heart rate. The gene responsible for production of the enzyme is inherited with incomplete dominance.

There are many unique characteristics of the rabbit kidney that make it a useful model for a variety of research focuses (Brewer, 2006). The anatomic structure of the rabbit kidney is simple with a single papilla and calyx. The rabbit is unique in that its renal tubules can be dissected without disrupting the basement membrane, making it useful for studies in renal tubule physiology (Brewer, 2006). The number of glomeruli in the kidneys is not static at birth but rather varies over time. Furthermore, ectopic glomeruli may be present in the kidney of adult rabbits (Brewer, 2006). Plasma urea nitrogen and creatinine can be used as markers for estimating rabbit renal function (Lassen, 2004; Campbell, 2004).

The volume of urine produced by a rabbit can vary widely (20–350 mL/kg/day) although a range of 20–75 mL/kg/day is typical (Kozma et al., 1974; Washington and Van Hoosier, 2012). Daily urine volume is influenced by many variables including an animal's food and water consumption, level of physical activity, and environmental temperature (Kozma et al., 1974). Crystalluria is a normal finding in rabbits with calcium carbonate, ammonium magnesium phosphate (triple phosphate), and anhydrous calcium carbonate crystals frequently produced (Benson and Paul-Murphy, 1999; McLaughlin and Fish, 1994). Urine is usually basic (pH 7.6–8.8) and with a specific gravity between 1.003 and 1.036. However, urine pH may become acidic (pH 6–7) during a fast (Kojima and Tanaka, 1974). Casts should not be seen although trace protein or glucose and an occasional WBC may normally be detected in urine (Kozma et al., 1974, 1967; McLaughlin and Fish, 1994). Red urine may be observed and should not automatically be assumed to be hematuria as dietary porphyrins may be excreted in the urine causing a red discoloration.

Rabbits are unlike most other mammals with regard to calcium metabolism and excretion. While most mammals maintain serum calcium levels within a tightly controlled range, the serum calcium level of rabbits is directly influenced by dietary calcium. Rabbit plasma calcium levels are frequently higher (13–15 mg/dL) than that observed in other species (Buss and Bourdeau, 1984; Brewer, 2006). Moreover, while most mammals' primary route of calcium excretion is through bile, the rabbit excretes calcium predominately through urine (Donnelly, 2003; Suckow and Douglas, 1997). Their fractional urinary excretion of calcium ranges from 45% to 60% as compared to less than 2% in most other mammals (Buss and Bourdeau, 1984).

Rabbits fed a high calcium diet can have secondary changes to their urine such as a very thick, cloudy, white, pasty consistency or calcium carbonate crystalluria. This is especially true in obese and sedentary rabbits. When coupled with an increased urinary pH, these rabbits are predisposed for development of urolithiasis (Hoefler, 2000; Pare and Paul-Murphy, 2004). Prolonged intake of elevated dietary levels of calcium can lead to calcification of the aorta and kidney (Donnelly, 2003). This effect is exaggerated if vitamin D is coadministered (Buss and Bourdeau, 1984). Rabbits may also absorb excess calcium from a calcium-rich water source. Diets low in calcium elicit a parathyroid hormone-mediated, tubular reabsorption of calcium with resultant hypocalcemia. A diet low in phosphorus causes a rapid increase in calcium excretion and phosphorus reabsorption by the kidneys (McLaughlin and Fish, 1994). Therefore, due to the noted influence of calcium, phosphorus, and vitamin D on rabbit kidney function, researchers should consider the level of these nutrients in the diet when using rabbit tissues in isolated renal tubule perfusion studies (Buss and Bourdeau, 1984).

The timing of sexual maturity is influenced not only by the age of an individual but also by the mature body weight of the breed or strain. In general, smaller breeds tend to reach sexual maturity at

an earlier age than larger breeds (Kozma et al., 1974; Donnelly, 2003). For instance, the age at sexual maturity for the smaller Dutch Belted rabbit is approximately 4 months as opposed to 5–7 months for the larger NZW and 9–12 months for the Flemish Giant (Suckow et al., 2002; Morrell, 1995).

Female rabbits do not exhibit an estrous cycle although they do have predictable periods of sexual receptivity. They are induced ovulators. The timing of ovulation is very predictable, 10–13 hours post-copulation or following injection of luteinizing hormone, human chorionic gonadotropin, or gonadotropic releasing hormone (Foote and Simkin, 1993; Kozma et al., 1974; Suckow and Douglas, 1997; Morrell, 1995). Their ova are large and develop rapidly (Brewer, 2006). They have a duplex uterus, consisting of two uterine horns each communicating with the vaginal chamber through separate cervixes (Brewer, 2006).

An approximately 16-day pseudopregnancy can result from sterile matings with a male, mounting by another female, or the presence of another buck nearby (Kozma et al., 1974; Suckow et al., 2002; Napier, 1963). Pseudopregnancy can also be reliably induced with administration of luteinizing hormone (Brewer, 2006). During this time, females may display many of the behavioral and physiological characteristics of pregnancy including nest building and milk production (Kozma et al., 1974; Napier, 1963). Matings will not be successful during pseudopregnancy as ovulation is suppressed during this time (Napier, 1963). Progesterone assays can be used to diagnose pregnancy (Morrell, 1995).

Gestation is approximately 31–32 days in duration with an average litter size of eight. Longer gestations may occur if the litter size is small. The rabbit has a hemochorial type of placentation, similar to that in the human. Maternal and fetal circulations are in very close contact allowing a high degree of placental transfer of substances from the dam to the offspring. Most passive transfer of immunity (globulins) occurs in utero with very little passive transfer through consumption of colostrum (Kozma et al., 1974; Suckow and Douglas, 1997). Dams produce approximately 160–220 g of milk per day and may allow kits to nurse for up to 10 weeks although weaning usually occurs by 5–8 weeks of age (Suckow et al., 2002).

Kits are altricial at birth and are ectotherms until day 7. They nurse only once daily for approximately 3–5 minutes at consistent times each day, often in the morning (Brewer, 2006). While nursing, a kit may consume milk equivalent to 20% of its body weight (Alus and Edwards, 1977). When raised with their dams, kits will consume milk exclusively up to 10 days of age. By 20 days of age, they will convert to a diet primarily of solid food and start to display coprophagy, consuming only a small amount of milk by approximately 30 days. During this time, the size of the cecum and the amount of cecal fermentation increases to accommodate the transitioning diet (Alus and Edwards, 1977).

Artificial insemination of females has been developed and is useful for controlled and efficient management of reproduction and to exclude transmission of pathogens either between breeders or from dam to offspring. Fresh or cryopreserved sperm can be used (Morrell, 1995). Embryo transfer was first developed in the rabbit and it has since been utilized to develop specific pathogen-free (SPF) and transgenic colonies of rabbits (Forcada and Lopez, 2000; Watanabe et al., 2005).

3.3 METHODOLOGY FOR SAMPLE COLLECTION

3.3.1 BLOOD COLLECTION

As detailed in Table 3.2, the common sites for phlebotomy in a rabbit include jugular vein, ear vasculature, cephalic vein, lateral saphenous vein, and the heart. Removal of the fur over the venipuncture site will often improve visualization of peripheral vessels. The recommended restraint technique and amount of blood that can be collected varies with each site. In general, potential venipuncture complications include hemorrhage, bruising, thrombosis, and stress secondary to improper restraint. Procedures such as proper restraint technique, proper preparation of the venipuncture site, and application of adequate pressure to the venipuncture site after blood collection should reduce the rate of complications (Joint Working Group on Refinement, 1993).

TABLE 3.2
Comparison of Blood Collection Sites

Blood Collection Site or Method	Relative Collection Volume (+ to ++++)	General Anesthesia Required	Multiple Collections Recommended from Site
Marginal ear vein/ central ear artery	++	No (use of local anesthetic recommended)	Yes
Jugular vein	+++	No	Yes
Cephalic vein	+	No	Yes
Saphenous vein	+	No	Yes
Cardiac puncture	+++	Yes	No

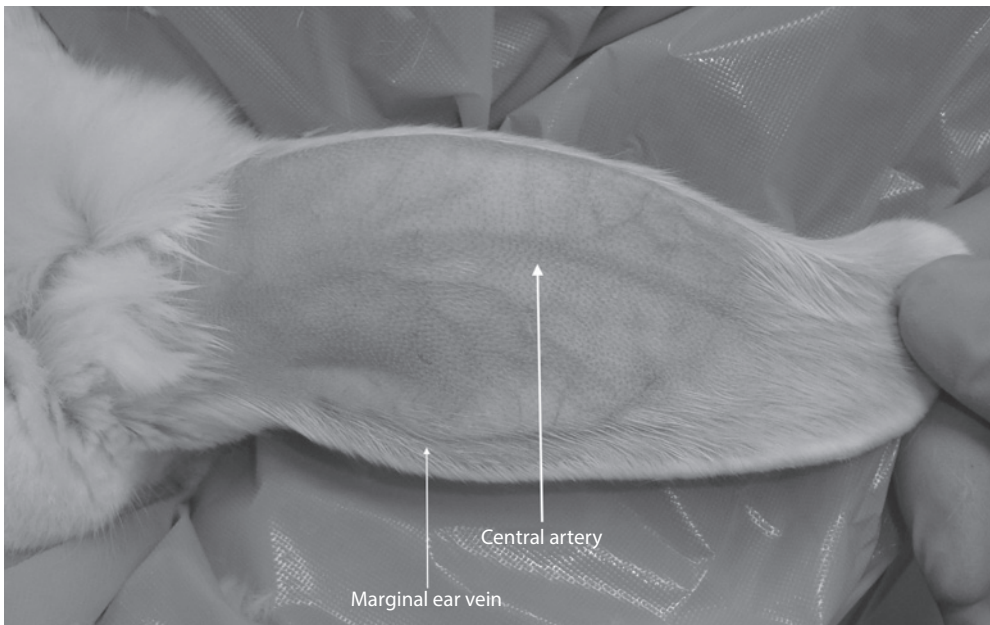

FIGURE 3.1 (See color insert.) Marginal ear vein and central ear artery.

3.3.1.1 Primary Sites for Collection

3.3.1.1.1 Ear Vessels

The marginal ear vein and central ear artery (Figure 3.1) are vessels commonly utilized for blood collection. The amount of blood that can be obtained from these vessels varies with the technique. A small amount of blood can be obtained through cannulation of the marginal ear vein with a 25–27 gauge (G) needle. With this technique, blood is allowed to passively enter the blood collection equipment. It is important to note that vessels collapse easily if a syringe or vacuum tubes are used (Mader, 2004). Vasodilation is recommended to facilitate obtaining a larger blood sample. The optimal method to induce vasodilation is heavily influenced by the animal handler's experience and comfort with a method and the potential influence of the method on experimental requirements and results. Dilation of the local vasculature can be achieved by warming the ear with a low wattage heat bulb or topical application of 40% D-limonene, 2% nitroglycerin ointment, or citrus oil (Adams, 2002; Hrapkiewicz et al., 2007; Smith et al., 1988). For example, the application of 2 mL

of 25%–40% D-limonene to the ear surface will result in vasodilation in 2–5 minutes lasting for at least 10 minutes (Bivin, 1994; Lacy et al., 1987). If a topical vasodilator agent is used it must be cleaned from the ear such as with 70%–95% ethanol following blood collection (Lacy et al., 1987) to minimize skin irritation.

Systemic administration of pharmacologic agents can be used to facilitate blood collection by inducing dilation of peripheral vasculature and reducing stress (Ludders et al., 1987). However, it must be noted that administration of any pharmacologic agent has the potential to affect blood parameters (Bivin, 1994). Therefore, the possible effects induced by a substance on parameters of interest in each experimental study must be considered prior to substance administration. Acepromazine maleate is one pharmacologic agent commonly used to induce a light sedation and vasodilation (Hrapkiewicz et al., 2007). Recommended dose ranges of acepromazine for this procedure most frequently vary between 0.5 and 5.0 mg/kg and differ largely on the level of animal sedation intended. Local anesthetics such as topical lignocaine-prilocaine (EMLA) cream applied to the collection site 1 hour prior to blood collection can be utilized to decrease induced pain or discomfort (Hrapkiewicz et al., 2007). A variety of techniques are described in the literature to help facilitate collection of a larger blood sample from the ear vasculature. Selected techniques are described here.

One method involves the placement of a hub-less 18 G needle into a dilated central ear artery (Bivin, 1994). This technique allows for the collection of 35–85 mL of blood in 1–3 minutes (Bivin, 1994). If more blood is required, an additional 10–15 mL can be collected from the vasculature of the other ear using the same technique (Bivin, 1994). In another method, a 22 G double-head needle or a standard 22 G needle and extension set assembly is inserted into the dilated ear vessel and then coupled with a vacuum blood collection tube. With this method, up to 20 mL of blood can be collected from a 4 kg rabbit (Barrera and Young, 1997). Although not often currently utilized, a miniperistaltic pump can be used with catheterization of the central ear artery to reliably obtain up to 40 mL of blood (Bivin, 1994; Ludders et al., 1987; Stickrod et al., 1981). Alternatively, if frequent and repeated blood collection is required, an indwelling catheter can be placed and maintained in the ear vasculature (Smith et al., 1988).

A negative sequela that can occur with ear venipuncture regardless of the technique used is thrombosis with subsequent epithelial sloughing. This complication occurs more often in rabbits with small ears and vasculature (Mader, 2004). Discomfort may also occur with venous and arterial blood collection involving a larger gauge needle. To help alleviate this potential discomfort, a topical anesthetic such as EMLA cream can be utilized. The hair overlying the marginal ear vein should be removed and 1 mL of EMLA cream applied topically 1 hour prior to the venipuncture procedure (Flecknell et al., 1990). In addition, it is essential that direct pressure be maintained on the vessel puncture site after blood collection to promote hemostasis. Prolonged pressure may be required with puncture of the central ear artery.

3.3.1.1.2 *Jugular Vein*

Jugular venipuncture can be performed in an awake rabbit with manual restraint provided by two technicians. This technique is useful when blood volumes greater than 0.5 mL are required (Benson and Paul-Murphy, 1999). The rabbit is placed on its stomach with its front legs held down off the edge of a table and its head extended up toward the ceiling (Figure 3.2) (Mader, 2004). When extending the head upward, it is important to be cautious not to overextend the neck and interfere with respiration. Alternatively, the rabbit can be placed on its back with its neck extended parallel to the table by the phlebotomist (Figure 3.3). The needle is inserted into the jugular vein near the base of the neck, the needle tip directed toward the head (Benson and Paul-Murphy, 1999). Chemical restraint may be required in rabbits that are not conditioned to human handling or are fractious with restraint.

The jugular vein is the preferred site for long-term venous catheterization. Catheterization is recommended when multiple blood samples are needed as this can help reduce the stress associated

FIGURE 3.2 Manual restraint for jugular venipuncture.

with repeated venipunctures. A plastic over-the-needle catheter can be placed in the jugular vein and maintained for approximately 1–2 days. An anticoagulant such as heparin should be left in the catheter between sample collections. Long-term catheter placement often requires surgery to expose the vessel and experienced personnel with surgical skills to perform the procedure is essential (Joint Working Group on Refinement, 1993).

FIGURE 3.3 (See color insert.) Manual restraint for jugular venipuncture with rabbit in dorsal recumbency.

3.3.1.1.3 Lateral Saphenous and Cephalic Veins

The cephalic vein of the rabbit can be used when only a small blood sample is needed (Stein and Walshaw, 1996). The rabbit is positioned for cephalic venipuncture by placing it on its stomach and extending the forelimb forward. Pressure is maintained around the upper forelimb by an assistant. Since the cephalic vein is a common site for catheter placement in rabbits, the vessel should not be utilized for venipuncture if future catheter placement is indicated (Graham, 2006). The lateral saphenous vein courses medial-to-lateral across the lateral aspect of the distal tibia (Mader, 2004). In the rabbit, this vein is flat and easily collapsible (Benson and Paul-Murphy, 1999). To access the vein, it is best to restrain the animal on its side with an assistant compressing the vein just above the caudal portion of the hock (Mader, 2004). A small gauge needle (>25 G) and 1 mL syringe should be utilized for venipuncture of both the cephalic and lateral saphenous veins (Benson and Paul-Murphy, 1999). In addition, shaving the region may improve visualization.

3.3.1.1.4 Cardiocentesis

Cardiocentesis (often termed as cardiac puncture) can be utilized to obtain a large amount of blood from live animals and for terminal exsanguinations (Bivin, 1994). However, artificially high levels of enzymes produced by striated and cardiac muscles (e.g., lactate dehydrogenase, aspartate aminotransferase, creatine kinase, and troponin) may contaminate the sample secondary to the inherent invasiveness of cardiac puncture (McLaughlin and Fish, 1994). Owing to the need for full animal restraint and the invasiveness of the procedure, this procedure must only be performed on fully anesthetized animals and at most institutions may only be performed as a terminal procedure. Sterile technique must be employed if the animal is allowed to recover from the anesthetic episode. Both ventral and lateral approaches can be utilized to access the heart. For the ventral approach, the anesthetized rabbit is placed on its back and may be stabilized in a restraining board to facilitate proper positioning (Bivin, 1994). A 18 G, 1.5 inch needle is inserted in a cranio-dorsal direction at a 30° angle to the plane of the sternum and immediately caudal to the xyphoid process (Bivin, 1994). Alternatively, the lateral technique is performed by inserting

the needle through the lateral chest wall at the site of maximum pulse intensity (Adams, 2002). The needlepoint can lacerate tissues if it is moved inappropriately while in the chest. Therefore, the needle must always be introduced along a straight line and not be repositioned while in the chest cavity. If the needle is not in the proper location, it should be completely removed from the chest cavity and then redirected prior to reinsertion (Bivin, 1994). Although not often currently utilized, a miniperistaltic pump can be used to facilitate blood collection during a terminal cardiac puncture. Blood volumes up to 190 mL can be obtained (Adams, 2002; Stickrod et al., 1981).

Several animal health complications can occur following cardiocentesis. Improper needle placement or repositioning may cause lacerations of the lung, the cardiac muscle, or blood vessels. Lung lacerations may cause a lung to collapse or the chest to inappropriately fill with air. Laceration of the cardiac muscle may cause accumulation of blood within the pericardial sac, potentially resulting in cardiac tamponade and subsequent shock and death. Laceration of blood vessels will result in uncontrolled internal bleeding. Given the severe potential complications, the authors very highly recommend that cardiocentesis be performed only as a terminal procedure. If performed as a recovery procedure, it is essential that personnel be highly trained and proficient prior to attempting the procedure and the animal be closely monitored during and after the procedure (Bivin, 1994).

3.3.1.2 Methods of Restraint

The most appropriate restraint mechanism to be employed will vary based on the selected blood collection technique as well as the temperament of the rabbit. Generally, samples can be obtained from the ear vessels with manual restraint of the animal or use of a restraint box. Commonly, rabbits can be calmed by covering their eyes or placing them on their backs (Graham, 2006). In addition, rabbits can often be calmed and easily restrained by wrapping them firmly in a towel (Benson and Paul-Murphy, 1999). Restraint boxes (Figures 3.4 and 3.5) are useful for blood collection because they provide secure restraint and easy access to the animal's head. Regardless of the restraint technique implemented, it is vital that the rabbit's hindquarters be appropriately supported in order to prevent spinal fractures. Chemical restraint may be indicated to reduce stress and the chance of injury with fractious rabbits or rabbits not acclimated to frequent handling and restraint.

3.3.1.3 Collection Volume and Frequency

The circulating blood volume of a mature rabbit is estimated to be 44–70 mL/kg of lean body weight. Many factors must be considered when determining the maximum volume of blood that can be safely collected from an individual. For instance, the total blood volume per kg body weight is

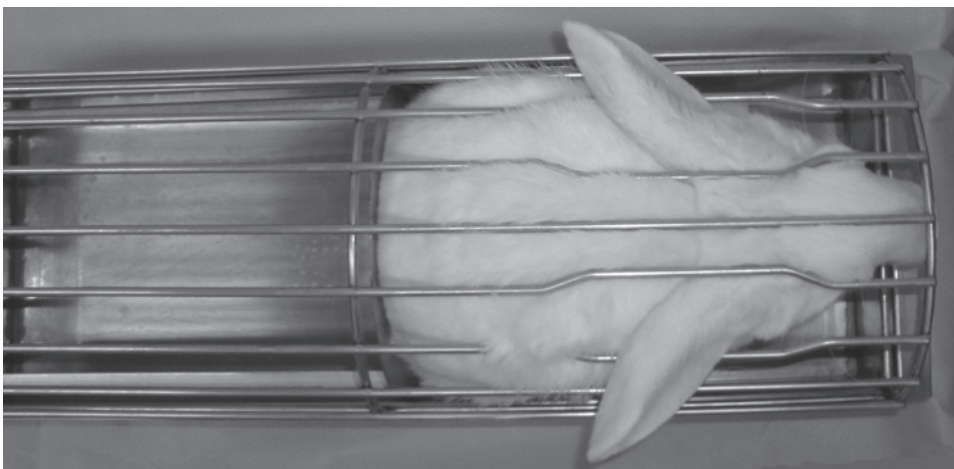

FIGURE 3.4 Top view of rabbit restrainer.

FIGURE 3.5 Side view of rabbit restrainer.

directly impacted by an animal's body composition and age with lower total blood volume for obese and older animals. The frequency and volume of prior blood collections must also be considered. In general, up to 10% of the circulating blood volume of a healthy adult rabbit can be withdrawn at one time point every 2–4 weeks without inducing clinical signs (Joint Working Group on Refinement, 1993; Diehl et al., 2001). Alternatively, up to 1.0% of the circulating blood volume can be collected every 24 hours if multiple, successive samples are required. Since animals may not respond uniformly to repeated blood collection, it is ideal to monitor an individual's complete blood count over time (Joint Working Group on Refinement, 1993; Benson and Paul-Murphy, 1999).

3.3.2 URINE COLLECTION

Standard techniques for rabbit urine collection include free catch, cystocentesis, and urinary catheter placement. If it is necessary to collect urine over an extended period of time, use of a commercially produced metabolism cage is recommended (Bivin, 1994). Use of metabolic cages is considered to be one of the least stressful methods of urine collection and allows for accurate quantification of urine production (Kurien et al., 2004). However, this technique does not eliminate urine contamination, which may adversely affect urinalysis parameters. Urine can be easily obtained in rabbits less than 10 days of age by manually stimulating urination. This is done by firmly restraining the young rabbit on its back with its head toward the wrist of the handler (Kurien et al., 2004). The other hand is used to stroke the abdomen beginning in the region of the stomach and ending in the region of the bladder (Kurien et al., 2004). Stroking should continue until urine is expelled. Excessive pressure or restraint should be avoided as they may have adverse consequences for the rabbit including internal injury or suffocation (Kurien et al., 2004).

Manual bladder expression can be performed on an awake animal; however, the procedure is more easily performed if the animal is anesthetized. Manual bladder expression is performed by palpating the abdomen, locating and isolating the bladder in the caudal ventral abdomen, and then applying firm steady pressure to the bladder. Urine is collected as it is expelled from the urethra. Excessive pressure can cause bladder rupture. The technique should be avoided if there is a possibility of urinary blockage (Bivin, 1994).

Cystocentesis is a reliable method to collect urine directly from the bladder and avoid contamination from the lower genito-urinary tract and environment (Kurien et al., 2004). Unless a rabbit is highly accustomed to restraint and manual manipulations, it is strongly recommended that the rabbit be anesthetized or sedated to facilitate the cystocentesis procedure. The rabbit is placed in dorsal recumbency and the bladder is palpated in the caudal ventral abdomen. The bladder is stabilized

between the thumb and forefinger and raised to the abdominal wall. The overlying skin is cleaned with an antiseptic solution and a 23–25 G needle (attached to a sterile syringe) is inserted through the skin directly into the bladder (Mader, 2004; Bivin, 1994).

An additional method of urine collection is the placement of a urinary catheter, which due to anatomical structure, is easier to accomplish in male rabbits (Bivin, 1994). It is recommended that the rabbit be sedated or anesthetized for this procedure (Graham, 2006). Sterile technique must be followed when performing all urinary catheterizations to avoid inducing a urinary tract infection. To catheterize a male, the rabbit is placed in a sitting position, the penis extruded by applying pressure to the surrounding tissues, and a well-lubricated, sterile 9 French catheter introduced into the urethra (Bivin, 1994). Females are placed on their stomach and the urethral opening is located on the floor of the vagina (Graham, 2006). The distance from the urethra to the neck of the bladder should be approximated and the catheter should not be inserted beyond this distance. The bladder can be evacuated by attaching a syringe to the catheter and gently aspirating urine. Care must be taken not to apply excessive suction through the catheter as this can cause damage to the urethra or bladder wall and contaminate the specimen with blood.

Ideally, urine should be examined and processed within 30 minutes of collection (Latimer et al., 2003). However, urine can be refrigerated up to 12 hours post-collection for culture and up to 48 hours for sediment evaluation (Loeb and Quimby, 1989).

3.4 PREANALYTICAL SOURCES OF VARIATION

When interpreting results obtained from blood chemistry and urinalysis, it is important to consider the wide source of potential variations resulting from the experimental procedures; environmental conditions; as well as the strain, breed, and/or individual animal. Sources of variation to be considered include the genetic variability within and between animal colonies, an animal's reproductive status, stress-induced metabolic changes from animal handling and transportation (both during and immediately prior to sample collection), administration of xenobiotics to the animals (e.g., anesthetics and experimental compounds), the vessel and anatomic location accessed for sample collection, the quality and source of testing reagents, and the equipment and analytic methods used to process and evaluate samples (McLaughlin and Fish, 1994; Lindena and Trautschold, 1986). Catheterization of vessels should be considered if multiple blood samples must be collected because it may decrease stress experienced by the animal and minimize tissue trauma. Meaningful and reliable results can only be obtained by recognizing and controlling these and other sources of variability.

3.4.1 SEX

Variations between sexes may be noted in selected biochemical parameters; however, these variations are typically slight and most frequently fall within normal reference ranges established for rabbits as a species. In the adult rabbit, sex variations are noted in cholesterol, typically with higher values in female rabbits (Mortensen and Frandsen, 1996; Kozma et al., 1974; Fox, 1989). Variation in cholesterol levels is typically not seen prior to adulthood (McLaughlin and Fish, 1994). Higher plasma albumin levels and lower alpha band protein levels may be seen in female than in male NZW rabbits (Kozma et al., 1967). When evaluating renal values, serum creatinine levels may be significantly higher in male than in female NZW rabbits (Aleman et al., 2000). Conversely, females tend to have a significantly higher serum blood urea nitrogen (BUN) level compared to that of males although strain variations may exist (Fox et al., 1970). In addition, total protein and phosphorous levels may be influenced by the sex of the rabbit (McLaughlin and Fish, 1994; Fox et al., 1970). Overall, it is important to consider the influence of sex on the variability of blood parameters when evaluating clinical pathologic findings. This is especially true when comparing values obtained from both sexes either within or between studies.

3.4.2 AGE

A rabbit's age and stage of growth can significantly affect clinical pathologic parameters. For some parameters, values may fluctuate over time in young animals until reaching more consistent values in adulthood. Hormonal influence, bone growth, diet, and general physiologic changes in a growing rabbit can influence biochemistry values. In general, alkaline phosphatase (ALP) is two to four times higher in young animals compared to that in adults (McLaughlin and Fish, 1994). At birth, serum cholesterol levels are similar to adult levels; however, as the rabbit matures, cholesterol levels rapidly rise then gradually decline back to adult levels. Additionally, cholesterol levels may increase with advancing age in adult rabbits (Fox, 1989). Typically, total serum protein levels increase with age in young rabbits. This may be attributed to the rise in globulin levels as the immune system is exposed to a greater number of antigens (McLaughlin and Fish, 1994; Fox, 1989; Laird and Fox, 1970). In NZW rabbits, it has been shown that triglyceride levels tend to decrease with age (Mortensen and Frandsen, 1996). Variations in glucose levels are observed between age groups. In young rabbits, glucose values can vary in relation to the timing of nursing (McLaughlin and Fish, 1994). In addition, young rabbits tend to have a lower fibrinogen level compared to that of older rabbits (Benson and Paul-Murphy, 1999). Because of these potential variations, it is important to consider the influence of age when analyzing blood chemistry values in rabbits.

Variations in hormone levels can also be seen in growing rabbits. One parameter to note is protein-bound iodine (PBI), which is an indicator of thyroid function and reflects blood levels of tri-iodothyronine (T_3) and tetraiodothyronine (T_4). PBI levels increase rapidly in growing rabbits for the first few days of life and then decrease until adult levels are reached (McLaughlin and Fish, 1994; Campbell, 2004; Laird and Fox, 1970).

Animal age may also influence the urinalysis. For instance, young healthy rabbits can have a small amount of albumin in their urine and trace proteinuria may be detectable in normal adults (Hoefer, 2000). Suckling rabbits should have clear urine in contrast to the yellow-, orange-, or red-tinged urine observed in adults (Harkness and Wagner, 1995).

3.4.3 STRAIN/BREED

Numerous breeds and strains of domestic rabbits have been developed, many with unique physical or physiological features. Parameters that may be affected by breed or strain include total protein, γ -globulins, blood glucose, BUN, inorganic phosphorus, cholesterol, ALP, and electrolyte concentrations (McLaughlin and Fish, 1994; Fox and Laird, 1970; Fox, 1989; Campbell, 2004).

Variations in hormone parameters can also be seen. Serum PBI (reflecting serum thyroid hormone levels), serum iron, total iron binding capacity, and growth hormone levels vary between inbred strains of rabbits. In general, the closer the genetic relationship of these strains, the less variation is seen. Furthermore, genetics can influence the plasma aldosterone concentration in rabbits. This makes it important to define the source, strain, age, and sex of rabbits in studies that relate to these endocrine functions (Schindler et al., 1974; Fox, 1974, 1989; Campbell, 2004).

Although there are several different rabbit breeds, the NZW and Dutch Belted rabbits are the most common breeds used in a research setting. Variations in biochemical parameters have been noted between these breeds. For instance, Dutch Belted rabbits have higher total protein and lower blood glucose levels than NZWs. In addition, Dutch Belted rabbits had a slightly higher sodium and chloride level compared to that of NZW rabbits (Kozma et al., 1974). Although these variations are subtle, they can play an important role when these parameters are specifically evaluated in a research setting.

3.4.3.1 WHHL Rabbits

As stated earlier in this chapter, WHHL rabbits have been developed as a model of human familial hypercholesterolemia. The single-gene mutation of the WHHL results in the absence of LDL

membrane receptors. This missing receptor characterizes the strain and leads to a significant increase of serum lipid levels. Because of these changes, WHHL rabbits are used as an animal model for the study of familial hypercholesterolemia, lipid metabolism, and cardiovascular atherosclerosis (Norido et al., 1993).

Because of the unique genetic makeup of this inbred strain, selected biochemical parameters of the WHHL can vary from outbred rabbits. WHHL rabbits have been purposely bred for hypercholesterolemia, thus homozygous WHHL rabbits have an elevated cholesterol and serum triglyceride level compared to that of other domesticated rabbit breeds (Norido et al., 1993). In contrast, heterozygous WHHL rabbits tend to have blood lipid levels similar to outbred, normolipidemic rabbits (Mortensen and Frandsen, 1996). Hyperlipidemia develops rapidly with age. For example, a 45-day-old WHHL rabbit has a greater than 10-fold higher lipid level than that of NZW rabbit controls. This elevation will gradually decrease as the rabbit ages, but still remains significantly elevated (Norido et al., 1993). Plasma cholesterol and triglyceride levels fluctuate as a WHHL rabbit ages and are influenced by the animal's sex. Females tend to have a higher cholesterol level than that of WHHL males, with the variation occurring earlier in heterozygous than homozygous rabbits. Furthermore, lipid levels can vary during the reproductive phases of the female. During gestation, heterozygous WHHL females typically show a decrease in the total cholesterol and LDL levels, reaching their lowest values during lactation, when values may be significantly lower than at mating. However, during gestation and lactation an increase in very low-density lipoprotein (VLDL) levels and a decrease in high-density lipoprotein (HDL) levels have been noted, which tend to reach their extremes during gestation (Mortensen and Frandsen, 1996). WHHL rabbits have been specifically bred for the changes that are seen physiologically, clinically, and in their biochemistry. When looking at specific changes in these selected parameters, knowing the normal changes to expect in WHHL rabbits is of paramount importance.

3.4.4 NUTRITIONAL STATUS

3.4.4.1 Diet Composition

A rabbit's cholesterol level can be easily manipulated by diet composition. Because of this, rabbit models are frequently used to study cholesterol metabolism. A rabbit fed a diet high in cholesterol will quickly develop a dose-dependent increase in serum cholesterol with a more pronounced effect noted in female rabbits. This rise in serum cholesterol can take several weeks to return to normal after discontinuing the high cholesterol diet (Borgman and Wardlaw, 1975; McLaughlin and Fish, 1994). Similarly, an increase in VLDL and LDL can be seen when feeding a diet high in cholesterol (Campbell, 2004). Serum cholesterol levels can also be influenced by dietary sucrose levels, the presence of fishmeal, the lysine-to-arginine ratio, the type of dietary protein, and the protein-fat interaction (McLaughlin and Fish, 1994; Sebesteny et al., 1985). Interestingly, it has been shown that a semi-synthetic diet high in casein and dextrose can elevate serum cholesterol, lipase, creatine kinase (CK), aspartate aminotransferase (AST), and alanine aminotransferase (ALT) in NZW rabbits. These values typically return to normal after discontinuing the diet (Hausner et al., 1995). Furthermore, female NZW rabbits may show an increase in plasma triglycerides if maintained completely on a liquid diet (Latour et al., 1998). It is important to note that serum cholesterol levels can be influenced by breed when a special cholesterol diet is fed (Adams et al., 1972).

Rabbits are unique in their metabolism and excretion of calcium. Serum calcium levels are not homeostatically regulated but vary directly with the dietary levels of calcium. Serum calcium can reach levels as high as 15 mg/dL due to dietary influences alone (Brewer, 2006; Hrapkiewicz et al., 2007; Suckow and Douglas, 1997). In contrast, due to rapid changes in parathyroid hormone and calcitonin levels, a four-time increase in dietary vitamin D has no effect on serum calcium levels. However, in some rabbits, a vitamin D deficiency can lead to a severe hypophosphatemia. Phosphorus levels can also be affected by the diet with a high phosphorous diet inducing elevated

serum phosphorus levels (McLaughlin and Fish, 1994). Although rare, nutritional secondary hyperparathyroidism can occur in the rabbit (Hoefler, 2000). Other factors that can be influenced by diet composition include protein and BUN levels. A high protein diet can cause an elevation in BUN values (Hoefler, 2000; Donnelly, 2003). Likewise, a decrease in dietary protein or protein restriction results in decreased BUN levels (McLaughlin and Fish, 1994).

As noted previously in this chapter, the concentrations of calcium present in the blood and urine is strongly influenced by dietary calcium levels. Diets high in calcium will directly influence select clinical chemistry values and may induce significant physiologic abnormalities. In addition, diets high in porphyrins, tannins, and other phenolic compounds often result in highly pigmented urine, ranging from a dark red to orange. This can be a normal variation; however, further diagnostics are required to differentiate pigment from blood (Hrapkiewicz et al., 2007; McLaughlin and Fish, 1994).

Small variations in diet composition can influence a variety of clinical pathology parameters. Therefore, the composition of all food sources (both routinely provided feed and food treats) must be determined and then evaluated for their potential influence on research outcomes.

3.4.4.2 Acute Fasting

There are numerous circumstances that may require a short period of fasting in a rabbit, the most common being preparation for sedation or anesthesia prior to a surgical procedure or sample collection. The necessity of fasting rabbits prior to anesthesia has been debated. Although rabbits cannot vomit, fasting prior to anesthesia or an oral procedure may be beneficial as it can reduce the amount of food remnants in the oral cavity and oropharynx. In addition, acute fasting can reduce the amount of digesta in the gastrointestinal tract. This decreases pressure on the diaphragm during anesthesia and may aid in visualization during a laparotomy or gastrointestinal surgery (Lipman et al., 2008). Plasma glucose levels are directly affected by the food consumption of an animal with the postprandial blood glucose concentration typically peaking 3 hours after a meal. These fluctuations in blood glucose levels in response to food consumption tend to decrease with age (Fox, 1989; Campbell, 2004). Administration of glucose to fasted rabbits may cause an increase in bilirubin excretion, thereby causing a decrease in plasma bilirubin and unconjugated liver bilirubin (McLaughlin and Fish, 1994). Furthermore, acute fasting can cause a decrease in urinary pH due to an induced catabolic state (Hoefler, 2000). Overall, a healthy adult rabbit can tolerate a short period of dietary restriction while still maintaining normal blood glucose levels. The effects of fasting may be more pronounced in geriatric, debilitated, or young rabbits or in all rabbits during prolonged periods of fasting.

3.4.4.3 Long-Term Dietary Restriction

Longer periods of caloric restriction can cause a greater variation in clinical pathology parameters and have a more detrimental effect on a rabbit's health. In the neonate, glycogen stores are depleted and blood glucose levels drop following 6 hours of food restriction. As the rabbit ages, the glycogen stores become sufficient to maintain blood glucose levels for longer periods of time (McLaughlin and Fish, 1994). Adult rabbits can maintain their serum glucose levels after 4 days of fasting. Continued maintenance of blood glucose values may be due to coprophagy or a residual bolus of food being continually digested in the intestinal tract during the fasting period (Fox, 1989; Kozma et al., 1974). Prolonged fasting or anorexia can be associated with abnormalities in gluconeogenesis and biliary metabolism and may result in a dramatic increase in plasma triglyceride levels (Harkness and Wagner, 1995). Bilirubinuria may develop secondary to starvation in the form of conjugated bilirubin (Hoefler, 2000; DiBartola, 1995). Rabbits often become polydipsic during periods of food deprivation. This can lead to loss of sodium due to urine excretion and a secondary hyponatremia (McLaughlin and Fish, 1994). Long-term caloric restriction can lead to progressive deterioration in the rabbit's general health and can be life threatening.

3.4.5 HOUSING ENVIRONMENT

Rabbits typically can adapt to gradual environmental changes and can be housed in a wide array of environmental climates and caging. Domesticated rabbits prefer a cool climate, with the recommended dry-bulb housing temperature ranging between 61 and 72 °F (16°C–22°C). When changing a rabbit's primary and secondary enclosure temperature, a gradual change is always recommended to allow the rabbit to adapt physiologically, behaviorally, and morphologically (Institute of Laboratory Animal Resources, 2011). Exposure to extreme cold can cause an increase in total protein levels and fibrinogen while causing a decrease in serum albumin levels (Harkness and Wagner, 1995; Fox, 1989; Sutherland et al., 1958).

Heat stress has been shown to increase AST, BUN, and creatinine levels. The associated hyperthermia can increase blood glucose levels, further increase BUN levels, and cause hyperproteinemia (McLaughlin and Fish, 1994; Campbell, 2004). In addition, heat stress can lead to a significant elevation in plasma corticosterone levels (Besch and Brigmon, 1991). Thus, it is important to avoid environmental temperature extremes in rabbits as it can not only affect blood parameters but also may affect their overall health status.

In addition to temperature changes, bedding, caging, and housing density may affect blood parameters. Chronic exposure to softwood bedding material (e.g., cedar wood) may increase liver enzymes (Johnston and Nevalainen, 2003). It has been shown that germ-free rabbits have a lower γ -globulin level compared to that of conventionally housed rabbits (Kozma et al., 1974). Maternal, prenatal γ -globulin levels in colostrum-deprived, newborn rabbits disappear rapidly. As the kit is exposed to environmental microflora the γ -globulin levels begin to increase. This process typically takes 4–5 weeks. Moreover, in the absence of environmental microflora, only a low γ -globulin level is reached (Wostmann, 1961). In addition to their caging and bedding, animal housing density has been shown to affect blood parameters in the rabbit. Specifically, group housed animals tend to have elevated plasma cortisol levels when compared to individually housed animals, with significant differences seen at day 8 (Fuentes and Newgren, 2008). Furthermore, a significant decrease in ALP levels has been noted in pair-housed compared to individually housed NZW rabbits (Nevalainen et al., 2007).

3.4.6 CIRCADIAN RHYTHM

The biology of the rabbit's circadian rhythm is complicated by many external factors. Rabbits in the wild are primarily nocturnal and demonstrate a pattern of leaving their burrows at dusk and returning in the early morning (Jilge and Hudson, 2001). Laboratory rabbits in well-controlled conditions also demonstrate a clear pattern of increased motor activity, food and water intake, urination, and hard feces excretion during the dark hours (Jilge and Hudson, 2001). Rabbits are sensitive to environmental influences and may demonstrate a diurnal rhythm when housed in captivity (Jilge and Hudson, 2001; Jilge, 1991). The rabbit's circadian rhythm has been shown to cause fluctuation in clinical chemistry and blood hormone parameters (Piccione et al., 2007; Lesault et al., 1991a, 1991b). Owing to the circadian variation associated with some parameters, it is important that the time samples collected for accurate comparison between time points are consistent. Serum cholesterol and BUN concentrations demonstrated circadian rhythm variation in rabbits kept on a 12-hour light/dark cycle and *ad libitum* feeding (Piccione et al., 2007). Furthermore, serum iron and PBI levels vary with the time of day (McLaughlin and Fish, 1994).

In addition to changes in blood chemistry parameters levels of blood hormones such as glucocorticoids, adrenocorticotrophic hormone (ACTH), follicle stimulating hormone (FSH), luteinizing hormone (LH), prolactin, and insulin vary with the time of day (Lassen, 2004; Lesault et al., 1991a, 1991b; Szeto et al., 2004; Cano et al., 2005). The glucocorticoid hormones, corticosterone, and cortisol peak during the afternoon and are lowest in the morning (Szeto et al., 2004). Although plasma glucose levels remain stable in fed and fasted rabbits during a 24-hour period, blood insulin levels

show diurnal variation (Lesault et al., 1991a, 1991b). Rabbit kits have a diurnal variation of FSH, LH, and prolactin. Prolactin has a similar circadian pattern in adult male and female rabbits with peak values in the afternoon and early morning (Cano et al., 2005).

3.4.7 ESTROUS CYCLE, PREGNANCY, OR LACTATION

It is important to consider an animal's reproductive state as it can have a direct effect on biochemical blood parameters. Ovulation is induced in rabbits, occurring on average 10–13 hours after natural mating. Several hormonal fluctuations occur near ovulation. Luteinizing hormone increases rapidly, peaks approximately 90 minutes postcoitus, and returns to basal levels within 6 hours. Follicle stimulating hormone levels spike at both 3.5 and 24 hours postcoitus. Plasma progesterone levels rise after coitus and ovulation (Orstead et al., 1988).

Information has been published on the hematologic and biochemical values of young, pregnant NZW (Tables 3.3 and 3.4), and DB rabbits (Table 3.4) as well as the expected rate of spontaneous fetal abnormalities in these breeds (Spence, 2003).

Several clinical chemistry parameters are significantly influenced over the approximately 31–32-day gestation period. Alkaline phosphatase, BUN, cholesterol, creatinine, and total protein decrease throughout gestation (Wells et al., 1999). Conversely, ALT and AST may progressively increase (Wells et al., 1999). Glucose is more variable and may begin a steady decrease around mid-gestation until parturition (Wells et al., 1999). In addition, an insulin-resistant state develops around day 24–30 of gestation (Hauguel et al., 1987). This condition is secondary to a decrease in insulin responsiveness in both glucose producing and utilizing tissues (Hauguel et al., 1987). Triglycerides may demonstrate a rise followed by a precipitous fall at the end of gestation (Wells et al., 1999). Total cholesterol is lower during gestation compared to values at mating (Mortensen and Frandsen, 1996). Calcium and phosphorus values also exhibit an overall decrease during pregnancy (Wells et al., 1999). Sodium, potassium, and chloride levels demonstrate a slight decrease, which is likely secondary to water retention (Hauguel et al., 1987).

Hormone levels are strongly influenced by the stage of gestation and the period of lactation. Estradiol 17 β and progesterone levels increase during pregnancy (Kriesten and Murawski, 1988). Serum cortisol elevates during the final days of pregnancy (Kriesten and Murawski, 1988).

During the period of lactation, total cholesterol and triglycerides are decreased compared to their levels at mating (Mortensen and Frandsen, 1996). Oxytocin and prolactin levels vary in the dam concurrent with the once daily nursing of her kits. Estradiol is present throughout the lactation period but at lower concentrations than during pregnancy (González-Mariscal et al., 2007). Progesterone is absent during the lactation period (González-Mariscal et al., 2007).

3.4.8 STRESS

Stress has been demonstrated to cause significant variations in physiologic parameters. A variety of environmental conditions may induce stress in rabbits including animal transport, handling, and restraint. Stress will generally result in an increased circulating level of glucocorticoid hormones (Toth and January, 1990). Increased levels of noise such as that produced by machinery (e.g., facility cage wash equipment) may produce physiologic changes in the rabbit such as elevations in blood glucose and corticosteroid levels (Hrapkiewicz et al., 2007; Fletcher, 1976). Social pairings can also stimulate an increase in glucocorticoid hormones that correlates with exhibition of defensive behaviors (Szeto et al., 2004). Conditioning animals to handling and new procedures prior to beginning a study can minimize stress and the associated physiologic consequences. Furthermore, allowing at least 48 hours for rabbits to acclimate to a new environment after shipping may decrease stress-related variables (Fowler, 1995). However, the appropriate length of the acclimation period must be determined for each anticipated stressor and evaluated parameter.

TABLE 3.3
Changes in Biochemical Parameter during Gestation in the New Zealand White Rabbit

Day of gestation	AST (IU/L)	ALT (IU/L)	ALP (IU/L)	BiIT (mg/L)	Chol (g/L)	Tg (g/L)	Glu (g/L)	Urea (g/L)	Creat (mg/L)	TP (g/L)	Ca (mg/L)	P (mg/L)	Na (mEq/L)	K (mEq/L)	Cl (mEq/L)
-1	Mean	46	247	2	0.69	0.53	1.23	0.55	12	61	163	51	142	4.6	107

3.4.9 ANESTHESIA

Anesthetic agents can directly affect blood parameters. It is therefore important to choose an appropriate anesthetic regimen based on the parameters of interest. As illustrated in Table 3.5, studies have demonstrated fluctuations in biochemistry parameters throughout anesthetic episodes and up to 24 hours postanesthesia in NZW rabbits. However, the values remained within the normal reference range for rabbits in most cases. The degree of fluctuation varies with the anesthetic agent.

TABLE 3.5
Influence of Commonly Utilized Anesthetic Agents on the Clinical Chemistry Values of NZW Rabbits

	Ketamine-Xylazine ^{a,b,c,d,e}		Ketamine-Diazepam ^{a,b,c,d,e}		Fentanyl-Droperidol ^{a,c,e}	Thiopentone ^{a,e,f}	Pentobarbitone ^{a,e,f}	Halothane ^{g,h}	Isoflurane ^{g,h}
ALT	↑↑	↑↑	↑↑	↑↑	NC	↑↑	NC	↑	NC

^f Gonzalez Gil et al. (2005).
^g Compared with baseline values.
^h Gil et al. (2007).

Based on this, to limit study variation, it is important that a consistent regimen of anesthesia be utilized for all animals on a study. In addition, the time at which samples are collected for a study should be standardized for a predetermined duration of anesthesia.

Similarly, blood hormone values can be influenced by anesthetic administration. For instance, serum ACTH, cortisol, corticosterone, and serotonin levels all vary with the administration of a variety of anesthetic agents (Gil et al., 2007; Illera et al., 2000).

3.4.10 SPECIMEN COLLECTION AND HANDLING ARTIFACTS

Proper collection and handling of blood samples is important to ensure accurate results. Prolonged exposure to erythrocytes can cause a spurious decrease in glucose (due to consumption by the red blood cell [RBC]) and an elevation of AST, lactate dehydrogenase (LDH), and inorganic phosphorus (Loeb, 1997). Erythrocytes should be promptly separated from serum or plasma to help minimize these effects. In addition, poor venipuncture technique or inappropriate equipment may result in hemolysis, which can cause artificial changes to blood parameters such as an increase in LDH, AST, creatine kinase, total protein, and potassium (Melillo, 2007). Moreover, lipemic samples can induce change in blood parameters and should be avoided.

While either serum or plasma can be used for the analysis of most blood chemistry parameters, variations may be observed in some chemistry values such as globulin and total protein (Loeb, 1997). For routine serum collection, the blood sample is typically allowed to clot for 30–45 minutes followed by centrifugation (Fox, 1989). Rabbit blood clots quickly at room temperature. When plasma collection is required, whole blood should be mixed with an anticoagulant during or immediately after collection in order to reduce clotting (Melillo, 2007) and then centrifuged immediately. The appropriate size collection tube must be chosen based on the anticipated sample volume in order to prevent significant dilution of the sample with the anticoagulant (Murray, 2000). However, the relative volume of anticoagulant required for the rabbit may vary due to their variable serum calcium levels (Bjoraker and Ketcham, 1981). Anticoagulants can interfere with some blood parameters. Heparin is often preferred over other anticoagulants, as it has a minimal effect on many biochemical parameters (Melillo, 2007).

3.5 COMMON PROCEDURES

Very few clinical pathology diagnostic procedures have been described in the rabbit. Some of these procedures may be invasive and only have experimental value. The value of these tests in a clinical setting is debatable. Even though the test can be performed, the results may be difficult to interpret in the context of disease.

3.5.1 LIVER FUNCTION EVALUATION

3.5.1.1 Sulfobromophthalein Clearance

Sulfobromophthalein (BSP) is a cholephilic dye that is cleared almost exclusively by the liver through bile; 75% of this is in the conjugated form (McLaughlin and Fish, 1994). Because of this, evaluation of BSP clearance can be utilized to measure liver function in the rabbit. Acquiring the BSP clearance rate requires injecting BSP intravenously and then measuring the plasma concentration at a given time point. At an intravenous dose of 60 mg/kg, the plasma clearance rate in the rabbit is approximately 1.8 mg/min and the BSP excretory capacity is 0.85 mg/min/kg, which is four times faster than in the dog (Klaassen and Plaa, 1967). BSP retention or a reduction in the normal clearance rate indicates a loss in liver function. It is important to note that biliary excretion is crucial to BSP clearance; thus if a biliary or posthepatic obstruction is present, the test is considered invalid.

Furthermore, BSP clearance rates can be falsely elevated if shock, dehydration, or competitive drugs are present (Jenkins, 2000).

3.5.1.2 Indocyanine Green Clearance

Measured clearance of the dye indocyanine green (ICG) from the blood can also be used to assess liver function (Plaa and Charbonneau, 2008; Klaassen and Plaa, 1969). Although similar in principle to BSP clearance testing, ICG clearance testing has some noted advantages (Plaa and Charbonneau, 2008; Cherrick et al., 1960). ICG is rapidly and completely bound to plasma protein and is excreted in bile in an unconjugated form. The dye does not undergo biotransformation prior to excretion. In addition, no extrahepatic methods of elimination have been identified. The ICG clearance assay is technically easy to perform. A known quantity of ICG is administered intravenously to the animal. At predetermined times plasma is collected from the animal and the concentration of ICG determined through spectrophotometric analysis. ICG is not irritating to subcutaneous tissues therefore tissues should not be damaged following inadvertent extravascular administration. Furthermore, as ICG administration does not stimulate a notable immune response, ICG can be administered multiple times to the same animal without apparent adverse effects.

In the rabbit as in other species (e.g., dog and rat), plasma clearance of ICG is exponential over at least a 32-minute period. Bile flow may be decreased with high ICG doses. The optimal dose of ICG for testing in the rabbit is 25–30 mg/kg. The half-life maximum clearance rates have been estimated over multiple doses (Klaassen and Plaa, 1969).

3.5.2 RENAL FUNCTION

3.5.2.1 Inulin Clearance

Rabbit renal function can be estimated by measuring the excretion pattern of exogenously administered inulin or endogenously produced creatinine. Inulin is an exogenous compound that is cleared from plasma freely and exclusively by glomerular filtration and is not secreted or metabolically altered by the renal tubules. Because of this, inulin clearance from plasma is considered the gold standard in determining the glomerular filtration rate (GFR) in the rabbit (Hofer, 2000).

The rabbit must be anesthetized for this procedure, thus the effect of the anesthetic agent on the GFR must be considered. Intravenous access is obtained and a method for collecting urine throughout the procedure is initiated. These can be achieved through use of an intravenous catheter and a urethral or ureter catheter, respectively. During this procedure, it is recommended that additional intravenous fluids be given to maintain hydration. Following anesthesia, inulin is administered intravenously first at an induction dose of 150 mg and then at a constant rate infusion of 3% inulin at 0.1 mL/min. A steady-state plasma inulin level is achieved after an hour of infusion. At this time, urine is collected for an hour and blood samples are collected at 0, 30, and 60 minutes. Inulin concentrations are determined in the urine and blood samples, and the rate of inulin clearance is calculated by the following equation (Homayoon et al., 1997; Wong et al., 1986):

$$\text{plasma clearance (mL/min)} = \frac{[\text{urine flow (mL/min)} \times \text{inulin concentration in urine}]}{\text{inulin concentration in plasma}}$$

The normal renal clearance rate of inulin in the rabbit is 7.0 (5.0–8.4) mL/min/kg (Kozma et al., 1974). With this information, information on the GFR can be extrapolated.

In the rabbit, glomerular clearance of endogenous creatinine is identical to glomerular clearance of inulin; thus, measuring the rate of plasma creatinine clearance by the kidney provides an

accurate estimate of the GFR (Buss and Bourdeau, 1984). Measuring creatinine clearance is less time consuming and invasive than measuring inulin clearance. Both endogenous and exogenous creatinine can be used. However, this test requires the quantitative collection of urine for 24 hours. The reported creatinine clearance rate in the rabbit is 3.2 (2.2–4.2) mL/min/kg (Hoefer, 2000). Although it is a technically easier procedure and is less invasive, it is not considered the gold standard for measuring GFR, thus inulin clearance is used more frequently in a research setting.

3.5.3 ADRENAL FUNCTION

3.5.3.1 ACTH Stimulation Assay

Although not frequently performed, the adrenocorticotropic hormone (ACTH) stimulation assay evaluates the adrenal gland–pituitary gland axis. In this test, ACTH is administered IM at a dose of 6 µg/kg and plasma corticosterone levels measured at time 0 and 30 minutes. In a rabbit with normal adrenal gland function, the baseline (T0) corticosterone level is 1.52 ± 0.52 µg/dL and raises to 19.9 ± 7.9 µg/dL 30 minutes after ACTH administration (Rosenthal, 2000). Although adrenal dysfunction is rare in the rabbit, this can be a valuable test experimentally and diagnostically if an adrenal-pituitary dysfunction is suspected.

3.6 CONCLUSION

The rabbit is a valuable and frequently utilized laboratory animal species. It has many characteristics that make it especially suited for use in research such as its ease of handling and sample collection, physical size, fecundity, and unique physiologic and biochemical characteristics. In addition, distinct breeds and strains of rabbits can be produced through natural breeding and genetic modification. However, with the rabbit, as with all species, both internal and external factors exist that can adversely affect test findings. Recognizing and controlling for these factors is of utmost importance in the conduct of research utilizing the rabbit.

TABLE 3.6
Clinical Chemistry Data for Rabbits

Analyte	Typical Value	Reference
Adrenocorticotropin hormone (ACTH)	25 pg/dL	Campbell (2004)
Alanine aminotransferase (ALT)	25–65 IU/L	Suckow et al. (2002)
Albumin	2.7–5.0 g/dL	Suckow et al. (2002)
Alkaline phosphatase (ALP)	10–86 IU/L	Suckow et al. (2002)
Amylase	200–500 IU/L	Suckow et al. (2002)
Aspartate aminotransferase (AST)	20–120 IU/L	Suckow et al. (2002)
Bicarbonate (Total CO ₂)	19–27 mEq/L	Mitruka and Rawnsley (1981)
Bilirubin (total)	0.2–0.5 mg/dL	Suckow et al. (2002)
Blood urea nitrogen (BUN)	5–25 mg/dL	Suckow et al. (2002)
Calcium	5.60–12.1 mg/dL	Suckow et al. (2002)
Chloride	92–120 mEq/L	Suckow et al. (2002)
Cholesterol	10–100 mg/dL	Suckow et al. (2002)
Corticosterone	1.54 µg/dL	Suckow et al. (2002)
Cortisol	2.6–3.8 µg/dL	Campbell (2004)
Creatine kinase (CK)	25–120 IU/L	Suckow et al. (2002)
Creatinine	0.5–2.6 mg/dL	Suckow et al. (2002)

4.1 USE OF DOGS IN BIOMEDICAL RESEARCH

Dogs have been used in research since the seventeenth century (Gay, 1984; Kohn, 1995). As dogs are popular companion animals, there is a wealth of information on congenital or acquired diseases in dogs (or particular breeds of dogs) from clinical practice, as well as information from research

studies. The dog is a common animal model for several reasons, including its relatively large body size, tractable behavior, and an organ system that is comparable to humans (Loeb, 1999; Tsai et al., 2007). Surgical models were developed in dogs for cardiopulmonary bypass, coronary artery bypass, aortic aneurysm repair, congenital heart defect correction, and heart valve replacement (Kohn, 1995). Canines are used for research in transplantation (kidney, lung, and heart), joint prostheses, gastrointestinal (GI) surgery, chronic pancreatitis, hemorrhagic pancreatitis, endocarditis (Kohn, 1995), aging, amyloidosis, radiation treatment, treatment of cardiogenic shock, and intervertebral disk disease (Gay, 1984). In pulmonary research, dogs have been used to study pulmonary inflammation, airway hyperresponsiveness (Chapman, 2008), chronic bronchitis, asthma, emphysema, and obstructive airway disease (Gay, 1984). In order to cover all the diseases for which dogs can serve as animal models, an entire book would be needed. In fact, a book of animal models, including the canine models, has already been written: *Spontaneous animal models of human disease* (Andrews et al., 1979).

In this chapter, we have limited our coverage to only some of the diseases for which the dog is an animal model. While Beagles are the standard research dog (Loeb, 1999), spontaneous diseases that arise in other breeds provide many models for similar, or even identical, diseases in humans. There are many cardiovascular diseases and conditions for which dogs serve as models. Recent interest in human familial dilated cardiomyopathy (DCM) has prompted a number of researchers to investigate the genetic basis of canine DCM (Moïse, 1999). It is clear that dogs, similar to humans, have a prolonged presymptomatic phase of the disease extending over years. Dog breeds affected by DCM include the large and giant breeds (Boxers, Great Dane, Weimaraners, Doberman Pinscher, German Shepherd, Irish Wolfhound, Newfoundland, Standard Poodle, and St. Bernard), and spaniels (Cockers and Springers) (Andrews et al., 1979; Moïse, 1999). Within these breeds, the disease is prevalent in certain family lines and therefore the disease has long been suspected to have a genetic basis. An autosomal dominant transmission has been reported in Irish Wolfhounds, Newfoundlands and Dobermans (Andrews et al., 1979; Dukes-McEwan et al., 2003; Moïse, 1999). Patent Ductus Arteriosus (PDA) with features either similar or identical to human disease occurs in Poodles (Kohn, 1995). Subvalvular aortic stenosis (SAS), defined as a congenital ridge or ring of fibrous tissue located below the aortic valve, is the second most common cardiovascular malformation in the dog. It is observed frequently in the Newfoundland, Golden Retriever, Rottweiler, German Shepherd, and other breeds (Buchanan, 1999). In dogs with SAS, the S-T segment, the flat, isoelectric section of the electrocardiogram (ECG) between the end of the S wave and the beginning of the T wave, appears to be depressed below the ECG baseline, presumably as a result of injury to the myocardium. The S-T segment depression (STD) is believed to be a clinically useful indicator of myocardial ischemia in both human patients with aortic stenosis and dogs with SAS. However, it is possible that the degree of myocardial ischemia that develops with SAS in the dog is less than that in the human patient because of the substantial cardiac collateral circulation observed in the dog (Davainis et al., 2004). Pulmonic stenosis (PS) in Beagles is phenotypically most similar to valvular PS in people (Andrews et al., 1979; Kohn, 1995). The pulmonary valve lesions of dogs affected with PS vary in severity and in various combinations. Lesions in some dogs are similar to what has been called pulmonary valve dysplasia in humans. Valvular PS, pulmonary valve dysplasia, and intermediate forms of these lesions can occur in members of the same litter of Beagles, indicating that these two types of pulmonary valve deformity are not separate etiologic or developmental entities in the Beagle (Patterson et al., 1981). A Tetralogy of Fallot model was developed in Keeshond dogs, and it closely resembles tetralogy of Fallot in man (Andrews et al., 1979; Kohn, 1995). Cardiac sudden death models exist within the German Shepherd, which mimics abnormal ventricular repolarization, and in the Boxer, which is similar to arrhythmogenic right ventricular dysplasia. Additional cardiac disease models include Sick Sinus Syndrome in Miniature Schnauzers, atrial standstill in English Springer Spaniels, and tricuspid valve dysplasia in Labrador Retrievers (Moïse, 1999).

Dogs also serve as models for hematologic disorders. Cyclic hematopoiesis (an intracellular protein trafficking defect) in the gray collie is a simple autosomal recessive trait with episodes of

neutropenia that mimics the human disease and has been employed for the development of novel therapeutics with translational implications (Dysko et al., 2002; Yanay et al., 2006). There is a canine leukocyte adhesion deficiency (CLAD) (Parker et al., 2010) similar to leukocyte adhesion deficiency in humans in which dogs and children develop life-threatening bacterial infections due to mutations in the leukocyte integrin CD18 (Hunter et al., 2011). Dogs with CLAD are used as gene therapy models for this disorder (Hunter et al., 2011). Three spontaneously occurring coagulation factor deficiencies that occur in dogs—Hemophilia A (Factor VIII deficiency), Hemophilia B (Factor IX deficiency), and FVII deficiency—are similar to their human counterparts both phenotypically and in their response to therapeutic intervention (Knudsen et al., 2010). Thus, these canine bleeding disorders provide excellent models of some of the most prevalent inherited human coagulopathies and are good predictors of efficacy of treatment in human hemophilia (Knudsen et al., 2010; Nichols et al., 2009). Dogs affected with Hemophilia A and Hemophilia B are now used in gene therapy trials for the treatment of these disorders (Tsai et al., 2007; Nichols et al., 2009). Hemophiliac dogs are useful for studying recombinant FVIIa (rFVIIa) treatment of hemophilia (in patients with factor inhibitors) because the interaction of human rFVIIa with canine tissue factor (TF) recapitulates that of the human proteins (Knudsen et al., 2010). Factor VII deficiency is described in the Alaskan Klee Kai, Alaskan Malamute, Beagle (research colony and companion dogs), among others (Kaae et al., 2007; Macpherson et al., 1999). The disease in Beagles is autosomal recessive, and although heterozygotes are asymptomatic carriers, dogs may have reduced clotting activity as demonstrated by thromboelastography (Fleischer et al., 2008; Callan et al., 2006). Canine Factor VII deficiency can be mild in presentation, or even asymptomatic, but can significantly impact research, as reduced FVII activity can alter hemostatic or cardiovascular endpoints (Callan et al., 2006). Thus, researchers using Beagles for studies that could be influenced by FVII deficiency should be aware of this defect and screen for both homo- and heterozygotes as needed. Von Willebrand's Disease (VWD) is the most prevalent inherited bleeding disorder in both dogs and humans, and dogs with VWD provide an excellent model for novel VWD therapeutics (Nichols et al., 2009; Kohn, 1995).

In musculoskeletal research, one of the well-developed canine models is that of Duchenne Muscular Dystrophy. Although this devastating muscle wasting disorder currently has no treatment, canine models are indispensable for studying disease pathogenesis and the development of therapies (Nakamura and Takeda, 2011). While numerous dog breeds with naturally occurring dystrophin-deficient muscular dystrophy have been characterized clinically, Golden retriever muscular dystrophy (GRMD) has been the most extensively examined and studied at the molecular level (Baltzer et al., 2007; Nakamura and Takeda, 2011). Duchenne Muscular Dystrophy in Golden Retrievers is caused by a mutation in the dystrophin gene resulting in the deficiency of dystrophin, a cytoskeletal protein that connects the muscle contractile machinery to the cell membrane (Dysko et al., 2002; Tsai et al., 2007; Sharp et al., 1992; Allen and Whitehead, 2011). The phenotype of GRMD closely mirrors that of human DMD with its severe skeletal and cardiac defects (Nakamura and Takeda, 2011). Gene therapy, exon-skipping therapy, and mesoangioblast stem cell treatments for DMD are being studied in GRMD with some preliminary success (Nakamura and Takeda, 2011; Sampaolesi et al., 2006).

Similar storage diseases affect dogs and humans. The autosomal recessive copper storage disease of Bedlington Terriers is presently the best characterized copper storage disease. The Bedlington defect in biliary copper excretion leads to hepatic copper accumulation and chronic progressive hepatitis and cirrhosis (Vonk et al., 2008). The clinical phenotype of copper storage disease in Bedlingtons is similar to Wilson disease in people, although neurologic defects observed in people are absent in the dogs (Vonk et al., 2008). The genetic mutation is different in people and dogs, with a deletion in the *COMMD1* gene affecting Bedlingtons and mutations in the *ATP7B* gene causing Wilson disease (Vonk et al., 2008). Both mutations, however, result in impaired intracellular copper transport (Vonk et al., 2008). Dogs have several lysosomal storage diseases, including Mucopolysaccharidosis (MPS) I & VII, glycogen storage Ia (glucose-6-phosphatase), globoid cell leukodystrophy (galactocerebrosidase), and G_{M1} gangliosidosis (β -D-galactosidase) (Ellinwood et al., 2004). Glycogen

storage disease Ia in the Maltese dog due to defective glucose-6-phosphatase activity is similar clinically, biochemically, and pathologically to the human disease. The canine model of lysosomal storage diseases is routinely used in retroviral and adenoviral vector gene therapy experiments. Dogs are also a model of cognitive aging (the role of mitochondria in oxidative stress and dementia) and Alzheimer's disease and are used to investigate novel cognitive-enhancing therapeutics for both age-associated memory disorder and dementia (Ikeda-Douglas et al., 2005; Studzinski et al., 2005).

Canine atopic dermatitis (AD) is remarkably similar to human AD and provides a tool for unraveling the pathogenesis of the human disease and investigating therapeutics (Marsella and Girolomoni, 2009). The dog is also an important animal model for periodontal disease because canine gingiva reacts similarly to human gingiva in response to dental plaque accumulation. The Beagle is the primary breed used in periodontal studies (Andrews et al., 1979).

There are several canine ophthalmic disease models, such as progressive retinal atrophy and collie eye anomaly (Parker et al., 2010). Glaucoma is inherited as a simple autosomal recessive trait in the Beagle (Andrews et al., 1979). Dogs are a model for cataracts, in part because the lens/globe ratio is closest to that in humans among the common lab animals, other than nonhuman primates (Andrews et al., 1979). Retinitis pigmentosa (RP, or progressive retinal degeneration) in humans is phenotypically and molecularly similar to progressive retinal atrophy (PRA) in dogs (Tsai et al., 2007). Identification of the causative genetic mutation of progressive rod-cone degeneration (PRCD), a late-onset, autosomal recessive form of PRA in dogs (a mutation in the *PRCD* gene) led to the discovery of the same mutation in a woman with RP whose genetic defect had been previously unknown (Tsai et al., 2007; Zangerl et al., 2006). Another canine hereditary retinal degeneration, the RPE65^{-/-} dog, suffers from early severe visual impairment that models the childhood blindness of Leber congenital amaurosis (LCA) (Acland et al., 2001). Gene therapy with adeno-associated virus carrying wild-type RPE65 restored vision to an affected dog and paved the way for successful gene therapy in humans with LCA (Tsai et al., 2007; Acland et al., 2001; Ashtari et al., 2011). The renal diseases for which the dog serves as an animal model include ectopic ureter urolithiasis, nephrogenic diabetes insipidus (NDI), and hereditary renal diseases including hereditary nephritis in various breeds, renal dysplasia in Lhaso Apsos and Shih Tzus, and Fanconi Syndrome in Basenjis (Andrews et al., 1979). Hereditary nephritis (HN) affects several dog breeds including Samoyeds (X-linked dominant), English Cocker Spaniel (autosomal recessive), mixed breed dogs (X-linked dominant), Bull Terriers, and Dalmatians (autosomal dominant) (Vaden, 2010). Canine HN, a defect in the basement membrane collagen type IV, serves as a model for human Alport syndrome (Vaden, 2010). HN in people and dogs is similar, except that the auditory and ophthalmologic abnormalities described in humans are uncommon in affected dogs (Tsai et al., 2007; Vaden, 2010). Currently, the only treatment for Alport syndrome is dialysis or renal transplant. However, the results of the preliminary studies of gene therapy that replaces the defective collagen gene in Samoyeds with HN are promising (Tsai et al., 2007; Harvey et al., 2003).

Many naturally occurring cancers in dogs share features with human cancers including histological appearance, tumor genetics, and biological behavior (Paoloni and Khana, 2008). Studying canine cancer can both identify genetic defects and environmental risk factors (in pet dogs) for similar human neoplasias (Paoloni and Khana, 2008). Furthermore, dogs provide a mechanism for evaluating novel cancer therapeutics, especially because survival studies in dogs can be much shorter in dogs than in people (Paoloni and Khana, 2008; Rowell et al., 2011). Some of the canine models for cancer include melanoma, gastric carcinoma, hemangiosarcoma, lymphoma, malignant histiocytosis (Shearin and Ostrander, 2010), and osteosarcoma (OSA; Rowell et al., 2011). Cytogenic aberrations are similar in dogs and people with non-Hodgkin lymphoma, and both have similar response profiles to different chemotherapeutic agents (Breen and Modiano, 2008; Paoloni and Khana, 2008). OSA in dogs recapitulates the human form of the cancer in terms of biologic behavior—such as propensity for pulmonary metastasis—and genetics, including frequent genome alterations affecting the oncogenes MYC and KIT in both species (Rowell et al., 2011). OSA, which is 20 times more prevalent in dogs than humans, makes canine OSA an incredibly useful tool

for studying cellular pathways of disease and investigating therapeutics (Rowell et al., 2011). The Scottish terrier has a 20-fold increased risk of developing transitional cell carcinoma, which makes this breed a good genetic and therapeutic model for human invasive urinary bladder cancer (Shearin and Ostrander, 2010; Mohammed et al., 2003).

Genetics is an area in which there is growing interest in using dogs as animal models. There are about 450 known hereditary diseases in dogs, with over half being clinically similar to corresponding human diseases (Tsai et al., 2007). The complete canine genome sequence is now available. The genetic analysis tools now available in canine research include dense linkage and radiation hybrid maps, oligo-based microarrays, and single nucleotide polymorphism (SNP) arrays (Tsai et al., 2007). Many cancer loci have been identified in dogs and, in general, humans are genetically more homologous with dogs than with mice (Shearin and Ostrander, 2010). Hematopoietic Stem Cell (HSC) gene therapy is expanding in dogs because they offer a few advantages over nonhuman primate models: larger litters, easier to handle, and easier collection of bone marrow biopsies (Trobridge and Kiem, 2010). In addition, unlike in the mouse, canine CD34⁺ bone marrow cells are similar to human *in vitro* and *in vivo* canine models of hematopoietic diseases, and leukocyte antigen-matched transplants are available (Trobridge and Kiem, 2010). As so many diseases are associated with particular breeds, the advances in genetic testing for breed genetic contribution is important. There is an SNP database searchable by chromosome and breed available online for dogs through the Broad Institute at MIT and the Inherited Diseases in Dogs (IDID) web site lists diseases of dog breeds that are likely either completely or partially transmitted genetically (Fleischer et al., 2008). In addition, the Canine Inherited Disorders Database (CIDDD) is searchable by organ system and by breed (Fleischer et al., 2008). Genetic testing is commercially available that can identify the breed of origin with 99% certainty (Fleischer et al., 2008).

4.2 UNIQUE PHYSIOLOGICAL CHARACTERISTICS OF DOG

The physiology of the dog is similar in most aspects to other animals used in research. Some physiologic features that are unique to the dog or unlike other research animals are highlighted in this section. Dogs are often used in pharmacologic studies. The overall dimensions of the canine gastrointestinal tract (GIT) are sufficiently similar to the human GIT to allow the dog to be used as a pre-clinical model for oral drugs that are intended for subsequent testing in humans (Dressman, 1986). The stomach of the dog has three types of glandular mucosa: cardiac mucosa (narrow zone around cardia), fundic glands (about 2/3 of mucosa of stomach), and pyloric mucosa (lining aboral portion). The size of each region is proportional to that of the human stomach in contrast to the pig (in which cardiac portion is large) or the rat (in which stratified nonglandular portion is large) (Kohn, 1995). However, several features of canine GI anatomy affect drug absorption and metabolism in dogs, and it must be considered when extrapolating canine bioavailability studies to humans. The pylorus of the stomach serves as a sieve, restricting the passage of materials on the basis of size so that only digestible-sized material enters the small intestine, the major site of absorption (Martinez and Papich, 2009). The canine stomach has a smaller pyloric sieve (>2–3 mm) than the human stomach (>7 mm), meaning that larger nondisintegrating dosage forms will stay in the canine stomach longer than the human stomach (Sagawa and Sutton 2006; Martinez and Papich, 2009). In dogs, the impact of food effects on oral drug bioavailability is dramatic, in that meals may result in delayed gastric emptying (Martinez and Papich, 2009). This effect is much more pronounced than that observed in humans (Martinez and Papich, 2009). In several drug studies, administering drugs to fed dogs compared to fasted dogs caused a delay in tablet emptying from the stomach, leading to delayed drug absorption and altered pharmacokinetics (Martinez and Papich, 2009). A much smaller food effect was observed in parallel studies in humans (Martinez and Papich, 2009). The small intestine of the dog is shorter than the human, which may result in lower absorptive capacity, although the fact that intestinal permeability is greater in the dog than the human helps compensate for the shorter small intestine (Sagawa and Sutton 2006). The body size variation among breeds results in differences in

pyloric sieving (larger dogs have larger sieves) and potentially intestinal permeability, which in turn result in breed variability in pharmacokinetic studies (Fleischer et al., 2008; Martinez and Papich, 2009; Randell et al., 2001). Sighthounds have lower volume of distribution of lipophilic compounds (like propofol), a result of their lower percentage body fat as compared with other breeds (Fleischer et al., 2008). The canine heart has extramural coronary blood vessels that differ from humans by having an increased frequency of interarterial anastomoses (Kohn, 1995). The main blood supply to the sinus node is from the right coronary artery, with a large supply of anastomoses, making experimental-induced ischemia via ligation difficult (Kohn, 1995).

There are over 12 canine blood groups, and dogs can currently be classified as positive or negative for the following blood types: dog erythrocyte antigen (DEA) 1.1, 1.2, 3, 4, 5, 7, 8, and Dal (Kohn, 1995; Hohenhaus, 2004; Blais et al., 2007; Kessler et al., 2010). Although dogs that have never been transfused do have naturally occurring alloantibodies against some blood group antigens, unlike in other species these antibodies appear to have limited clinical significance (Hohenhaus, 2004). Furthermore, unlike humans, pregnancy has not been shown to induce alloantibodies in bitches (Blais et al., 2009). The most immunogenic of the DEA is 1.1 and transfusion of DEA 1.1 positive erythrocytes into a previously sensitized DEA 1.1 negative recipient can result in a severe hemolytic transfusion reaction (Hohenhaus, 2004). A canine universal donor is often defined as a dog negative for DEA 1.1, 1.2, 3, 5, and 7, and positive for DEA 4. Given that this definition is somewhat restrictive, ideally a donor dog should at least be DEA 1.1 negative (Hohenhaus, 2004).

In contrast to human, rat, or nonhuman primate erythrocytes, canine erythrocytes have high sodium to potassium ratio, meaning that hemolysis does not affect potassium levels as much as in other species (Evans, 2009). The major anaphylactic shock organ in the dog is the liver, instead of the lung, which is the shock organ in other animals and humans. The first signs of anaphylaxis in the dog are GI such as diarrhea and vomiting, due to hepatic vein congestion and portal hypertension (Waddell, 2010). GI signs may then progress to respiratory distress, and collapse secondary to hypovolemic shock (Waddell, 2010). Dogs with anaphylaxis may also demonstrate generalized wheals, angioedema, and pruritis. In severe cases, angioedema of the larynx and pharynx can result in respiratory distress secondary to upper airway obstruction (Waddell, 2010). Dogs have some unique features that can affect their response in toxicity studies. Dogs lack N-acetyltransferase, which detoxifies sulfonamides and predisposes them to sulfonamide hypersensitivity (Fleischer et al., 2008). Different breeds have different levels of thiopurine S-methyltransferase (TMPT) activity, an enzyme that plays an important role in metabolism of thiopurine drugs. Dogs with lower TMPT activity are predisposed to azothioprine toxicity. There are breed differences in inhibition of platelet aggregation in response to arachidonic acid, which must be considered when using the dog for coagulation or cardiovascular studies (Fleischer et al., 2008). Different cytochrome P450 (CYP) oxidative enzyme variations exist among breeds of dogs, so breed variation should be considered when studying pharmacokinetics of drugs that are metabolized by P450 (Fleischer et al., 2008). The Collie MDR-1 mutation results in increased toxicity after administration of compounds with *p*-glycoprotein substrates (for example, ivermectin) (Fleischer et al., 2008). The predisposition to sulfonamide polyarthropathy in large breeds may be the result of a limited capacity to detoxify hydroxylamine metabolites of sulfonamides (Fleischer et al., 2008).

The dog has some unique reproductive features. Unlike many other species, the dog is nonseasonal and monoestrous, ovulating only once or twice a year at a 5–12 month interval (Songsasen and Wildt, 2007). Estrous cycle intervals increase with age from 7.5 months to 12–15 months near the end of life (Cunningham, 1997). Canine proestrus does not begin within 48 hours of the end of luteal phase, the proestrual bitch is under the influence of estrogen and this is the dominant hormone during this stage of the cycle. Estrogen is responsible for most of the clinical signs observed in bitches during proestrus, because this hormone stimulates growth and activity of the glandular epithelium of the uterus and promotes swelling and increased vascularity of the lining of the uterus (mucosa). Serum progesterone concentrations during proestrus are at basal levels (<0.5 ng/mL) and then start a gradual rise at the end of proestrus. Preovulatory follicular luteinization (transformation

of the estrogen secreting follicle to a progesterone secreting structure), unique to the canine, is responsible for this increase in progesterone concentration (Wildt et al., 1979). The long lifespan of semen means fertilization can occur in the oviduct as late as eight days after coitus, but oocytes are usually viable only 12–24 hours once ovulated (Dysko et al., 2002).

Dogs also have some endocrine idiosyncrasies. In dogs, only approximately 15% of the triiodothyronine (T_3) and thyroxine (T_4) is reabsorbed from the intestinal tract (vs. 79%–100% in primates) so dogs have a higher thyroxine production rate and replacement requirement (Engelking, 2002). Thyroxine (T_4) values in several animals, including the dog, are lower than in humans (Evans, 2009) because their thyroid transport proteins have a comparatively lower affinity for T_4 (Loeb, 1999). Dogs with diabetes mellitus in the majority of cases are hypoinsulinemic with mild to severe ketosis and are similar to humans with type 1 diabetes (Engelking, 2002). In a minority of cases, diabetic dogs are hyperinsulinemic, have elevated growth hormone, and are similar to humans with type 2 diabetes (Engelking, 2002).

Isoenzymes of alkaline phosphatase (ALP) from intestine and kidney have a short half-life and do not contribute substantially to total ALP in serum (Loeb, 1999). Serum ALP is increased in the dog by biliary stasis, elevated glucocorticoids (GCs; exogenous or endogenous), or osteoblastic hyperactivity, each of which induces a specific isoenzyme (Loeb, 1999). The ability of glucocorticoids to induce ALP activity, termed “steroid-induced ALP,” is a unique canine feature (Evans, 2009). Via the biliary or GC mechanism, serum activity of ALP may be increased by 10–60 times that of the upper reference value, in contrast to less-pronounced increases due to osteoblastic hyperactivity (Loeb, 1999).

In dogs, stress will only cause a mild increase in glucose, compared to the dramatic increases it can induce in cats and nonhuman primates (Loeb, 1999). The estrus cycle in the bitch does not cause a change in baseline blood glucose or insulin values, but the cycle does impair glucose tolerance during estrus (Loeb, 1999). Cortisol is the major glucocorticoid in dogs, as in humans and nonhuman primates (vs. corticosterone in rodents) (Evans, 2009). C-reactive protein is the primary acute phase protein in the dog (also in nonhuman primates and humans) (Evans, 2009).

Canines can excrete bilirubin easily via the kidney (Loeb, 1999). Accordingly, conjugated bilirubin may be found in the urine before bilirubinemia is detected (Evans, 2009). Increases of serum urea nitrogen occur rather readily in canines. Decreased urine osmolality and specific gravity are more highly sensitive determinants of renal capacity than blood urea nitrogen (BUN) or creatinine (Loeb, 1999). Other (nonrenal) factors can increase BUN or creatinine. There can be increases in plasma urea and creatinine postprandially, which vary with diet (Evans, 2009). Plasma creatinine measurement can be falsely elevated by up to 45% by endogenous noncreatinine chromogens (such as bilirubin and ketones) (Evans, 2009). There are four isoenzymes of amylase identified in the dog. Isoenzyme 3 is of pancreatic origin (>50%), whereas isoenzyme 4 is found in all tissues. Pancreatic serum amylase is removed by a mechanism other than a renal one, or it is inactivated by the kidney, such that the high serum amylase is not followed by the high amylase levels in urine, in contrast to what occurs in humans (Loeb, 1999). Dexamethasone can have greater effect in the altering levels of serum lipase than that of serum amylase (Evans, 2009). There are sex differences in the values of *N*-acetyl- β -glucosaminidase, in that males have higher values (which are also true in rats) (Evans, 2009).

Total cholesterol and triglycerides do not vary across breeds, but high-density lipoprotein (HDL) and low-density lipoprotein (LDL) levels are breed-dependent (Fleischer et al., 2008) and primary hyperlipoproteinemias have been reported in several breeds of dogs including the Beagle (Elliott and Schenck, 2010). Serum cholesterol in the dog is primarily HDL cholesterol, in contrast to humans (Evans, 2009). Intact female dogs have higher HDL cholesterol than do intact male dogs (Johnson, 2005; Loeb, 1999). Cholesterol ester transfer protein (CETP) activity is low in the dog (Evans, 2009). This means that dogs are unable to perform cholesterol shuttling and therefore do not form cholesterol ester-rich LDL. In humans, cholesterol-ester rich LDL can be removed from circulation by macrophages lining arteries. Ingestion of oxidized LDL and the foam cell formation of macrophages are the hallmark of atherosclerosis development. As dogs lack CETP activity, they are resistant to the development of atherosclerosis, and are therefore a poor model for human cholesterol disorders (Johnson, 2005). Furthermore, the

canine lack of CEPT leads to the formation of a unique HDL molecule that is cholesterol-ester rich called HDL₁. This HDL isoform is absent in humans (Johnson, 2005). The cholesterol-ester rich HDL can be removed from the circulation by endocytosis in the liver (Johnson, 2005).

4.3 METHODOLOGY FOR SAMPLE COLLECTION

4.3.1 BLOOD COLLECTION (FOR SERUM OR PLASMA)

Inconsistent data can result from factors such as variability in sample collection and handling methods (McGuill and Rowan, 1989), the stress levels of the dogs, or the signalment of the dogs used. To minimize these variables, it is important that dogs should be properly acclimated to their environment and to restraint during routine procedures. Environmental enrichment programs should be in place and a reward-based training program can be used to encourage dogs to readily accept common procedures such as blood draws; therefore, anesthesia or sedation is rarely necessary for minor procedures. For the safety of both the animals and the handlers, it is important that dogs with good dispositions be selected. Handlers must also demonstrate patience and should be skilled at both handling and sample collection techniques.

The preferred collection sites in the dog are the jugular, cephalic, and lateral saphenous veins (Morton et al., 1993). Large volume samples are best drawn from the jugular vein, as its thicker wall is less likely to collapse under the pressure asserted by a large syringe. Smaller samples (<5 cc) can be easily drawn from the cephalic or saphenous veins, but care must be taken to use a small amount of pressure. This can be accomplished by asserting a slow, steady pull on the syringe plunger and by utilizing only small 1, 3, or 5 cc syringes. Blood withdrawn from the saphenous vein provides the benefit of allowing the collector to be positioned away from the dog's mouth and face; however, this vein will typically "roll" more than the cephalic. It is important to prepare all necessary sample collection items and have them readily accessible prior to bringing the dog to the procedure area. Select a needle and syringe size appropriate for the size of the dog and the quantity of blood to be collected. An 18–20-G, 1 inch needle will yield the best results and can be used in larger dogs; however, a 22-G needle may be necessary for smaller dogs but can result in hemolysis (Weiser, 2004). The area surrounding the venipuncture site can be clipped to better visualize the vessel and allow for more thorough cleaning of the region.

It is very important to the safety of both the dogs and staff that dogs be firmly yet gently restrained during the procedures. When dogs are placed on an elevated structure such as a table, a handler should have a hand on the dog at all times. To obtain blood from the right jugular vein, with the dog either sitting or in sternal recumbency, the holder stands on the left side of the dog and cradles his or her right arm over and around the thorax of the dog with his or her fingertips at the point of the right shoulder. The left hand of the holder cradles the chin of the dog while gently directing the nose up and slightly to the left. The phlebotomist occludes the vessel with the nondominant thumb by applying gentle pressure to the ventral region of the jugular furrow to the right of the trachea (Taylor, 2010). This will cause the vessel to become distended with blood and stand out from the surrounding tissues. The holder can be asked to redirect the head of the dog to allow better visualization and distention of the vein. However, in some heavier dogs, the vein may not become visually apparent and hence must be palpated. Once the vein is identified, 70% alcohol is applied to the area. The needle is directed through the skin and then into the vessel with the needle bevel facing the phlebotomist and the syringe held at approximately 20–30° from the neck of the dog. Care must be taken to neither puncture through the other side of the vessel nor pierce surrounding structures such as the recurrent laryngeal nerve or the trachea. Once blood is visualized in the hub of the needle, a gentle force can be applied to fill the syringe. Too much pressure may result in the collapse of the vein and hemolysis of the sample. Once the syringe has been filled, the pressure is released, both by releasing the syringe plunger and by removing the finger from occluding the vessel. The needle is removed and digital pressure is maintained over the venipuncture site for approximately 60 seconds to minimize the hematoma formation.

The reverse can be done to collect from the left jugular vein. Vacutainer-type needles, which seat directly into the vacutainer tubes, can also be used as an alternative to a syringe.

Collection from the cephalic vein can be accomplished similarly with the holder restraining the head of the dog from behind with the upper arm and the trunk region against the back of the dog for preventing backward movement. The other hand holds off the vessel by placing the proximal medial portion of the thumb over the vessel, and rolling the vessel laterally and proximally to straighten the vessel. Downward pressure is then applied to occlude the vessel. The phlebotomist holds the carpus and/or metacarpus in the palm of the nondominant hand with the thumb placed lateral to the vein to stabilize while blood is collected as previously described.

To restrain a dog for phlebotomy of the lateral saphenous vein, the dog is placed in lateral recumbency. The forearm of the arm nearest the head gently keeps the head of the dog from rising and the hands are used to secure the forelimbs. The other arm applies gentle pressure on the upside of the lateral hip while the hand rolls the vessel while stabilizing the upside leg from which the blood will be drawn.

When drawing blood from peripheral veins such as the cephalic and saphenous, the needle may mistakenly be placed completely through the vessel resulting in what is termed a “blown” vein. For this reason, the attempts for collection should begin distally with further attempts being moved proximally. Repeat attempts should be very limited. If damage has occurred to the vessel, a small pressure bandage is placed on the site for a short period of time to minimize hematoma formation.

If multiple blood draws will be necessary over a short period of time, cannulation can be considered. Indwelling long catheters provide the advantage of providing a repeated sampling port without necessitating repeated venipuncture. However, their initial placement requires sedation or anesthesia, depending on the temperament of the dog. A long catheter (18–20 gauge) can be placed in a central vein (jugular or lateral saphenous fed to the femoral vein). The area where the catheter is to be placed is shaved and sterilely prepared. The authors often use a local subcutaneous lidocaine injection to numb the area of catheter placement. A stab incision is made with a blade, and the catheter is then placed in the vein. This catheter is sutured in place and wrapped, with wooden splints (popsicle sticks) on either side of the leg to help stabilize the bandage. Dogs usually tolerate these catheters well, although placing an Elizabethan collar is recommended as a precaution. When sampling blood, it is recommended that a “dump” sample the volume of the catheter (usually 3–6 mL) be taken in a syringe prior to obtaining your sample. The “dump” sample can be collected in a heparinized syringe so that it can be returned to the dog after the sample is taken. The catheter should be flushed with saline after each sample is taken, and flushed every 6 hours to retain patency. An indwelling long catheter can be kept in place for up to 3 days.

Sample volume limitations are typically set by each research institution’s animal care and use committee. Many such standards are based upon the 1993 recommendation of the Joint Working Group on Refinement that a single collection is limited to a quantity equal or less than 10% of the animal’s circulating blood volume, which can then be repeated in 3–4 weeks (Morton et al., 1993). The circulating blood volume of a mature, healthy dog ranges from 79 to 90 mL/kg (Morton et al., 1993) but can be lower in obese dogs and may vary according to the breed. Other institutions have set the recommendation of 1% of total body weight every 3 weeks (McGuill and Rowan, 1989). The physiologic responses to the blood loss can be offset by the administration of intravenous (IV) fluids to compensate for the volume lost. Advances in technology have led to the ability to analyze smaller quantities than were previously necessary. Whittemore and Flatland compared the chemistry and CBC blood values obtained from healthy dogs using both standard and microsample blood collection tubes and found no statistically significant difference between the two (Whittemore and Flatland, 2010).

An arterial sample can be collected from either the femoral or the dorsal pedal arteries. The sample can be collected with a 22- or 25-gauge needle attached to a heparinized 3 cc syringe or an arterial blood gas syringe containing a lyophilized heparin tablet (Taylor, 2010). Firm pressure should be placed over the collection site for at least three minutes to mitigate hematoma formation (Taylor, 2010).

4.3.2 URINE COLLECTION

Urine samples are also commonly collected to evaluate parameters such as renal clearance of a compound, glomerular filtration rate (GFR), or the health status of the urinary tract. This can be accomplished via free-catch, catheterization, or cystocentesis. Although a free catch sample is not suitable for culture, it should be obtained mid-stream as the initial void may contain a higher number of contaminants from the vulvar and preputial skin, which can interfere with protein values and sediment analysis (Reine and Langston, 2005). Free-catch samples are relatively easy to obtain in housebroken dogs, but timing can be more challenging in a kennel setting.

Urinary catheterization of the dog is achieved by threading an appropriately sized sterile red rubber catheter along the urethra. While some male dogs may allow the procedure without sedation, some males and most females will require sedation. The male dog is positioned in lateral recumbency and the penis extruded from the prepuce, and the tip gently wiped with dilute chlorhexidine solution (Reine and Langston, 2005). The catheter tip is dipped in a sterile lubricant, carefully and gently inserted into the external urethral orifice, and then advanced just into the bladder. The wrapped catheter can be held against the dog prior to unwrapping for estimating the point on the catheter that will be visible once the tip has entered the bladder. The first 5–6 mL should be discarded for analyzing the remaining sample (Taylor, 2010).

The female dog is typically sedated and placed sternally with the hindlimbs hanging off the back end of the procedure table with the pelvis elevated by sandbags placed under the inguinal region. The external genitalia is cleansed with dilute chlorhexidine scrub and a sterilized speculum is placed to allow visualization of the tubercle residing on the ventral floor of the vaginal vault. The urethral orifice lies centrally on the dorsal aspect of this tubercle. The catheter tip is lubricated with a sterile lubricant and gently directed under the index finger of a sterile gloved hand into the orifice into the bladder lumen. Once the bladder has been reached, urine should stream from the free end of the catheter. As with the male, the first few milliliters of urine should be discarded (Reine and Langston, 2005). In both cases, the free end of the catheter should be clamped off with a hemostat prior to withdrawal from the urethra. With experience and knowledge of the structures, catheters may be placed using a blind digital approach.

Should there be a need for continuous sampling or quantitation of output, an indwelling catheter can be secured in place. The strong disadvantage to the use of this method, however, is the high risk for ascending infection. Two recent studies have reported that the respective overall rates of nosocomial bacteriuria in a small animal hospital setting are 10.3% and 9.8% (Smarick et al., 2004; Sullivan et al., 2010). The risk of infection can best be mitigated by establishing protocols to ensure strict sterile technique at the point of insertion, proper care of the catheter system while in use, and the selection of a catheter made of a material resistant to the growth of a biofilm layer. A foley catheter impregnated with antimicrobials is a good selection, as the balloon anchors the catheter into the bladder and the material may decrease the risk of ascending infection. The foley catheter is inserted as described previously such that the balloon is inside the bladder. The location of the catheter can be checked via an abdominal radiograph if necessary. The balloon is then filled with the amount of sterile water or saline indicated on the package insert, and the catheter is gently pulled caudally to settle the balloon into the trigone of the bladder. The sterile attachment of a collection bag to the catheter constitutes a “closed collection system.”

Standardized collection bags offer the advantage of an antireflux chamber and ports to allow removal of urine from the system without opening the system (Bard Medical, Gainesville, VA). Alternatively, some small animal hospitals adapt used fluid bags (which have never contained dextrose) as reservoirs. The disadvantage of using this system is the need to open the system for urine drainage and the lack of the antireflux chamber; yet in one study, no difference was observed in the rate of nosocomial infections among dogs in which either system was used (Sullivan et al., 2010).

With either system, the bag should be placed at a level lower than the bladder to ensure outward flow. To facilitate this, an optional IV drip set can be added to extend the length of the system. The catheter can be secured to the prepuce or the perivaginal skin by the placement of two sutures through a tape “butterfly,” created by sticking an approximately 6–8 cm section of tape across the catheter near the skin region to be sutured. Then, pressing the sticky sides of the tape together such that the catheter is secured in the middle with a “wing” on either side. The proximal tubing can also be taped to the hindlimb for added security.

Indwelling catheters should remain in the dog for the shortest amount of time necessary to complete the study as the incidence of infection increases with time. Proper catheter maintenance entails frequently checking patency of lines and security of connection points as well as cleansing of the lines and vaginal or preputial orifices with a dilute chlorhexidine solution. Sterile technique, including the use of sterile gloves, should always be followed any time the catheter is handled.

Urinary samples can be collected via cystocentesis when a sterile sample is necessary for culture. However, the use of this collection method introduces the risk of damaging the bladder wall or worse yet, puncturing an abdominal structure other than the bladder itself. The use of an ultrasound to guide collection may decrease the risk of damage and facilitate recognition of the bladder. Regardless, it is absolutely imperative that the dog is still while the needle is within the abdomen. With the dog in lateral recumbency, the bladder is palpated and held in the nondominant hand. Excessive pressure on the bladder either during or immediately following collection can cause urine leakage into the abdomen, and therefore it should be avoided. Alcohol is applied to the skin overlying the bladder and a 22-g 1½ inch needle attached to a 6 cc syringe placed through the lateral abdominal wall and into the bladder. The needle is directed slightly caudally so the needle is maintained in the lumen of the bladder as the bladder wall retracts (Reine and Langston, 2005). Care is taken to avoid piercing the finger of the nondominant hand. The syringe plunger is only pulled back once the needle tip is in the bladder lumen to avoid aspirating tissue into the sample. If the bladder is not hit, redirection of the needle intra-abdominally is contraindicated as this can cause damage to surrounding structures. Instead, a second attempt should be made using a clean needle. Keep in mind that if the bladder is relatively empty, a cystocentesis may not be possible until the bladder fills sufficiently. Pressure against the plunger should also be released prior to removal of the needle from the bladder once the sample has been collected.

Alternatively, a ventral approach to the bladder may be easier in overweight dogs or others in which the bladder is difficult to palpate. As in the lateral approach, the dog is held very still, but in dorsal recumbency. The bladder is not palpated, but rather a blind stick is utilized in this approach, subsequently increasing the potential risk of damage to other organs. On the female, the needle is inserted along the midline of the caudal abdomen about midway between the umbilicus and the brim of the pelvis. This site typically corresponds to the lowest point of the abdomen in dorsal recumbency; thus, the optimal site (on the female, but not the male) can often be identified by dousing the caudal abdomen with a 70% alcohol solution and identifying the area the solution settles into as the lowest point. The needle is inserted perpendicular to the skin at the point where the liquid pools. On male dogs, the collection site is accessed by gently retracting the prepuce and penis or by approaching lateral to the penis.

4.4 PREANALYTICAL SOURCES OF VARIATION

4.4.1 ANIMAL SOURCE AND SELECTION

The number of dogs used in research has been on a downward trend over the last 20 years. The United States and Japan are the main world users of dogs in research and testing (ILAR, 1994). The United States Department of Agriculture (USDA) collects annual statistics on the use of some laboratory animals (Prescott et al., 2004). Dogs used in research are generally segregated into two

classes: purpose-bred (Class A) and random source (Class B). Facilities can purchase dogs through USDA designated Class A or B licensed dealers, respectively. Class A dealers breed and raise dogs on their own premises in closed or stable colonies and are the major source of dogs used in biomedical research in the United States. Class B dealers are involved in the purchase of dogs from other individuals (including animals from municipal pounds) and subsequent resale of animals to research facilities (USDA, 1985).

Dogs from Class A dealers have known genetic backgrounds and medical histories (e.g., vaccination status, exposure to infectious diseases) and usually have received veterinary care throughout their stay at the facility. Random-source dogs are obtained from any source that did not breed and raise the animals on their premises. These dogs will have unknown or incomplete medical histories. Once random-source dogs have been quarantined, vaccinated, and determined free of parasites and any other medical or biological anomaly, they are considered “conditioned.”

To minimize animal variability, animal resource programs should provide normal, healthy, well-adapted animals that represent a physiological model characterized by a narrow range of physical, behavioral, and clinical parameters. Dogs that are purpose-bred should arrive at the facility adequately vaccinated and from disease-free colonies compatible with the current animal program health status or be segregated upon arrival. It is helpful to obtain the animals from the same dealer to take advantage of group immunities (Meunier, 2006). In general, closed colonies are easier to manage and help ensure a disease-free population. Newly introduced dogs and staff with dogs at home pose a potential risk to the animal colony. The use of dedicated work clothing and segregating animal groups from the same vendor source together maintains a disease-free health status. In some cases, the diseases can be subclinical but this can still affect research results in terms of blood values, immune suppression, healing times, and so on (NRC, 1994).

Most dogs used in research and testing are Beagles, although other breeds (e.g., canine familial disorders, mongrel foxhounds) are purpose-bred for use in research (Meunier, 2006). The Beagle was originally chosen for use in the laboratory owing to its placid temperament, and it can easily be housed in kennels. In addition, its relatively small size and ease of access to the cephalic vein for blood sampling allows for dosing and measuring body responses with relative ease (ILAR, 1994).

4.4.2 SEX

The importance of classifying clinical chemistry data groups by sex is generally accepted and has been justified for certain parameters by statistical testing (Maxwell and Delaney, 1985). Significant differences between males and females exist in many chemistry values depending on the breed size and hormone levels but lack clinical relevance in most cases (Kley et al., 2003). The differences between males and females become less obvious with age (Kaspar and Norris, 1977). For example, with increasing age in the Beagle, serum cholesterol levels are initially higher in females, but increase faster in males over time, so that after a 10-year span the values are at similar levels.

4.4.3 AGE

In neonates and geriatric animals, the ranges for many tests tend to show greater variation compared to late juveniles and mature adults (Evans, 2009). Plasma alkaline phosphatase (ALP) is probably the best-known example of an age-dependent parameter. The presence of higher calcium and phosphorus concentrations in young dogs attributed to skeletal growth and increased osseous activity is attributed to high skeletal ALP isoenzyme in young growing animals (Sanecki et al., 1993). Creatine kinase activity is higher in young dogs and decreases when the animals reach adulthood (Kaspar and Norris, 1977; Kraft et al., 1995; Keller and Wall, 1982). Plasma total protein, albumin (Alb), total bilirubin, creatinine, urea, alanine aminotransferase (ALT), gamma-glutamyl transferase (GGT), and iron all tend to increase with age, reflecting changes in muscle mass and

immune maturity and possibly a decrease in the GFR. The age-associated increase for total bilirubin is also considered to be due to increasing hemoglobin concentrations (Kraft et al., 1995). Furthermore, increased immune stimulation results in an elevated globulin fraction, but also to an increasing albumin production, as a result of better liver function and intestinal absorption (Hall, 2006).

4.4.4 BREED

Bred and raised for laboratory use, the Beagle is the standard research dog in toxicology studies (Dysko et al., 2002). The breed is fairly uniform and tends to be free of breed-related diseases except for coagulation factor VII deficiency, which is often asymptomatic and can be detected by the one-stage prothrombin time test (PTT). Random source or pound dogs are generally unacceptable due to nonuniformity. However, breeds other than Beagles and purpose-bred mongrels are occasionally used for special purposes, such as when a larger body size than that of the Beagle is required. Significant breed effects have been found among many clinical chemistry parameters. Reference ranges for total protein, creatine, total bilirubin, potassium, calcium, amylase, ALP, GGT, and lipase varies among breeds. However, lower total protein concentrations for retrievers, lower total bilirubin concentrations for terriers, higher total bilirubin for mastiff-type dogs, and lower lipase activity for sled-type dog are the only clinical chemistries found to be significantly statistically different among breeds (Kley et al., 2003). Prestudy clinical pathology testing is useful for general health screening of dogs before studies commence.

4.4.5 NUTRITIONAL STATUS

Feeding regimens at facilities vary and should be dependent on study requirements. There are basically three methods of feeding dogs: free choice (*ad libitum*), time limited, or food limited (Meunier, 2006). Upon arrival to a new facility, a dog may not adapt readily to dietary and environmental changes. Therefore, close attention should be paid to be certain that an animal is eating adequately and maintaining its weight. Ideally, the facility should provide a diet that is the same as that of the kennel of origin. The diet can then be changed over several days to a new food if a diet change is necessary. Adult dogs can adapt to one meal per day feeding (Morris et al., 2005). In contrast to *ad libitum* feeding used for some other laboratory animal species, dogs should be meal fed an optimal amount of food to prevent obesity (Fillman-Holliday et al., 2002). Adult dogs that are consuming food voluntarily should be fed relative to their body condition and not necessarily by a formula (Morris and Rogers, 2000). Eating habits vary among dogs. For example, if provided free choice feeding, some dogs may demonstrate an eating pattern more like cats (e.g., eating several times between the light and the dark period) (Meunier, 2006). This may result in over-feeding or under-feeding dogs that are pair housed.

The diet composition can impact the clinical chemistry values of the dog. Dietary protein intake, urea production rates, and the renal and extrarenal urea excretion will impact blood urea nitrogen (BUN) levels. For example, over-feeding, feeding high protein diets, upper gastrointestinal bleeding, and disorders that increase endogenous protein catabolism can alter the amino acids absorbed in the gastrointestinal tract and contribute to an increase in BUN caused by increased hepatic ureagenesis. Animal manipulations prior to sequential blood sampling in toxicological studies should be similar with respect to food and water intake to minimize within-animal variations of plasma and urinary chemistry values. Fasting is characterized by low glucose concentrations, and accordingly, low levels of insulin and high glucagon. Daily level variations of serum lipids (nonesterified fatty acids (NEFA), triglycerides, phospholipids, total cholesterol, and total lipids) occur in healthy dogs, particularly in temporal relationship to lighting and fasting cycles. Bertolucci et al. found levels of serum NEFA patterns were significantly higher during fasting due to mobilization of adipose

tissue NEFA mediated by the decrease in insulin with its lipolytic effects (Bertolucci et al., 2008). Blood glucose will increase, while triglycerides, urea nitrogen, calcium, inorganic phosphorus, and ALP have all been shown to decrease with fasting (Matsuzawa et al., 1993). In addition, Lawler et al. (2007) studied the effects of 25% diet restriction in dogs. The study showed that lifetime food restriction resulted in erythrocyte levels slightly higher among dogs fed *ad libitum*—a possible reflection of the need to support both higher body fat mass and lean mass that uses energy less efficiently. Among serum biochemistry variables, glucose and triglycerides were lower, while creatinine was slightly higher (in the absence of renal disease or failure) over the life spans of diet-restricted dogs (Lawler et al., 2007).

4.4.6 HOUSING ENVIRONMENT AND STRESS

Extreme and continuous stress can significantly affect experimental outcomes due to neuroendocrine effects (Clark et al., 1997). Stressed animals may divert energy into adaptation, generally at the expense of other biological processes such as behavior, immune function, growth, and reproduction. It is important to anticipate the stressful events that dogs may experience to prevent physiological changes during data collection.

Dog pens are usually constructed of concrete, stainless steel, galvanized metal, and wood. Stainless steel is preferable to galvanized metal, which may damage the feet or flake away if the quality of the galvanization is poor. Flaking galvanized metal may have toxic effects due to the zinc being absorbed during licking (Dysko et al., 2002; Prescott et al., 2004). Dogs should be housed in pairs or groups whenever possible. Boredom in dogs may have as much effect as any stressor on the overall well-being of an animal. As demonstrated in previous studies, animals will subject themselves to aversive conditions or engage in stereotypic behavior, including self-mutilation, to attain some stimulation (Wemelsfelder, 1990). An enriched environment is very important, whether or not a dog is bored. Primary sources of enrichment include interaction with people and/or a conspecific companion and the provision of manipulanda. Enrichment allows the dog to work off extra energy and occupy its mind, which will aid the animal to behave more naturally in a restricted environment. Enriched animals learn to cope better with stressful situations (Loveridge, 1998). It is important to establish that the introduction of environmental enrichment does not interfere with experimental data being measured, for example, foreign body ingestion. It is essential to select dogs that are well socialized to people and with other dogs. Most Class A research dogs are raised in a research facility, and habituated to people during their sensitive socialization periods and become adapted to these specific surroundings. These animals tend to be less fearful or reactive to procedures (Hirsjarvi and Junnila, 1986). Social isolation or restriction is regarded as a major stressor for a social species like the dog (Wolfe, 1990). Furthermore, dogs housed singly are usually less active or exhibit more repetitive nonsocial repetitive behaviors (Hubrecht et al., 1992; Hughes et al., 1989). The withdrawal of a conspecific contact can be detrimental, particularly, to dogs used to such contact. It is important for facility personnel to handle dogs from the time they arrive and throughout their lives to provide and develop environmental diversification and trusting relationships.

4.4.7 TRANSPORTATION

Transportation is an especially powerful stressor for dogs (Kuhn et al., 1991). Transporting animals can produce a number of effects ranging from weight loss, altered immune function and behavior, and changes in blood characteristics linked with stress and shock reactions (Tuli et al., 1994). Even moving within a facility can cause an animal stress (Swallow et al., 2005). With this in mind, a period of acclimation is useful following transportation, prior to the beginning an experimental study. This allows animals a period of time for physiological, psychological, and nutritional stabilization before their use. The length of time for stabilization will depend on the type and duration of animal

transportation, the dogs involved, and the intended use of the animals (Obernier and Baldwin, 2006; NRC, 1996). If dogs are to be paired or group housed, it is advisable to pair- or group-house dogs upon arrival. Ideally, animals should be purchased from a sole vendor. Preexisting stable groups will enhance the acclimation period within the new facility by minimizing dog-to-dog aggression and utilizing group immunity to prevent the spread of disease (Prescott et al., 2004). When forming a new pair or group, potential for conflict may be reduced by housing together individuals of different ages and/or body weights. Quarantine periods vary between institutions and depend on the animal source, health history, and current health status on the animal colony at the receiving institution. Most institutions recommend 7–14 days for newly purchased dogs and allow at least 3 days for animals to acclimate when they have been moved in individual containers between buildings on-site and/or entering an acute terminal study (Prescott et al., 2004). At least 24 hours should be permitted for acclimatization when there is a permanent change of pen location, assuming similar husbandry and care procedures are (Prescott et al., 2004).

4.4.8 CIRCADIAN RHYTHM—TIME OF COLLECTION

It is well known that there is diurnal variation in plasma corticosteroids in the dog (Reilly, 1998). Plasma levels of hormones and metabolites (including insulin, testosterone, and growth hormones) have shown diurnal variations (Fukuda, 1990), which may cause variation in clinical chemistry parameters. In particular, it should be taken into account that total lipids, total cholesterol, phospholipids, and triglycerides show daily rhythmicity in dogs maintained under 12:12-hour light:dark cycles (Bertolucci et al., 2008). Samples should be collected and synchronized, if needed, in a manner harmonious with the natural circadian cycle of the study cohort. Seasonal effects alter analyte values in most species. Among clinical chemistry, the parameters found to show seasonal effects with highest values in the summer were creatinine, phosphorus, uric acid, total protein, globulin, lactate dehydrogenase, γ -glutamyl transpeptidase, and total and direct bilirubin (Sothorn et al., 1993). Significant circannual variation with highest values in winter was found in urea nitrogen, amylase, glucose, chloride, albumin, ALP, alanine aminotransferase, calcium, and sodium (Sothorn et al., 1993).

4.4.9 PREGNANCY, PARTURITION, AND LACTATION

Pregnancy, parturition, and lactation can influence plasma protein concentrations. For example, serum albumin may decrease due to dilutional effects secondary to water retention and globulin levels may increase in preparation of pregnancy to facilitate passive transfer to offspring, respectively.

4.4.10 ANESTHESIA

Anesthetic agents induce two types of artifact into data values: physiological and biochemical. Physiological effects are produced by alterations in blood pressure and cardiac output, respiration, and excitement, whereas biochemical effects are the result of enzyme induction, tissue hypoxia, and direct toxic damage. Xylazine and medetomidine are sedative analgesic/muscle relaxants routinely used in dogs and are reported to interfere with growth hormone, glucagon, insulin, glucose, follicle-stimulating hormone, and possibly antidiuretic hormone (Greene and Thurmon, 1988). Horber et al. (1990) found that isoflurane induces a mild hypoinsulinemia in dogs. Thiopental sodium has been the major anesthetic agent used to induce dogs for major surgery; however, at the time of publication, its future availability is questionable. Researchers have found that thiopental sodium promotes insulin responsiveness to glucose plasma levels (Ishihara et al., 1981). IV glucose tolerance tests during infusion of thiopentone indicated an increased insulinogenic index compared to halothane. The anesthetic used should minimize struggling and muscle activity. Muscle activity above resting levels may produce significant effects on many analytes. Potassium is released from the liver,

and serum creatine kinase, plasma lactate, and circulating leukocytes and erythrocytes may be increased as animals struggle or become excited (Garber and Carey, 1984).

4.4.11 SPECIMEN COLLECTION/HANDLING ARTIFACT

The deleterious effects of storage are the result of multiple factors operating on the sample. Storage conditions for one analyte (serum creatine kinase) are not necessarily ideal for others (isoenzymes of lactate dehydrogenase) (Reilly, 1998). Factors affecting storage include: evaporation, interaction of the sample with the container (for example, platelet clumping), temperature, light, and humidity. Erythrocyte lysis or hemolysis in serum and plasma is a common collection artifact best avoided. Hemolysis is the breakdown of erythrocytes (*in vivo*-circulating blood *after* blood collection). Poor venipuncture technique, prolonged blood storage, temperature extremes (hot or cold enough to freeze the cells), and certain anticoagulants (fluoride-oxalate) will cause artifactual hemolysis. Hemolysis after blood collection or due to a difficult venipuncture is an artifact, whereas *in vivo* hemolysis signifies a disease process. However, erythrocytes are also more fragile in lipemic samples and tend to lyse more readily in these samples even if the blood is stored or handled correctly. Artifactual hemolysis can mimic intravascular hemolysis and it can be very difficult to tell them apart (particularly in the laboratory setting where clinical correlation is unavailable). Upon blood collection, it is important to determine if the sample has hemolyzed and either redrawn the sample or document the hemolysis appropriately in the record. With this in mind, if the animal is anemic and has hemoglobinuria, true intravascular hemolysis (or a pathological hemolytic anemia) is likely. The canine erythrocyte is high in sodium and low in potassium, in contrast to that of rat, the nonhuman primates, or man whose erythrocytes are low in sodium and high in potassium (Harris and Kellermeyer 1970). Hemolysis can artifactually increase or decrease normal substances in the serum or interfere with results from spectrophotometer assays. Specimens must be handled in a timely manner and stored appropriately. Lipemia, the presence of visibly detectable lipid in serum or plasma, is much more common in the dog than in other laboratory animals. Lipemia will invalidate or interfere with analytic methodologies by falsely decreasing the concentrations of analytes within the serum. With some analyzers and reagents, hemolysis and lipemia will cause artifactually high bilirubin values.

Samples collected from different sites in the animal do not necessarily have comparable analyte values (Garber and Carey, 1984). Leukocyte, platelet, and erythrocyte numbers vary dependent on sampling site and may lead to sample contamination. In addition to variations in leukocyte and differential counts, variations are commonly found in red blood cell (RBC), hemoglobin (HGB), and hematocrit (HCT) values when comparing sampling sites (Reilly, 1998). The method of sample collection and processing can also influence analyte concentration. For example, hemolysis results in a significant reduction or elevation depending on measurable analyte. Mechanical injury to and subsequent damage to tissue may release an analyte into circulation (e.g., cardiac stick not appropriate site for creatine kinase (CK) or troponin) resulting in high plasma values. The canine cephalic vein is smaller than the jugular vein and, consequently, is more susceptible to trauma during blood sample collection. The jugular vein is ideal for repeat serial sampling, compared to samples collected from the cephalic vein. In order to minimize the influences of variables it is important that the blood should be collected in the same manner (e.g., ideally same handler and/or phlebotomist) at each sampling time and that the volume of blood be limited to the minimum required to perform the desired analysis. When collecting urine for clinical chemistry evaluation every effort must be made to avoid contamination with food, drinking water, and feces.

Appropriate blood tubes (various anticoagulant, nonanticoagulant, or serum separator) can be selected based on experimental design, but consistency is essential. Switching between tube types may cause analyte measurements to vary, especially if switching between plasma (e.g., green or lavender tops) and serum (e.g., red tops). If utilizing the services of a clinical pathology reference lab or core-lab, be certain to check their tube preferences and volume requirements prior to commencing

your study. Gel separator tubes may confer an advantage in obtaining “clean” (cell-free) serum or plasma from small specimens; however, caution should be used if the serum is also utilized for pharmacologic studies or therapeutic drug monitoring as the gel substance may bind the drug metabolite to be measured, causing falsely decreased measurements. Lithium heparin anticoagulant tubes are useful when hematology [complete blood count (CBC)] evaluations are to be performed on the same specimen. The fluid phase of blood should be removed from cellular elements as soon as separation has occurred because the cells left in contact will metabolize certain chemical components in the serum. Glucose will be metabolized by cells, thus decreasing measured values at the rate of approximately 10% per hour if left in contact with red blood cells. Harvested serum should be analyzed quickly; otherwise, it can be stored in a refrigerator for 24–48 hours or frozen afterward at -70°F . All samples should be handled in the same manner. Serum enzymes, as a general rule, should be analyzed within 24 hours of collection. ALT, aspartate aminotransferase (AST), ALP, CK, and amylase are satisfactorily stable (>70% activity) when stored at 4°C (Loeb, 1999). Samples stored in frost-free and nonfrost-free -20°C freezers should not differ significantly through day 90, but repeated freeze/thaw cycles may result in statistically significant difference in some parameters. Factors such as storage time and temperature should be considered when designing any retrospective study (Cray, 2009). In addition to sources of variation that occur before sample analysis, the analytical procedure (e.g., analyzer, quantitative methodology) itself is a source of variation. It is important to caution that one must use reference ranges specific to a machine or reference lab and to use other reference ranges (including those in this chapter) only as guides. Analytic variation is minimized by robust quality control systems and appropriate study design (Hall and Everds, 2007).

4.5 BRIEF DESCRIPTION OF COMMON PROCEDURES

4.5.1 ADRENAL FUNCTION TESTING

4.5.1.1 Hyperadrenocorticism Diagnosis

Given the high incidence of hyperadrenocorticism (HAC; Cushing’s syndrome) in dogs, dogs demonstrating cardinal features of the disease (such as polyuria and polyphagia, a pendulous abdomen, and hair loss) should be evaluated for HAC (Willeberg and Priester, 1982; Kooistra and Galac, 2010).

The ideal screening test in a calm dog is a urine cortisol:creatinine ratio (UCCR) measured on a voided urine specimen. Because urine is stored in the bladder for several hours, urinary cortisol measurement integrates the impact of pulsatile ACTH secretion and variable plasma cortisol concentrations over time (Kooistra and Galac, 2010). Basal UCCR in healthy dogs varies from 0.3 to 8.3×10^{-6} (Kooistra and Galac, 2010). Given the high predictive value of a negative test result (0.98) (Rijnberk et al., 1988), a UCCR in this normal range accurately rules out HAC. However, since stress can generate false positives (the test is sensitive but not specific), the positive predictive value of the UCCR is only 0.88 (Rijnberk et al., 1988). An elevated UCCR requires further diagnostics to confirm the HAC diagnosis: a low-dose dexamethasone suppression test (LDDST) or an adrenocorticotropic stimulation test.

HAC can be diagnosed by testing the integrity of the glucocorticoid feedback system on the hypothalamic–pituitary–adrenal axis via the LDDST (Kooistra and Galac, 2010). The LDDST is the most sensitive (95%) test for HAC in dogs and is considered by many to be the test of choice for HAC diagnosis in dogs (Feldman, 2009; Behrend and Kennis, 2010). The specificity of the LDDST can be low (40%–50%), especially when measured in a population of sick dogs (Kaplan et al., 1995). In the LDDST, 0.01 mg dexamethasone sodium phosphate per kg of body weight is administered IV. Cortisol measurements are performed using plasma or serum (ethylenediaminetetraacetic acid or EDTA) collected before, and at 4 and 8 hours after dexamethasone administration. Cooling of plasma is not necessary, but serum should be stored and shipped frozen (-20°C) (Behrend et al., 1998). An 8-hour plasma cortisol $>1.4 \mu\text{g/dL}$ is consistent with the diagnosis of HAC (Feldman, 2009). Only the 8 hour sample is necessary for HAC diagnosis, but the 4-hour sample may be useful in determining if the hypercortisolism is adrenal or pituitary-dependent (Kooistra and Galac,

2010). If the 8 hour sample is consistent with HAC and the plasma cortisol concentration at 4 or 8 hours is $\geq 50\%$ lower than the baseline value, the hypercortisolism is pituitary-dependent (Kooistra and Galac, 2010). The high-dose dexamethasone suppression test (HDDST) is a discriminatory test used in dogs already diagnosed with HAC in order to determine if the dog has PDH or ADH. It is performed just as the LDDST except that a higher dose of dexamethasone (0.1 mg/kg) is administered (Feldman, 2009).

An alternative diagnostic test for HAC is the adrenocorticotrophic hormone stimulation (ACTH) test. Because of its low sensitivity, (80%, meaning 20% of dogs with HAC will have test results within the reference range) some clinicians no longer recommend this diagnostic approach for dogs with hypercortisolism (Feldman, 2009; Behrend and Kennis, 2010). Furthermore, due to the cost of ACTH (see below), the ACTH test is markedly more expensive than the LDDST and may be cost-prohibitive in the research setting. However, since the ACTH test is used to monitor therapy of HAC, others still employ it as a diagnostic test in order to obtain baseline therapeutic parameters. The ACTH stimulation is the test of choice for initial testing in dogs with history of exogenous steroids (suspected iatrogenic HAC) (Scott-Montcrieff, 2010). The ACTH stimulation test is also the only test that is capable of diagnosing atypical HAC, as discussed below. The specificity of the ACTH stimulation test is higher than that of the LDDST (85%–90%) (Melian et al., 2010). Finally, the ACTH stimulation test remains the gold standard for diagnosis of hypoadrenocorticism.

Caution must be taken in interpreting an ACTH stimulation test result in dogs with nonadrenal illness. It is possible for stressed and sick dogs without HAC to have exaggerated ACTH test responses (Behrend and Kennis, 2010). Fourteen to 36% of dogs with nonadrenal illness but without HAC have ACTH stimulation results consistent with HAC (Chastain et al., 1986; Kaplan et al., 1995). However, both the UCC and the LDDST generate even more false positive results (76% and 56%, respectively) than the ACTH stimulation test in dogs with nonadrenal illness (Kaplan et al., 1995). The ACTH test is the best choice for HAC diagnosis in dogs with concurrent disease, but ideally testing a sick dog for HAC should be avoided altogether (Chastain et al., 1986; Kaplan et al., 1995).

The ACTH stimulation test assesses the adrenal gland's cortisol producing capacity in response to a maximal stimulus (Klein and Peterson, 2010). It is conducted as follows:

1. Draw a baseline blood sample for plasma (EDTA tube) or serum (plain tube) preparation (serum or plasma depends on your laboratory's requirements). Centrifuge the samples (allow non-anticoagulated samples to clot first) and collect serum or plasma. Ensure serum is kept cold (-20°C); plasma does not need to be cooled (Behrend et al., 1998).
2. Inject ACTH gel (2.2 mg/kg intramuscularly (IM) or cosyntropin (5 $\mu\text{g}/\text{kg}$ IV; maximum dose 250 $\mu\text{g}/\text{dog}$; see Table 4.1).
3. Collect a blood sample 1 and 2 hours after ACTH gel administration or just 1 hour after cosyntropin administration. We recommend collecting a second plain tube for serum preparation and storing frozen serum in case testing for atypical HAC becomes necessary (Cook, 2011).
4. Centrifuge the samples (allow non-anticoagulated samples to clot first) and collect serum or plasma. Ensure serum is kept cold.
5. Measure cortisol levels in baseline and poststimulation samples.

Available formulations of ACTH include synthetic ACTH and gel preparations (Klein and Peterson, 2010). These products are costly and sometimes plagued by poor availability (Kemppainen et al., 2005). Gel preparations are administered at a dose of 2.2 mg/kg IM, and blood samples must be collected at both 1 and 2 hours post-ACTH stimulation because of variability in the time to peak response among different compounded products (Kemppainen et al., 2005).

Standardly, ACTH stimulation involves 250 μg synthetic ACTH (cosyntropin, Cortrosyn; Amphastar Pharmaceuticals, Rancho Cucamonga, CA) given IV or IM followed by blood

sampling one hour later (Klein and Peterson, 2010). Alternatively, a more cost effective approach employs a lower (5 µg/kg) IV cosyntropin dose (Klein and Peterson, 2010). This low-dose ACTH stimulation test (5 µg/kg) when compared with the standard dose (250 µg/dog) resulted in maximal stimulation of the adrenal cortex in normal dogs and dogs with HAC (Kerl et al., 1999), and produced equivalent results to the standard dose of 250 µg/dog in dogs with suspected hypoadrenocorticism (Lathan et al., 2008). The cosyntropin dose regimen based on the low-dose ACTH protocol currently used for diagnosis of both hyper- and hypo-adrenocorticism at the NCSU College of Veterinary Medicine is detailed in Table 4.1. To maximize the financial benefit of the low-dose ACTH protocol, cosyntropin can be stored stably in frozen aliquots (-20°C) in plastic syringes for up to 6 months (Frank and Oliver, 1998). Care should be taken when aliquoting the drug since the reconstituted cosyntropin does not contain preservatives (Klein and Peterson, 2010).

The ACTH stimulation test is useful in diagnosing the syndrome of atypical HAC, a syndrome that has been rarely documented in dogs (Benitah et al., 2005; Behrend and Kennis, 2010). In this syndrome, increased circulating concentrations of adrenal hormones other than cortisol (such as progesterone or 17-hydroxyprogesterone) are proposed to cause clinical signs that are indistinguishable from those due to excess glucocorticoids (Scott-Moncrieff, 2010). These dogs have clinical signs and/or laboratory abnormalities consistent with HAC, but have LDDST or ACTH stimulation tests (Behrend and Kennis, 2010). An extended panel of adrenal corticosteroids should be measured before and after ACTH stimulation in dogs with clinical and laboratory evidence of HAC, but normal cortisol testing. The protocol is the same as that of the ACTH stimulation test, but pre- and poststimulation serum is submitted for an extended panel of adrenal steroid measurement (currently being performed at the Clinical Endocrinology Service at the University of Tennessee) (Scott-Moncrieff, 2010). Serum can be stored at -20°C to -70°C for at least 1 month before measuring these hormone concentrations and can be measured on the same sample collected for serum cortisol measurement (Benitah et al., 2005). Increases (1.5–2 times greater than the upper end of the reference range) in 2–3 adrenal steroid hormone concentrations are supportive of atypical HAC (Scott-Moncrieff, 2010). Levels of adrenal sex steroid hormones must be considered in the context of sex and neuter status (Benitah et al., 2005). The reader is referred to Benitah et al. for reference

intervals for serum 17-hydroxyprogesterone concentrations in healthy dogs of different sex and neuter status following ACTH stimulation (Benitah et al., 2005). The specificity of the adrenal sex hormone testing, however, has not been evaluated, and some debate whether sex hormone elevation is truly a form of HAC or simply a nonspecific reflection of nonadrenal illness (Behrend and Kennis, 2010). Sex hormone concentrations of normal dogs, HAC dogs, and dogs with nonadrenal illness can overlap (Scott-Moncrieff, 2010). Interpretation of the extended adrenal steroid panel must be performed with the understanding that there is limited published information relating elevations in these cortisol precursors to clinical signs and that some authors are not convinced that an atypical HAC syndrome truly exists in dogs (Behrend and Kennis, 2010; Cook, 2011).

4.5.1.2 Hypoadrenocorticism Diagnosis

The gold standard for diagnosing hypoadrenocorticism in dogs is an ACTH stimulation test, which demonstrates an inability of the zona fasciculata and reticularis to produce cortisol response to a maximal stimulus (Klein and Peterson, 2010). However, the measurement of a normal, resting cortisol concentration can exclude a diagnosis of hypoadrenocorticism, avoiding the cost of the ACTH stimulation test (Lennon et al., 2007). Dogs with basal cortisol levels ≥ 2 $\mu\text{g/dL}$ are very unlikely to have hypoadrenocorticism (Lennon et al., 2007). A baseline cortisol < 2 $\mu\text{g/dL}$ is nondiagnostic, and requires further evaluation with an ACTH stimulation test. For dogs with basal cortisol levels ≥ 2 $\mu\text{g/dL}$ in which a strong suspicion for hypoadrenocorticism remains, a full ACTH stimulation test should be performed (Lennon et al., 2007).

The protocol for the ACTH stimulation to diagnosis hypoadrenocorticism is the same as that to diagnose HAC. To confirm the diagnosis, pre and post-ACTH cortisol concentrations should be less than 2 $\mu\text{g/dL}$ (Scott-Moncrieff, 2010a). While in normal dogs, synthetic ACTH can be administered IV or IM to ensure adequate absorption, IV cosyntropin is recommended in dehydrated dogs like those in Addisonian crisis (Hansen et al., 1994; Peterson et al., 1996).

4.5.2 THYROID FUNCTION TESTING

Although hypothyroidism is one of the most common canine endocrinopathies, diagnosis can be challenging. Usually, a combination of low plasma total thyroxine (TT_4) concentration and elevated thyroid stimulating hormone (TSH) is diagnostic for hypothyroidism (Diaz Espineira et al., 2007). Unfortunately, TSH concentrations are normal in up to one third of dogs with primary hypothyroidism (Ramsey et al., 1997; Scott-Moncrieff et al., 1998b; Diaz Espineira et al., 2007). This, coupled with the fact that plasma TT_4 concentrations are frequently decreased in dogs with nonthyroidal illness (euthyroid sick), makes it challenging to differentiate between dogs with hypothyroidism and those that are euthyroid sick (Diaz Espineira et al., 2007). Further tests of thyroid function become necessary.

4.5.2.1 Thyrotropin (TSH) Response Test

The TSH response test is considered by some authors as the most accurate test for thyroid gland function (Feldman and Nelson, 1996). It tests the thyroid gland's reserve by evaluating the thyroid gland's responsiveness to exogenous TSH administration. Most importantly, the TSH response test is the best biochemical thyroid function test for differentiating between true hypothyroidism and the euthyroid sick syndrome in dogs (Feldman and Nelson, 2004; Diaz Espineira et al., 2007). However, the "gold standard" status of the TSH response test for hypothyroidism diagnosis has recently been questioned because it can still falsely classify euthyroid sick dogs as hypothyroid (Diaz Espineira et al., 2007; Daminet et al., 2007). Thyroid pertechnetate uptake may be the only reliable way to distinguish between dogs with nonthyroidal illness and those with primary hypothyroidism (Diaz Espineira et al., 2007).

Recombinant human TSH (rhTSH) (Thyrogen, Genzyme Corporation, Cambridge, MA) is the recommended pharmaceutical for the TSH response test. Reconstituted rhTSH can be stored in plastic syringes for up to 8 weeks at -20°C or 4 weeks at 4°C , making use of this expensive product more cost-effective (De Roover et al., 2006; Daminet et al., 2007). The traditionally used bovine TSH is no longer available as a pharmaceutical preparation (Boretti et al., 2006). We do not recommend use of chemical grade bovine TSH as life-threatening reactions can occur in dogs following its administration (Scott-Moncrieff, 2010b).

The protocol using rhTSH is as follows:

1. Collect a blood sample in a plain tube. Following clot retraction at room temperature, harvest serum via low-speed centrifugation. Transfer to *plastic* tubes for storage at -20°C until subsequent hormone assay (Boretti et al., 2006). Samples can be shipped without cooling if assayed within 5 days (Behrend et al., 1998).
2. Administer $150\ \mu\text{g}$ rhTSH IV per dog. Use of a lower dose ($75\ \mu\text{g}$), especially in a diseased dog or a dog taking medications known to affect thyroid function, may lead to an inappropriate diagnosis of hypothyroidism (Boretti et al., 2009).
3. Collect a blood sample 6 hours later and harvest serum as above. Serum must be stored in plastic tubes (Behrend et al., 1998).
4. Measure pre- and post-TSH serum TT_4 concentrations.

The expectation is that there will be minimal change in post-TSH TT_4 concentration compared with basal concentration in dogs with hypothyroidism (Boretti et al., 2006). If both pre and post-TSH serum TT_4 concentrations are below the reference range for basal TT_4 , a diagnosis of hypothyroidism is likely; if post-TSH TT_4 is $>2.5\ \mu\text{g}/\text{dL}$ and increased to at least 1.5 times basal TT_4 concentration, dogs are classified as being euthyroid (Scott-Moncrieff, 2010b). Post-TSH serum TT_4 values between 1.6 and $2.5\ \mu\text{g}/\text{dL}$ are nondiagnostic (Boretti et al., 2009).

Because thyroxine causes thyroid atrophy, dogs being treated with thyroxine cannot be tested with the TSH response test until they have been off supplementation for 6-8 weeks (Scott-Moncrieff, 2010b).

4.5.2.2 Thyrotropin-Releasing Hormone (TRH) Response Test

The TRH response test can be used to evaluate thyroid function in dogs in place of the TSH response test (Feldman and Nelson, 2004). An expected normal response to the TRH test would be the endogenous production of TSH by the pituitary gland with subsequent increase in serum TT_4 concentration due to stimulation of the thyroid gland (Lothrop et al., 1984). However, the TRH response test is less reliable than the TSH response test for the diagnosis of canine hypothyroidism because normal dogs have a small, inconsistent increase in serum TT_4 and some sick euthyroid dogs fail to respond to TRH (Frank, 1996; Kempainen and Behrend, 2001); thus, this test cannot be used to differentiate primary hypothyroidism from euthyroid illness (Frank, 1996; Diaz Espineira et al., 2007). Furthermore, dogs with primary hypothyroidism have an unusual blunted response to TRH administration: they produce minimal or no TSH in response to TRH (Diaz Espineira et al., 2007; Diaz-Espineira et al., 2008). We would expect primary hypothyroid dogs to produce exaggerated TSH in response to TRH because of the reduced negative feedback of thyroxine on the pituitary. In people, TRH stimulation does indeed lead to this expected exaggerated release of TSH in patients with primary hypothyroidism; people with condary hypothyroidism have a blunted TSH response to TRH (Diaz-Espineira et al., 2008). Therefore, in people the TRH response test can differentiate primary from secondary hypothyroidism. However, in dogs the TRH response test cannot be used to differentiate primary from secondary hypothyroidism since all hypothyroid dogs have a blunted TSH response in the TRH test (Scott-Moncrieff and Nelson, 1998a; Diaz-Espineira et al., 2008). In sum, clinical utility of the TRH response test in dogs is limited.

The protocol for the TRH response test is as follows (Feldman and Nelson, 2004):

1. Collect baseline blood samples, centrifuge, and harvest serum, transfer to a plastic tube.
2. Give 200 μg TRH per dog IV.
3. Collect blood 30 minutes and 4 hours after TRH administration. Centrifuge and harvest serum, transfer to *plastic* tubes (Behrend et al., 1998).
4. Store at -20°C until measurement can be performed. Samples can be shipped at ambient temperature as long as they are assayed within 5 days (Behrend et al., 1998). Measure serum TT_4 concentration at 0 and 4 hours; measure serum TSH at 0 and 30 minutes.

Although higher doses of TRH have been evaluated (>0.1 mg/kg TRH), increasing the dosage of TRH does not increase the magnitude of TT_4 stimulation, but does increase the occurrence of adverse effects due to the central cholinergic properties of TRH such as salivation, miosis, vomiting, urination, defecation, tachycardia, and tachypnea (Lothrop et al., 1984; Feldman and Nelson, 2004).

One schematic for interpreting results of the TRH response test is as follows:

- Euthyroidism likely: post-TRH TT_4 concentration >2 $\mu\text{g}/\text{dL}$ and relative increase in TSH $>100\%$ at 30 minutes post-TRH (Scott-Moncrieff, 2010b).
- Possible hypothyroid diagnosis: Post-TRH TT_4 is <1.5 $\mu\text{g}/\text{dL}$ (Scott-Moncrieff, 2010b).
- Post-TRH serum TT_4 concentrations between 1.5 and 2 $\mu\text{g}/\text{dL}$ are nondiagnostic (Feldman and Nelson, 2004).

4.5.3 LIVER FUNCTION TESTING

4.5.3.1 Pre- and Postprandial Bile Acids

Measurement of serum bile acids provides a simple, highly specific test of liver function and perfusion that evaluates the enterohepatic circulation of bile acids (Center et al., 1991; Webster, 2010). After meal ingestion, cholecystokinin (CCK) release stimulates gallbladder contraction and subsequent release of bile acids to intestine. From the ileum, bile acids are transported back to portal circulation, where they are removed by hepatocytes and recycled back into the biliary system (Ruland et al., 2010; Webster, 2010). Postprandial entry of bile into the small intestine leads to an increase in bile acids in portal circulation that exceeds the hepatic clearing capacity, leading to a small transient postprandial increase in serum bile acids in dogs with normal hepatic function (Center, 1993; Ruaux et al., 2002). If enterohepatic circulation is disrupted, serum bile acids increase above normal concentrations. This can occur due to loss of functional hepatic mass, due to portosystemic shunting of blood, or due to cholestasis (Bain, 2003; Ruland et al., 2010).

Although fasting serum bile acids can be measured and interpreted alone, the best application of the serum bile acid test involves a paired pre- and postprandial bile acids measurement to optimize the chance of detecting elevated values (Balkman et al., 2003). In detecting shunting associated with portosystemic vascular anomalies (PSVA) and cirrhosis, the postprandial serum bile acid concentration is more sensitive than the fasting bile acid concentration (Center et al., 1991).

To obtain the preprandial sample, the dog is fasted for 12 hours and blood is drawn into a plain tube for serum preparation. A meal is then fed. The meal must have adequate fat or amino acid content to lead to CCK release and gallbladder contraction. Ideally, the dog should be fed a typical sized meal (Center, 1993). Minimally, at least two teaspoons of food for dogs less than 5 kg and two tablespoons of food for dogs greater than 5 kg should be consumed (Webster, 2010). If the dog will not eat voluntarily, the food can be ground in a blender and syringe-fed (Center, 1993). To ensure test accuracy, the dog must be observed to eat the meal (Webster, 2010). Blood is then sampled for postprandial serum bile acids measurement 2 hours after feeding. Although serum bile acids are stable at room temperature, hemolysis and lipemia must be avoided as they interfere with

the spectrophotometric endpoints of most commonly used assays for bile acids (Webster, 2010). Hemolyzed samples cannot be analyzed accurately, but lipemia can be cleared by high-speed centrifugation of the sera (Center, 1993).

About 20% of dogs have higher fasting than 2-hour postprandial bile acids due to differences in the rates of gastric emptying, gallbladder contraction, and enteric motility (Center, 1993; Balkman et al., 2003). The accuracy of the postprandial bile acids measurement depends on the meal adequately stimulating CCK release and subsequent gall bladder contraction. Variables such as the rate of gastric emptying, anorexia, and vomiting can influence postprandial bile acid concentrations (Bridger et al., 2008). To ensure adequate gall bladder contraction, injection of a CCK analog (ceruletide) has been proposed as an alternative testing procedure (Bridger et al., 2008). Ceruletide serum bile acid stimulation has been shown to perform equally well as postprandial bile acids stimulation in dogs with portosystemic shunts (Bridger et al., 2008). The test needs to be evaluated more extensively for accuracy in the context of other liver diseases and for potential side effects such as pancreatitis induction (Webster, 2010).

Maltese dogs can have elevated postprandial bile acids in the absence of hepatobiliary disease (Tisdall et al., 1995). The reason for this breed-anomaly is unknown but necessitates the use of the ammonia tolerance test (ATT) to evaluate liver function in Maltese.

When interpreting serum bile acid levels, we need to remember that the test is only capable of discriminating normal from abnormal hepatic function (Webster, 2010). Bile acids values do not indicate the type of hepatobiliary disease (Center, 1993). Furthermore, the histologic severity of the disease or the degree of portovascular shunting is not well correlated with the degree of bile acid elevation (Center, 1993; Webster, 2010).

4.5.3.2 Ammonia Tolerance Test (ATT)

The liver detoxifies ammonia that is generated in the GIT by degradation of amines, amino acids, purines, bacterial hydrolysis of urea, and intestinal deamination of glutamine (Walker et al., 2001; Webster, 2010). Ammonia that is released from the gut into portal circulation is converted by hepatocytes to urea and is used in glutamine synthesis in the liver and other tissues (Walker et al., 2001; Webster, 2010). In hepatic synthetic failure, or when blood is shunted away from the liver, ammonia escapes hepatic metabolism, leading to hyperammonemia (Webster, 2010). Since the hepatic urea cycle normally operates at only 60% capacity, hepatic synthetic failure must be advanced to cause hyperammonemia (Webster, 2010). Unlike serum bile acids, plasma ammonia is not influenced by cholestasis (Gerritzen-Bruning et al., 2006). Like bile acid testing, ammonia levels only assess the hepatic function and not the underlying reason for the dysfunction (e.g., portosystemic shunting vs. hepatocellular disease).

In dogs, fasting blood ammonia elevation has a sensitivity of 100% for congenital PSVA and 86% for acquired shunts; the specificity of fasting hyperammonemia for portosystemic shunting is 89% (Gerritzen-Bruning et al., 2006). Elevated fasting ammonia in dogs is more specific for the detection of portosystemic shunting than are elevated fasting serum bile acids (Gerritzen-Bruning et al., 2006; Ruland et al., 2010). The sensitivity of blood ammonia levels for detection of portosystemic shunting is increased by sampling 6 hours after feeding (Walker et al., 2001). Elevated blood ammonia levels are less common in dogs with parenchymal liver disease in the absence of acquired shunting, making blood ammonia an insensitive test for detecting hepatocellular disease regardless of feeding status (Walker et al., 2001; Webster, 2010).

Hyperammonemia has also been reported in dogs without liver disease. Increased plasma ammonia can occur with urea-cycle enzyme deficiencies or conditions resulting in decreased availability of urea-cycle substrates (Webster, 2010). Hyperammonemia was reported in a dog with selective cobalamin deficiency that led to urea cycle dysfunction and in two dogs with a deficiency of the urea cycle enzyme arginosuccinate synthetase (Strombeck et al., 1975a; Battersby et al., 2005). Transient hyperammonemia occurs in Irish Wolfhound puppies under 4 months of age due to an incompletely characterized urea cycle enzyme deficiency (Zandvliet and Rothuizen,

2007). These nonhepatic causes of hyperammonemia should be considered when interpreting plasma ammonia levels or ATT results. False negative baseline ammonia levels have also been documented (Webster, 2010).

Improper sample handling can lead to artificially increased plasma ammonia and reduced specificity of the test (Gerritzen-Bruning et al., 2006). Samples should be drawn directly into cold, closed ammonia-free lithium heparin or EDTA tubes (anticoagulant depends on the method of measurement). The sample should be put on melting ice, spun in a refrigerated centrifuge, and ammonia measured within 30 minutes to avoid *in vitro* generation of ammonia (Hitt and Jones, 1986). Hemolysis or failure to immediately separate erythrocytes from plasma (within 20 minutes) can also lead to spurious ammonia increases because erythrocytes contain three times more ammonia than plasma (Prytz et al., 1970; Webster, 2010). A baseline sample from a normal dog should always be submitted as a quality control of sample management and the assay (Center, 2003). Samples cannot be frozen and stored (Hitt and Jones, 1986; Webster, 2010).

The diagnostic accuracy of blood ammonia concentrations, especially in identifying dogs with PSVA, is increased significantly by the ATT (Meyer et al., 1978). Before performing an ATT, a baseline ammonia level should always be measured. An ATT should be avoided in dogs in which the baseline ammonia is already increased, as this could cause severe neurologic decompensation (Bain, 2003). Since ammonia is one of the factors responsible for hepatic encephalopathy (HE), an ATT could exacerbate HE and is thereby contraindicated dogs with suspected HE (Strombeck et al., 1975b; Berent and Weisse, 2010).

The ATT can be performed by administration of ammonium chloride orally or rectally. The rectal route is better tolerated, easy to perform, and avoids the aspiration potential of PO ammonia administration or vomiting subsequent to PO administration (Walker et al., 2001; Berent and Tobias, 2009). Blood is drawn for ammonia measurement before and 30 minutes after ammonium chloride administration. To administer ammonium chloride per rectum, a cleansing enema is first performed. Thirty minutes later, ammonium chloride (2mL/kg of a 5 % ammonium chloride solution in water, not to exceed 3 g) is administered via a lubricated urinary catheter inserted at least 20 cm beyond the anal sphincter (Rothuizen and van den Ingh, 1982). Ammonia should be retained in the rectum for 5 minutes by digital pressure on the anus (Tisdall et al., 1995).

4.5.4 RENAL FUNCTION TESTING

4.5.4.1 Glomerular Filtration Rate

GFR is the best and most sensitive indicator of overall renal function (Heiene and Lefebvre, 2007). Increases in plasma urea and creatinine levels only occur once 75% or more of the renal functional mass has been lost. Early renal dysfunction is better identified by measuring GFR because GFR is directly related to functional renal mass (Heiene and Lefebvre, 2007; DiBartola, 2010).

GFR can be estimated by the renal clearance of a filtration marker by measuring marker levels in the plasma and urine, or by plasma clearance by measuring only plasma marker levels (Heiene and Moe, 1998). Although urinary inulin clearance is considered the gold standard for GFR measurement, the lack of general availability of inulin and laboratories that measure inulin preclude its common use (Bexfield et al., 2008). Iohexol and creatinine can be used in place of inulin as both substances meet the characteristics of ideal GFR markers: they are freely filtered, not reabsorbed, secreted, or extrarenally excreted, and are not metabolized (Heiene and Lefebvre, 2007).

Urinary clearance methods in general are cumbersome. Complete bladder emptying is required so that GFR is not underestimated. However, when bladder catheterization is used to ensure complete bladder emptying and urine collection, there is a risk of introducing infection (Heiene and Moe, 1998). For this reason, only plasma clearance methods are described here.

Single injection plasma clearance methods have been developed using inulin, iohexol, or creatinine to estimate GFR. Plasma clearance of these substances is calculated as quotient of administered dose divided by area under plasma concentration versus time curve (AUC) (DiBartola, 2010). The accuracy of plasma clearance methods depends on the pharmacokinetic model used to calculate AUC and the timing and number of samples used to make calculations (DiBartola, 2010). Extensive comparison of different methods of plasma clearance estimation of GFR in dogs has been reviewed elsewhere (Heiene and Moe, 1998). Plasma inulin clearance is significantly higher than urinary clearance, suggesting that there are other nonrenal routes of removal of inulin from plasma, thus making the plasma inulin clearance an inferior method for GFR measurement (Watson et al., 2002).

In contrast to what is observed in human medicine, GFR in dogs does not necessarily decrease with age (Bexfield et al., 2008). One study found that only in the smallest weight quartile of dogs was there an age-related decrease in GFR (Bexfield et al., 2008). GFR is, however, much higher in puppies than in mature dogs (Laroute et al., 2005). A significant negative linear relationship has been described in dogs between body weight and GFR (Bexfield et al., 2008). Thus, in interpreting GFR values, body size and age (for small dogs and puppies) of the patient should be considered (Bexfield et al., 2008).

Fasting prior to and during GFR studies is important because protein intake can influence GFR in individual dogs, with increases in GFR occurring 1.5–8 hours after protein ingestion (Brown and Finco, 1992). Free access to water is equally important during these studies because dehydration decreases GFR in dogs (Tabaru et al., 1993).

4.5.4.2 Iohexol Plasma Clearance

Iohexol is an iodinated, water-soluble nonionic low osmolar contrast agent used to estimate GFR (DiBartola, 2010). Unlike inulin, iohexol is stable in plasma so blood samples can be sent for lab analysis without special handling, making the iohexol plasma measurement more practical (Heiene and Lefebvre, 2007). Iohexol measurement is performed in many laboratories, and iohexol itself is widely available. Accurate GFR results using plasma iohexol measurements have been described in dogs (Goy-Thollot et al. 2006; Heiene et al., 2010). Some experts believe that iohexol could replace inulin as a reference marker (Brown and O'Reilly, 1991).

Although the ideal GFR marker is nontoxic, rare toxic reactions to iohexol are possible (allergy, skin reactions, and reversible nephropathy) (Cochran, 2005; Heiene and Lefebvre, 2007; Heiene et al., 2010). Iohexol has been shown to affect GFR in dogs potentially through effects on adenosine receptors (Arakawa et al., 1996). In dogs with normal renal function, renal plasma flow, and GFR increased after iohexol injection. In dogs with experimentally induced renal insufficiency, a low dose of iohexol did not change GFR, but a high dose of iohexol first increased and then reduced renal plasma flow and GFR (Arakawa et al., 1996). Despite these caveats, the iohexol plasma clearance in dogs appears comparable to other methods of GFR estimation (Heiene et al., 2010).

Iohexol clearance can be determined via protocols that minimize the number of blood samples that are required. These limited sampling strategies yield similar results to the 9- and 10-sample reference methods, and are probably acceptable for most clinical and research situations (Goy-Thollot et al., 2006; Heiene and Lefebvre, 2007). If necessary for the application, accuracy can be increased by increasing the sampling frequency (Heiene et al., 2010). A 3-sample method described by Heiene and colleagues for determining the iohexol clearance that appears to optimize accuracy and practicality is detailed below (Heiene and Lefebvre, 2007; Heiene et al., 2010):

1. Withhold food for 12 hours prior to procedure.
2. Provide free access to water during the study; withhold food.
3. Weigh the dog.

4. Take a baseline blood sample in heparinized tubes for plasma preparation. Volume of blood drawn depends on the requirements of the laboratory being used for iohexol measurement. At the time of writing, the Diagnostic Center for Population and Animal Health at Michigan State University was measuring iohexol via HPLC with a minimum sample volume of 1.2 mL. Contact the laboratory prior to performing the test. Some laboratories require serum rather than plasma.
5. Administer iohexol (300 mg iodine/mL) solution as an IV bolus via a peripheral IV catheter. Give 1 mL/kg to dogs without azotemia and 0.5 mL/kg to azotemic dogs.
6. Flush the catheter with 2 mL saline after injection and begin timing. Remove the catheter after flushing.
7. Sample blood at 2, 3, and 4 hours after administration from a different site from where iohexol was given. Indwelling sampling catheters (separate from the catheter through which iohexol was infused) may be used for blood collection, but the first milliliter of blood collected from the sampling catheter at each time-point must be discarded and the catheter flushed with saline following each sample collection (Heiene et al., 2010). Record the exact time of sampling.
8. Prepare plasma from blood samples via centrifugation and send to a laboratory.
9. Clearance is then calculated using a 1-compartmental model (CL_{1comp}), using the formula $CL_{1comp} = \text{dose}/AUC$, where $AUC = C_0/k$, C_0 is concentration at time 0, and k is the elimination rate constant corresponding to the terminal monoexponential phase of the concentration-time curve (Heiene and Moe, 1999; Bexfield et al., 2008). This value is then corrected to account for having neglected the first part of the concentration-time curve with the dog-specific equation generated by Heiene and colleagues:

$$\text{Clearance} = 0.03 + (1.06 \times CL_{1comp}) - (0.07012 \times [CL_{1comp}]^2) \quad (\text{Heiene et al., 2010})$$

In an extended-sample protocol, samples are collected at the following times after iohexol administration: 5, 15, 30, and 60 minutes and 2, 3, 4, 5, and 6 hours (Heiene et al., 2010). Clearance is then calculated as the quotient of dose divided by the AUC, where AUC calculated using a noncompartmental (trapezoidal) method (Heiene et al., 2010). No correction is needed, as the distribution phase of the concentration-time curve is not being neglected. Such extended and more frequent sampling times are recommended in cases of severely decreased renal function, or when extreme accuracy in GFR calculation is necessary (Bexfield et al., 2008). However, the optimal time points for sample collection in dogs with poor kidney function have not yet been determined (Heiene et al., 2010).

4.5.4.3 Creatinine Clearance

Plasma exogenous creatinine clearance is another method that is practical, cost-effective, and comparable to urine inulin clearance (Watson et al., 2002). Laboratory analysis of creatinine is widely available. While the accuracy of endogenous creatinine clearance is impeded by measurement of noncreatinine chromagens by many creatinine assays, exogenous administration of creatinine increases plasma concentrations of creatinine, thereby minimizing the effect of these substances. One drawback to exogenous creatinine clearance measurement is that creatinine has a volume of distribution and half-life that are three times greater than the corresponding parameters for other markers, thus requiring longer sampling times (Heiene and Lefebvre, 2007). Male dogs do have minimal renal tubular creatinine secretion, but this does not appear to impact exogenous creatinine clearance measurements (O'Connell et al., 1962; Watson et al., 2002).

The following protocol for exogenous creatinine clearance is adapted from Heiene and Lefebvre (Heiene and Lefebvre, 2007):

1. Fast the dog overnight. This is essential because plasma creatinine may change postprandially (Watson et al., 2002).
2. Provide water during the test; withhold food.
3. Weigh the patient.
4. Take a baseline blood sample for basal creatinine value measurement. Plasma or serum can be collected depending on what your laboratory is equipped to measure.
5. Prepare an 80 mg/mL creatinine solution by dissolving anhydrous creatinine (Sigma-Aldrich) in distilled water or 0.9% saline. Filter sterilize with a 0.2 μm filter.
6. Administer 1 mL/kg creatinine as a bolus via a peripheral IV catheter. Flush with 2 mL saline. Begin timing. Remove the catheter.
7. Sample blood (1 mL) at 10 minutes, 1, 2, 6, and 10 hours after creatinine administration.
8. Measure creatinine of all samples on the analyzer within the same batch for consistency.
9. Determine plasma clearance by dividing the dose by the area under the curve from the plasma creatinine versus time profile with AUC calculated from a noncompartmental approach (Watson et al., 2002). AUC is calculated by the trapezoidal rule (Watson et al., 2002). The reader is referred to the appendix of the article by Watson et al. for an example of this calculation (Watson et al., 2002). In creating the plasma versus time curve, basal values should be subtracted from the measured values of creatinine after administration.

Dogs with severe renal dysfunction may require sampling between 10 and 24 hours for more accurate GFR estimation, but the exact schedule necessary is unknown (Watson et al., 2002). As with determination of iohexol clearance, the accuracy of GFR measurement by exogenous creatinine clearance will be increased by increasing the number of blood samples taken to 10 over a 24-hour period (Watson et al., 2002).

4.5.4.4 Modified Water Deprivation Test (WDT)/ADH Response Test

In dogs with confirmed polyuria and polydipsia, the WDT can be performed as a provocative test of urine-concentrating ability. Administering just oral desmopressin in the absence of the rest of the WDT has been advocated as an alternative test (Syme, 2007). These tests should *only* be performed to distinguish between primary NDI, psychogenic (primary) polydipsia, and central diabetes insipidus (CDI) (Heiene and Lefebvre, 2007). All other causes of polyuria/polydipsia must be ruled out before considering these tests (Syme, 2007). The WDT should not be performed in patients who are azotemic, dehydrated, or have known renal disease or causes of secondary NDI (Heiene and Lefebvre, 2007). Dogs with secondary NDI such as pyelonephritis, hypercalcemia, renal insufficiency, pyometra, and HAC and dogs with partial CDI have similar WDT results (Syme, 2007). If all secondary NDI causes are not ruled out prior to the WDT, it may be impossible to distinguish dogs with secondary NDI from those with partial CDI and the test may cause significant patient morbidity (Nichols, 2001; Syme, 2007). The WDT is difficult to perform, unpleasant for the dog, and potentially dangerous if the dog is not appropriately monitored for signs of dehydration or neurologic signs secondary to hyponatremia (Heiene and Lefebvre 2007; Syme, 2007). Results of the test can also be confusing and inconclusive, especially with partial deficiency syndromes (Feldman and Nelson, 2004).

The WDT works on the principal that if the dog loses 5% body weight due to water deprivation, plasma osmolality will thereby increase sufficiently to stimulate maximal ADH secretion (Syme, 2007). If the kidneys can respond to this ADH stimulus, urine concentration will similarly increase (Feldman and Nelson, 2004). If the dog has normal ADH production, the exogenous ADH administration should not further increase the urine concentration, as the kidney should have been fully stimulated by endogenous ADH (Syme, 2007).

TABLE 4.2
Protocol for the Modified Water Deprivation Test [Adapted from Feldman and Nelson (2004) and Syme (2007)]

Phase I. Preparation for the test

1. Gradually withhold water over 3-5 days. Restrict water to 120 mL/kg/day 72 hours before, to 90 mL/kg/day 48 hours before, and to 60 mL/kg/day 24 hours before the WDT.^a These volumes of water should be given in 6–8 aliquots through the day.
2. Fast the dog for 12 hours, allow access to water.

Phase II. Water deprivation

1. Withhold food and all water.
2. Place an indwelling urinary catheter (ideally) and empty the urinary bladder.
3. Weigh the patient (exactly).
4. Measure urine specific gravity and osmolality.
5. Take a plasma/serum sample to measure creatinine/BUN and sodium concentration and osmolality.
6. Document the dog's baseline hydration and CNS status.
7. Completely empty the bladder every 1–2 hours.
8. Measure urine osmolality and specific gravity at each interval.
9. Weigh the dog after each urine collection.
10. Recheck serum/ plasma sodium and creatinine/BUN every 2–4 hours.
11. Check the hydration and CNS status each hour.
12. Stop Phase II if:
 - a. The dog loses 5% of its body weight
 - b. The dog is clinically dehydrated or ill
 - c. Urine specific gravity >1.030
 - d. Neurologic signs occur
 - e. Hypernatremia or azotemia are identified
 - f. After 3% body weight loss has occurred, when changes in urine concentration plateau so that there is <5% (or <30 mOsm/kg) increase in urine osmolality between three consecutive determinations, 1 hour apart.^a

NOTE. False plateaus can be detected with urine specific gravity; urine osmolality is more reliable.
13. On completion of phase II:
 - a. Empty bladder
 - b. Measure urine osmolality and specific gravity
 - c. Measure plasma/ serum osmolality
 - d. Measure plasma/serum creatinine/BUN and sodium

Phase III. Response to exogenous ADH

1. Administer aqueous vasopressin (Pitressin) IM (0.55 U/kg, maximum total dose 5 U).
2. Continue withholding food and water.
3. Empty the bladder every 30 minutes for 2 hours.
4. Measure urine osmolality and specific gravity at each interval.
5. With each urine collection, take serum/plasma for osmolality measurement.
6. Check serum/plasma creatinine/BUN and sodium.
7. Check hydration and CNS status.

Phase IV. Test End

1. Introduce small amounts of water (10–20 mL/kg) every 30 minutes for 2 hours.
2. Monitor for vomiting, check hydration and CNS status. (Acute water overload and cerebral edema can result if water is not reintroduced gradually.)^b
3. If dog has tolerated water reintroduction, return to ad lib water 2 hours after ending test.

^a Adapted from DiBartola (2006).

^b Adapted from Nichols (2001).

TABLE 4.3
Expected Results of the Water Deprivation and ADH Administration Phases of the Modified Water Deprivation Test

Diagnosis	Response to Water Deprivation to 5% Loss Body Weight	Response to ADH Administration Following Water Deprivation
Normal	Urine concentrates to mean peak osmolality of 2,289 mOsm/kg (range 1,768–2,738 mOsm/kg); mean urine SG 1.062 (range 1.050–1.076) ^a	<10% increase in urine osmolality ^b
Psychogenic (primary) polydipsia	Urine concentrates to osmolality > plasma osmolality; urine SG up to 1.030	<10% increase in urine osmolality
Central diabetes insipidus	<i>Complete CDI:</i> Urine osmolality does not increase above that of plasma (290–310 mOsm/kg); urine SG < 1.012 <i>Partial CDI:</i> Urine osmolality may increase > plasma osmolality; urine SG 1.012–1.020	<i>Complete CDI:</i> Urine osmolality increases by 50%–800% of pre-ADH value; urine SG > 1.025 <i>Partial CDI:</i> Urine osmolality increases by 10%–50% of pre-ADH value; urine SG > 1.025
Primary nephrogenic diabetes insipidus	Urine osmolality ≤ plasma	No change in urine osmolality/urine SG

Secondary NDI should be excluded before performing the test (see text); results of secondary NDI may overlap with those of partial CDI. SG, specific gravity.

^a Hardy and Osborne (1979).

^b Mulnix et al. (1976).

Because dogs with primary polydipsia likely have renal medullary washout, they will not be able to concentrate their urine effectively in the face of water deprivation (Syme, 2007). For this reason, the gradual (modified) WDT is considered superior to the WDT because the associated gradual water deprivation allows time for correction of the medullary washout prior to the WDT (Syme, 2007). In the traditional WDT, dogs with primary polydipsia can be mistakenly identified as having (NDI) due to their medullary washout.

The modified WDT is described in Table 4.2, a protocol adapted from Syme and Feldman and Nelson (Feldman and Nelson, 2004; Syme, 2007). In normal dogs, sufficient dehydration to induce maximal urine concentration usually occurs after a mean of 42 hours, but may not occur until after 96 hours (Hardy and Osborne, 1979). In dogs with polyuria and polydipsia, time until reaching 5% dehydration, that is, the completion of the first phase of the test, may range from a few hours to 12 hours (DiBartola, 2006).

If a dog does not concentrate urine during water deprivation, either the kidneys cannot respond to ADH (NDI) or an ADH deficiency exists (CDI) (Hardy and Osborne, 1979). In dogs with complete CDI, urine osmolality will increase by 50% or more following administration of vasopressin. In the partial forms of central CDI, urine osmolality after vasopressin will increase, though less dramatically ($\geq 10\%$), and in NDI there will be very little or no rise in urine osmolality (Kooistra and Galac, 2010). Table 4.3 summarizes the expected modified WDT results for each syndrome. Some authors have advocated incorporating plasma vasopressin measurements into phase II of the WDT

to improve its accuracy in discriminating between the different disorders affecting urine concentration (Feldman and Nelson, 2004). However, the erratic vasopressin responses to osmolality that have been documented in some dogs make the utility of vasopressin measurement questionable (van Vonderen et al., 2004). One complicating factor in interpreting the WDT in dogs is that psychogenic polydipsia may not be a uniform syndrome in dogs (van Vonderen et al., 1999). Some dogs with psychogenic polydipsia have abnormalities in their vasopressin release and thus have WDT results consistent with partial CDI (van Vonderen et al., 1999; Rijnberk, 2010). Dogs with HAC may also have similar WDT results to those of dogs with psychogenic polydipsia and partial CDI. HAC must be considered in a dog with equivocal WDT results, especially given the greater frequency of HAC compared to the relatively rare CDI, NDI, and psychogenic polydipsia (Feldman and Nelson, 2004).

An alternative to the modified WDT is a response to oral desmopressin, in which dogs receive oral desmopressin (0.05–0.2 mg/dog every 8 hours) for 5–7 days (Syme, 2007). The dog is monitored for resolution of polyuria/polydipsia. Urine specific gravity is evaluated before and after desmopressin treatment. Only dogs with CDI will respond to desmopressin by concentrating their urine to >1.025 SG. Dogs with NDI or primary polydipsia will not respond or respond minimally and cannot be differentiated from each other by this test (Feldman and Nelson, 2004; Syme, 2007). Water intoxication is a potential complication of this test if dogs continue to be polydipsic during the antidiuretic effects of vasopressin (Hardy and Osborne, 1982).

4.6 REFERENCE RANGES IN THE DOG

Analyte		Concentration	Units	Reference
Ammonia	–	45–120	µg/dL	Silverstein and Hopper (2009)
Bile acids	Fasting	<10	µM	Silverstein and Hopper (2009)
	Radioimmunoassay	0.2–4.3	µmol/L	Counsell and Lumsden (1988)
	Enzymatic	0–8.6	µmol/L	
Cardiac troponin I	–	0.00–0.11	ng/mL	Payne et al. (2011)
Cardiac troponin T	–	<0.05	ng/mL	Tarducci et al. (2004)
Gamma-glutamyl transferase (GGT)		1.2–6.4	U/L	Kaneko et al. (2008)
Ornithine carbamyl transferase (OTC)		2.7 (±) 0.7	U/L	Kaneko et al. (2008)
Sorbitol dehydrogenase (SDH)	–	2.9–8.2	U/L	Kaneko et al. (2008)
Thyroid function				
Triiodothyronine (T3)	–	48–154	ng/dL	Silverstein and Hopper (2009)
Thyroxine (T4) serum	–	20–55	nmol/L	Kemppainen and Behrend (2001)
	–	1.5–4.3	µg/dL	Kemppainen and Behrend (2001)
Free T4	Dialysis	10.0–45.0	pmol/L	Kemppainen and Behrend (2001)

	Intact male	0.2–12.0	ng/mL	
	Castrated male	9.8 (±) 2.7	ng/mL	
	Male Beagles	4.6 (±) 2.7	ng/mL	Urhausen et al. (2009)
Progesterone	Proestrus	1.7 (±) 0.3	ng/mL	Nett et al. (1975)
	Early estrus	3.5 (±) 0.3	ng/mL	
	Day 5 after LH peak	23.3 (±) 2.8	ng/mL	
	One day prior to whelping	3.3 (±) 1.2	ng/mL	
	Day of whelping	1.1 (±) 0.2	ng/mL	
<i>(continued)</i>				
Prolactin	Male	<6.0	ng/mL	Corrada et al. (2006)
	Male beagles	3.8 (±) 0.9	ng/mL	Urhausen et al. (2009)
Testosterone	Intact male	0.4 - 6.0	ng/mL	DePalatis et al. (1978)
	Castrated male	Undetectable		
Gastrointestinal absorption and digestion				
Cobalamin	–	284–836	ng/L	Silverstein and Hopper (2009)
Folate	–	7.5–17.5	µg/dL	Silverstein and Hopper (2009)
Iron	–	94–122	µg/dL	Silverstein and Hopper (2009)
	–			
Pepsin-like immunoreactivity (PLI)	–	4.4–276.1	µg/L	Silverstein and Hopper (2009)
Trypsin-like immunoreactivity (TLI)	–	5–35	µg/L	Silverstein and Hopper (2009)
Serum gastrin	–	<100	pg/mL	Altschul et al. (1997)
	–	10–40	pg/mL	Green and Gartrell (1997)

Because methodologies and analyzers may vary, it is best to use the reference ranges of the reference laboratory generating the results.

5.1 INTRODUCTION

The pig has become an important tool as a laboratory animal for biomedical research. The increasing importance of swine as an animal model for human diseases and testing is related to the highly correlated anatomical and physiological similarities between the two species, and to a lesser justification, the lowered animal rights group interest in swine use as compared to primate [nonhuman primate (NHP)] or dog use. For example, because swine demonstrate similarities to man in cardiovascular anatomy and physiology (e.g., comparable heart-to-body size ratio, coronary vasculature anatomy, lipoprotein structure/profile, development of hypercholesterolemia and atherosclerosis, tendency toward obesity, insulin resistance, and susceptibility to a variety of stress factors), they have become a valuable animal model for cardiovascular research. Concordance between swine and human dermal wound healing studies was 78% while a significantly lower concordance was reported for rodents (Sullivan et al., 2001). Pigs are monogastric omnivores and exhibit a resemblance to man in dietary habits and digestive physiology. Numerous references describe similarities between pigs and humans, thus laying the foundation for the extrapolation of experimental pig data to humans (Horstman et al., 1960; Bustad and McClellan, 1966; McClellan, 1968; Douglas, 1972; Mitruka et al., 1976; Tumbleson, 1986; Swindle and Adams, 1988; Swindle et al., 1992; Tumbleson and Schook, 1996; Brown and Terris, 1996; Reeds and Odle, 1996; Mortensen et al., 1998; Swindle and Smith, 1998, 2000; Schook et al., 2005; Vodicka et al., 2005; Svendsen, 2006; Nunoya et al., 2007).

Besides the obvious functional and anatomical similarities, swine provide other advantages for the biomedical investigator. As intelligent, sociable, and trainable animals, they are adaptable to a wide variety of experimental conditions. They are readily available at a relatively lower cost as compared to primates and are capable of producing large litters in a reasonably short period of time. Though considered large laboratory animals along with dogs, ruminants, and primates, miniature and young domestic pigs are of manageable size and can accommodate performance of complicated surgical techniques, dosing of test article by all routes, serial blood collections, and many other research manipulations. “Micropigs” or microswine offer even greater advantages regarding size, handling ease, and food and caging requirements. Examples of microswine include the Micro-Yucatan, currently marketed by Sinclair BioResources, LLC, and the Göttingen Minipig® (Ellegaard Göttingen Minipigs A/S), which is marketed by Marshall BioResources. Pigs can be downsized as evidenced by these Micros but along with the smaller size from inbreeding comes higher rates of birth defects. Swine models are acceptable surrogates for the canine and primate models in most regulatory safety studies (Jacobs, 2006). In summary, there are good scientific, economic, and sociological reasons why domestic swine and miniswine are appropriate research models.

5.2 USE OF PIGS IN BIOMEDICAL RESEARCH

The anatomy of the pig was documented in the twelfth century by Copho, a professor teaching anatomy at Salernum, Italy, in his treatise entitled *Anatomica Porci*. Earlier Greek works on porcine anatomy also existed. In 1543, Andreas Vesalius, a Flemish anatomist from Brussels, taught anatomy at the University of Padua, Italy, where he performed vivisection on pigs for teaching medical students (Ball, 1910). Since early times, the truffle-loving pig with the exquisite olfactory sense has found refined use as a teaching tool and an animal model, especially in agricultural, biomedical, and nutrition research.

The laboratory swine (*Sus scrofa*) has been utilized as a mammalian model for human nutrition and biology research, gnotobiology, toxicology testing, and experimental surgical modeling for many decades and is well established (Phillips and Tumbleson, 1986; Miller and Ullrey, 1987; Lunney, 2007; Swindle and Smith, 2008; Swindle, 2007; Gad et al., 2008). The United States Department of Agriculture (USDA)–National Agriculture Library (NAL) Information Resources on Swine in Biomedical Research (Swindle and Smith, 2000) addresses comparative anatomy and physiology of research swine in some detail. Most miniature swine organs and systems are physiologically mature

by sexual maturity (4–6 months) (Swindle and Smith, 2008). The similarity in size, physiology, and in organ development and disease progression make the swine an ideal model for studies during almost all developmental periods (fetal, perinatal, juvenile, adolescence, adulthood, geriatric). The United States Food and Drug Administration (FDA, 2000), Buelke-Sam (2002), Beck et al. (2006), and Padgett (2009) have addressed approximate ages of miniswine, which are comparable to human developmental periods for central nervous system (CNS) and reproductive development up through adolescence. Since biological systems may develop, advance, or mature at differing timeframes, the age equivalent period for CNS and brain may not necessarily apply for skeletal, immunological, reproductive, or other systems.

Similarities to human organ size and human leukocyte antigen (HLA) haplotyping (compared to swine leukocyte antigen [SLA]) have made the swine the primary choice for organ, tissue, and cell xenograft transplantation procedures. Genetically altered (knock-out or gene insertion) porcine models show promise for xenotransplantation research (Prather et al., 2003). The ability to use matched littermates facilitates comparison of genetically homogeneous treatment and control animals. The U.S. National Swine Resource and Research Center (NSRRC), established in 2003 at the University of Missouri in Columbia, Missouri, facilitates specialized genetic studies as a resource for frozen embryos, germplasm, cells, tissues, and organs.

Because of the considerable skin surface area in young adult swine, control and treatment dermal application or wound sites can be placed side by side for ready comparison. Swine skin is fixed or tightly adherent to the hypodermis and heals primarily by re-epithelialization like that of humans rather than primarily by contraction as in loose-skinned rodents or rabbits.

The ease of deliberately timing studies— imaging internal vessels, organs, and bone using standard technologies (fluoroscopy, dual Energy x-ray [DEXA], computed axial tomography [CT], magnetic resonance imaging [MRI], intravascular ultrasound [IVUS]); and collecting necropsy specimens, repeated peripheral blood, urine, synovial fluid, and cerebrospinal fluid (CSF) samples of generous quantity—has provided evidence that the pig is a workable biomedical model.

Over the past 50 years, application of the pig as a research model has expanded to include models for many experimental biomedical designs, including paradigms for the study of a wide variety of human disease conditions, biological processes/mechanisms, and for preclinical testing (Table 5.1). Animal models, such as swine, are necessary for study of human disease biology, processes, pathology, treatment modalities, surgical methods, and for testing of potential pharmaceutical drugs, biologics, and implantable biomedical devices. Miniature swine models are extensively used in preclinical safety and efficacy studies, and applications listed in Table 5.1.

Porter (1993) and Pond and Mersmann (2001) have identified current domestic pig breeds of the world. As adapted from Porter (1993), Pond and Mersmann (2001) listed 172 breeds of domestic pigs and, as adapted from Panepinto (1996), 24 breeds of miniature swine. Panepinto (1996) has reviewed the history and background of miniature swine breeds used in worldwide research. Swindle and Smith (2008) suggest there are over 50 miniature swine breeds worldwide but only a few are important in biomedical research. Common miniature swine used in research include the Yucatan, Hanford, Sinclair S-1, Ossabaw, Göttingen, Banna, Vietnamese Potbellied, and Meishan (Swindle and Smith, 2008). Table 5.2 lists almost all historical and contemporary miniature and microswine lineages. The Vita Vet or Pitman Moore, Chicago Medical School, Labco, and Nebraska are historical miniature swine strain names. Reference data, including clinical pathology, are usually available either from the literature or from companies or institutes producing or using each contemporary breed, strain, or lineage of miniature swine.

Domestic swine breeds commonly used in biomedical, nutritional, agricultural, and environmental research in North America include the Yorkshire, Yorkshire-cross, and Duroc, while in European research settings the Landrace or Landrace-cross and British Large White are most popular. Other domestic breeds such as the Pig Improvement Company (PIC), United States, genetic lines from Franklin, Kentucky, are in use for environmental Superfund soil oral bioavailability studies (Casteel et al., 1997). Select miniature swine lineages have found

Genetics	Trauma or traumatology
Hemorrhagic shock and hemostasis	Vaccine safety and infectious disease models
Hypotension/hypertension	Whole body composition
Immunology	Wound healing

Intended to present examples but not an exhaustive list of uses.

application in specific research categories but almost all lineages function equally well for most applications. Popular North American miniature swine lineages and example uses include the Micro- or Mini-Yucatan for ventricular septum defect (VSD), diabetes, and wound healing; the Sinclair S-1 for osteoporosis, malignant melanoma, and dental models; and the Hanford for atherosclerosis and dermal toxicology testing. The thrifty feral island Ossabaw miniature pig has recently been applied to diabetes and cardiometabolic syndrome model research (Sturek et al., 2007). The Standard or Mini Yucatan is commonly used in the research and contract research organization (CRO) settings in the United States. Domestic swine are applied widely for many models such as familial hypercholesterolemia (FHC) and atherosclerosis, hypertrophic dermal scarring (Duroc), wound healing and thermal burns (Yorkshire), neonatal or pediatric nutrition, trauma, surgical training, metabolism, stent and other cardiovascular studies.

5.3 UNIQUE PHYSIOLOGICAL CHARACTERISTICS OF THE LABORATORY PIG

Swine models show important anatomical, physiological, and biochemical concordance with higher-order mammals, especially humans. This is the main reason why they are valuable for biomedical research. Only a few dissimilar unique aspects exist such as the neurogenic instead of myogenic heart conduction, a paucity of eccrine glands in the skin, the lack or low activity of CYP2B, CYP2C, and CYP22D and low drug sulfation activity. Ornithine carbamoyltransferase (OCT) is an enzyme that is liver-specific in the pig and could be useful for the detection of hepatocellular injury

(Cornelius, 1989); it has been recommended as a useful serum marker of liver damage in the pig (Wilson et al., 1972). Arginase and sorbital dehydrogenase (SDH, also called iditol dehydrogenase or IDH) are other liver-specific enzymes in swine (Kahn, 2008a, 2008b). The $T_{1/2}$ of SDH in swine is reported to be only 1.6 hours (Hoffmann and Solter, 2008; Boyd, 1983), which limits its usefulness in most long-term toxicology studies but it may have utility in acute hepatocellular testing.

Gad et al. (2008) has reported that swine have a liver cytochrome P-450 system that is comparable to humans, although there are a few exceptions for certain cytochromes P450 (CYP) isoenzymes

and the amounts and activities of specific enzyme isoforms occasionally vary between minipigs and humans. In swine, there is a low level of CYP2C, and CYP2D is absent (Swindle, 2007).

Swine are useful models for atherosclerosis, coronary heart disease, and obesity, because pigs and humans have similar lipoprotein patterns (Mahley and Weisgraber, 1974); the majority of the plasma cholesterol is carried as low-density lipoprotein (LDL) in pigs and humans (Attie et al., 1992); vascular plaques readily forms in swine on high-fat high-cholesterol (HFHC) diets, especially after intimal or vascular wall damage by balloon; and both have a similar propensity for obesity. In the progression of these lesions, vascular streaks precede complex vascular lesions containing cholesterol clefts and macrophages. There are multiple techniques for acceleration of the natural tendency for formation of arteriosclerotic or atherosclerotic plaque lesions in swine, as follows:

1. Dietary HFHC (2%–4% cholesterol, 40% dietary fat; generalized lesions in 6 months) (Swindle and Smith, 2008)
2. Balloon catheter denuding of specific intimal sites (coronaries, iliacs) with HFHC diet (lesions by 3 months) (Swindle and Smith, 2008; Gal and Isner, 1992) (for laser angioplasty denuding, see White et al., 1988; also White and Ramee, 1989)
3. Overstretching of arterial wall by catheter balloon (Gerdes et al., 1996; Saitoh et al., 1998; Eto et al., 2000)
4. Diabetes plus HFHC diet (Gerrity et al., 2001; Dixon et al., 2002)
5. Blood flow stenosis by aneurid or ligation restriction (carotids) (Ishii et al., 2006; Shi et al., 2009)

Attie et al. (1992) described a mutant, spontaneously hypercholesterolemic pig resembling FHC in humans (Type Ha), which is the most common type of hypercholesterolemia involving an increase in LDL. The mutant pigs had increased LDL and normal LDL receptor activity (Rapacz et al., 1986). Two variants of the familial hypercholesterolemic pigs, Lpb5.1 and Lpb5.2, were described, and both had alterations of the predominant apoprotein, apo-B, which serves as the ligand for the receptor. The altered protein caused a decreased affinity of LDL for the receptor, resulting in a decreased clearance rate of LDL from the blood. The Lpb5.1 pigs displayed an approximately threefold increase of serum cholesterol concentration, while the Lpb5.2 pigs had only a moderate 20%–25% increase. Besides the cholesterol concentration difference, the cholesterol increase in the Lpb5.1 pigs was characterized by a marked elevation in the concentration of a more buoyant form of LDL; there was a greater cholesterol ester/protein ratio than that found for the denser form of LDL. The Lpb5.2 pigs did not demonstrate an increase of this buoyant LDL variant. Additionally, the more buoyant form of LDL was catabolized more slowly than the denser LDL (Checovich et al., 1988). Small dense LDL (sdLDL) is less buoyant and more atherogenic in humans so buoyancy or flotation rate of LDL is a logical interest factor for atherosclerosis researchers (Norata et al., 2009). Hasler-Rapacz et al. (1995) reported that the University of Wisconsin domestic herd of complex familial hypercholesterolemia (c-FHC) phenotype pigs were characterized by elevated levels of total plasma cholesterol (TC) and apoB and reduced levels of high-density lipoprotein cholesterol (HDL-C) and apoA-I is associated with the spontaneous atherosclerotic lesions in the swine. Certain apo B genotypes (Lpb2/3, 3/3, 3/5, 5/5, 3/8) of these animals developed stenotic coronary lesions containing necrotic cores, fibrous caps, calcification, neovascularization, hemorrhage, and fissuring, which resembled advanced coronary artery disease (CAD) in humans (Prescott et al., 1995). The familial dyslipidemia appeared to be polygenic.

Aminophenylboronic acid affinity chromatography methods have been used to demonstrate that pigs have lower glycosylated hemoglobin (A1c) values than other commonly used laboratory animal species (e.g., the dog, rat, mouse, gerbil, and rabbit) and man (Rendell et al., 1985).

Spontaneous, genetically manipulated (e.g., transgenic or knockout), and conventionally induced models are available. Most organs and systems in pigs are physiologically mature by sexual maturity (Swindle and Smith, 2008), which occurs at a relatively young age (4–6 months) in minipigs. As the knowledge base expands, further unique aspects of swine models may be uncovered.

5.4 METHODOLOGY FOR SAMPLE COLLECTION

5.4.1 BLOOD COLLECTION

Blood collection from swine can be a labor-intensive procedure that, in most instances, requires special restraint methods and/or equipment. For example, Carle and Dewhirst (1942) described a method for blood collection from the anterior vena cava during which a hog snare was used to immobilize the animal for venipuncture. A number of restraining devices have been described (Bustad and McClellan, 1966; Earl, 1968; Huhn et al., 1969; Mackellar, 1970; Terris et al., 1986; Tumbleson et al., 1968), and methods of physical and chemical restraint have been reviewed (Panepinto, 1986; Riebold and Thurmon, 1986). More established techniques of restraint, including the snare and V-trough, were designed for livestock handling and, as a forceful means of restraint, can cause stress to the animal. There are less stressful methods, including a hoisting rack, a portable confinement unit, farrowing crates, tethering, the Panepinto sling, and socialization to facilitate little or no restraint.

In young and adult pigs, blood collection has been accomplished from several sites; the site for collection depends on the frequency of sampling and the volume of blood required. For single blood samples, methods have been described for collection from the orbital sinus (Huhn et al., 1969; Muirhead, 1981) and by cardiac puncture (Calvert et al., 1977). Venous sites include the auricular veins (Muirhead, 1981), cranial vena cava (Brown, 1979; Carle and Dewhirst, 1942), cephalic vein (Tumbleson et al., 1968), and lateral saphenous vein (Bobbie and Swindle, 1986). The auricular and lateral saphenous veins can be visualized for venipuncture while the cephalic vein and cranial vena cava are usually blindly approached for percutaneous venipuncture. The cranial vena cava is the venous site of choice for procedures requiring a large volume of blood. Swindle (2007), Popesko (1984), and Ghoshal (1975) have previously addressed anatomical considerations for swine vascular access.

For serial blood sampling, indwelling catheters have been implanted in one of several vessels such as the external jugular (Bailie et al., 1986; Brown et al., 1973; Rodriguez and Kunavongkrit, 1983; Takahashi, 1986; Terris et al., 1986; Wingfield et al., 1974), ear vein (Bustad, 1966), femoral vein (Brown et al., 1978), vena cava via the external jugular (Ford and Maurer, 1978), midsacral artery or subcutaneous (SC) abdominal vein (Witzel et al., 1973), abdominal aorta via the superficial femoral artery (Weiskopf et al., 1986), medial saphenous vein (Bobbie and Swindle, 1986), pulmonary artery via the innominate vein (Weiskopf et al., 1986), and carotid artery (Bossone and Hannon, 1985; Hannon et al., 1981a, 1981b; Terris et al., 1986). Fleming and Arce (1986) described a method of portal vein and carotid artery catheterization which, with appropriate familiarization of the animals regarding handling procedures and personnel, allowed the collection of timed serial samples with minimal stress to the animals. Techniques for the chronic implantation of catheters in fetal pigs have also been reviewed (Hill, 1986; Randall, 1986; Spencer et al., 1986).

5.4.1.1 Restraint for Venipuncture

Agricultural methods of restraint such as snout tying or snaring and squeeze chutes should be avoided where possible in research swine. These methodologies are stressful to the pig and make it more difficult for personnel to interact with the animals when they are on a chronic study. Vocalization during this type of restraint is stressful to personnel who are working with the animals, and the pig stress response also causes variability in many blood values. Swine may be restrained in humane restraint slings or with the use of minimal manual restraint in smaller animals.

If animals need to be chemically restrained, several methods may be utilized. Administration of diazepam 0.5–5 mg/kg *per os* (PO) in a food treat or by SC injection will provide relaxation for most swine within approximately 15 minutes postadministration. Diazepam sedation will last for 4–6 hours. Swine may also be induced under gas anesthesia with isoflurane or sevoflurane delivered via a face mask for blood sampling. In large and/or fractious animals, intranasal (IN) administration

of 0.2–0.4 mg/kg midazolam is very effective in providing short-term sedation in <5 minutes after administration. The sedation lasts approximately 20 minutes. For IN administration, the injectable agent is pulled into a syringe, the needle is removed, and the solution is rapidly injected into a nostril while the pig is being distracted with a hand-held food treat or toy. The object for distraction is held above the level of the pig's head causing the snout to be elevated.

5.4.1.2 Venipuncture Sites and Techniques

Bleeding sites may be rotated between the vessels discussed in this section. Lidocaine patches can be used to desensitize the skin to repeated needle sticks (Swindle, 2007; Hawk et al., 2005). For chronic projects involving frequent blood samples, the implantation of catheters or vascular access ports may be indicated. Short-term catheterization with intravenous catheters (Intracath™ with through the needle introducer, Becton Dickinson) may also be performed for up to 3 days (Swindle, 2007; Swindle et al., 2005). Yen (2001) has reviewed blood sampling and surgical techniques in research swine.

Retro-orbital bleeding has been described in the agricultural literature but it should be avoided because it is both distressing to the pig and may cause ocular complications. Vacutainers can be used for the larger vessels but they will not function well for the cephalic, coccygeal, and auricular veins. Alcohol applied to the skin over the superficial veins will facilitate the identification and dilation of the vessels.

5.4.1.2.1 Cranial Vena Cava

The cranial vena cava (precava) is the largest vessel that is commonly accessed for blood samples (Figure 5.1). The sample size from this vessel is only limited by the amount of blood which can be safely removed without causing harm to the animal (generally not to exceed 1% of the total blood volume for nonterminal procedures). Examples of clinical signs resulting from excess blood removal include death, collapse, pale mucous membranes, lethargy, anemia, bruising, hematoma, and avoidance behavior. This occurs very infrequently with large animal miniature swine models. Animals may be positioned in a restraint sling or placed in dorsal recumbency to access this vessel. The vessel is always accessed from the right side of the thoracic inlet to avoid the vagus and recurrent laryngeal nerves which are more prominent on the left side. The needle is advanced at

FIGURE 5.1 (See color insert.) Cranial vena cava venipuncture.

a 45° angle toward the left shoulder of the pig. Repeated blood sampling from this area will result in hematoma or blood clot formation in the thoracic inlet, because it is not possible to stop leakage from the venipuncture with digital pressure. In swine <50 kg the vessel can be accessed using a 20 gauge (G), 1.5" needle. For animals >50 kg, needles as large as 18 G, 2.5" may have to be used (Swindle, 2007; Hawk et al., 2005).

5.4.1.2.2 External Jugular Vein

The external jugular vein can be accessed in the jugular furrow which is visualized after extending the neck and retracting the forelegs caudally (Figure 5.2). The vein runs along a line drawn from the caudal aspect of the mandible to the thoracic inlet on the same side. The amount of blood that can be withdrawn from this vessel is also unlimited, but generally it is used for samples <20 mL because of the manipulations of the pig that are required. This is a large blood vessel which can be accessed with a 20 G, 1.0–1.5" needle in most swine (Swindle, 2007; Hawk et al., 2005).

5.4.1.2.3 Internal Jugular Vein and Carotid Artery

The internal jugular vein, carotid artery, and vagus nerve are all located in a sheath on either side of the trachea on the ventral surface of the cervical vertebrae (Figure 5.3). Positioning of the head and neck are the same as for the external jugular vein. The carotid pulse can be used to locate these vessels. The vein will be slightly lateral to the artery and the nerve. The carotid artery is frequently used as the vascular access site for terminal bleeding under general anesthesia. These vessels can be accessed with a 20 G, 1.0–1.5" needle. Bradycardia or arrhythmias may occur if the vagus nerve is accidentally stimulated with the needle (Swindle, 2007; Hawk et al., 2005).

5.4.1.2.4 Cephalic Vein

The cephalic vein can be accessed along the cranial surface of the radius on the foreleg and also as it crosses the ventral surface of the neck to enter the external jugular vein at the thoracic inlet (Figures 5.4 and 5.5). A tourniquet is placed around the foreleg at the level of the proximal radius and the elbow (ulnar head) is pressed to extend the leg. In order to access the vessel on the ventral surface of the neck the animal is placed in dorsal recumbency and digital pressure is applied to the thoracic

FIGURE 5.2 (See color insert.) External jugular vein accesses.

FIGURE 5.3 (See color insert.) Internal jugular vein and carotid artery access.

FIGURE 5.4 (See color insert.) Cephalic vein access on the foreleg.

inlet alongside the trachea. The cephalic vein can then be visualized. This vessel can be accessed with a 20 G, 1.0" needle. The amount of blood that can be withdrawn is usually < 5 mL (Swindle, 2007; Hawk et al., 2005).

5.4.1.2.5 Femoral Vein and Artery

The femoral artery and vein are located in the femoral groove formed by the borders of the sartorius and gracilis muscles (Figure 5.6). They may be located by palpation of the femoral pulse or

FIGURE 5.5 (See color insert.) Cephalic vein access on the neck.

FIGURE 5.6 (See color insert.) Femoral artery and vein access.

by following the pulse of the medial saphenous artery, which disappears as this superficial vessel disappears into the femoral groove (Figure 5.7). The vessels are located under the medial edge of the gracilis muscle rather than directly in the groove. The pig is placed in dorsal recumbency and the rear leg is gently extended to access this site. Sedation is required for this procedure. The femoral vessels can be accessed with 20 G, 1.0–1.5" needles. The amount of blood that can be withdrawn is usually 5–10 mL (Swindle, 2007; Hawk et al., 2005).

FIGURE 5.7 (See color insert.) Medial saphenous artery access.

5.4.1.2.6 Cranial Abdominal (External Mammary) Vein

The cranial abdominal vein is located along the deep lateral edge of the most cranial three mammary glands (Figure 5.8). This vessel greatly enlarges in sows that have had litters. Digital pressure is applied at the caudal edge of the last rib along the line of mammary glands to distend this vessel. This vessel can be accessed using 20 G, 1.0" needles. In animals that have not reached sexual maturity, usually only 5 mL of blood can be obtained. In sows that have had litters, volumes up to 20 mL can be obtained (Swindle, 2007; Hawk et al., 2005).

5.4.1.2.7 Ear (Auricular) Vein

The ear veins are located along the medial and lateral edges of the dorsal aspect of the pinnae (Figure 5.9). Digital pressure can be applied at the base of the ear or a tourniquet can be used to dilate the vessels. The central vessel on the ear is an artery. Depending upon the size of the pig the veins can be accessed using 20–22 G, 1" needles. However, it is better to access them with a butterfly catheter or an intravascular catheter. Use of 18" intravenous catheters (Intracath™) will allow you to pass a catheter into the maxillary or external jugular vein in most animals. For this technique, the catheter is passed to the base of the ear and then the ear is pulled cranially and a finger is used to facilitate passage of the catheter beyond the base of the ear into the larger vessels. Catheters placed in the ear veins can be maintained successfully for up to 3 days. Only 1–2 mL of blood can usually be obtained from the ear vein itself; however, if the method of passing a catheter is used then the amount of blood that can be obtained is unlimited (Swindle, 2007; Hawk et al., 2005).

5.4.1.2.8 Tail (Coccygeal) Vein

The coccygeal veins accompany the artery on the ventral surface of the tail. These vessels may be accessed by raising the tail and performing venipuncture at the base of the tail (Figure 5.10). These vessels can be accessed using 20 G, 1.0" needles. Only 1–2 mL of blood can be obtained from these vessels (Swindle, 2007; Hawk et al., 2005).

FIGURE 5.8 (See color insert.) Cranial abdominal vein access.

FIGURE 5.9 (See color insert.) Ear vein access with a catheter.

5.4.2 URINE COLLECTION

Timed urine collections can be performed for swine with the use of metabolism cages. Equipment and methods for timed urine collection from male and female pigs of various sizes have been reviewed (Terris et al., 1986). Since these authors suggested that most of the methods and equipment available did not allow adequate freedom of movement for the experimental animals, they described a portable metal unit that did allow more motion. They indicated, however, that the urine

FIGURE 5.10 Coccygeal vein access.

was obtained from an unrefrigerated collecting pan, and there were no provisions for the quantitative separation of urine and feces, which can significantly impact results of urinalysis.

Metabolism cages for swine are commercially available and can be used for collection of total urine volume over time. Invariably these urine samples will become mixed with feces, food, and water, and potential contamination has to be taken into consideration when using this methodology. Assimos et al. (1986) described the use of a metabolism cage for the collection of a timed urine sample that allowed the animals to eat, drink, and sleep; urine was transported through a central floor port via a hose to a refrigerated container. Assimos et al. indicated that there was little fecal contamination of the collected urine. Urine samples were, however, filtered through a #1 Whatman filter paper prior to analysis.

Other methods of urine collection have involved catheterization and surgical techniques. For example, renal clearance studies have been performed on catheterized gilts using a 16 Fr Foley retention catheter (Zatzman et al., 1986). Also, surgical cannulation of ureters (O'Hagan and Zambraski, 1986) and an *in situ* isolated kidney preparation (Loveday et al., 1989) have been used for urine collection in pigs.

It is possible to collect samples during normal urination of a caged animal by manually catching the urine in a suitable container. However, collection of an adequate and clean sample from a pig by using this method would be haphazard at best. Cystocentesis has been used to collect urine but the bladder of the pig is thin walled and can easily be sucked onto the needle tip during cystocentesis if excess positive suction with the syringe is applied while collecting urine (Wills et al., 1997).

The most reliable method for the collection of an uncontaminated urine sample in the pig involves acute or chronic catheterization of the urinary bladder. Females are more easily catheterized and can be done so in either dorsal or ventral recumbency. Animals should be anesthetized or sedated when performing this procedure. Catheters used in females should either have some degree of stiffness or have a stylette inserted into them prior to attempting the catheterization (Figure 5.11).

FIGURE 5.11 Foley urinary catheters composed of 100% silicone with retention balloons.

Flexible rubber catheters tend to bend and not advance retrograde into the bladder. The urethral opening is on the floor of the vagina a short distance beyond the caudal edge of the pubis. The urinary papilla can be visualized and catheterized directly if a vaginal speculum is utilized to spread the vaginal opening laterally and a laryngoscope or endoscope with a light is then inserted to press the dorsal surface of the vagina. With the female in sternal position, the papilla becomes evident and the catheter can be inserted directly. The urethra can also be catheterized directly if the animal is in dorsal recumbency and a catheter is slid along the ventral floor of the vagina into the urethra. Catheterization is facilitated if a sterile lubricant is applied to the tip of the catheter. Catheters with balloons can be inflated to be chronically maintained in the bladder or the catheter may be sewn to the vagina. The catheter can be plugged and periodically opened and a sample collected with the animal either sedated or restrained in a sling (Figure 5.12). Catheter sizes from 5 to 14 Fr will fit pigs between 10 and 70 kg (Swindle, 2007).

Male pigs are more difficult to catheterize due to the anatomy of the penis. Obstacles include the preputial diverticulum, the corkscrew-shaped tip of the penis, and the sigmoid flexure on the ventral surface of the pubis. While catheterization of males is not routinely performed, a recent abstract (Hite, 2009) presented a technique for catheterization of male pigs by using a guide wire. In larger pigs, the urethra can be palpated as it crosses the caudal aspect of the pubic bone to enter the pelvic cavity, and this portion of the urethra can be percutaneously or surgically approached and an indwelling catheter inserted into the bladder. Retention of a chronic catheter is performed in the same manner as for the female (Swindle, 2007).

Alternatively an indwelling catheter can be surgically implanted into the bladder of either gender with a midline or paramedian surgical approach in the caudal abdomen cranial to the pubis. The bladder catheter can be sutured into place and exteriorized for collection with sedation or restraint in a sling when a sample is required. Human pediatric collection bags have an adhesive edge and can be placed over the vulva of a female for short-term collection (Swindle, 2007).

FIGURE 5.12 Urinary catheterization of a female with a urinary collection bag attached.

5.5 PREANALYTICAL SOURCES OF VARIATION

Besides choosing appropriate endpoints for analysis, the research investigator must consider several preanalytical sources of variation prior to the inclusion of clinical chemistry evaluations in any study design involving swine (Tumbleson and Schmidt, 1986).

5.5.1 GENDER

As observed in many other species, gender differences for clinical chemistry values have been documented in swine. For example, for Sinclair (S-1) miniature swine evaluated in a 36-month study, serum urea nitrogen decreased for female pigs after 13 months and up to 24 months of age when urea nitrogen concentration stabilized for the remainder of the study (Hutcheson et al., 1979). In males, serum urea nitrogen increased from 7 to 24 months of age and then remained stable. Additionally, 5- to 36-month-old female Sinclair miniature pigs had higher cholesterol and triglyceride concentrations than males (Tumbleson et al., 1976a). There were no gender differences for serum total protein, creatinine, inorganic phosphorus, calcium, sodium, potassium, and chloride concentrations between male and female Sinclair (S-1) miniature pigs (Hutcheson et al., 1979; Tumbleson et al., 1976b). Tumbleson et al. (1976b) reported that, at 14 months of age, albumin concentration was 3.7 and 3.9 g/dL for male and female minipigs, respectively. By 36 months of age, albumin concentrations declined to 3.0 g/dL for male and 3.1 g/dL for female minipigs. It has been reported that serum cholesterol in swine decreases with age (Tumbleson et al., 1976a).

In Yucatan miniature swine, no gender differences were observed for clinical chemistry reference values of animals ranging in age between 8 and 54 months (Radin et al., 1986). In another study, however, Yucatan miniature swine with an average age of approximately 35 weeks demonstrated gender differences for several clinical chemistry reference values (Parsons and Wells, 1986). The authors

demonstrated higher serum creatinine (123.8 vs. 106.1 $\mu\text{mol/L}$), triglyceride (341 vs. 192 mg/L) concentrations, and lactate dehydrogenase (LDH) activity (557 vs. 451 U/L) and a lower albumin concentration (46 vs. 53 g/L) for female and male minipigs, respectively. Additionally, female Yucatan swine have been observed to have greater concentrations of cholesterol along with higher HDL and LDL fractions when compared to male Yucatan swine (Thomas et al., 2002). These authors also noted a more pronounced increase in cholesterol, HDL, and LDL in female Yucatan swine placed on a high-fat diet when compared to male swine.

In a study evaluating age, gender, and line differences for hematological and biochemical variables in Göttingen miniature pigs, Oldigs (1986) indicated that in general gender differences were small and not important; a gender effect, however, was demonstrated for creatine kinase (CK) activity. The general lack of a gender effect was related to the fact that castrated male pigs were evaluated. A more recent study of Göttingen pigs, using data at both 8-week and 8-month ages, indicates that female pigs, while having similar blood glucose levels to intact males of similar age, have higher insulin levels along with higher levels of total cholesterol, triglyceride, HDL-C, and lower free fatty acids (Christoffersen et al., 2007).

A study evaluating lipid parameters in Meishan pigs comparing castrated and intact males to female animals at 5 months of age found that total cholesterol, triglycerides, LDL, and phospholipids were higher in female animals than intact males. These parameters were reportedly not significantly different between females and males that had been castrated at 1 month of age (Kojima et al., 2008).

5.5.2 AGE

In swine, age-dependent changes occur for a variety of clinical chemistry variables, and many of these changes occur within the first days, even hours, of life. For example, Tumbleson et al. (1972) described the changes in concentrations, or activities, of 20 biochemical variables for crossbred pigs during late fetal (gestational days 85, 92, 99, and 106) and neonatal (birth, 12 hours, 1, 2, 3, 4, 5, 6, and 7 days) life. Calcium concentration was higher (approximately 14.1 mg/dL) at gestational days 85 and 92, declined to a low of 10.7 mg/dL at birth, and increased to approximately 12.2 mg/dL after 1 day of age. Inorganic phosphorus and potassium concentrations demonstrated a pattern similar to that reported for calcium. Inorganic phosphorus concentration was approximately 8.3 mg/dL at gestational days 85, 92, and 99, declined to a low of 4.5 mg/dL at birth, and increased to approximately 9.1 mg/dL after 2 days of age. Potassium concentration was approximately 8.2 mg/dL at gestational days 85 and 92, declined to a low of 5.1 mg/dL at birth, and increased to approximately 6.2 mg/dL after 12 hours of age. Chloride concentration was lower (approximately 108.5 mg/dL) during late fetal life but after birth increased to approximately 118 mg/dL after 4 days. Creatinine concentration was higher (approximately 3.8 mg/dL) during late fetal life, declined to 1.65 mg/dL at birth, but then increased to approximately 2.2 mg/dL after birth. In general, urea nitrogen concentration was similar during fetal (approximately 17 mg/dL) and neonatal life (approximately 18 mg/dL); however, 12 hours after birth, urea nitrogen was increased (27.9 mg/dL). Glucose was higher during fetal life (approximately 143 mg/dL), declined to 54 mg/dL at birth, but then increased to approximately 123 mg/dL after day 5. Cholesterol was low during fetal life and at birth (approximately 61 mg/dL), increased to a peak of 197 mg/dL at day 4, and then decreased 140 mg/dL at day 7. In general, neonatal serum activities of LDH, alkaline phosphatase (ALP), and aspartate aminotransferase (AST) were higher than during late fetal life; marked increases of activity occurred either at birth (ALP) or 12 hours after birth (LDH and AST). Total protein, albumin, and globulin concentrations were markedly lower during fetal life and at birth than after birth. For example, total protein concentration was approximately 2.75 mg/dL for piglets prior to or at parturition; after birth, the concentration increased to approximately 7.5 mg/dL. While albumin also was higher 12 hours after birth, the concentration continued to increase during the first week, α -globulin increased from fetal concentrations of approximately 0.82–1.17 mg/dL at birth, increased again to 2.07 mg/dL at day 3, and

then decreased to 1.48 mg/dL at day 7. Additionally, γ -globulin increased from fetal concentrations (approximately 0.65 mg/dL) to 3.67 mg/dL at 12 hours, and then declined thereafter to 1.79 mg/dL at day 7.

In neonates, albumin was lower in weak or underweight piglets, and α -fetoprotein, α 2-macroglobulin, α 2-antitrypsin inhibitor, and α 1-protease inhibitor levels were lower in those that were weak, underweight, stillborn, or traumatized (Svendsen et al., 1986).

Glucose concentrations were higher in stillborn and weakborn piglets compared to unaffected piglets (Svendsen et al., 1986). In a 28-day study by Khan et al. (1986), neonatal, colostrum-free, Hormel:Hanford piglets demonstrated an increase in serum glucose and total protein concentrations at 6–8 hours of age (post-colostrum ingestion); these values continued to rise until stabilization by day 7 postpartum. Total and direct bilirubin also increased markedly at 6–8 hours postpartum and remained stable to the end of the study. Globulin concentrations dramatically increased by 6–8 hours postpartum and remained high at day 3; concentrations then declined, almost returning to precolostral concentrations by day 28. Cholesterol and albumin concentrations also increased from birth; these values, however, continued to increase to the end of the study at day 28 postpartum. Creatinine concentrations decreased 50% from birth to day 3 but stabilized. Slight increases of calcium and phosphorus concentrations occurred by day 3 postpartum. There was an increase in the activities of alanine aminotransferase (ALT), AST, LDH, ALP, and γ -glutamyl transpeptidase (GGT) by 6–8 hours postpartum. By day 3, however, AST, ALP, and GGT activities declined to or below the activity levels at birth. There was a progressive increase of LDH activity; similar findings for LDH were reported for miniature and crossbred domestic pigs (Earl et al., 1971; Tumbleson and Kalish, 1972). Weaned Pitman-Moore miniature pigs showed age-related decreases of ALP and increases of urea nitrogen, albumin, and calcium from 14 to 28 days of age (Filer et al., 1986).

In the Ossabaw obese pig, plasma insulin concentrations were greater than those for conventional breeds at 10 weeks of age (Wangsness et al., 1981); they were not hyperglycemic at 10 weeks or 5 months of age (Wangsness et al., 1981; Martin et al., 1972).

In one 8-week study, crossbred domestic swine, from birth (pre-colostrum) to 8 hours of age (postcolostrum), demonstrated increases of total protein, urea nitrogen, total bilirubin, and activities of LDH, AST, and ALP (Tumbleson and Kalish, 1972). Concentrations of sodium, chloride, and potassium decreased. There was no change in cholesterol concentration during the first 24 hours postpartum, but cholesterol increased from 1 to 3 days postpartum and then declined to 6 weeks of age.

Alterations in clinical chemistry analyses have been observed once piglets are weaned from the sow. For example, McClellan et al. (1966) evaluated the clinical chemistry variables for miniature swine from weaning to 6 years. They reported that serum cholesterol was highest at weaning, declining to a stable concentration (80–100 mg/dL) by 3 months of age. Urea nitrogen and creatinine concentrations increased from weaning, stabilizing at approximately 19 mg/dL at 3 months of age for the former and 1.6 mg/dL at 3 years for the latter. Protein increased and inorganic phosphorus decreased from weaning, but they stabilized at 6 months and 4 years, respectively. ALP activity decreased markedly from weaning to 1 year, then slowly decreased to a stable level at 3 years. In another study, ALP activity declined for conventional and miniature pigs up to 20 weeks of age (Pond et al., 1968). In crossbred swine, after weaning at 5 weeks of age, potassium concentrations increased while sodium and chloride concentrations decreased (Tumbleson and Kalish, 1972).

In Sinclair miniature swine, age variances in several analytes have been reported. Serum cholesterol has been shown to decrease with age, from 5 to 36 months (Tumbleson et al., 1976a). In a separate study, Tumbleson et al. (1976b) demonstrated increases of serum total protein concentration, from 6.4 g/dL at 1 month to 8.2 g/dL at 10 months; afterward, protein values remained stable to 36 months of age. Globulin concentrations increased, from 2.8 g/dL at 1 month to 4.9 g/dL at 36 months. Albumin concentrations dropped from 3.6 g/dL at 1 month to 3.0 g/dL at 3 months, increased to approximately 3.8 g/dL at 14 months, and decreased to approximately 3.0 g/dL at 36 months. Similar findings for proteins were reported for conventional swine (Miller et al., 1961).

For Sinclair miniature swine at 1–36 months of age, serum urea nitrogen increased after 1–2 months (Hutcheson et al., 1979). After 13 months, the serum urea nitrogen decreased for the female pigs, becoming stable after 24 months. In males, however, serum urea nitrogen began to increase after 7 months, stabilizing after 24 months. Serum creatinine was similar for male and female pigs, decreasing from 1 to 20 months; after 20 months, creatinine concentration increased to the end of the study at 36 months. The decrease in inorganic phosphorus concentration throughout the first 3 years of life was similar for males and females (Hutcheson et al., 1979); comparable findings were reported for gilts, ranging in age from 4 to 10 months (Hlousek, 1978). In male and female Sinclair swine up to 3 years old, calcium was highest in young animals, decreasing from 1 to 28 months (Hutcheson et al., 1979). In contrast, serum calcium and magnesium were lowest in the youngest gilts, ranging in age from 4 to 10 months (Hlousek, 1978). During the first 3 years of life, male and female Sinclair swine demonstrated decreases in serum sodium from 20 to 36 months, potassium during the first 12 months, and chloride during the first 30 months (Hutcheson et al., 1979).

In Göttingen miniature pigs between the ages of 60 and 276 days, Oldigs (1986) demonstrated a decrease of ALP, leucine aminopeptidase (LAP), and LDH activity with advancing age. Age effects were also found for sodium, phosphorus, phospholipid, and iron concentrations. A study examining parameters related to metabolic syndrome in Göttingen pigs at 8 weeks and 8 months of age (before and after sexual maturity) found that triglyceride decreased significantly with age in male pigs while cholesterol decreased in both sexes with increased age, though the decrement was greater in males. HDL-C was noted to decrease with age in both sexes as well (Christoffersen et al., 2007).

Amoss and Beattie (1986) demonstrated that during the first year of life, Sinclair boars had low (<200 pg/mL) serum testosterone concentrations until 20 weeks of age, when testosterone began increasing, reaching maximum concentration (approximately 1300 pg/mL) at 32 weeks. In the boars, changes of serum estradiol coincided with changes in testosterone and were <20 pg/mL until 20 weeks of age, reaching maximum concentration of approximately 250 pg/mL at 32 weeks. Estradiol concentrations for Sinclair gilts less than 30-weeks-old were approximately 16.5 pg/mL; these increased to approximately 23.7 pg/mL for gilts 30 weeks or older. No pre-luteinizing hormone (LH) estradiol surges were observed in this study; however, pre-LH estradiol surges of up to 85 pg/mL have been documented (Shearer et al., 1972). The development of the LH surge mechanism is an age-dependent process (Elsaesser et al., 1992). Immature gilts have shown a delayed, low-amplitude LH surge in response to administration of estradiol benzoate. Further, the maturation of the LH surge mechanism is estrogen dependent and ovarian secretions of estrogens appear to be required for the final peripubertal maturation maintenance of this mechanism in the sexually mature gilt. Testosterone concentrations were consistently low (<25 pg/mL) for gilts. Orchidectomy or ovariectomy at 6 weeks of age caused serum testosterone to decrease to <20 pg/mL and remain at these concentrations for the first year. Estradiol concentrations of both orchidectomized and ovariectomized animals were similar to those for gilts; that the estradiol originated from the adrenal cortex or peripheral conversion of an adrenal cortical metabolite was suggested.

Ford and Christenson (1986) reported that serum testosterone exhibits three periods of elevated concentrations for developing male pigs. Baseline testosterone for developing and neonatal males was <1 ng/mL. Testosterone concentrations were increased in fetuses at gestational days 35–40 (approximately 5 ng/mL), and postnatally during the first month (approximately 1.5 ng/mL) and after 4 months of age (ranging between 3 and 6 ng/mL). Concentrations of follicle-stimulating hormone (FSH), LH, and testosterone were greater for Meishan boars than Duroc or white composite breeds (Borg et al., 1993; Wise et al., 1994, 1996; Zanella et al., 1996). Mean FSH concentrations were approximately 550 ng/mL for Meishan boars versus approximately 100 ng/mL for composite animals. Additionally, Meishan boars have been divided into high- and low-FSH secreters (>750 and <500 ng/mL, respectively). Baseline testosterone concentrations were approximately 14 and 2 ng/mL for Meishan and composite boars, respectively, while LH concentrations were approximately 1.5 and 0.2 ng/mL, respectively. Orchidectomy caused a significant increase of serum gonadotropin concentrations compared to levels in intact boars (Minton and Wettemann, 1988).

In another study, castration caused a greater increase of FSH concentration in the white composite breed (190% increase) versus the Meishan breed (28% and 82% increase for high- and low-FSH secreters, respectively) (Zanella et al., 1996).

Basal concentrations and clearance rates of adrenocorticotrophic hormone (ACTH), growth hormone, thyroxine, and prolactin have been determined for the fetal pig (Spencer et al., 1986). McCauley and Hartmann (1984) demonstrated that newborn pigs had 12 times higher cortisol concentrations than adults. The cortisol levels decreased rapidly after birth, slightly increased at weaning, then decreased to adult concentrations by 21 days postweaning.

5.5.3 STAGE OF REPRODUCTIVE CYCLE/ESTRUS/PREGNANCY/GESTATION/LACTATION

A study examining lipoproteins in conjunction with 17β -estradiol in the estrous cycle of Yucatan swine revealed that total cholesterol, total HDL, and LDL were all elevated at the point of higher 17β -estradiol levels in the cycle (Liu et al., 2004). In an evaluation of the effects of the estrous cycle on biochemical variables in sows, Tewes et al. (1977) reported that cyclical changes occurred for blood pH, bicarbonate, total CO_2 , base excess, and protein and glucose concentrations. The pH, bicarbonate, total CO_2 , and base excess levels were lowest during proestrus. Glucose concentrations were low during the luteal phase, increased after luteolysis, and then decreased again during the follicular phase. Protein concentrations were greatest at ovulation and lowest at the end of the luteal phase of the estrous cycle.

Reports looking at the effects of gestation, parturition, and lactation on clinical chemistry endpoints have demonstrated a variety of findings. For example, gestation caused a decrease in serum concentrations of cholesterol, urea nitrogen, and α -globulin and an increase of β -globulin for Sinclair miniature swine (Tumbleson et al., 1970). Gotze et al. (1984), however, reported that sodium, total protein, calcium, inorganic phosphorus, blood urea nitrogen (BUN), cholesterol, and ALP were similar for pregnant and nonpregnant gilts. In a study on 1-year-old domestic crossbred swine, gilts, and sows, serum concentrations of total protein, globulin, cholesterol, and calcium were decreased in lactating swine, compared to gestating swine (Reese et al., 1984). Additionally, CK activity and concentrations of creatinine and triglycerides were increased in these gestating swine, compared to lactating swine (Reese et al., 1984).

In a hyperphagic obesity study, pregnant and nonpregnant sows were allowed to overeat or were intake-restricted (Hausman et al., 1986). The pregnant sows had an approximately 30% decrease in the glucose clearance rate, which was most pronounced in the overfed pregnant sows, showing an approximate 60% decrease.

In their evaluations of the effects of pregnancy on biochemical variables in sows, Tewes et al. (1979a) reported that plasma proteins increased during gestation and demonstrated peak concentrations at 6 and 12 weeks postbreeding. Plasma protein concentrations then declined to prebreeding levels at parturition. These investigators also demonstrated that glucose, inorganic phosphorus, and LDH levels were lower, but stable, for pregnant versus nonpregnant sows. A decrease of plasma LDH activity during gestation has been reported for the pig (Nachreiner and Ginther, 1972).

In sows, blood glucose decreased during lactation (Tewes et al., 1979b; Tumbleson et al., 1970); decreases in serum total protein, albumin, and β -globulin were also observed. Tumbleson et al. (1970) also reported decreases for calcium and sodium in lactating sows while no changes in inorganic phosphorus occurred.

For the sow, serum activities of AST and CK increased immediately after parturition to 24 hours postpartum (Bostedt, 1978). After parturition, GGT decreased until the second day and remained decreased at 3 weeks postpartum. By 3 weeks postpartum, activities of AST, ALT, LDH, and glutamate dehydrogenase (GDH) were the same as prepartum levels; the activities of GGT, creatine phosphokinase (CPK), and SDH were decreased. In another study, glucose, inorganic phosphorus, and LDH activity were decreased for 2 weeks postpartum, and plasma protein decreased during lactation (Tewes et al., 1979b). Serum proteins (total, albumin, β -globulin), glucose, calcium,

and sodium were decreased, and cholesterol and ALP activity were increased during lactation in Sinclair miniature swine (Tumbleson et al., 1970).

5.5.4 BREED/LINEAGE/GENETICS

Breed and line differences in preanalytical clinical biochemistry determinations and reference ranges have been described. The Ossabaw obese pig had lower growth hormone and higher insulin values than conventional swine (Kasser et al., 1981; Wangsness et al., 1981). Pigs genetically selected for obesity generally had lower growth hormone concentrations (Althen and Gerrits 1976; Lund-Larsen and Bakke, 1975). Pond et al. (1968) compared conventional and miniature pigs up to 20 weeks of age. Serum cholesterol was lower in suckling miniature pigs, and urea nitrogen was lower in miniature pigs from 10 to 12 weeks of age. ALP activity declined more rapidly for miniature pigs during the first 6 weeks of the study; they also had higher serum protein concentrations throughout the study. In another study, plasma sodium, potassium, and glucose concentrations were higher, and bicarbonate, urea nitrogen, and creatinine concentrations were lower in the Kangaroo Island strain of pig compared to an equivalent population of domesticated Large White breed pigs from Australia (McIntosh and Pointon, 1981). It also has been reported that the Hormel:Hanford strain of miniature pig has approximately a 50% lower serum creatinine concentration than the Sinclair strain (Hutcheson et al., 1979).

Oldigs (1986) examined line differences for hematological and biochemical variables in 204 (120 white and 84 colored) Göttingen miniature pigs and demonstrated that the white line had higher values for ALP, CK, and GGT activity; no differences were observed for aldolase (ALD), ALT, AST, LAP, and LDH. Additionally, the white line had higher total protein, albumin, and β -globulin concentrations and lower concentrations of α -globulin, iron, creatinine, urea nitrogen, and triglyceride. Another study also reported the breeding family of Göttingen pig can affect triglyceride and cholesterol levels (Christoffersen et al., 2007).

The Ossabaw pig, a feral strain of obese pig living on Ossabaw Island off the Georgia coast, has lower growth hormone and higher T3, insulin, triglyceride, and cholesterol concentrations than conventional breeds (Etherton and Kris-Etherton, 1980; Martin et al., 1972; Wangsness et al., 1981). During fasting, Ossabaw pigs had lower concentrations of growth hormone and T4 and higher glucagon and free fatty acid concentrations than Yorkshire pigs (Wangsness et al., 1981).

High-ovulating Meishan sows have had greater baseline estradiol and higher and longer estradiol peaks than large-white hybrid sows (Hunter et al., 1996). Mean baseline estradiol concentrations were approximately 70 pmol/L for Meishan sows versus approximately 43 pmol/L for hybrid animals; estradiol peaks were approximately 105 and 78 pmol/L for Meishan and hybrid sows, respectively. Mean inhibin concentration was higher for the Meishan sows (approximately 1.0 μ g/L) than for large-white hybrid sows (approximately 0.75 μ g/L). LH and FSH secretion did not differ between the breeds; however, the time from the onset of the LH surge to the increase in plasma progesterone was shorter for the Meishan sows.

5.5.5 HEALTH STATUS

Changes in swine lymphoid cell numbers are commonly associated with viral (lymphopenia or lymphocytosis), bacterial (neutrophilia), and parasitic disease (monocytic or eosinophilic responses). Shifts in clinical chemistry parameters are also reported for inflammatory processes (Odink et al., 1990) and common swine diseases (Friendship and Henry, 1992). Many of these changes occur in plasma proteins, especially the acute phase plasma proteins (haptoglobin, C-reactive protein, and serum amyloid A [SAA]) (Petersen et al., 2004). Researchers have shown that respiratory infections caused by different serotypes of *Actinobacillus pleuropneumoniae* (Agersø et al., 1998; Hall et al., 1992; Heegaard et al., 1998), *Mycoplasma hyorhinis* (Magnusson et al., 1999), or porcine reproductive and respiratory syndrome virus (Asai et al., 1999) are reflected by increased haptoglobin concentration.

In an *Escherichia coli* sepsis model, septic animals had increases of ALP, AST, and ALT activities, suggesting hepatic injury, and increases of urea nitrogen and creatinine, indicating impairment of renal function (Hoban et al., 1992). Microscopically, lesions of thrombosis and vasculitis were observed in several organs, including the liver and kidney, and there were cortical infarcts in the kidneys. In a total parenteral nutrition model, sepsis related to catheter implantation was preceded by glucosuria, and as the sepsis resolved, so did the glucosuria; no other changes of urine or serum chemistries were observed (Buckley et al., 1986). Straw et al. (2006) discuss many porcine disease and intoxication conditions that affect serum biochemical parameters.

5.5.6 NUTRITIONAL STATUS/DIET

Fasting in pigs can alter a variety of blood constituents. Fasting for 27 hours caused an increase in serum cholesterol and total protein concentrations of 3-month-old pigs (Kornegay et al., 1964). Prolongation of the fast to 167 hours caused decreases of glucose, calcium, sodium, urea nitrogen, and ammonia concentrations. In another study, fasting for 115 hours caused increases of bilirubin, CPK, total protein, albumin, globulin, cholesterol, phospholipids, free fatty acids, and urea nitrogen, and decreases of ALP, chloride, calcium, magnesium, and triglycerides (Baetz and Mengeling, 1971).

The effects of short-term starvation (up to 5 days) on hepatic ketone body production were investigated in the conscious unrestrained miniature pig (Muller et al., 1982). During starvation, arterial free fatty acid and glucagon concentrations increased (in addition to ketones), and arterial insulin levels decreased. Cortisol levels remained unchanged.

Fasting pigs for various durations has resulted in increased total protein, albumin, and globulin concentrations (Kornegay et al., 1964; Baetz and Mengeling, 1971), but chronic diet restriction caused no effects in serum total protein or its electrophoretic patterns (Wilson et al., 1972). Protein-restricted diets fed to swine, however, have led to decreased concentrations of total protein and albumin (Pond and Houpt, 1978; Rippel et al., 1965; Tumbleson, 1973; Wilson et al., 1972; Yen et al., 1982), and pigs fed a diet containing cornstarch as the source of carbohydrate demonstrated a slight decrease of serum total protein compared to those fed a glucose-containing diet (Mateo and Veum, 1980). Lowered diet consumption for cornstarch was recorded. The globulin fractions are also susceptible to alterations in nutrition. Increases in absolute and relative concentrations of α -globulin have been reported for pregnant (Rippel et al., 1965) and growing (Tumbleson, 1973) swine during periods of protein restriction. Absolute and relative β -globulin concentrations were decreased and absolute and relative γ -globulin concentrations were increased in malnourished swine (Baetz and Mengeling, 1971; Tumbleson, 1973). In contrast, α -globulin decreased with increased duration of food-intake restriction for male collard peccaries (Lochmiller et al., 1985). Yen et al. (1982) have shown that serum transferrin (a major β 1-globulin) concentration is a good indicator of protein status in swine. Total β -globulin decreased with increased duration of intake restriction for male collard peccaries and was reflected by decreases of both β 1- and β 2-globulin (Lochmiller et al., 1985). β -Globulin also decreased in protein-restricted malnourished swine (Tumbleson, 1973). γ -Globulin concentrations were increased in malnourished swine (Baetz and Mengeling, 1971; Tumbleson, 1973) and intake-restricted male collard peccaries (Lochmiller et al., 1985). Total serum protein and albumin concentrations were not affected for intake-restricted male and female collard peccaries (Lochmiller et al., 1985).

Serum urea nitrogen and creatinine concentrations can be influenced by extrarenal factors such as nutritional status. For example, prolonged fasting has caused decreased (Kornegay et al., 1964) and increased urea nitrogen concentrations (Baetz and Mengeling, 1971; Wilson et al., 1972). The effects of long-term severe undernutrition of the wild boar resulted in increased creatinine and, initially, slightly decreased then increased urea nitrogen concentrations (Wolkers et al., 1994). In intake-restricted male collard peccaries, serum urea nitrogen was increased after 9 weeks of feed restriction, though creatinine concentrations were not affected (Lochmiller et al., 1985). Protein source

and concentration of the diet are important factors determining serum urea nitrogen concentrations. For example, groups of pigs maintained on diets of different protein concentrations demonstrated that the higher the protein content of the diet, the higher the blood urea nitrogen concentration (Wilson et al., 1972). In neonatal pigs, serum urea nitrogen increased with greater concentrations of soy proteins in the diet, as compared to milk proteins (Veum et al., 1986). In another neonatal pig study, urea nitrogen levels were markedly lower for diets containing casein as a protein source in lieu of dried egg albumen (Watkins and Veum, 1986). Additionally, the type of carbohydrate in the diet can affect urea nitrogen levels. For example, Mateo and Veum (1980) fed pigs a diet containing glucose, sucrose, or cornstarch as sources of carbohydrate. The cornstarch diet caused a decrease in serum urea nitrogen concentration, compared to the glucose- and sucrose-containing diets.

Fasting of pigs caused decrease of calcium, chloride, magnesium, and sodium concentrations (Baetz and Mengeling, 1971; Kornegay et al., 1964). In Yucatan swine, it has been shown that feeding low-phosphorus or low-calcium diets increased production of 1,25-dihydroxycholecalciferol, approximately 2.5-fold and fourfold, respectively. Metabolic clearance of the vitamin decreased with the low-calcium diet but not the low-phosphorus diet (Fox and Ross, 1985). Inorganic phosphorus was decreased in pregnant and lactating sows (Tewes et al., 1979a, 1979b).

In swine, there are reports indicating that during fasting or low-protein diets glucose concentrations are maintained (Atinmo et al., 1974; Baetz and Mengeling, 1971; Doornenbal et al., 1983; Grandhi and Strain, 1982; Tumbleson et al., 1972); however, in 3-month-old pigs, prolongation of a fast to 167 hours caused decreases in glucose concentrations (Kornegay et al., 1964). Also in an experimental fast of prepubertal (130 days old) mixed breed gilts, blood glucose was reported to be decreased throughout the fast; however, insulin levels were not noted to decrease until the 28-hour period of the fast (Barb et al., 2001). Serum glucose concentrations were consistently lower in intake-restricted male and female collard peccaries (Lochmiller et al., 1985). Fifteen-days-old baby pigs reared artificially and fed diets containing glucose, sucrose, or cornstarch as carbohydrate sources plus isolated soybean protein were evaluated for alterations of serum glucose, total protein, and urea nitrogen (Mateo and Veum, 1980). The diet containing sucrose caused a slight decrease in serum glucose compared to the glucose-fed group, but values were considered within the reference range. When cornstarch instead of glucose was utilized as the source of carbohydrates decreases in serum glucose, total protein, and urea nitrogen occurred. Sows allowed *ad lib* access to feed from 60 days of gestation were evaluated for altered glucose tolerance (Weldon et al., 1994). Compared to sows fed a standard level of feed, the *ad lib* sows were less tolerant of glucose infusion in the form of an intravenous glucose tolerance testing (IVGTT) on day 1 of lactation. Nonesterified fatty acids were greater in the *ad lib* sows than in sows fed at a standard level, and release of nonesterified fatty acids in response to an epinephrine challenge also was greater in the *ad lib* sows. Insulin concentrations were not affected by feeding status.

Fasting of pigs has increased serum concentrations of cholesterol, phospholipids, and free fatty acids, and decreased triglycerides (Baetz, 1973; Baetz and Mengeling, 1971; Kornegay et al., 1964). A study of Göttingen swine fasted for a period of 48 hours reported that bilirubin level increased and magnesium decreased in males (Tsutsumi et al., 1999). Long-term and severe undernutrition causing increased nonesterified fatty acid concentrations in the wild boar has also been reported (Wolkers et al., 1994). Serum triglyceride concentrations decreased and nonesterified fatty acids increased in intake-restricted (25% of *ad lib*) male collard peccaries, though cholesterol concentrations were not altered (Lochmiller et al., 1985). Female collard peccaries, restricted to 55% of *ad lib* intake, exhibited increased nonesterified fatty acid concentrations but no changes in the triglyceride concentrations.

Besides diet restriction or undernutrition, altering diet composition or components can also affect lipid profiles. For example, feeding a semisynthetic diet containing 0.25% cholesterol to Pitman-Moore miniature pigs for 28 days resulted in approximately a fourfold increase in serum cholesterol (Filer et al., 1986). Addition of 15% cellulose to the diet dampened the response, as the serum cholesterol increased only twofold. In another study, feeding a HFHC diet to crossbred

domestic pigs for 6 months induced an approximately sixfold increase in cholesterol concentration with concomitant increases in very-low-density lipoprotein (VLDL), LDL, and HDL-C of approximately eightfold, sevenfold, and twofold, respectively; triglyceride concentrations were not affected (Fuster et al., 1986). A study using young Bama miniswine fed a high-fat, high-sucrose, high-cholesterol diet produced a linear increase in serum glucose over a 5-month period resulting in a level 2.15-fold higher than control at 5 months. Insulin levels began to increase at 2 months, peaked at 4 months, and declined from that point. Total cholesterol and triglyceride significantly increased over control from the first month onward (Liu et al., 2007). A high-fat diet in Yucatan swine also produced increases in cholesterol, LDL, and HDL over normal fed in a 20- and 24-week study (Thomas et al., 2002; Otis et al., 2003). Additionally, sows fed a high cholesterol and fat diet during lactation showed increased serum and milk cholesterol concentrations, resulting in higher serum cholesterol concentrations in the nursing offspring (Heald and Naseem, 1986). In protein-restricted malnourished swine, cholesterol and triglyceride concentrations were higher than for *ad lib* controls (Tumbleson, 1973).

Serum enzyme activities also can be affected by nutritional status. It has been demonstrated that fasting increases the serum activity of CK and decreases the activity of ALP (Baetz and Mengeling, 1971). Long-term and severe undernutrition caused decreased serum ALP activity in the wild boar (Wolkers et al., 1994). In male collard peccaries restricted to 25% of *ad lib* intake, serum ALP activity doubled after 3 weeks of restriction; thereafter, ALP activity decreased to control levels by 9 weeks of restriction (Lochmiller et al., 1985). The activities of LDH, GGT, AST, and ALT were unaffected; although total LDH activity was not altered, there was an increase in the percentage of LDH1 and LDH2 in the LDH isoenzyme profiles of the intake-restricted animals. In female collard peccaries restricted to 55% of *ad lib* intake, serum activity of AST increased.

Fasting pigs for up to 167 hours caused decreases in calcium, chloride, magnesium, and sodium concentrations (Baetz and Mengeling, 1971; Kornegay et al., 1964). In diet-restricted male collard peccaries, serum concentrations of copper, calcium, magnesium, sodium, and chloride were decreased, compared to the *ad lib* control animals; there also were relationships between intake and phosphorus, potassium, zinc, and iron concentrations (Lochmiller et al., 1985). In protein-restricted malnourished swine, inorganic phosphorus and calcium concentrations decreased, while potassium concentration increased (Tumbleson, 1973).

Endocrine function can also be affected by nutritional status. Male collard peccaries restricted to 25% of *ad lib* intake had approximately one-half the triiodothyronine (T3) but not thyroxine (T4) concentration, compared to controls; testosterone concentration also was approximately 50% lower (Lochmiller et al., 1985). Female collard peccaries restricted to 55% of *ad lib* intake, however, demonstrated a consistent decrease in serum T4 but not T3 concentrations.

Cholesterol concentration increased in neonatal pigs 2 days postpartum and remained elevated during the nursing period (Mersmann et al., 1979; Tumbleson and Kalish, 1972); triglyceride concentrations in the piglets also increased during nursing and decreased after weaning. Serum total lipid, cholesterol, HDL, and LDL were low in neonates compared to adult pigs but increased to an elevated concentration after colostrum/milk ingestion (Johansson and Karlsson, 1982). By 8 weeks, total lipid, cholesterol, and LDL decreased to adult concentrations; HDL remained elevated. In the sow, serum cholesterol was increased during lactation (Tumbleson et al., 1970).

There are breed and line differences affecting preanalytical clinical biochemistry determinations and reference ranges. Ossabaw obese pigs had higher triglyceride and cholesterol concentrations at 10–12 months of age than conventional breeds (Etherton and Kris-Etherton, 1980). For genetically selected obese lines, lower growth hormone and higher fasting free fatty acids were the most common findings. Lower growth hormone concentrations in weanling pigs, or pigs of 90–95 kg, have also been observed for conventional breeds selected for obesity (Althen and Gerrits, 1976; Lund-Larsen and Bakke, 1975). From birth to 5–6 months of age, these pigs were not hyperglycemic, hyperinsulinemic, hypertriglyceridemic, or hypercholesterolemic, and they all exhibited a normal glucose tolerance (Mersmann et al., 1973). In the fed state, obese pigs had higher free fatty acid

concentrations than lean pigs (Mersmann and MacNeil, 1985); the reverse was true for the fasted state (Bakke, 1975; Mersmann and MacNeil, 1985). A line of domestic pigs selected for leanness had higher fasting free fatty acid concentrations than control pigs (Gregory et al., 1980). In contrast, Ossabaw pigs did not have lower fasting free fatty acid concentrations, as had been observed for the genetically selected lines (Wangsness et al., 1981). One line of obese pig had higher plasma cortisol concentrations (Lunstrom et al., 1983) and a higher fasting glucose (Bakke, 1975).

Increasing lipid or cholesterol content in the diet caused increases of serum cholesterol concentration, with a large increase of cholesterol content occurring in the LDL fraction and a modest increase in the HDL fraction (Beynen et al., 1983; Kim et al., 1984); however, the magnitude of serum cholesterol increase can be altered by the type of lipid added to the diet. For example, the addition of corn oil to the diet resulted in lower serum cholesterol concentrations than the addition of butter (Kim et al., 1984). Including propionic acid or calcium propionate in the diet caused decreases of serum cholesterol, HDL-C, LDL cholesterol, and triglycerides (Thacker and Bowland, 1986). Dietary whey lessened the increases of serum cholesterol in pigs fed a hypercholesterolemic (high-cholesterol) diet. Serum cholesterol concentrations in these animals were similar to pigs fed non-cholesterol supplemented diets, with or without whey (Beames et al., 1986).

Foudin et al. (1986) demonstrated that, in boars, voluntary consumption of alcohol for a period of 17 weeks caused serum triglyceride concentrations to increase, peaking at 4 weeks and remaining increased to the end of the 17-week test period. Triglyceride concentrations increased twofold within 3 days post-alcohol removal, after which they began to decline. During alcohol consumption, the triglyceride concentration elevation was attributed to increases of 16:0, 18:0, and 18:1 fatty acids; 18:2 fatty acids decreased. The increase that occurred during withdrawal was attributed to triglycerides containing 18:1, 18:2, and 16:0 fatty acids.

The source and concentration of protein in the diet are important determining factors for serum urea nitrogen concentrations. Groups of pigs maintained on diets of different protein concentrations demonstrated that the higher the protein content of the diet, the higher the blood urea nitrogen concentrations (Wilson et al., 1972). In neonatal pigs, serum urea nitrogen increased with greater concentrations of soy proteins in the diet, compared to milk proteins (Veum et al., 1986). Piglets fed diets containing a 50:50 ratio of casein:whey protein had lower plasma urea nitrogen concentrations than those fed diets containing casein:whey at ratios of 80:20 or 0:100 (Newport and Henschel, 1986). The authors suggested that the equal proportions of protein types caused an improvement in protein utilization. It was indicated that casein is the predominant protein of cow milk, whey predominates in human milk, and sow milk contains approximately equal proportions of both. In another neonatal pig study, urea nitrogen levels were markedly lower for diets containing casein as a protein source as compared to those containing dried egg albumen (Watkins and Veum, 1986). That the type of carbohydrate in the diet can affect urea nitrogen levels was exemplified by the work of Mateo and Veum (1980), who fed pigs diets containing glucose, sucrose, or cornstarch as sources of carbohydrate. The use of cornstarch in the diet caused a decrease in serum urea nitrogen concentration, compared to diets containing glucose and sucrose.

Gestation caused a decrease in urea nitrogen concentration (Tumbleson et al., 1970); this phenomenon was not observed by Gotze et al. (1984). Oldigs (1986) demonstrated that a white line of Göttingen miniature pig had creatinine and urea nitrogen concentrations that were lower than for a colored line.

The fact that urea nitrogen and creatinine concentrations are affected by age differences has been documented. Urea nitrogen increased (Tumbleson and Kalish, 1972) and creatinine decreased (Khan et al., 1986) in neonatal pigs from birth to 72 hours of age. After weaning, urea nitrogen and creatinine concentrations increased, stabilizing at 3 months for urea nitrogen and at 3 years for creatinine (McClellan et al., 1966). Similar findings occurred for urea nitrogen in Sinclair miniature swine (Hutcheson et al., 1979). In Yucatan miniature swine, a gender difference was observed for creatinine, 123.8 for female versus 106.1 $\mu\text{mol/L}$ for male (Parsons and Wells, 1986); no gender difference was observed for Sinclair miniature pigs (Hutcheson et al., 1979).

5.5.7 HOUSING ENVIRONMENT/ENRICHMENT

Researchers examining salivary cortisol levels in pigs housed in an enriched or barren pen environment noted a blunted circadian rhythm of cortisol in pigs in the barren environment during light but not dark periods (de Groot et al., 2001).

5.5.8 CIRCADIAN RHYTHM

Circadian rhythms also exist for certain biochemical constituents. In a study to evaluate the role of the photoperiod on the secretion of cortisol and melatonin in boars, Minton et al. (1989) demonstrated a circadian rhythm for cortisol and that the rhythm shifted in conjunction with a 6-hour phase shift advance. In general, higher cortisol concentrations were observed during the late subjective evening and darkphase, while lower concentrations occurred about 6–10 hours after onset of the lightphase. Circadian rhythms of ACTH, prolactin, and melatonin have also been investigated (Griffith and Minton, 1991, 1992).

A study of diurnal variation in Göttingen swine found that glutamic oxaloacetic transaminase (aspartate transaminase) increased from morning through afternoon then decreased from midnight to early morning in both male and female animals. Urea nitrogen was described as decreasing in morning in both sexes and increasing through the afternoon and into the night for males but increasing in females only in afternoon. Calcium levels in female swine decreased in the morning and increased through the afternoon into night. Inorganic phosphorus was reported to decrease in the afternoon and increase from midnight to morning in both males and females. All of these variations were reportedly eliminated by fasting the animals (Tsutsumi et al., 1999).

Yorkshire gilts (110-day-old), maintained under 14-hour light/10-hour dark lighting conditions, were placed into two groups that were 180° out of phase. When estradiol (15 mg/kg) was administered intramuscular (IM) during the subjective light phase, the LH surges demonstrated a biphasic pattern with lower peaks (between 4 and 8 ng/mL). When estradiol was administered during the subjective dark phase, the LH surges demonstrated a single higher peak (between 8 and 12 ng/mL). This pattern reversed when the light regime was reversed, suggesting an interaction between light–dark cycle and estrogen affecting the release of LH in the pig. For all gilts, baseline LH concentrations were <2 ng/mL, and LH peaks were >5 ng/mL (Evans et al., 1994).

5.5.9 STRESS

In studies requiring clinical chemistry analyses, the effect of experimental procedures upon the analytes considered for evaluation is often a concern. Acute responses to stress-inducing factors such as introduction to a new environment, introduction of a gilt to a boar, unfamiliar or rough handling procedures, restraint, transportation, and mixing of unfamiliar swine have been reported (Barnett et al., 1982, 1984; Spencer and Hallet, 1986; Wade et al., 1986). For example, sling restraint of untrained pigs caused immediate increases in epinephrine and norepinephrine concentrations and slower increases of ACTH, cortisol, aldosterone, and renin concentrations (Wade et al., 1986). The use of a maxillary sling restraint resulted in increased concentrations of cortisol, ACTH, lactate, and glucose (Brenner et al., 1979).

Spencer and Hallet (1986) demonstrated that the stress of loading for transport resulted in rapid increases of plasma glucose, insulin, lactate, and thyroxine, reaching peak values within 10 minutes. Triiodothyronine and cortisol also increased but did not reach peak concentrations until 15–20 minutes poststress. The values for all analytes returned to baseline by 1 hour postloading. In the same study, free fatty acid concentrations were immediately decreased, remained decreased for an hour, and then increased to above baseline at approximately 110 minutes poststress, remaining elevated at 210 minutes. Detectable somatomedin activity by bioassay was rapidly depressed and remained decreased for > 2 hours. In other studies on the response to the stress of transport and slaughter, increased activities of CK, LDH, AST, malic dehydrogenase (MDH), ALP, and

isocitric dehydrogenase (ICDH) occurred, as well as increases in concentrations of urea nitrogen and potassium (Lengerken and Pfeiffer, 1978; Moss and McMurray, 1979; Yu et al., 2007). One study also found serum proteins such as major acute phase protein (Pig-MAP), haptoglobin, SAA, C-reactive protein were increased over control in two boars after 24 hours of transport (Pineiro et al., 2007).

Thermal stress has been shown to cause changes in acid–base balance, demonstrated as respiratory alkalosis and characterized by increased blood pH and decreased PCO_2 (Bartko et al., 1984). In their studies of halothane-induced physiological changes, Henning et al. (1986) indicated that it had been reported that exogenously induced hyperthermia in stress-susceptible pigs led to an increase of lactic acid concentration and activities of ALT, AST, LDH, and CK and a decrease in plasma base excess. They also pointed out that stress-susceptible pigs have been identified by increased CK activity 24 hours after treadmill exercise; pH decreases and increases of lactic acid and LDH have also been observed after exercise in stress-susceptible pigs.

Parsons et al. (1986) demonstrated that with endurance training, pigs developed clinical chemistry changes similar to those in marathon runners (Wood and Haskell, 1979): total cholesterol decreased while HDL-C increased. Also, iron concentration decreased while the hemoglobin content remained the same. Like humans, pigs become acidotic with exercise.

In a study determining the effects of floor temperature, supplemental heat, and drying on piglet survival, McGinnis et al. (1981) demonstrated that T4 concentrations at 5 days of age were lower for male pigs, pigs on the warmer floor, and pigs given supplemental heat. No treatment effects were noted for T3 concentrations.

Short-term overcrowding caused mild increases of glucose concentration and ALD activity (Kolataj et al., 1988). Barnett et al. (1983) reported that chronic stress was associated with higher concentrations of total protein and glucose and lower uric acid. In their review of handling and housing practices and chronic stress, Barnett and Hemsworth (1986) reported that unpleasant rough handling, administered either on a regular or irregular basis, resulted in increased free corticosteroid concentrations.

Housing methods, resulting in a high level of confinement (tether stalls), have caused higher corticosteroid concentrations when compared to those in group-housed animals (Barnett and Hemsworth, 1986). The pigs in tether stalls displayed aggressive behavior compared to group-housed animals in which a social order was established and little aggression observed. Baldi et al. (1989) also demonstrated that cortisol, proteins, and CK levels were negatively correlated with social hierarchy.

Pigs housed with adequate space had higher CK values than those housed under restricted (50%) space (Meldrum et al., 1986). The increases were related to greater space for movement and fighting among the pigs with adequate space versus those in cramped conditions.

Chronic increases of cortisol have been reported in space-restricted pigs but providing straw reduced cortisol concentrations (Warnier and Zayan, 1985). In contrast, crowding crossbred male pigs did not alter cortisol concentrations when compared to uncrowded animals (Meunier-Salaun et al., 1987; Pearce and Paterson, 1993). Tethered pigs (Von Borell and Ladewig, 1989) and crowded pigs (Meunier-Salaun et al., 1987) have demonstrated higher cortisol responses to an ACTH challenge than non-tethered, group-housed pigs or those housed in lower densities.

In an evaluation of intensive housing for parturient, crossbred gilts and sows, Becker et al. (1986) described the changes in cortisol concentrations related to tethering versus individual housing (gestation stalls and pens). The authors indicated that chronic restrictive housing is not a chronic stress based on the circadian rhythm of cortisol and its responses to ACTH and dexamethasone administration. They showed that, depending on the animals' previous housing experience, placement of parturient gilts and sows in tether or gestation stalls did not necessarily result in increased cortisol concentrations. The cortisol circadian rhythm of gilts placed in tether stalls became altered for a period of 3–8 days, after which the animals adapted.

Acute responses to stress factors can alter some hormone concentrations such as epinephrine, norepinephrine, ACTH, cortisol, aldosterone, and renin (Barnett et al., 1982, 1984; Spencer and

Hallet, 1986; Wade et al., 1986). For example, sling restraint of untrained pigs caused increases in epinephrine, norepinephrine, ACTH, cortisol, and aldosterone concentrations and renin activity (Wade et al., 1986). The stress of physical restraint for blood collection of swine resulted in increased concentrations of cortisol and ACTH (Brenner et al., 1979). The stress of loading for transport resulted in rapid increases of insulin, T₄, T₃, and cortisol concentrations (Spencer and Hallet, 1986); the values for analytes peaked within 10–20 minutes and returned to baseline by 1 hour postloading. Bioassayable somatomedin activity was also rapidly depressed and remained decreased for >2 hours. Housing methods may likewise alter cortisol concentrations (Barnett and Hemsworth, 1986) or cortisol response to ACTH challenge (Meunier-Salaun et al., 1987; Pearce and Paterson, 1993; Von Borell and Ladewig, 1989).

5.5.10 EFFECTS OF ANESTHESIA

Malignant hyperthermia (MH) is a slight risk when anesthetizing pigs. It may occur in any breed but is commonly encountered in Hampshire, Landrace, Pietrain, Poland China, and Yorkshire breeds (McGrath et al., 1981). Halothane triggers MH in susceptible pigs, resulting in a marked decrease of arterial pH and an increase of arterial blood lactate that occurs almost immediately after administering the anesthetic (Nelson, 1986). Succinylcholine can initiate an episode and increase the incidence in swine anesthetized with halothane (Nelson, 1986). Isoflurane, enflurane (Nelson, 1986), sevoflurane (Shulman et al., 1981), and chloroform (Hall et al., 1972) can also trigger an episode, while barbiturates (Gronert, 1980), narcotics, and nitrous oxide (Nelson, 1986) do not. In some highly susceptible animals, restraint-associated stress can initiate the syndrome (Riebold and Thurmon, 1986).

In a study of halothane-induced MH, Landrace piglets were exposed to the anesthetic for 5 minutes, and several biochemical variables were serially evaluated (Henning et al., 1986). Stress-susceptible animals showed a more pronounced decrease in blood pH during inhalation and slower recovery than resistant animals; the positive pigs also showed a more pronounced increase of pCO₂ during inhalation. Lactate increased more during inhalation and demonstrated a slower recovery in the reactors: lactate concentrations increased from approximately 9 mg/dL at baseline to 75 mg/dL at the onset of halothane inhalation, increasing again to 95 mg/dL at the end of the 5-minute exposure. Peak concentrations of 106 mg/dL occurred at 15 minutes postinhalation. LDH activity progressively increased in the reactors, starting 60 minutes postinhalation, and at 120 and 180 minutes, LDH activity was approximately 2170 and 2680 mU/mL. Preinhalation LDH activity for the reactors was approximately 700 mU/mL. In their discussion, these authors indicated that a similar response had been reported for CK activity. Henning et al. (1986) also demonstrated that AST activity progressively increased, starting 60 minutes postinhalation, peaking at approximately 75 mU/mL at 180 minutes, and not returning to basal activity (approximately 16 mU/mL) until 96 hours postinhalation. ALT activity progressively increased, starting 180 minutes postinhalation, peaking at approximately 41 mU/mL between 24 and 48 hours, and not returning to basal activity (approximately 30 mU/mL) until 96 hours postinhalation.

A study using Yucatan swine reported that isoflurane anesthesia caused decreased glucose tolerance and decreased insulin levels (Laber-Laird et al., 1992). This decreased glucose-induced insulin secretion is also reported with sevoflurane anesthesia (Saho et al., 1997). Another study reported that ketamine–xylazine combination anesthesia resulted in decreased insulin levels in female Yucatan swine (Heim et al., 2002). Use of a telazol–ketamine–xylazine mixture in mixed breed swine resulted in decreased LH levels in barrows and increased cortisol levels in barrows and gilts (Clapper, 2008). ALT has been used to evaluate potential hepatic damage caused by anesthetics (Weiskopf et al., 1992) and sepsis (Hoban et al., 1992). Epinephrine, norepinephrine, and vasopressin concentrations and renin activity have been used to evaluate responses to alterations of blood pressure by anesthetic agents (Weiskopf et al., 1992). Increasing the depth of anesthesia caused increases in vasopressin concentrations and renin activity. In a model of hemorrhagic shock, rapid

blood loss resulted in changes in vasoactive hormones characterized by increases in plasma renin activity and concentrations of epinephrine, norepinephrine, vasopressin, aldosterone, ACTH, and cortisol (Hannon, 1992).

5.5.11 BLOOD COLLECTION SITE AND HANDLING

The use of physical restraint for blood collection in swine can be stressful; for example, the use of maxillary sling restraint resulted in increased concentrations of cortisol, ACTH, lactate, and glucose (Brenner et al., 1979). There also appears to be significant intra-animal variability in stress response when this type of restraint is used.

The effect of the site of blood collection has been investigated and differences, such as those in concentrations of plasma amino acids, have been described (Stockland et al., 1971). CPK activity was higher for samples collected from the anterior vena cava than those from the auricular vein (Bruss and Becker, 1981). Flushing the needle in the anterior vena cava with saline after insertion ameliorated this effect. A study examining the feasibility of using tibial intraosseous blood sampling as compared to auricular venous sampling found that, though many blood chemistry parameters were comparable to the venous sample, potassium and AST were higher in intraosseous samples (Greco et al., 2001). Researchers examining LH and progesterone levels in the jugular vein and caudal vena cava of Landrace and Hungarian Mangalica swine reported that the caudal vena cava had a higher mean level of progesterone (Brussow et al., 2008). Baldi et al. (1989) showed that the different techniques of blood sampling influenced LDH and CK activities. Researchers examined blood obtained by jugular venipuncture as compared to blood drawn from a cannula placed in the anterior vena cava. They noted jugular CK, AST, total bilirubin, GGT, albumin, and total protein were increased while Na, CO₂, and P were decreased as compared to cannula samples. They also report statistical differences in chemistry values when comparing results of experienced versus inexperienced samplers (Dubreuil et al., 1990). The effect of repeated blood sampling in weanling pigs has been described as well (Kornegay, 1967). In a comparison between the use of an indwelling catheter and an external jugular venipuncture, total protein, albumin, and creatinine concentrations were increased for catheter-collected blood (Tumbleson, 1986). No changes were observed for cholesterol, lipoproteins, triglycerides, urea nitrogen, or protein electrophoresis. As mentioned in Section 5.5.10, certain anesthetics and, in some highly susceptible individuals, restraint-associated stress can initiate a MH response.

Serum testosterone and estradiol concentrations can vary depending on the sampling site. Testosterone concentrations for blood collected from the testicular vein of white composite breed boars were approximately 40 times higher than the values (approximate mean value of 80 ng/mL) obtained for blood collected from the jugular vein (approximate mean value of 2 ng/mL) (Wise et al., 1996).

Unilateral ovariectomy caused FSH, but not LH, to increase 24 hours postsurgery; bilateral ovariectomy induced both FSH and LH to increase (Redmer et al., 1984). Unilateral ovariectomy also caused ovarian venous blood estradiol concentrations to be increased at 2 and 4 days postsurgery; 8 days postsurgery, estradiol concentrations were similar to sham control values (Redmer et al., 1984). The estradiol concentration for peripheral blood collected from the jugular vein, however, did not demonstrate these changes. In another study, plasma estrone concentration in blood collected from the jugular vein was unchanged for unilaterally ovariohysterectomized white composite breed gilts at days 30, 31, 38, and 45 of pregnancy (Vallet and Christenson, 1994).

Hemolysis interfered with several biochemical analyses, and hemoglobin added as blood hemolytate, caused increases of creatinine, total protein, albumin, inorganic phosphorus, calcium, potassium, total bilirubin, ALT, AST, and LDH (Dorner et al., 1983). Bilirubin was affected starting at a hemoglobin concentration of 54 mg/dL, and ALT and AST activity increases started at 133 and 215 mg/dL, respectively. The other affected variables demonstrated increases at 400 mg/dL. The authors concluded that if serum contained hemoglobin at 400 mg/dL (cherry red), the sample should

not be tested. If serum contained <100 mg/dL hemoglobin, the effect was insignificant and the sample was acceptable for biochemical analyses. In another study, free hemoglobin of <500 mg/dL had no effect on the analyses of creatinine, urea, inorganic phosphorus, sodium, calcium, copper, and CK (Naumann et al., 1983). Hemoglobin concentrations of at least 180 mg/dL caused interference with total protein, albumin, potassium, zinc, and ALP; hemoglobin >500 mg/dL caused interference with urea, inorganic phosphorus, γ -globulin, ceruloplasmin, and AST analyses. Hemolysis was not influenced by relative centrifugal force during the separation of serum from cells, and there were no differences in the concentrations or activities of 14 serum variables in pig blood centrifuged at various forces between 2.5 and 45,000 \times g for 10 minutes (Mulder and Tumbleson, 1972).

5.5.12 EXPERIMENTAL MANIPULATION

In immature domestic pigs, loss of 50% (but not 30%) of the estimated blood volume over a 1-hour period resulted in increased serum concentrations of glucose, lactate, arterial PO₂, urea nitrogen, creatinine, sodium, magnesium, and inorganic phosphorus; there were decreases in arterial pH, arterial PCO₂, bicarbonate, base excess, potassium, total protein, albumin, and globulin (Hannon and Bossone, 1986). For the most part, these changes were partially resolving 5 hours posthemorrhage.

Hannon (1992) reviewed the physiological responses to hemorrhagic hypotension in pigs. Significant rapid blood loss resulted in increased concentrations of creatinine and urea nitrogen due to decreased renal clearance. There were decreases in urine volume and in sodium, potassium, and osmolal excretion related to decreased renal blood flow. Decreases in arterial pH, arterial PCO₂, and bicarbonate were related to increased lactic acid concentrations. Protein decreases were related to a shift of water from the extravascular to intravascular space. It was suggested that potassium decreases were related to increased cellular glucose utilization. It was noted, however, that pigs subjected to prolonged hemorrhagic hypotension using the Wiggers method demonstrated increases of plasma potassium and phosphorus concentrations; these changes were rarely observed for fixed-volume hemorrhage paradigms. Vasoactive hormones demonstrated increases in plasma renin activity, epinephrine, norepinephrine, vasopressin, aldosterone, ACTH, and cortisol; fixed-volume and Wiggers models of hemorrhage gave qualitatively similar hormone responses. Increases in the activities of hepatic transaminases may also occur during prolonged fixed-pressure hemorrhage, though function tests were not compromised.

Surgical manipulations can also alter chemistry values. For example, a 95%–98% small intestinal bypass caused decreases of albumin, total protein, calcium, and cholesterol concentrations; urine protein excretion decreased, and there was an increase in the urine activity of β -galactosidase (Assimos et al., 1986). The authors also observed that similar postoperative decreases of albumin, total protein, calcium, and cholesterol have been reported for humans. Splenectomy resulted in alterations of the resting arterial PO₂, pH, arterial PCO₂, and bicarbonate values (Hannon et al., 1990). Hepatotoxic effects resulting in cholestasis and characterized by marked increases of total and direct bilirubin (>11 and >5 mg/dL, respectively) occurred after chronic intravenous hyperalimentation (Cohen et al., 1986). Additionally, activities of ALP, LDH, and AST were increased.

5.6 BRIEF DESCRIPTION OF COMMON AND SPECIALIZED PROCEDURES

Common clinical chemistry procedures in swine biomedical research models include serum biochemistry panels, clotting factors, urinalysis, serum protein and immunoglobulin profiles, plasma lipoprotein and triglyceride profiles, blood gases and electrolytes, cardiac, liver, and kidney function analytes, and hormone bioassays. Nutritionists are also targeting minerals, vitamins, sugars, proteins, metabolites, and other nutritional factors in blood. Categorized typical and special biochemistry parameters for swine models are listed in Table 5.3.

TABLE 5.3
Swine Peripheral Venous Blood Serum Biochemistry Parameters

Category	Parameter ^a	Units
Electrolytes/Ions		
Cations	Sodium	mmol/L or mEq/L
	Calcium	mg/dL
	Potassium	mmol/L
	Iron	µg/dL or µmol/L
	Magnesium	mg/dL
Anions	Chloride	mmol/L or mEq/L
	Bicarbonate (TCO ₂)	mmol/L or mEq/L
	Phosphorus/phosphate	mg/dL
	<i>Anion gap</i>	mmol/L
	<i>Osmolality</i>	mOsm/kg
Carbohydrates		
Carbohydrates	Glucose	mg/dL
	Fructosamine	mmol/L
Metabolic Products		
Metabolic Products	Urea or blood urea nitrogen (BUN)	mg/dL
	Creatinine	mg/dL
	BUN/creatinine ratio	ratio
	Total bilirubin	mg/dL
	Direct bilirubin	mg/dL
	Indirect bilirubin	mg/dL
	<i>Lactate</i>	nmol/L or mg/dL
	<i>Uric acid</i>	mg/dL
Proteins		
Proteins	Total protein	g/dL
	Albumin	g/dL
	Globulin (α,β,γ)	g/dL
	A/G ratio	ratio
	<i>Fibrinogen^b</i>	mg/dL or µmol/L
	<i>Immunoglobulins</i>	mg/dL or µmol/L
Lipids		
Lipids	Cholesterol	mg/dL
	<i>High-density lipoprotein (HDL)</i>	mmol/L
	<i>LDL</i>	mmol/L
	<i>Very-low-density lipoprotein (VLDL), IDL</i>	mmol/L
	Triglycerides	mg/dL
	<i>Free fatty acids</i>	mg/dL
Enzymes		
Enzymes	Alkaline phosphatase (ALP)	IU/L or µkat/L
	Aspartate aminotransferase (AST)	IU/L or µkat/L
	Alanine aminotransferase (ALT)	IU/L or µkat/L
	Gamma-glutamyl transferase (GGT)	IU/L or µkat/L
	Lactate dehydrogenase (LDH)	IU/L or µkat/L
	Creatine phosphokinase (CPK)	IU/L or µkat/L
	<i>Sorbitol dehydrogenase (SDH) or iditol dehydrogenase (IDH)</i>	IU/L
	<i>Ornithine carbamoyltransferase (OCT)</i>	IU/L
	<i>Isocitric dehydrogenase (ICDH)</i>	IU/L

TABLE 5.3 (Continued)
Swine Peripheral Venous Blood Serum Biochemistry Parameters

Category	Parameter ^a	Units
	Malic dehydrogenase (<i>MDH</i>)	IU/L
	Lipase	IU/L
	Amylase	IU/L
	Arginase	IU/L
Hormones	<i>Total T3</i>	ng/mL
	<i>Total T4</i>	µg/mL
	<i>Free T4</i>	ng/mL
	<i>ACTH</i>	pg/mL
	<i>Cortisol</i>	µg/dL or mg/mL
	<i>Insulin</i>	µIU/mL
	<i>Corticotropin-releasing factor (CRF) or corticotropin-releasing hormone (CRH)</i>	
	<i>Glucagon</i>	
	<i>Insulin-like growth factor 1 (ILGF-1/IGF-1)</i>	ng/mL
	<i>C-peptide</i>	
	<i>Follicle-stimulating hormone (FSH)</i>	ng/mL or µIU/mL
	<i>Leutinizing hormone (LH)</i>	ng/mL or µIU/mL
	<i>Somatostatin</i>	pmol/L
	<i>GH (somatrophin)</i>	ng/mL
	<i>Somatomedin (Substance P)</i>	U/mL
	<i>Estrogen</i>	nmol/L or ng/mL
	<i>Testosterone</i>	nmol/L or ng/mL
	<i>β-Endorphin</i>	pg/mL
	<i>Epinephrine</i>	pg/mL
	<i>Renin</i>	ng A1/mL/h
Vitamins	<i>Cobalamin (Vit B₁₂)</i>	ng/L
	<i>Folate</i>	µg/L
Other	<i>Pig-MAP (major acute phase protein-)</i>	
	<i>Haptoglobin (HPT)</i>	ng/mL or g/L
	<i>Heat shock protein (HSP-)</i>	
	<i>C-reactive protein (CRP)</i>	mg/dL
	<i>Serum amyloid A (SAA)</i>	
	<i>Leptin, resistin, ghrelin</i>	ng/mL
	<i>B₂ microglobulin</i>	
	<i>Neopterin</i>	nmol/L

^a Typical analytes are in regular font (non italics); special (non-routine) analytes are in italics.

^b Plasma fibrinogen. Enzymes units are occasionally reported as µkat/L, an SI unit; for conversion of µkat/L to IU/L, multiply µkat/L by 60.

Additionally, sophisticated toxicogenomics technologies (proteomic, genomic, or metabolomic) procedures for assaying unique biochemical entities can include molecular biology (polymerase chain reaction [PCR]), immunology, or classical chemistry (tandem mass spectrometry [MS/MS], nuclear magnetic resonance [NMR]) methods (NRC, 2007). Established biochemical markers are now reported in the swine literature, such as troponin for cardiac and skeletal muscle function (O'Brien et al., 1997). Other potential biomarkers or biosignatures include sialic acid,

acute phase proteins (B_2 microglobulin, C-reactive protein [CRP], haptoglobin, SAA), leptin, and metallothionein for environmental metal exposures.

Specialized biochemical tests in swine include ACTH response testing, sulfobromophthalein (BSP) clearance, glucose tolerance testing, dexamethasone suppression test (DST), inulin and creatinine clearance, and thyrotropin-releasing hormone (TRH) stimulation test. Of these tests, the glucose tolerance testing is the most commonly practiced at Sinclair Research Center.

5.6.1 ACTH STIMULATION TESTING

The ACTH stimulation test is used to assess the functional state of the adrenal gland. Following ACTH administration, the adrenal should respond by releasing glucocorticosteroid hormone (cortisol). If no increase in cortisol is noted, the adrenal may be fatigued. A chronically stressed animal will normally have higher levels of cortisol post-ACTH challenge than will unstressed animals. Becker et al. (1986) described an ACTH stimulation test in the pig using 10 International Units (IU) of ACTH IV and collecting samples at 0, 15, and 30 minutes, and 1, 2, 4, 6, and 8 hours postinjection. In a different study, response to an exogenous ACTH challenge was performed by collecting blood via an indwelling jugular catheter every 15 minutes from 12.00 to 16.30 hours. During the collection period, 25 IU ACTH/pig was administered by IM injection at 13.55 hours (Pearce and Paterson, 1993).

5.6.2 BSP CLEARANCE

BSP is a cholephilic dye that is used for testing hepatic function (portal circulation, function of hepatocytes, patency of biliary tract) (Cornelius, 1989). In their reviews, Wilson et al. (1972) and Cornelius (1989) cited reports investigating the use of BSP clearance as a test for hepatic function in the pig. BSP retention for 100 kg pigs (administered 6 mg BSP/kg) was 3%–4% at 15 minutes postadministration. In another study, after intravenous (IV) administration of 5 mg BSP/kg, 30 kg pigs had a 5-minute retention of $5.3\% \pm 2.0\%$; the retention at 10 minutes was $1.4\% \pm 0.9\%$ and at 15 minutes $0.6\% \pm 0.6\%$. In that study, after a protein-deficient diet for approximately 5 months, the BSP retentions were between 10.5% and 16.7%, 1.7% and 6.0%, and 0.6% and 2.6% for 5, 10, and 15 minutes postadministration, respectively. Chloroform toxicosis increased the BSP retention in the protein-deficient pigs by three- to fourfold. In another investigation, 6 hours after intragastric administration of aflatoxin to pigs, BSP half-time increased from baseline (approximately 2 minutes) to approximately 19 minutes. Another report suggested that BSP retained at >0.3 mg dye/100 mL at 30 minutes postinjection of 5 mg/kg was indicative of hepatic dysfunction. In their review, Wilson et al. (1972) concluded that the BSP function test, while difficult to perform, was a useful test for hepatic function in the pig.

5.6.3 GLUCOSE TOLERANCE TESTING

Oral or intravenous glucose tolerance testing is frequently used to evaluate swine models of the metabolic syndrome (Larsen et al., 2002; Shoumin et al., 2004). Diabetes research (Bellinger et al., 2006; Larsen and Rolin, 2004) has made significant strides using these swine models. Renner et al. (2010) have created RIP II-GIPR^{dn} transgenic swine with glucagon-like peptide 1 receptor (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP) receptor deficiency, disturbed incretin function, and glucose intolerance for Type 2 diabetes modeling. Researchers have also studied the use of insulin sensitivity testing in swine as a potential alternative to the longer time course of the glucose tolerance testing (Otis et al., 2003; Christoffersen et al., 2009). Swine oral and intravenous glucose tolerance tests (OGTT and IVGTT, respectively) are well established. Stimulation tests were performed in swine after an overnight fast and insulin therapy had been stopped for 30 hours (Mullen et al., 1992). The IVGTT was performed by IV injection

of 0.5 g/kg glucose of a 50% solution and collection of blood samples at 0, 5, and 10 minutes, and every 10 minutes thereafter up to 60 minutes (Mullen et al., 1992). Additionally, blood samples collected at -15 and 2.5 minutes were used to calculate *K* values. In another study, the IVGTT was performed using an injection of 0.5 g glucose/kg given intravenously over 2 minutes, with blood samples collected at 0, 3, 5, 7, 10, 20, 30, 45, 60, and 90 minutes post glucose administration; *K* values were determined from the IVGTT data (DaFoe et al., 1989). An OGTT can be performed by giving 1.75 g glucose/kg in solution PO or 2 g glucose/kg mixed with a small amount of feed. Blood can be collected every 15 minutes up to 90 minutes (Wilson et al., 1986) or every 30 minutes up to 120 minutes (Mullen et al., 1992). Intravenous arginine tests have been performed by giving 0.5 g arginine/kg as a 0.6 g/mL solution during a 1-minute period. Blood was collected at 15 minute intervals, and concentrations of glucose, insulin, glucagon, somatostatin, and/or C-peptide were measured (Mullen et al., 1992). A tolbutamide response has also been used in the pig (Romsos et al., 1971). OGTT, IVGTT, isoglycemic and euglycemic clamps, hyperinsulinemia, and modified insulin tolerance tests are a few of the many diabetic protocols performed in swine models (Christoffersen et al., 2009).

5.6.4 DEXAMETHASONE SUPPRESSION TEST (DST)

The DST is classically used to assess pituitary–adrenal disturbances induced by chronic stress (Hay et al., 2000). Determination of blood cortisol levels before and after administration of dexamethasone also assists in diagnosing Cushing’s syndrome and identifying the cause (i.e., primary disease due to adrenocortical tumors versus secondary hyperadrenocorticism from pituitary adenoma), depending on the protocol and dose used. Dexamethasone suppresses pituitary secretion of ACTH in normal animals and therefore the blood level of cortisol is decreased postadministration; low doses do not suppress cortisol levels in dogs and putatively in pigs with pituitary-dependent Cushing’s syndrome, while high doses do cause suppression. High-dose dexamethasone administration differentiates between pituitary tumor and tumor elsewhere, such as the adrenal or another location. Cortisol production by functional adrenal tumors is not affected by dexamethasone. Urinary measurements of swine cortisol were as useful as blood cortisol determinations (Hay et al., 2000). The stress application for the DST has more utility than for Cushing’s disease confirmation in research swine but the test will function for both purposes.

5.6.5 INULIN AND CREATININE CLEARANCE

This test is a procedure by which the filtering capacity of the glomeruli (the main filtering structures of the kidney) is determined by measuring the rate at which inulin, the test substance, is cleared from blood plasma. Inulin is the most accurate substance to measure this capacity because it is a small inert polysaccharide molecule that readily passes through the glomeruli into the urine without being reabsorbed by the renal tubules. The steps involved in this measurement, however, are quite involved; consequently, inulin is seldom used in clinical testing, although it is used in the research setting. Creatinine clearance is the more practical procedure used to assess renal function (Wendt et al., 1990; Bauer et al., 2000).

5.7 SUMMARY AND CONCLUSIONS

Swine have become increasingly important research models for the study of human disease and pre-clinical testing. Clinical biochemistry analysis is an important component of these studies to qualify animals for study and evaluate the post-dosing effect of the candidate drug, device, or procedure. Understanding and appreciating preanalytical sources of variation which can impact changes in biochemical parameter levels in biological fluids (blood, serum, plasma, urine, CSF, synovial fluid, peritoneal fluid, pleural fluid, ocular fluid) is important when conceiving experimental designs and

during data interpretation. These potential preanalytical chemistry-impacting factors include age, sex, breed/genetics, fasting/feeding regimen/diet, health status, anesthesia, collection site, handling of animals or samples, housing/environment/enrichment, season, time of day/circadian rhythm, estrus/pregnancy/parturition/lactation, experimental manipulation, and stress. Availability of lineage- and age-specific reference ranges for biochemical parameters are useful during analyte data analysis and interpretation of shifts from baseline or control animal ranges. Multiple sources for domestic swine and miniature swine reference ranges have been cited. Reference ranges are provided in tabular form for selected representative breeds (Appendices A and B). While published reference ranges are helpful, use of pretest, concurrent or parallel control group and historical laboratory ranges are recommended, when available.

Evaluation of clinical chemistry variables has been an important part of investigations using swine research models. This review has provided general information concerning biochemical assays and factors affecting their variability and application for swine in a biomedical research setting.

5.8 REFERENCE VALUES

The concept of reference values and intervals are discussed in detail by Stockham and Scott (2008). Reference values for a wide variety of blood chemistry variables have been established and reported for several breeds and ages of pigs (Eisenhauer et al., 1994; Hannon et al., 1990; Horstman et al., 1960; Khan et al., 1986; McIntosh and Pointon, 1981; Parsons and Wells, 1986; Pond and Houpt, 1978; Radin et al., 1986; Tumbleson and Schmidt, 1986; Rispat et al., 1993; Oldigs, 1986; Hutcheson et al., 1979; McClellan et al., 1966; Miller et al., 1961; Burks et al., 1977; Drougas et al., 1996; Dungan et al., 1995), including fetal pigs (Spencer et al., 1986). Multiple veterinary biochemistry, clinical pathology, toxicology, and other laboratory reference textbooks offer reference biochemistry ranges for swine (Duncan and Prasse, 1986; Meyer et al., 1992; Kaneko et al., 1997; Plumb, 2005; Swindle, 2007; Gad, 2008; Evans, 2009). The Merck Manual (Kahn, 2008a, 2008b) and Oregon State Veterinary Diagnostic Laboratory (2009) offer online domestic swine reference ranges. Reference domesticated swine chemistry data (biochemical values [2–4 months age], blood gas and acid base status, plasma electrolytes and metabolites, plasma hormone concentrations, porcine serum constituents, serum constituents in pregnant and lactating females) are presented in Appendix A (Tables A.1 through A.6). Reference chemistry and urinalysis data for representative ages of Yucatan miniature swine are also presented in Appendix B. Appendix C presents key references on clinical chemistry of laboratory swine. Sinclair BioResources, LLC, offers clients a “Miniature Swine Book of Normals 2011” CD which covers serum chemistry for the Yucatan and other lineages (Sinclair S-1, Micro-Yucatan, Hanford), plus normals for hematology, EKG, organ weights, histopathology and gross necropsy findings, and many other categories of data. Marshall BioResources has published “Reference Data Guide 2008,” which offers serum chemistry and other data on the Göttingen Minipig®. Because numerous factors can affect biochemical profiles of swine, these values should be used as general guidelines and should not preclude the use of individual animal pretest evaluations, concurrent control animal data for individual studies, and historical control data established by the laboratory controlling the study or individual animal samples. However, sometimes published reference ranges are the only data available for comparison.

Potential treatment group serum chemistry comparisons include the use of the historical control data ranges, pretest data for individual animals (these data serve as internal control data for each animal), and the concurrent control group data range. Wells and Gosselin (1996) have outlined methods for clinical pathology data interpretation. Predose baseline biochemical data are of value for qualification of an animal’s health for study assignment. Comparison to historical institute normal/control data or reference ranges from the clinical pathology laboratory is commonly practiced. Study control animal group data collected at the same time point (concurrent) is most useful

for comparison to study treatment group changes. Published reference ranges from the literature become very important when these values are the sole source for comparison.

DNA or protein microarray screening and biomarker research may also change the regulatory framework and the way in which traditional xenobiotic, drug, and new chemical entity (NCE) safety and efficacy studies are conducted, including the selection of biochemical profile parameters. However, adoption of novel markers by regulatory arms has been slow because of rigorous validation requirements, so the standard safety testing biochemistry profile will not be likely to change in the near future.

With large-scale studies involving hundreds or even thousands of samples in multiple treatment groups, it is difficult to interpret the resulting complex, high-density clinical chemistry data. Using a heat map to visualize large-scale chemistry data in a graphic facilitates the identification of previously unrecognized trends (Auman et al., 2007). This technique is simple to implement and maintains the biological integrity of the data. The value of this clinical chemistry data transformation and visualization will manifest itself through integration with other high-density data, such as genomics data, to study biology and toxicology at the systems level.

Values obtained for a particular analyte may vary among laboratories depending on prevailing conditions, experimental protocol, instrumentation, reagents, and method of analysis. Thus, individual laboratories should establish in-house reference values appropriate for the animals and laboratory conditions in which their studies are conducted.

Preanalytical sources of variation are common for clinical biochemistry determinations and reference ranges. For example, factors including gender, age, breed, and diet can affect variables such as serum protein, urea nitrogen, cholesterol concentrations and activities of ALT, ALP, AST, GDH, LDH, and SDH (Wilson et al., 1972). Understanding potential preanalytical sources of variation for different parameters are important for successful research or preclinical testing with porcine models.

ACKNOWLEDGMENT

We wish to thank Gregory S. Travlos, the author of this chapter in the second edition of this book, for his vision and contributions to this chapter.

APPENDIX A

REFERENCE RANGES FOR DOMESTIC SWINE

TABLE A.1
Biochemical Values—Domestic Farm Swine (2–4 Months of Age)

Parameter	Units	Presurgery Baseline Values (Mean ± SEM)
Sodium (Na)	mEq/L	142 ± 1
Potassium (K)	mEq/L	4.8 ± 0.2
Chloride (Cl)	mEq/L	101 ± 1
Calcium (Ca)	mg/dL	10 ± 0.1
Phosphorous (P)	mg/dL	9.5 ± 0.4
Iron (Fe)	µg/dL	137 ± 20
Total protein	g/dL	5.6 ± 0.1
Albumin	g/dL	3.1 ± 0.1
Globulin	g/dL	2.5 ± 0.1
Urea	mg/dL	10 ± 1
Creatinine	mg/dL	1.2 ± 0.1
Bicarbonate	mEq/L	26 ± 1
Hemoglobin	g/dL	11.2 ± 0.3
Bilirubin	mg/dL	0.15 ± 0.04
Alkaline phosphatase	IU/L	164 ± 12
Alanine aminotransferase (ALT)	IU/L	38 ± 3

Source: Drougas, J.G. et al., *Lab Anim Sci.*, 46, 648–655, 1996. With permission.

Animals were 8–16-weeks-old, crossbred (Yorkshire × Hampshire × Duroc), domestic swine. Gender included female ($n = 18$), castrate male ($n = 5$), and intact male ($n = 4$). Body weight range was 20.6–70.7 kg (mean 30.6 ± 9.8kg).

TABLE A.2
Blood Gas and Acid–Base Status—Domestic Swine

Measurement	N	Mean	SD	Range
Blood Oxygenation				
Arterial PO ₂ (mmHg)	36	82	4.2	73–92
Arterial HbO ₂ (%)	18	94	0.7	92–95
Arterial O ₂ capacity (mL/dL)	21	13.1	1.04	10.1–14.2
Arterial O ₂ content (mL/dL)	21	12.4	1.62	8.7–15.1
Arterial carboxyhemoglobin (%)	18	4	0.4	4–5
Arterial methemoglobin (%)	18	1	0.3	0.6–1.8
Mixed venous PO ₂ (mmHg)	22	41	3.3	32–45
Mixed venous HbO ₂ (%)	22	60	5.7	48–71
Mixed venous O ₂ Content (mL/dL)	20	8.0	1.27	5.3–10.8
Art.-ven. O ₂ cont. diff. (mL/dL)	26	4.3	0.43	3.4–5.7
Acid–Base Status				
Arterial pH	36	7.48	0.033	7.40–7.53
Arterial PCO ₂ (mmHg)	36	40	2.3	35–44
Arterial plasma HCO ₃ (mEq/L)	36	29	2.2	22–33
Arterial buffer base (mEq/L)	40	45	3.3	40–52
Mixed venous pH	23	7.42	0.024	7.38–7.48
Mixed venous PCO ₂ (mmHg)	22	49	3.2	44–55
Mixed venous plasma HCO ₃ (mEq/L)	14	31	2.1	28–35

Source: Hannon, J.P. et al., *Lab Anim Sci.*, 40, 293–298, 1990. With permission.
The values are normal for 20–25 kg Yorkshire/Duroc cross farm pigs.

Data represent mean (X) and standard deviation (SD) for 85–109 domestic pigs in each class. Pigs on 11 different farms were sampled with approximately 10 pigs/class/farm. Breed nonspecified commercial pigs in various age groups (weanling, feeder, adult breeder) were housed on farms in Ontario, Canada.

Source: Rispat, G. et al., *Lab Anim.*, 27, 368–373, 1993.

^a Values are given as mean ± standard deviation.

^b Values are smallest and largest observed values.

^c 20–80 weeks Yucatan, *n* = 36 males and 35 females.

Original Rispat et al. values in μ kat/L were multiplied by 60 to yield IU/L. All other data from Sinclair Research Center, LLC, unless otherwise stated: 32–35 days: *n* = 24 males, 25 females; 3–6 months: *n* = 20 males, 20 females; 6–12 months: *n* = 19 males, 19 females. Analysis by ANTECH Diagnostics or ANTECH GLP.

TABLE B.2 (Continued)
Urine Chemistry Data for Young Adult Yucatan Miniature Swine (6 months)

	Yucatan ^a		Range ^b	
	Male	Female	Male	Female
Phosphorus (mg/dL) ^a	17.5 ± 11	19.3 ± 7.1	5.0–30.9	5.0–28.7
Magnesium (mg/dL) ^a	10.7 ± 6.8	21.3 ± 15.8	1.2–20.6	8.9–58.0

^a An *n* of 10 animals of each gender is represented. All samples were collected by cystocentesis of approx. 6-month-old animals; samples were spun, aliquoted off, frozen, then shipped to laboratory; ½ the limit of detection was used for samples reported out as < value and ≥ value reported as the value. Analytical methods are outlined below. Analysis was performed by Antech GLP, Morrisville, NC. Values are given as mean ± standard deviation.

^b Values are smallest and largest observed values. All data from Sinclair Research Center, LLC, unless otherwise stated.

TABLE B.3
Miniswine Urinalysis Analytical Methods^a

Test	Method	Instrument	Reagent	Units
pH	Dipstick	Bayer Clinitek 200+	Siemens	None
Specific gravity	Visual	Refractometer	NA	None
OSMO	Freezing point depression	Osmometer	NA	mOSMO
Creatinine	Modified jaffe, kinetic	Olympus 640e	Olympus	mg/dL
Glucose	Hexokinase, UV/NAD	Olympus 640e	Olympus	mg/dL

FIGURE 7.1 Hamster skull—showing location of the orbital venous sinus. Since the orbital venous sinus resides in the caudal one-half to two-thirds of the orbit, the microhematocrit tube should be inserted into the lateral canthus of the eye in a posterior and medial direction. (a) Orbital venous sinus. (b) External ophthalmic veins.

FIGURE 9.1 Restraint for blood collection from right jugular vein in an awake ferret. Clipping the hair at the venipuncture site is recommended.

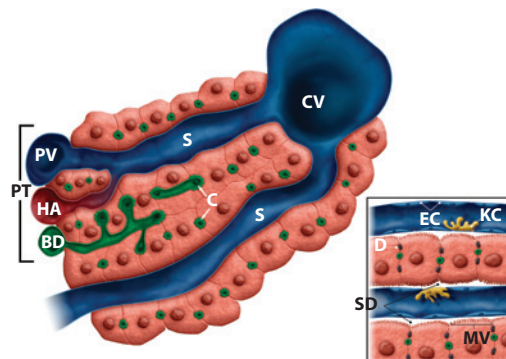

FIGURE 11.1 Schematic presentation of the liver microanatomy. Hepatic sinusoids (S) are surrounded by one to two layers of cords of hepatocytes. The portal veins (PV), hepatic arterioles (HA), and bile ductules (BD) comprise the portal triad (PT). Blood flows from the portal triad (PV and HA) through the sinusoids to the central vein (CV). Bile flows from the bile canaliculi (C) to the BD of the PT. The inset depicts a close up of the sinusoids lined by fenestrated epithelia (EC) and Kupffer cells (KC). A perisinusoidal space (aka, space of Disse [SD]) is located between the hepatocytes and sinusoids. The basolateral hepatocyte surface has microvilli (MV) that extend into the SD that allows plasma components from the sinusoids to be absorbed by the hepatocytes. Bile canaliculi are formed on the lateral surface of adjacent hepatocytes and the hepatocytes attach to their neighbors with specialized junctions (desmosome; D). Original concept by Chuck Wiedemeyer and Greg Travlos; drawing by David Sabio.

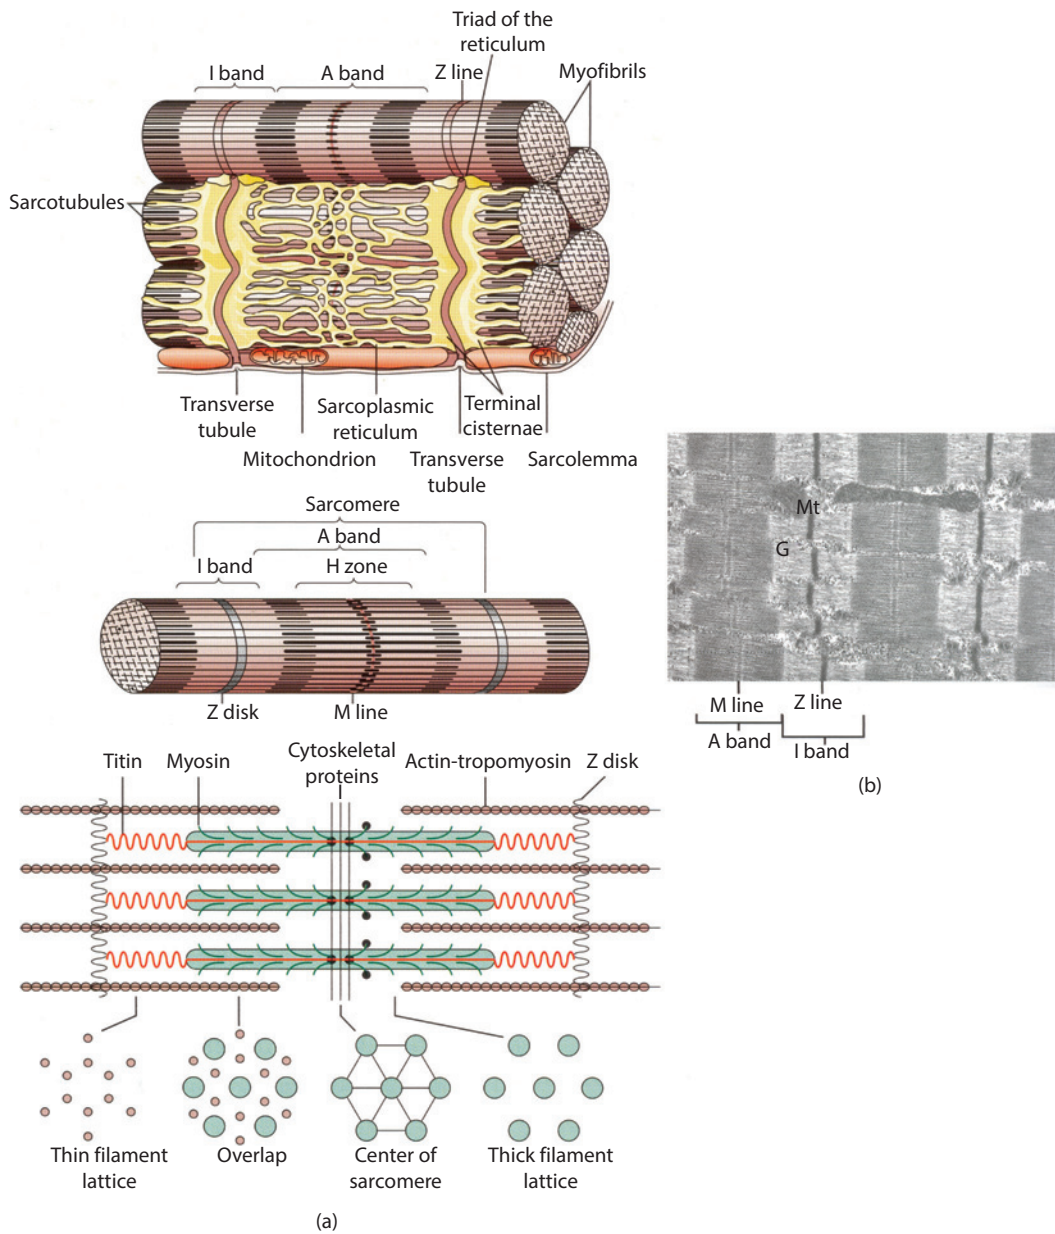

FIGURE 14.2 Myofiber structure. (a) Schematic representation of myofiber orientation, secondary organelles, and ultrastructural arrangement of cytoskeletal proteins within sarcomeres. (From Copstead-Kirhorn, L.E. and Banasik, J.L., *Pathophysiology Biological and Behavioral Perspective*, Saunders, St. Louis, 2005.) (b) Skeletal muscle, longitudinal section, normal mammalian skeletal muscle. Sarcomeres are defined by Z lines, A bands composed of thick myosin filaments, and I bands composed of thin actin filaments. Dense M lines with adjacent clear H zones occur in the center of the A band. Mitochondria (Mt) and glycogen (G) are interspersed between the myofibrils. Transmission electron microscopy (TEM). Uranyl acetate and lead citrate stain. (Courtesy of Dr. BA Valentine, College of Veterinary Medicine, Oregon State University). 6.1 TAXONOMY

Nonhuman primates (NHPs) belong to the order Primata, which is composed of three suborders: (1) Prosimii, considered as pre-primates, is rarely used in research; (2) Anthroipoidea, which contains the true primates, is divided into two infraorders: the Platyrrhine or New World (NW) monkeys and the Catarrhine, consisting of Old World (OW) monkeys, apes, and humans; and (3) Tarsioida, a newly recognized order, represents the bridge between pre-primates and true primates. NW monkeys are found in Central and South America and consist of two families: (1) Callitrichidae, which include marmosets and tamarins, and (2) Cebidae, which include owl and squirrel monkeys (Fortman et al., 2002). Although many Prosimian NHPs are nocturnal, owl monkeys are the only nocturnal species of simian NHPs and the only nocturnal NHP that is commonly used in research. OW monkeys and apes originate from Africa and Asia. Of all the apes, only the chimpanzee has played a prominent role in biomedical research; however, in recent years, the use of the chimpanzee has decreased substantially due to the high costs associated with housing and ethical considerations.

6.2 UNIQUE PHYSIOLOGICAL CHARACTERISTICS AND USE IN BIOMEDICAL RESEARCH

The most widely used NHP species in biomedical research are the OW monkeys that belong to the Cercopithecinae subfamily: the cynomolgus monkey (*Macaca fascicularis*), the rhesus monkey (*Macaca mulatta*), and the baboon (*Papio* spp.). Macaques are robust, sexually dimorphic animals with a large geographic distribution. Rhesus monkeys are the larger of the two macaque species with adult females typically weighing from 4 to 9 kg and adult males from 6 to 11 kg. Cynomolgus monkeys are smaller; adult males and females typically weigh 4–8 kg and 2–6 kg, respectively (Fortman et al., 2002).

Both the rhesus monkey and the cynomolgus monkey play important roles in biomedical research, vaccine studies, and pharmaceutical development. The majority of preclinical safety studies that require NHPs are conducted in one of these two species. Cynomolgus monkeys are the most widely used macaque in pharmaceutical studies due to several important advantages over rhesus monkeys; they are less aggressive, cheaper, and smaller so they can be housed more efficiently and

require less test article for preclinical safety assessment. Both the rhesus and cynomolgus monkeys have factored heavily in neuroscience studies, particularly those involving aging and behavior.

Rhesus monkeys are a highly relevant and well-characterized model for studying human obesity and associated comorbidities, particularly type II diabetes mellitus (Hansen and Bodkin, 1986; Bodkin et al., 1989, 1993a; Hotta et al., 2001). Numerous reports have documented the importance of this model to human medicine (Bodkin et al., 1993b, 2000). More recently, the cynomolgus monkey (Wagner et al., 2001) and baboons (Chavez et al., 2008, 2009) have also been developed as models for obesity and type II diabetes. Similar to humans, the incidence of type II diabetes in each of these three species is associated with increasing age and body weight (Hotta et al., 2001; Hansen and Bodkin, 1993; Wagner et al., 1996; Chavez et al., 2009). The pathogenesis of type II diabetes in NHPs parallels that of the human disease. The initial phase, which includes normal glucose tolerance and insulin resistance with compensatory hyperinsulinemia, is followed by continued alterations in carbohydrate metabolism (Wagner et al., 2001; Bodkin, 2000).

For over 20 years, the rhesus monkey has served as an important model for human immunodeficiency virus (HIV) research. Although chimpanzees are susceptible to infection with HIV-1, they have functioned primarily as an apathogenic model (Jumpan et al., 2008). Following exposure to human-adapted variants, the vast majority of chimpanzees control infection and are relatively resistant to developing acquired immunodeficiency syndrome (AIDS) because they avoid the immunopathologic events that affect the function of lymphoid tissues (Rutjens et al., 2010; Henney et al., 2006). In contrast, rhesus macaques infected with certain strains of SIV (e.g., SIVmac) or the chimeric SIV/HIV virus termed simian hybrid immunodeficiency virus (SHIV) recapitulate many of the pathologic events that occur in human AIDS (Baroncelli et al., 2008).

Baboons are a sexually dimorphic and relatively large NHP. Adult males and females weigh approximately 22–30 kg and 11–15 kg, respectively. *Papio anubis* (olive baboon) and *Papio cynocephalus* (yellow baboon) are the most common species used in biomedical research (Fortman et al., 2002). Given their size and robust nature, these Cercopithecine primates are amenable to multiple blood collections and a relatively large amount of blood product can be obtained for diagnostic and experimental purposes.

The baboon has also served as an important model for researching human disease, particularly in the areas of obesity, reproduction, surgery, and vascular research. Reproductively, the baboon shares many anatomic and physiologic features with humans (Nyachio et al., 2007). They have similar placentation, particularly in the initial stages and can serve as a model for studying transplacental transport (Carter, 2007; Van Calsteren et al., 2009). Endometrial function, including uterine receptivity and embryo implantation, is also similar, and studies have shown that fetal loss and maternal risk factors associated with stillbirths in baboons were similar to those in women.

Baboons have also served as effective large animal models for certain areas of cardiac and vascular research. Baboons develop atherosclerosis both naturally and experimentally and are the most relevant model for investigating the effect of circulating risk factors on endothelial dysfunction and arterial wall susceptibility to vascular disease (Wang et al., 2004). In cardiac xenotransplantation, the orthotopic pig-to-baboon model is the accepted preclinical model (Brandl et al., 2005). Following lipopolysaccharide administration, the kinetics of cytokine release, hemodynamic changes, and hematologic alterations are similar to humans; consequently, the baboon can function as a model for trauma, shock, and sepsis studies (Redl and Bahrami, 2005).

The African green monkey (*Cercopithecus aethiops*) is another member of the Cercopithecinae subfamily that has also been referred to as a vervet monkey or a grivet. Recently, the African green monkey is being explored in pharmaceutical research as an alternative to macaques, which have practical limitations that include relatively high cost and short supply. (Ward et al., 2008). Recent reports by Ward et al. (2008, 2009) concluded that the African green monkey may be an appropriate NHP for modeling both oral and intravenous pharmacokinetics and drug–drug interactions. African green monkeys have fulfilled other important roles in vaccine development biomedical research. They are frequently used as a model for presymptomatic Parkinson's disease and

have been utilized in developing vaccines for plague and respiratory syncytial virus (Sato, 2008; Patterson and Carrion, 2005; Pessiglione et al., 2003).

Chimpanzees (*Pan troglodytes*) are the only Great Apes that have played an important role in biomedical research. They have had limited but very important roles in vaccine and small molecule development for hepatitis C virus (HCV), behavioral and evolutionary studies, and certain safety and efficacy studies of therapeutics such as monoclonal antibodies that require a high degree of homology with humans. To date, the chimpanzee is the only established model of HCV infection that is susceptible to viral infection (Brass et al., 2007). Historically, chimpanzees were crucial to the successful development of a vaccine for Hepatitis B virus (HBV) in humans, and critical work with chimpanzees is ongoing to develop a vaccine against antiviral drug-resistant HBV mutants (Prince and Brotman, 2001; Kamili et al., 2009).

The most commonly used NW monkeys in biomedical research include three members of the family Callitrichidae: common marmoset (*Callithrix jacchus*), cotton-top tamarin (*Sanguinus oedipus*), and the moustached tamarin (*Sanguinus mystax*); and two members of the family Cebidae: the owl monkey (*Aotus trivirgatus*) and the squirrel monkey (*Saimiri* spp.) (Fortman et al., 2002). In general, NW monkeys provide practical, economic primate models for institutions lacking the space and/or resources to house larger primates.

Although not widely used, marmosets have been used in pharmaceutical research due to several beneficial qualities that include decreased test article dosages, smaller housing requirements due to its small size, reduced biohazardous risks as compared to macaques, and the ease of reproduction in captivity. Despite these benefits, the inability to obtain large blood volumes and the lack of assays validated specifically for marmosets can pose substantial disadvantages (Zuhlke and Weinbauer, 2003). Additionally, captive-bred marmosets develop a frequently fatal disease termed Wasting Marmoset Syndrome (WMS) that has limited their usefulness in toxicology studies. WMS is generally considered a type of inflammatory bowel disease with many potential causes including viral diseases, nutritional imbalances, and nematodes. To date, the exact cause of WMS remains unknown (Sousa et al., 2008; Gore et al., 2001).

The common marmoset has been used extensively in infectious disease research and is probably the most widely used NW monkey in drug development and preclinical studies. Marmosets are highly susceptible to herpes simplex virus-1 encephalitis and have been used to model hepatitis A virus, malaria and measles (Blagbrough and Zara, 2009; Mansfield, 2003). Marmosets can be infected with GB virus B (GBV-B) and thus, serve as a surrogate model for studying HCV infection. GBV-B is a flavivirus similar to HCV that shares similar mechanisms for processing viral gene products. Both viruses result in persistent infections in their respective host, and infected marmosets develop similar hepatic pathology to humans infected with HCV (Jacob et al., 2004; Weatherford et al., 2009; Mansfield, 2003).

Marmosets have also been used widely in neurologic research, particularly in the areas of Parkinson's disease and multiple sclerosis. Several mechanisms for recapitulating the pathogenesis and clinical outcome of Parkinson's disease have been established in the marmoset in part because of the diversity of behavioral assessments available for this species as well as its suitability for stereotaxic surgery (Eslamboli, 2005). Infectious allergic encephalitis in marmosets following immunization with myelin or myelin proteins creates an inflammatory demyelinating disease similar to multiple sclerosis. Another unique characteristic of marmosets is that they give birth to twin or triplet siblings that are full bone marrow chimeras. This feature allows for transfer of functional T-cell populations ('t Hart et al., 2000; Massacesi et al., 1995).

Although the natural host is still unknown, the GB viruses (GBV-A and GBV-B) were originally identified and cloned from pooled tamarin sera that were obtained from experimentally inoculated animals (Simons et al., 1995). Like the marmoset, GBV-B-infected tamarins have served as a surrogate model for HCV research. Cotton-top tamarins routinely live for greater than 20 years in captivity and naturally deposit AB amyloid into plaques and blood vessels in the brain; consequently, they may represent a model for the pathogenesis of early Alzheimer's disease (Lemere et al., 2008).

Additionally, cotton-top tamarins spontaneously develop colitis in captivity and the wild. In chronic cases, the colitis may progress to colorectal cancer. These findings have allowed the tamarin to become a resource for investigating therapeutics directed at key mediators of colonic inflammation (Tobi et al., 2000; Watkins et al., 1997).

The owl monkey is an unusual NW monkey in that it is nocturnal and displays no sexual dimorphism. The most important characteristic of the owl monkey that has led to its establishment as a laboratory primate is its susceptibility to *Plasmodium falciparum* and *Plasmodium vivax*. The World Health Organization has recommended this species as a model for evaluating malaria vaccines (Nino-Vasquez et al., 2000). Similar to the marmoset, the owl monkey is highly susceptible to herpes simplex virus-1 encephalitis and has served as one of the standard NHP models for this infection (Blagbrough and Zara, 2009). In addition, it is a useful model for studying hepatitis A (Purcell and Emerson, 2001).

Similar to the owl monkey, several malarial strains have been adapted to squirrel monkeys, and this species has become an alternative malarial model that accurately recapitulates most of the clinical pathologic changes of human malaria (Contamin et al., 2000). Until recently, an animal model demonstrating BK virus had not been described. BK virus is a polyomavirus that causes several clinical syndromes including interstitial nephritis and cystitis in immunosuppressed humans, particularly transplant patients. Zaragoza et al. (2005) demonstrated that squirrel monkeys could be successfully infected with BK virus and potentially used as a model for testing antiviral agents intended for human use. Squirrel monkeys also contribute to studies on Alzheimer's disease. Aging squirrel monkeys naturally develop senile plaques and cerebral amyloid angiopathy, which may exacerbate the dementia associated with this disease (Elfenbein et al., 2007).

6.3 METHODOLOGY FOR SAMPLE COLLECTION

6.3.1 BLOOD COLLECTION

Blood from NHPs can be collected from a number of venipuncture sites depending on the size of the animal, the method of restraint, and the sample volume required. Depending on the species, animals are restrained manually, chemically, or physically with squeeze cages or chairs. Some animals, particularly chimpanzees and macaques, may be trained to extend an arm from the cage for venipuncture (Coleman, 2008). The most common site for the collection of large blood volumes is the femoral vein. The cephalic vein of the forearm, the saphenous vein on the caudal aspect of the hind limb, the coccygeal vein of the tail, and the jugular vein can also be used. For small samples, a sterile lancet may be used to puncture the marginal ear vein, a finger or a heel. The preferred methods for blood collection from commonly used NHPs are provided in Table 6.1. The average circulating blood volume of rhesus macaques, cynomolgus macaques, and marmosets has been estimated as 56, 65, and 70 mL/kg, respectively. Guidelines for the maximum amount of blood that can be taken in a single sample or multiple samplings have been established. Up to 15% of the animal's blood volume typically can be removed in a single collection without causing significant disturbance to the animal's normal physiology. The recovery period for single samplings ranging from 7.5% to 15% of total blood volume is 1 and 4 weeks, respectively. A higher blood volume (20%) can be collected in a 24-hour period through multiple samplings for toxico- or pharmacokinetic studies (Diehl et al., 2001). Individuals are recommended to check with their Institutional Animal Care and Use Committee (IACUC) or Ethics Committee for specific guidelines or limits on blood volume collection.

6.3.2 URINE COLLECTION

Urine collection in the NHP can be performed using methods similar to other species. NHPs can be trained to urinate into pans or other collection devices. Sterile collection via catheterization or cytocentesis should be performed in sedated or anesthetized animals (Wolf and White, 2012).

TABLE 6.1
Blood Collection Sites

Species	Site	Needle Gauge	Reference
Marmoset	Femoral vein	25–26, 23–27	Hearn (1987) Fortman et al. (2002)
Squirrel monkey	Femoral vein	21–23	Bernacky et al. (2002)
	Femoral vein (large samples > 0.25 mL)	23–27	Brady (2000)
	Lateral tail veins (large samples > 0.25 mL)		
	Saphenous veins (small samples)		
Owl monkey	Femoral vein ^a	23–27	Baer (1994)
Macaques	Femoral vein ^a	20–23	Fortman et al. (2002)
		(if greater than 3 kg)	Dysko and Hoskins (1995)
Baboons	Femoral vein ^a	20–23	Fortman et al. (2002)
		(if greater than 3 kg)	
Chimpanzees	Femoral vein	18–22	Hanley (2009)
	Antecubital vein		
	Saphenous veins		

^a Alternative sites include cephalic, saphenous, tail, and jugular veins.

6.4 PREANALYTICAL SOURCES OF VARIATION

Given the complex taxonomy and longevity of NHPs, many sources of preanalytical variability exist that can have a significant impact on the results of biochemical analyses. These include sex, age, breed/strain/geographical origin, nutritional status, time in captivity, husbandry practices, stress, anesthesia, menstruation, and pregnancy. Consideration should be given to the potential effects of these variables when interpreting bioanalytical data.

6.4.1 SEX

Sex has a wide range of effects on biochemical analytes in all NHP species used in biomedical research. Ideally, sex-specific reference intervals should be utilized when interpreting biochemical data. For example, in a study of 80 male and 60 female African green monkeys, males had significantly higher levels of total bilirubin, direct bilirubin, creatinine, glucose, phosphorus, calcium total CO₂, and potassium (Sato et al., 2005). A second study by Liddie et al. (2010) that determined chemistry values for 331 African green monkeys also showed significant elevations for total bilirubin and creatinine in male monkeys; while females had significantly higher alkaline phosphatase (ALP), aspartate aminotransferase (AST), cholesterol, blood urea nitrogen (BUN), triglycerides, and creatine kinase (CK). Although some of the same sex-based trends identified for African green monkeys were also seen in cynomolgus monkeys, for certain analytes, the opposite trend was reported. Creatinine, albumin, gamma glutamyl transferase (GGT), CK, amylase calcium, phosphorus, and sodium were significantly higher in males, while globulin total bilirubin, triglycerides, and chloride were significantly higher in females (Schuurman and Smith, 2005). Sodium, uric acid, AST, and CK are reportedly higher in male chimpanzees than females (Howell et al., 2003). Male baboons greater than 5 years of age had increased creatinine levels as compared to females of similar age due to their larger muscle mass (Harewood et al., 1999). Additionally, male rhesus monkeys demonstrated that serum ALP activity is approximately 1/3 times higher than females. Beland et al. (1979) reported higher serum ALP values in female squirrel monkeys (*Saimiri sciureus*) than in males.

The effect of sex on bone markers was studied in Mauritian cynomolgus monkeys. Important markers of bone formation, osteocalcin (OC), bone-specific alkaline phosphatase (BALP), and carboxy-terminal propeptide of type I procollagen (PICP) were statistically higher in young males than young females. Several markers of bone resorption including free deoxypyridinoline (DPD), urinary carboxyterminal pyridinoline cross-linked telopeptide of type I collagen (CTX-1), and serum CTX-1 were also statistically higher in young males as compared to females. No significant differences were noted between males and females for urinary pyridiniums, urinary N-telopeptide (NTX-1), and pyridinoline cross-linked carboxyterminal telopeptide of type I collagen (ICTP) (Chen et al., 2000).

6.4.2 AGE

Significant changes in the level of many biochemical analytes occur throughout neonatal development. Hsieh et al. (2008) reported significant changes in 11/23 analytes in neonatal baboons from 6 to 12 weeks postpartum. Serum cortisol levels are reportedly lower in infant and juvenile squirrel monkeys than in adults (Kaack et al., 1979a). Neonatal physiological hyperbilirubinemia, comparable to that in human infants, has been described in newborn rhesus monkeys.

BUN and/or creatinine increased in aged cynomolgus and rhesus monkeys (Kapeghian et al., 1984; Smucny et al., 2001). Decreased albumin, calcium, and total protein, and increased globulin and triglycerides have also been described as an effect of aging in rhesus monkeys (Smucny et al., 2001, 2004; Nakamura et al., 1998). Biologically significant changes in clinical chemistry parameters occurred in both male and female chimpanzees from middle to old age. BUN, creatinine, sodium, potassium, and globulin increased while phosphorus, chloride, and albumin decreased (Videan et al., 2008).

C-reactive protein (CRP) is an acute phase reactant that has been used extensively in human medicine as a marker of acute inflammation. Male and female chimpanzees younger than 3 years of age had mean CRP levels of 0.65 and 0.60, respectively. Males and females 7 years or older had mean CRP levels of 0.86 and 1.08, respectively (Lamperez et al., 2005).

Young growing animals have high serum BALP activity, proportional to their growth rates, and total serum ALP has been shown to decline throughout life in male rhesus monkeys (Perretta et al., 1991; Lane et al., 1999). In baboons, a drop in ALP gives clear indication of the completion of skeletal maturation in both males and females (Harewood, 1999). This trend has been reported in many other NHP species (Sato, 2005; Kapeghian et al., 1984; Beland et al., 1979). Lane et al. (1999) attributed the decrease in total ALP in rhesus monkeys to a lower percentage of BALP. Juvenile animals had approximately 91% BALP and 9% liver-specific ALP; whereas, adult animals dropped to 88% and 12% and old animals dropped to 85% and 15% of bone-specific and liver-specific ALP, respectively.

Bone turnover is elevated during growth and development as evidenced by increased levels of serum OC and ICTP in female rhesus monkeys (Colman et al., 1999). The osteopenic, ovariectomized, aged cynomolgus monkey has been established as a model for human osteoporosis. Legrand et al. (2003) demonstrated that three major markers of bone formation (ALP, OC, and PICP) and a single marker of bone resorption, NTX-1, were statistically higher in young female cynomolgus monkeys as compared to mature females. An additional study in female cynomolgus monkeys showed that procollagen type 1 N-terminal propeptide decreases with age while PICP does not change and tartrate resistant acid phosphatase (TrACP) fluctuates throughout the entire lifespan (Chen et al., 2000).

Sato et al. (2005) reported that yearling and juvenile African green monkeys have elevated calcium levels that generally normalize at the time of skeletal maturity and phosphorus values that steadily decline through the yearling and juvenile stages. In chimpanzees and baboons as well as African green monkeys, serum creatinine levels have been positively correlated with body weight, and creatinine fluxuations that can occur during the growth phase are generally absent once growth

is stabilized (Eder 1996; Sato 2005; Harewood et al., 1999). Phosphorus values decreased from yearlings to juveniles in African green monkeys (Sato, 2005). Although these age-related trends in calcium phosphorus and creatinine were described for three NHP species, similar trends are commonly noted in other NHPs.

Age can have a significant effect on blood gas values. In aged squirrel monkeys, PaO₂, pH, TCO₂, base excess, and HCO₃ were significantly decreased as compared to young monkeys (Brizzee et al., 1988).

Although it is often assumed that glucose regulation becomes progressively impaired with age, a study in nondiabetic rhesus monkeys showed that fasting plasma glucose, the mean level of fasting insulin, glucose and insulin levels 2 hours following an oral glucose tolerance test (OGTT), and the area under the curve for insulin do not change significantly with age. This trend is not seen for diabetic animals, which show significant decreases in glucose tolerance by middle age (Tigno et al., 2004).

Age-related decreases in the basal levels of several steroid hormones, dehydroepiandrosterone, dehydroepiandrosterone sulfate, pregnenolone, and 17-hydroxy-pregnenolone were identified in male baboons. These decreases occur similarly in man and may be caused by decreased adrenal cortical cell capacity (Goncharova and Lapin, 2000). Consistent with observations in man and rat, serum cholesterol and triglycerides levels increase with age in adult rhesus monkeys (Szymanski and Kritchevsky, 1980).

6.4.3 STRAIN/BREED

Biologically relevant differences in blood and urine analyte between various strains and species of monkeys highlight the importance of interpreting reference ranges from animals of different origin with caution. The geographical origin or strain of a particular NHP species can have significant effects on serum biochemistry. Notable differences exist in cynomolgus monkeys that originate from Mauritius as compared to those from Southeast Asia (China, Vietnam, and Philippines). These differences are likely related to the isolated geography and lower degree of genetic variability in monkeys of Mauritian origin (Leuchte et al., 2004). As compared to monkeys of Southeast Asian origin, Mauritian monkeys have approximately 20%–40% higher serum enzyme activity of glutamate dehydrogenase (GDH), alanine aminotransferase (ALT), ALP, and GGT, approximately 25% higher total bilirubin, lower serum high-density lipoprotein (HDL) cholesterol and higher free fatty acid levels, and approximately 40% lower CRP (Zuehlke et al., 2006). Minor differences include slightly lower creatinine levels and slightly higher phosphorus levels in Chinese, Vietnamese, and Philippine monkeys (Zuehlke et al., 2006; Drevon-Gaillot et al., 2006).

Several genetic markers have shown that rhesus monkeys originating from India are divergent from those from Mainland China. A study by Champoux et al. (1996) showed that total protein was higher in Chinese–Indian hybrid rhesus monkey infants from age 14 to 150 days of age as compared to Indian derived. In addition, GGT activity was notably higher in the Chinese–Indian hybrid monkeys from days 90 to 150.

Weller et al. (1996) measured many of the same urine and serum analytes from one squirrel monkey species, *Saimiri peruviansis*, and one owl monkey species, *Aotus nancymae*. Despite the fact that squirrel and owl monkeys share similar characteristics in geographical origin, distribution, and body weight, a majority of the analytes demonstrated significant differences between the two species. Only serum calcium, creatinine, and phosphorus, and urine sodium, potassium clearance, glucose clearance, and the fractional excretion of sodium were comparable. Additionally, blood and urine analytes were compared between two species of owl monkeys, *A. nancymae* and *Aotus vociferans*. While the majority of the parameters were similar between the two owl monkey species, significant differences still existed. Serum calcium, phosphorus, sodium, potassium, and BUN were significantly higher in *A. nancymae* while urine calcium, calcium clearance, and fractional excretion of calcium were higher in *A. vociferans* (Weller et al., 1993a).

Amylase activity in the tissues and serum of several species of NHPs has been described by McGeachin and Akin (1982). Rhesus monkeys, squirrel monkeys, and Great Apes all demonstrated high levels of amylase activity in the pancreas, whereas only rhesus monkeys and Great Apes had high amylase activity in the parotid salivary gland. Both the parotid and salivary glands from squirrel monkeys reportedly contain very low levels of salivary amylase. In general, OW monkeys including rhesus, cynomolgus, and African green monkeys have notably high serum amylase levels (typically 600–1200 IU/L) as compared to humans and other NHP species (Gatesman, 1992; Altshuler and Stowell, 1972). Serum amylase values from Great Apes are similar to humans. In a study that determined reference ranges for six species of apparently healthy marmosets, serum amylase values were shown to be elevated as compared to humans and Great Apes but significantly lower than macaques and African green monkeys. Normal serum amylase values for several species of baboons were similar to marmosets (Gatesman, 1992). Increased adrenalin has been associated with elevated amylase, and the effects of stress due to handling and restraint may contribute to some degree to the elevated amylase in NHPs as compared to humans.

Bahr et al. (2000) compared the metabolism and excretion of cortisol among the common marmoset, cynomolgus monkeys, and chimpanzees through quantitation of urinary and fecal cortisol. In all three species, cortisol metabolites (>80%) were excreted predominantly in the urine; however, native cortisol was the major urinary excretory product only in the marmoset. Relatively small amounts of cortisol were found in the urine from chimpanzees and cynomolgus monkeys. A small amount of native cortisol was detected in marmoset feces, but cortisol was virtually absent from the other two species.

Phenotype was shown to have an effect on blood gas parameters in normal Colombian and Bolivian squirrel monkeys. The PaCO₂, CO₂, HCO₃, and base excess were all significantly lower in Colombian monkeys as compared to Bolivian (Brizzee et al., 1988).

Creatine kinase activity in owl monkeys was similar to cynomolgus monkeys, lower than red-bellied tamarin and the common marmoset but substantially higher than humans and most other animal species (Weller et al., 1991a).

6.4.4 NUTRITIONAL STATUS

6.4.4.1 Dietary Protein

The amount and type of protein in the diet may affect biochemical parameters. In African green monkeys, Johnson et al. (2001) showed that ALT was elevated on a high protein diet consisting of maize and legumes. Total protein, albumin, bilirubin, and glucose were significantly elevated on a high protein diet consisting of milk solids. Neither diet had a significant effect on AST or GGT. The effect of a high and low-protein diet on the renal function of baboons with experimentally impaired renal function was studied by Bourgoignie et al. (1994). Animals had unilateral nephrectomy and partial infarction of the contralateral kidney, and they were fed diets containing 8% or 25% casein. Animals that fed the high protein diet had lower serum creatinine and higher serum and urine urea nitrogen. Glomerular filtration rate, as determined by inulin clearance, and creatinine clearance were substantially higher in the animals fed the high protein diet.

6.4.4.2 Bilirubin

In general, normal bilirubin metabolism in NHPs strongly resembles that of humans. In addition, the genetic syndrome of fasting hyperbilirubinemia, which occurs in Bolivian and Peruvian squirrel monkeys but not in Brazilian or Guyanese squirrel monkeys, in many aspects resembles Gilbert's syndrome of benign, chronic nonhemolytic unconjugated hyperbilirubinemia in man (Cornelius and Freedland, 1992; Portman et al., 1984). The mechanism of fasting hyperbilirubinemia in affected squirrel monkey species may be attributed to two different components of bile metabolism. In Bolivian squirrel monkeys, increased bilirubin turnover/production with a twofold increase in endogenous bilirubin excretion into bile occurred following a 24-hour fast (Myers et al., 1991).

Second, a decreased hepatic conjugation potential for bilirubin developed secondary to reduced uridine diphosphate glucuronyltransferase activity (Cornelius and Freedland, 1992; Portman et al., 1984). Postprandially or following the administration of glucose, affected monkeys have concentrations of serum bilirubin comparable to those of unaffected squirrel monkeys.

Gartner et al. (1997) characterized the hepatic transport and metabolism of bilirubin in normal rhesus monkey neonates. In this study, physiologic unconjugated hyperbilirubinemia was shown to have a biphasic pattern. Phase I was characterized by a rapid increase in serum bilirubin concentration by 19 hours and an equally rapid decline by 48 hours following parturition. Phase II was characterized by a stable elevation that was approximately four times greater than normal adult levels from 48 to 96 hours after birth followed by a decline to normal adult concentrations.

6.4.4.3 Dietary Lipids

Similar to humans, the amount of dietary cholesterol can significantly alter certain serum biochemistry parameters. A study in cynomolgus monkeys showed that increased dietary cholesterol caused a marked increase in cholesterol and serum triglycerides and a marked decrease in HDL cholesterol. In addition, slight elevations in BUN, uric acid, and AST were observed (Bush, 1985). Neonatal baboon infants frequently receive formulas supplemented with dietary long-chain polyunsaturated fatty acids (LCPUFA). Although most parameters were unaffected by these supplements, triglycerides were significantly decreased at all levels of LCPUFA and calcium was significantly decreased at high levels of LCPUFA (Hseih et al., 2008).

6.4.4.4 Caloric Restriction

Rhesus monkeys that received a calorie-restricted diet had reduced blood glucose and insulin levels, improved insulin sensitivity, and decreased triglycerides and cholesterol levels (Mattison et al., 2017; Higami et al., 2005). In fasting rhesus monkeys and baboons, Goodner et al. (1977) observed periodic oscillations of insulin, glucose, and glucagon. Glucose and insulin oscillated in phase with each other and out of phase with glucagon. No similar effect has been observed in man. In rhesus monkeys, these oscillations had a periodicity of 9 minutes, and c-peptide oscillated in phase with insulin. The release of insulin and c-peptide was equimolar (Koerker et al., 1978).

Food restriction also induces a significant delay in skeletal development. Rhesus monkeys that received 30% less food per body weight had a reduced but otherwise normal skeleton, lower level of total serum ALP activity, and normal levels of parathyroid hormone (PTH), calcium, phosphorus, and OC (Lane et al., 1999).

6.4.4.5 Obesity

Female cynomolgus monkeys show similar obesity characteristics to humans. In a study of eight females, aged 6–34 years, serum insulin, leptin, glucose, and triglyceride positively correlated with body weight (Chen et al., 2002). In geriatric cynomolgus monkeys, obesity was associated with higher fasted blood sugar, acetylated hemoglobin, and triglycerides but comparable levels of cholesterol, low-density lipoprotein (LDL)/HDL, and insulin (Zuehlke et al., 2006).

Obese male rhesus monkeys had markedly elevated serum insulin values and slightly elevated fasting serum glucose values when compared with nonobese controls (Jen et al., 1985). Anticipation of feeding did not affect serum insulin levels in rhesus monkeys (Natelson et al., 1982).

In African green monkeys, Meis and Rose (1983) determined that feeding resulted in rapid elevation of cortisol, with a subsequent decrease to minimal values 5 hours after feeding. Feeding, rather than exposure to light, synchronized the circadian rhythm of cortisol.

6.4.5 HOUSING ENVIRONMENT AND SOCIAL STATUS

Transferring a NHP to a new facility shortly before initiation of an experimental study may confound the assessment of biochemical parameters as the monkeys begin to adapt to new surroundings.

A study by Hassimoto et al. (2004) showed that ALP, glucose, and sodium significantly decreased following a 6-month acclimation period. Yoshida (1981) found that the average value from over 200 cynomolgus monkeys for BUN, glucose, and albumin gradually increased during a 6-month interval following importation. It was postulated that these changes might have resulted in part from nutritional changes. In the same study, ALT and AST also increased 6 months following importation. The reason for the increased enzyme levels was not determined.

A monkey's social status within a colony can affect cortisol levels and glucocorticoid regulation. In a colony of common marmosets, morning plasma cortisol and ACTH levels were determined before, and 1, 2, and 3 days following dexamethasone administration. Subordinate animals had low baseline cortisol levels as compared to dominant animals; however, no differences were noted at any time point for ACTH suggesting that adrenocorticotrophic hormone (ACTH) secretion may be restrained by a steroid-independent mechanism (Saltzman, 2004). Similarly, dominant male cynomolgus monkeys showed higher baseline cortisol levels than subordinate, but the adrenal response differed in that subordinate monkeys showed enhanced responsiveness (Czoty et al., 2008).

The relationship between dominance in the troop and resting cortisol was studied in male African green monkeys. In stable groups, dominant and subordinate males had similar cortisol values. However, in unstable groups, males becoming dominant had higher serum cortisol values than did subordinate males (McGuire et al., 1986).

6.4.6 CIRCADIAN RHYTHM

Circadian periodicities have been demonstrated in many species. For example, in the rhesus monkey, cortisol levels decrease throughout the day with the lowest levels in the evening, whereas in the squirrel monkey, values are highest at the start of the light period and lowest 4 hours after the onset of darkness (Garg et al., 1978; Leshner et al., 1978; Quabbe et al., 1982; Rose et al., 1978; Wilson et al., 1978). Although light cycles are frequently related to circadian rhythms, one study in rhesus monkeys demonstrated that the marked differences occurring between day and night for testosterone, cortisol, prolactin, and luteinizing hormone were not principally determined by photoperiodicity (Dubey et al., 1983).

A study in cynomolgus macaques provided evidence of circadian rhythms in calcium metabolism. These rhythms showed partial similarity to humans, but the authors stated that endogenous corticosteroid release associated with stress in the monkeys might have affected some findings. Serum total calcium (reflection of albumin) increased at night while a distinct rhythm for ionized calcium was not identified. Serum phosphorus also displayed a circadian rhythm that was higher at night. In contrast to humans, however, parathyroid hormone and ALP failed to show a rhythmic change (Hotchkiss and Jerome, 1998b).

In owl monkeys, total serum protein displays clear diurnal rhythmicity with peak levels at the beginning of the light cycle and a total fluctuation of approximately 10%. In addition, serum iron showed a marked bimodal rhythmicity with fluctuations of approximately 60% (Klein et al., 1985).

6.4.7 EFFECTS OF ESTROUS CYCLE, PREGNANCY, LACTATION, AND MENOPAUSE

Baboons and macaques are an important model for physiological changes associated with menopause due to reproductive similarities with humans that include a menstrual cycle, natural menopause, and bone-remodeling processes in both cancellous and cortical bone (Colman et al., 1999). Many studies have examined the effect of natural menopause or surgically induced menopause through ovariectomy on serum biomarkers. In rhesus monkeys, OC was elevated after natural menopause. ICTP and ALP were not elevated, which likely reflects the lack of specificity for these markers (Colman et al., 1999).

Lees et al. (1998) studied changes in bone biomarkers in cynomolgus monkeys during pregnancy and lactation. They concluded that urinary pyridinium did not change while BALP and bone Gla

protein (BGP) were below baseline throughout pregnancy with the lowest levels occurring in the third trimester. In contrast, BALP, BGP, and urinary pyridiniums were increased during lactation. Both urinary CTX-1 and OC have a significant circatrigintan (menstrual) rhythm in cynomolgus monkeys, and urinary CTX-1 was markedly decreased when estrogen levels were maximal (Hotchkiss et al., 2000).

Baboons and chimpanzees display marked turgescence and detumescence of the sex skin in association with the follicular and luteal phases of the menstrual cycle, respectively. In baboons, plasma volume contracts during turgescence and up to 2 L of extracellular fluid (ECF) can accumulate in the perineum. During detumescence, the ECF is rapidly “auto-infused” back into the circulation (Harewood et al., 2000). These fluid shifts can affect biochemical indices and the renin–angiotensin–aldosterone (RAA) system (Table 6.2). Plasma renin activity is significantly increased in the follicular phase and suppressed in the luteal phase. The activity of the RAA system is considerably greater during the menstrual cycle of baboons as compared to normal adult males. In a study of baboons (Harewood et al., 2000), alterations in red blood cell indices were consistent with a contracted plasma volume in the follicular phase and an expanded plasma volume in the luteal phase. However, increased total protein and albumin in the luteal phase as compared to the follicular phase did not correlate with plasma volume, and the reason for this finding was not determined (Harewood et al., 1996, 2000).

Pregnancy alters numerous biochemical parameters in many NHP species and humans. Harewood et al. (2000) described in detail the changes identified at various stages of gestation in the baboon. Decreased sodium, potassium, BUN, creatinine, cholesterol, and osmolality developed in early gestation and persisted throughout pregnancy. Total protein, albumin, and ALP were reduced from mid-gestation. Additionally, calcium decreased throughout pregnancy and iron concentration was elevated.

Meis et al. (1982) reported that during gestation, cynomolgus monkeys had a decrease in fasting glucose and an increase in the peak plasma insulin response to glucose challenge. Peak plasma insulin response remained elevated during lactation, but glucose clearance rates were unaffected. Serum cholesterol is decreased in pregnant rhesus macaques, pigtail macaques (*Macaca nemestrina*), and baboons. In pigtail macaques, this is associated with a decrease in HDL cholesterol (Rudel et al., 1981a).

Pregnant female squirrel monkeys have lower total protein, albumin, and total cholesterol levels. ALP activity increases in late pregnancy and throughout nursing (Suzuki et al., 1996). In pregnant marmosets, biochemical parameters were reported to be generally within the reference range with the exception of lower glucose, AST, and BUN (Casetti et al., 1995).

TABLE 6.2
Plasma Analytes to Assess the Renin–Angiotensin–Aldosterone System in Baboons
(Mean ± SEM)

	Female Follicular Phase (N = 10)	Female Luteal Phase (N = 10)	Female Lactating (N = 16–19)	Adult Males (N = 6–10)
Plasma renin activity (fmol/L/second)	2081 ± 927	1051 ± 966	1654 ± 693	841 ± 331
Angiotensin I (pg/mL)	96 ± 6	101 ± 10	–	–
Angiotensin II (pg/mL)	32 ± 6	21 ± 4	30 ± 10	6.5 ± 3
Aldosterone (pg/mL)	1938 ± 400	1059 ± 400	1880 ± 1370	287 ± 45

Source: Harewood, W.J. et al., *J Med Primatol*, 25, 267–271, 1996.

Fecal cortisol concentrations are significantly affected by reproductive status. Wild, cycling, female chacma baboons displayed relatively high levels of cortisol during pregnancy while the lowest cortisol levels occurred during the menstrual cycle (Weingrill et al., 2004). Elevated fecal cortisol levels have also been found in late gestation in black tufted-ear marmosets (Smith et al., 1997) and cotton-top tamarins (Ziegler et al., 1995).

6.4.8 STRESS

As in many other mammals, NHP species commonly display elevated glucose levels in association with stress. Glucose levels greater than 200 mg/dL are common in squirrel and owl monkeys. Lambeth et al. (2006) demonstrated that chimpanzees that trained to voluntarily present for an injection had much less stress and lower glucose levels as compared to chimpanzees that had to be involuntarily restrained.

Glucocorticoid release is an important biomarker for stress in NHP that is frequently used by primatologists and clinicians to evaluate the level of stress caused by husbandry practices, experimental procedures, and other manipulations. Basal cortisol levels in primates vary according to psychosocial factors such as rank in dominance hierarchy, individual personality, and social group composition (Bentson et al., 2003). Cortisol levels from normal animals may also vary as a result of immobilization, psychological stress associated with blood collection, and anesthetic reagents used for chemical restraint. One study showed that the stress of capture caused an elevation in plasma cortisol for 60 minutes in rhesus monkeys (Blank et al., 1983). An additional study in rhesus monkeys showed that blood sampling does not affect cortisol levels in animals trained to extend an arm; conversely, cortisol levels increase in untrained monkeys. In physically restrained rhesus monkeys, plasma ACTH and cortisol were elevated within 15 minutes after the start of restraint (Norman and Smith, 1992).

Juvenile rhesus monkey offspring of stressed mothers also showed higher ACTH and cortisol levels as compared to control offspring (Clarke et al., 1994). The excitement of restraint induces hyperglycemia more readily and to a greater degree in small, NW monkeys than in macaques, baboons, or chimpanzees (Dubey et al., 1983).

Testosterone levels declined progressively in serial samples obtained from cage-restrained male rhesus monkeys; however, this decrease was not detected when serial blood samples were collected following ketamine injections (Puri, 1981).

6.4.9 ANESTHESIA

Blood collection from NHP frequently requires chemical restraint. The most commonly used anesthetic agent is ketamine hydrochloride, but other agents such as tiletamine-zolazepam (Telazol®), pentobarbital, propofol, isoflurane, and sevoflurane are frequently used. Hom et al. (1999) reported no significant differences in biochemical parameters from rhesus monkeys anesthetized with ketamine, pentobarbital, isoflurane, and propofol with the exception of triglycerides, which are elevated with propofol administration due to the presence of soybean oil. Woodward and Weld (1997) also reported minimal significant differences in rhesus monkeys anesthetized with ketamine, ketamine/acepromazine, or Telazol®. Potassium was significantly elevated in animals administered Telazol®; however, the difference was not considered biologically relevant.

Although the choice of inhalant anesthetic regimen has little effect on chemistry parameters, many changes have been described in rhesus monkeys prior to and 15 minutes after an intramuscular injection of ketamine. Sodium, potassium, chloride, calcium, glucose, total protein, albumin, total cholesterol, lactate dehydrogenase (LDH), GGT, ALP, and ALT were significantly decreased and BUN and CK were significantly increased following the ketamine injection (Bennett et al., 1992). Conversely, few alterations were detected in marmosets before and shortly after ketamine

administration. AST and CK were significantly increased and GGT was decreased (Taglioni et al., 1996). Administration of ketamine and diazepam for 150 minutes in baboons also resulted in minimal changes in blood parameters (du Plooy et al., 1998). Soma et al. (1995) showed that increases in AST, ALT, LDH, and CK occurred following an initial three weekly injections of sevoflurane; however, with continued dosing three times per week for 7 weeks, these elevations were resolved. These findings suggested that tolerance develops following multiple periods of anesthesia. Although ketamine injections caused a sustained elevation in cortisol in baboons, this pharmacologic effect was absent in rhesus monkeys given ketamine (Bentson et al., 2003).

A number of anesthetic regimens have been shown to decrease ionized calcium and PTH in humans and animals. Following isoflurane anesthesia in cynomolgus monkeys, ionized calcium was significantly decreased and both PTH and OC were significantly increased. Serum fluoride levels were elevated following isoflurane anesthesia and fluoride has been shown to decrease ionized calcium. Although increased fluoride may have contributed to the decrease in calcium, other factors likely contributed. The elevation in PTH and OC was presumed to be secondary to the decrease in ionized calcium (Hotchkiss et al., 1998a).

6.4.10 SAMPLE COLLECTION

The method selected for sample collection can have significant effects on laboratory values. A recent study compared values from samples obtained by venipuncture with samples obtained by an indwelling venous catheter connected to a subcutaneous vascular access port. Serum obtained by venipuncture had higher levels of potassium, phosphorus, and LDH that may have been caused by erythrocyte hemolysis. Serum obtained from the indwelling catheter had an elevated glucose level that may have resulted from the 50% dextrose and heparin used to maintain patency (Iliff et al., 2003).

6.4.11 SAMPLE HEMOLYSIS

Hemolysis in marmosets affects both AST and ALT with a greater effect on ALT (Cowie and Evans, 1985). LDH increases even with low levels of hemolysis. Higher levels of hemolysis correlate with increased levels of ALT, isocitrate dehydrogenase, glutathione reductase, bilirubin, AST, and sorbitol dehydrogenase (SDH) (Davy et al., 1984a). In tamarins, moderate hemolysis caused significant elevations in albumin, total protein, potassium, AST, and total bilirubin. Severe hemolysis additionally caused an elevation in phosphorus and a decrease in ALT and carbon dioxide (Ramer et al., 1995).

6.4.12 SAMPLE STORAGE

Few reports that specifically address the effects of storage on primate sera or plasma exist in the literature. In cotton-top tamarins, biologically relevant differences in clinical chemistry analytes were not detected between fresh sera and sera stored frozen at -70°C for 4 weeks (Ramer, 1995). Kuo et al. (2008) found that in sera from cynomolgus monkeys AST, ALT, and SDH were stable for up to 24 hours at both room and refrigerated temperatures, and up to 3 months at -80°C . In addition, AST and SDH were stable for up to 3 months at -20°C , but ALT became unstable by 7 days at -20°C . Short-term stability (24 and 48 hours) of multiple enzymes in sera from common marmosets has been described. Refrigerated conditions (4°C) were considered optimal for AST, LDH, and GGT while freezing at -20°C was considered optimal for ALP. Both SDH and GGT were stable at 4°C or -20°C for 48 hours, but 4°C was considered optimal for SDH. The stability of SDH in marmoset sera differs from human sera in which SDH has been reported to be extremely unstable at both room and refrigerated temperatures (Davy et al., 1984b).

6.5 SPECIFIC SERUM CHEMISTRY ANALYTES IN NHPs

6.5.1 BLOOD GAS

Reported values for arterial and/or venous blood gas analysis in rhesus monkeys, squirrel monkeys, and baboons are detailed in Tables 6.3 and 6.4.

6.5.2 BONE BIOMARKERS

NHP are frequently used in bone research owing to the similarities in reproductive physiology and skeletal structure as compared with humans. Bone metabolism studies commonly use biomarkers in blood and urine to assess bone formation and resorption. Reference ranges for markers of formation and resorption were established for young (2–3 years) and mature (>10 years) Mauritian cynomolgus monkeys (Table 6.5).

6.5.3 CALCIUM AND PHOSPHORUS

Serum parathyroid hormone and calcitonin in the rhesus monkey are known to have some degree of cross-reactivity with the human hormones, and human assays have been successfully validated and adapted for use in the rhesus monkey (Arnaud et al., 2002). A calcitonin radioimmunoassay was validated for rhesus monkeys by Hargis et al. (1978). The assay used a ^{131}I -labeled synthetic human tracer and showed that the mean basal concentration of calcitonin in plasma from normal rhesus monkeys was not significantly different from normal human plasma and that rhesus monkey calcitonin responds to changes in serum calcium concentration similarly to human calcitonin.

A study by Fincham et al. (1993) demonstrated sufficient cross-reactivity between humans and African green monkeys for intact parathyroid hormone using a commercially available immunoradiometric diagnostic kit. A second radioimmunoassay that was validated for parathyroid hormone in healthy rhesus monkeys showed very similar hormone levels as compared to humans. In addition,

a study of rhesus parathyroid hormone and calcium levels following experimentally induced hypocalcemia and hypercalcemia demonstrated a very similar physiologic response between monkeys and humans (Hargis et al., 1977).

An extensive study of calcium kinetics in African green monkeys as a model for man has been reported (Fincham et al., 1993). Parathyroid hormone responded to chelation-induced hypocalcemia by a fourfold increase within 10 minutes, followed by an increase in calcium and a decrease in parathyroid hormone. Published normal values for analytes associated with calcium metabolism in several NHP species are provided in Table 6.6.

6.5.4 SKELETAL AND CARDIAC BIOMARKERS

6.5.4.1 Lactate Dehydrogenase

As in most animal species, cynomolgus monkeys have five LDH isoenzymes. Isoenzymes 1–3 are the most prevalent and similar quantities of each are found in serum (on average 22%–28%). Isoenzyme 5 is the least prevalent. In many species, including cynomolgus monkeys, the activity of isoenzymes 1 and 2 is high in the myocardium, kidneys, and brain; however, monkeys also have a high percentage of these isoenzymes in red blood cells (Preus et al., 1989). In rhesus monkeys, substantial day-to-day variability and diurnal variation for LDH were documented. In addition to these normal physiologic fluxuations, the stress of both physical and chemical restraint procedures can cause significant LDH elevations (Scott et al., 1976).

6.5.4.2 Creatine Kinase

CK is a cytoplasmic enzyme that originates primarily from brain, skeletal muscle, cardiac muscle, and smooth muscle. Although brain contains a high level of CK activity locally, it is not known to cause an increase in serum CK activity (Stockham and Scott, 2008). The primary cause of CK elevation in NHP is skeletal muscle injury. Vahle (1998) studied the distribution of total CK in cynomolgus monkeys. He found the highest activities (6,000–12,000 IU/g of wet weight) in pectoral and gastrocnemius muscles, slightly less in the diaphragm, approximately 2000 IU/g in the esophagus, heart freewall, and heart septum, and minute activities in the stomach, cerebrum, colon, jejunum, and urinary bladder.

The activity of CK and its isoenzymes have been used to evaluate myocardial damage in NHP; however, this testing strategy lacks a high degree of specificity and sensitivity for myocardial injury and has been replaced largely by highly specific markers such as cardiac troponin I (CTnI) or T (CTnT) and the brain natriuretic peptides. At least three isoenzymes have been identified in all evaluated mammalian species: BB (or CK-1), MB (or CK-2), and MM (or CK-3). A fourth isoenzyme, mitochondrial CK (or CK-Mt) has been detected in some species but is currently of limited diagnostic utility for preclinical studies (Walker, 2006). In humans, the activity of CK-BB is almost entirely in the brain while CK-MM activity is found in both skeletal and cardiac muscle, and CK-Mt activity occurs in the mitochondria of many tissues. Although the majority of CK-MB activity occurs in cardiac muscle, skeletal muscle also contributes to elevations in this isoenzyme.

Although specific studies have not been published for many NHP species regarding the specific distribution of CK isoenzyme activity, it is likely that the trends are similar to humans. In a study of CK isoenzyme distribution in cynomolgus monkeys, MM was the only isoenzyme found in skeletal muscles; from heart muscle, it was predominantly MM with about 10% MB. In the cerebrum, stomach, jejunum, colon, and bladder, it was predominantly BB. In the diaphragm and esophagus, it was predominantly MM with traces of MB and BB (Vahle, 1998). A second study performed in cynomolgus monkeys showed that total CK content was higher in skeletal muscle than that in heart muscle and the CK-MB/total CK ratio was lower in skeletal muscle than that in heart muscle. As a reference, the mean activity of total CK and CK isoenzymes in skeletal and cardiac muscle from cynomolgus monkeys is provided in Table 6.7 (Fredericks et al., 2001). Although CK determination alone is not specific or sensitive enough to reliably indicate cardiac disease, a study by Gozalo et al. (2008) suggested that CK, AST, CK/AST ratio, LDH, and proteinuria together may provide a reliable way to diagnose clinical and/or subclinical cardiomyopathy.

6.5.4.3 Cardiac Troponin I and T

Cardiac troponin I (CTnI) and T (CTnT) possess high sensitivity and specificity for myocardial injury and have been used effectively in NHP to identify cardiac disease and assess drug-induced myocardial injury in preclinical studies (Minomo et al., 2009). Quantitative assessment of these markers in cynomolgus monkeys showed that the mean content of both CTnI and CTnT in skeletal muscle was less than 0.6% of that found in cardiac muscle (Fredericks et al., 2001). Numerous

TABLE 6.7
Mean Activity (SD) of Total Creatine Kinase (CK) and CK Isoenzymes per mg of Protein in Cynomolgus Monkeys

		Total CK	CK-MM (CK-3)	CK-MB (CK-2)	CK-BB (CK-1)

commercial assays are available for monitoring CTnI. Different analytical characteristics associated with each assay have made harmonization difficult and values obtained from different assays should be evaluated with caution. A recent study by Apple et al. (2008) showed good CTnI immunoreactivity for rhesus and cynomolgus monkeys by using nine different commercially available assays. CTnT assays are produced by a single vendor and therefore pose less of a heterogeneity problem. Rhesus and cynomolgus monkeys show good and weak responses to this assay, respectively.

6.5.4.4 Atrial and Brain Natriuretic Peptides

Atrial and brain natriuretic peptides (ANP and BNP, respectively) are structurally related hormones secreted from the heart following increased tension of the atrial or ventricular wall, respectively. In humans, BNP has been correlated well with the severity of left ventricular dysfunction, and several recent publications have suggested that this association is also present in NHP (Ely et al., 2011; Izumi et al., 2009). A study by Wondergem et al. (1999) concluded that the plasma concentration of ANP was an important parameter for subclinical cardiac damage; however, the literature contains little recent information regarding the utility of ANP as a cardiac biomarker in NHP. Although few comprehensive studies have been published to date regarding the utility of these cardiac biomarkers in evaluating cardiac disease and myocardial injury in preclinical studies, the early evidence indicates that these hormones have conserved function across species and will likely be important cardiac biomarkers for NHP in the future (Walker, 2006). Currently, commercial assays with known cross-reactivity to ANP and BNP in some NHP species are readily available.

6.5.5 CORTISOL

Cortisol (the primary glucocorticoid of NHPs) and corticosterone are heavily metabolized by the liver and intestinal bacteria prior to fecal elimination; consequently, the most reliable assays for most NHP species use group-specific antibodies for glucocorticoid metabolites (Heistermann et al., 2006). Bahr et al. (2000) recommended measurement of fecal 11,17-dioxoandrostanones rather than native cortisol as a more effective noninvasive way to measure adrenal function. Quantitation of urinary cortisol is an alternative noninvasive method frequently used to assess the level of stress associated with procedures and husbandry practices in captive NHPs (Paramastri et al., 2007).

A method of detecting cortisol in salivary specimens was also developed for squirrel monkeys to avoid the stress associated with venipuncture. Specimens were collected on cotton-tipped applicators and analyzed by immunoassay with time-resolved fluorescence detection (Fuchs et al., 1997).

The corticosteroid binding proteins of NHPs have been studied and are quite similar to human with several notable exceptions. Squirrel monkeys, marmosets, and tamarins are unique among NHPs in that they maintain a high circulating level of free plasma cortisol and a low corticosteroid-binding globulin (CBG) binding capacity. The magnitude of the increase in free plasma cortisol in squirrel monkeys is approximately 10-fold higher than that of the humans (Klosterman et al.,

1986). Despite this marked elevation, squirrel monkeys maintain normal electrolytes and blood pressures (Scammell, 2006). A recent study identified several alterations in cortisol metabolism that likely contribute to the adaptive mechanisms that minimize the effects of high cortisol in squirrel monkeys. These included increased peripheral 11β -hydroxysteroid dehydrogenase-2 activity and increased 6β -hydroxycortisol in the urine (Scammell, 2006).

6.5.6 C-REACTIVE PROTEIN

CRP is an acute-phase reactant produced by the liver that is very sensitive to inflammation and correlates well with the other indicators of inflammation. In recent years, the interest in CRP as a marker for inflammation in toxicology, virology, and microbiology studies has grown. CRP is measured by a variety of immunoassay methods, the majority of which are human-specific. It is important to validate these assays in each NHP, as significant differences in cross-reactivity may exist. A monkey-specific enzyme-linked immunosorbent assay (ELISA) for CRP was developed using sera from several macaque species that displayed greater sensitivity than that of the human-specific assay (Jinbo et al., 1998).

6.5.7 HEPATIC ENZYMES

6.5.7.1 Alanine Aminotransferase and Aspartate Aminotransferase

In marmosets, Mohr et al. (1971) showed the highest activity of ALT to occur in the liver, though cardiac muscle and kidney also had substantial quantities of the enzyme. The highest level of AST activity occurred in cardiac muscle. Although other tissues had activities of only one-third or one-fourth of that in cardiac muscle (by wet weight), tissues having relatively high activity included the liver, skeletal muscle, kidney, and brain.

The differences in ALT values among healthy chimpanzees, as well as the responses of ALT to inoculation with HCV, have been shown to be genetic in origin (Williams-Blangero et al., 1994). This underscores the importance of pre-study testing in primates, in which, typically, few animals per treatment group are used and animals are not inbred. In NHPs, ALT is not as specific for liver cell injury as it is in the dog, rat, or mouse.

Both hepatic injury and muscle injury can cause equally high elevations in ALT and AST. Mild to moderate elevations in ALT and AST of skeletal muscle origin are commonly seen in NHP species following normal chemical restraint, administration of intravenous substances, and blood collection procedures. Consequently, caution must be taken in attributing elevations of ALT and AST to hepatic injury when concurrent elevations in creatine kinase and/or lactate dehydrogenase are present.

6.5.7.2 Alkaline Phosphatase

In NHPs, the biliary and osteoblastic isoenzymes are the principal components of serum activity; however, the sensitivity of ALP as an indicator of cholestasis and biliary disease is much poorer than in many other laboratory animals such as the dog. This is particularly true in macaques, where the normal range of enzyme activity can be as high as 1500 IU/L, and the activity level in individual animals can vary considerably over time (Hall and Everds, 2003).

6.5.7.3 Gamma Glutamyltransferase

The tissue distribution of GGT was studied in baboons and macaques. In both species, GGT was found primarily in liver, pancreas, and kidney (Braun et al., 1980). In macaques, GGT has been described as a more sensitive and specific marker for biliary disease than ALP (Hall and Everds, 2003). In rhesus and cynomolgus monkeys, GGT levels are markedly higher in young animals of both sexes and decrease with age (Perretta et al., 1991). This trend is similar to humans in which the neonatal GGT activity is five to seven times higher than the upper limit of the adult reference

range with adult levels being reached by approximately 7 months of age (Cabrera-Abreu and Green, 2002). In chimpanzees, GGT levels have less daily intraindividual variation than AST or ALT, and smaller changes are considered more significant than comparable changes in AST or ALT. The initial increase in GGT may follow ALT or occur simultaneous. In most cases, it is the last enzyme to return to normal (Valenza and Muchmore, 1985).

6.5.8 IRON METABOLISM

The amount of iron in commercially available primate diets can have a substantial impact on analytes used to determine iron status. This is particularly true for NW monkeys such as lemur, squirrel monkeys, and owl monkeys, which frequently develop hemosiderosis in captivity owing to excessive dietary supplementation (Barnhart, 2008; Wood et al., 2003; Glenn et al., 2006; Miller et al., 1997; Smith et al., 2008). The reasons for this iron sensitivity are not completely understood, but they may be related to increased iron absorption as a physiologic adaptation to an arboreal habitat. In a recent report, the incidence of elevated serum iron ($>160 \mu\text{g/dL}$) was 34.3% in owl monkeys and 35.6% in squirrel monkeys with serum iron ranging from 162 to 351 $\mu\text{g/dL}$. Total iron binding capacity (TIBC) was frequently markedly elevated, ranging from 243 to 950 $\mu\text{g/dL}$, and percent iron saturation ranged from 35.5% to 97.6% (Barnhart, 2008). Monkeys that chronically receive high levels of dietary iron are at risk for hepatic hemosiderosis. Removing iron from the diet and adding iron-chelators such as tannins and phytates has been shown to effectively prevent this syndrome (Wood et al., 2003). A recent study in marmosets suggested that ferritin, serum iron, and percent transferrin saturation could be used to assess the severity of hemosiderosis (Smith et al., 2008).

Iron accumulation has not been reported for OW monkeys. Reference values for parameters to assess iron metabolism in normal cynomolgus monkeys are provided in Table 6.8.

6.5.9 LIPIDS AND LIPOPROTEINS

Cholesterol, triglycerides, and lipoproteins have been studied very extensively in NHPs, particularly with respect to models of dyslipoproteinemia and atherosclerosis. Many of these studies were performed in animals fed experimental diets (Portman et al., 1985; Spray et al., 1994; Rudel et al., 1981b; Srinivasan et al., 1974). Determination of serum cholesterol before and after a high-cholesterol diet allows for the classification of *M. mulatta* and other primate species into high- and low-cholesterol responder categories that are believed to be genetically controlled (Bhattacharyya and Eggen,

^a Nonpregnant.

1983). In addition, variation in plasma lipid and lipoprotein response to a high-cholesterol diet in cynomolgus monkeys (*M. fascicularis*) was attributed to additive genetic effects (Spray et al., 1994).

The lipoprotein profile of cynomolgus monkeys is very similar to that of humans with approximately equal amounts of HDL- and LDL-cholesterol and little very low-density lipoprotein (VLDL) cholesterol. Both density-gradient centrifugation and fast protein liquid chromatography have been used to quantitate lipoproteins in NHP (Lehmann et al., 1993). Reference ranges for lipoproteins and lipids in healthy, young adult cynomolgus monkeys are provided in Table 6.9.

Brazilian squirrel monkeys on a lithogenic diet were highly susceptible to cholelithiasis, whereas Bolivian males were resistant. This was associated with HDL-2, which is high in the Brazilian subspecies and low in the Bolivian subspecies. The transport of cholesterol to bile is attributed to HDL-2 (Portman et al., 1985).

Serum lipid profiles were compared in lean and obese chimpanzees (Steinetz et al., 1996). The obese animals had higher total cholesterol, LDL-cholesterol, and triglycerides, though the differences were not statistically significant (Table 6.10).

Sera from many NHP including chimpanzees, rhesus, cynomolgus, squirrel, and owl monkeys frequently have high serum triglyceride levels with no visible evidence of lipemia. The most likely reason for this finding is an increase in free glycerol in the serum. A study in baboons showed that free glycerol concentrations are highly variable and may account for 32% of the serum triglyceride levels (Mott and Rogers, 1978). Most standard assays for serum triglyceride actually measure total triglyceride, which includes free glycerol. Triglyceride blanking to correct for endogenous glycerol may be performed by quantitating the glycerol prior to adding lipase, which is the necessary enzyme for calculating total triglycerides (Rifai and Warnick, 2006). Possible causes of the increased glycerol include stressful situations such as restraint and disease that increase epinephrine, which activates hormone-sensitive lipase, resulting in glycerol release into the circulation (Mott and Rogers, 1978).

6.5.10 PEPSINOGEN I

Pepsinogen I is the inactive precursor to pepsin that is produced and secreted by the gastric chief cells. The majority of pepsinogen I is secreted into the gastric lumen and converted into pepsin in the presence of hydrochloric acid. A small amount of pepsinogen I is also present in blood. Lynch et al. (2004) evaluated a human ELISA for measuring pepsinogen I in cynomolgus monkeys and concluded that serum pepsinogen I provides a sensitive and specific biomarker for gastric toxicity for preclinical studies.

6.5.11 PROTEIN

In owl monkeys, a positive linear relationship between serum total calcium and both albumin and protein have been identified. The findings were similar to dogs, and the adjusted formula for calcium based on albumin concentration for dogs correlated with monkeys and could be potentially used to provide an accurate estimate of total calcium in monkeys (Weller et al., 1990).

Changes in serum proteins of *M. fascicularis* during lactation have been studied (D'Ovidio and Turillazzi, 1994). During the 48 weeks of lactation, the absolute values of $\alpha 1$ and γ globulins decreased while $\alpha 2$ and β globulins increased. Several positive acute-phase proteins including $\alpha 1$ acid glycoprotein, haptoglobin, and ceruloplasmin, as well as the negative acute-phase protein transferrin were decreased. It was considered likely that these trends were caused by estrogen and progesterone variations after delivery.

6.5.12 URIC ACID

Serum uric acid is an insensitive indicator of renal function in certain NHP species that has limited diagnostic applications. Despite its lack of practical application, uric acid production has important evolutionary implications. Uric acid is a product of purine metabolism that is converted to the more soluble and readily excreted allantoin by the copper-binding enzyme urate oxidase (uricase). During primate evolution, uricase activity was lost and eventually silenced due to genetic mutations; consequently, NHP species that underwent mutation developed elevated levels of uric acid (Oda et al., 2002; Johnson et al., 2009). Johnson et al. (2005) theorized that these mutations occurred as a way of increasing blood pressure in response to a low-sodium and low-purine diet. OW monkeys, including baboons and rhesus monkeys, have a moderate degree of urate oxidase activity and a low serum uric acid level (Christen et al., 1970). Similar to humans, urate oxidase activity is not detectable in liver homogenates from chimpanzees, which have serum uric acid levels of approximately 3 mg/dL (Johnson et al., 2009; Friedman

et al., 1985). With some exceptions, most NW monkeys have high urate oxidase activity in the liver and consequently low serum uric acid levels. In a study by Christen et al. (1970), one tamarin (*S. oedipus*), one wooley monkey, and two Cebus monkey species showed moderate serum uric acid levels.

6.5.13 SERUM AMYLOID A

Serum amyloid A (SAA) is an apoprotein of monkey HDL and lymph chylomicrons that is released as part of the acute-phase response (Parks and Rudel, 1985). Commercially available ELISA kits for human diagnostics have been used successfully to detect SAA in primate sera; however, validation of the assay must be performed for the specific species of interest. Hukkanen et al. (2006) recently reported that an immunoassay developed by different companies performed with varying results in NHPs.

6.5.14 SEX HORMONES AND GONADOTROPINS

NHPs have been extensively utilized in investigations of pituitary and sex hormone responses due to their similarities to humans in these respects. Table 6.11 provides reference values for some analytes used to assess endocrine function in NHP.

6.5.14.1 Testosterone

In male cynomolgus monkeys, normal androgen levels can be segregated into four phases: neonatal, infancy, prepubertal, and pubertal. The neonatal period is associated with elevated testosterone and dihydrotestosterone (DHT) levels that have been attributed to testicular steroidogenic activity. Levels of these hormones subsequently decreased throughout the infancy and prepubertal phases before sharply increasing with the onset of puberty (Meusy-Dessolle and Dang, 1985). The average levels for testosterone at each phase are provided in Table 6.12. Unlike testosterone and DHT, D4-androstenedione remained relatively constant from birth to 3 years of age with a decrease from 3 to 4.5 years (Meusy-Dessolle and Dang, 1985). High serum testosterone levels of testicular origin are also present in neonatal male rhesus monkeys and pigtail macaques, whereas neonatal females have testosterone levels

comparable to castrated, postnatal males (Robinson and Bridson, 1978). In male chimpanzees, serum testosterone levels increased with age from an average juvenile value of 13 ng/dL at 1–6 years, to an adolescent value of 178 ng/dL at 7–10 years and an adult value of 397 ng/dL (Martin et al., 1977).

Diurnal variations of testosterone, DHT and androstenedione have been described for rhesus monkeys. In general, testosterone levels are significantly lower in the morning and early afternoon as compared to nighttime (Winters et al., 1991; Schlatt et al., 2008; Chambers et al., 1982; Goncharov et al., 1981). However, these diurnal patterns may change to some degree depending on the season of the year (Rose et al., 1978). Testosterone and DHT also have an annual periodicity. The highest levels are typically seen in winter with the lowest levels occurring in the summer (Gordon et al., 1978; Goncharov et al., 1981). Additionally, Schlatt et al. (2008) showed that these diurnal rhythms were enhanced in older rhesus monkeys. The circadian rhythm of androstenedione is characterized by minimum values in the evening, an increase during the night, and a peak in the early morning (Goncharov et al., 1981).

Squirrel monkeys and other NW monkeys have high levels of testosterone as compared to OW monkeys (Wilson et al., 1978). In the owl monkey, the lowest serum levels of testosterone occur during the dark period with fivefold higher levels occurring during the light period, the reverse of patterns reported in diurnal primates (Dixson and Gardner, 1981). During the breeding season, a dramatic rise in testosterone accompanied by more modest elevations in DHT and androstenedione occurred in male squirrel monkeys. The testosterone:DHT level was approximately 7:1 in the nonbreeding season but rose dramatically to 34:1 in the breeding season. In contrast, the testosterone:DHT ratio in humans is approximately 12. In squirrel monkeys, lower 5 α -reductase activity during the breeding season may lead to a compensatory increase in androgen production (Gross et al., 2008).

In male vervet African green monkeys, circadian rhythms were demonstrated for androgens, with peak values at 2100 to 0600 hours, and for 17 β -estradiol, with peak values at 2400 to 0600 hours (Beattie and Bullock, 1979). In the nocturnal male owl monkey (*A. trivirgatus*), the lowest levels of serum testosterone occurred during the dark period, and approximately fivefold higher levels are present during the light period. This pattern is the reverse of the pattern reported for diurnal primates (Dixson and Gardner, 1981).

Given the importance of monitoring testosterone metabolism in many studies involving NHP, non-invasive methods for quantitating testosterone metabolites are ideal in that they allow repeated sampling without creating significant stress in the animal. Mohle et al. (2002) investigated the feasibility of measuring testosterone metabolites in urine and feces from a chimpanzee, cynomolgus monkey, and common marmoset as a method for studying testosterone metabolism. In all three species, testosterone metabolites were excreted primarily in the urine; however, the quantity of each individual metabolite varied significantly between species and between urine and feces. Thus, noninvasive assessment of testosterone metabolism should be investigated and validated for each species.

6.5.14.2 Estrogen and Progesterone

The major biologically active estrogen varies between NHP species. For example, estrone is the major circulating plasma estrogen in the owl monkey while 17β -estradiol predominates in rhesus monkeys (Bonney et al., 1980). Serum estradiol levels in neonatal male and female macaques did not differ during the first 14 weeks of life and never exceeded 50 pg/mL (Robinson and Bridson, 1978). Many NW monkeys including owl monkeys, tamarins, the common marmoset, and the squirrel monkey have plasma estrogen and progesterone levels that are 50–100 times greater than OW monkeys (Bonney et al., 1979).

Given the many similarities in placentation, pregnancy, menstruation, and the hormonal dynamic, the NHP functions as an important model of human reproduction. Quantitative assessments of estrogens, progesterone, and other reproductive hormones during the menstrual cycle have been described for the chimpanzee (Machatschke et al., 2006), baboon (Koyama et al., 1977), rhesus (Hotchkiss et al., 1982), cynomolgus (Mehta et al., 1986; Goodman et al., 1977), and African green monkeys (Hess et al., 1979). Not surprisingly, these NHP share many similar characteristics with humans. Studies have shown that the hormonal dynamics of chimpanzees are similar to those of women, and levels of estrogen, progesterone, and 17α -hydroxyprogesterone vary throughout the menstrual cycle of rhesus monkey in a similar manner to humans (Hobson et al., 1976; Bosu et al., 1972). However, significant differences between species and humans do exist, and the specific hormonal patterns unique to each species should be established prior to initiation of reproductive studies. In a natural environment, the menstrual cycles of rhesus monkeys are ovulatory in the fall and winter, and anovulatory (with low levels of follicle-stimulating hormone [FSH] and estradiol) in the spring and summer (Walker et al., 1984). The mean levels of estrogen, progesterone, luteinizing hormone (LH) and FSH for female rhesus monkeys throughout the menstrual cycle are provided in Table 6.13.

The owl monkey and other NW monkeys differ from OW monkeys in that they lack a detectable menstrual cycle. Consequently, hormonal assays are often required to index ovarian function. In the owl monkey, a defined peak of 17β -estradiol can be used to time ovulation (Bonney et al., 1980). Owl monkeys and tamarins also differ from OW monkeys and some NW monkey species such as the squirrel monkey and the common marmoset in that they do not have clear hormonal distinctions between the follicular and luteal phases (Bonney et al., 1979).

Postmenopausal rhesus and cynomolgus macaques have low concentrations of 17β -estradiol (Kavanagh et al., 2005). Additionally, low levels of daily urinary estrone conjugate have also been described for postmenopausal rhesus monkeys (Gilardi et al., 1997).

FSH, follicle-stimulating hormone; LH, luteinizing hormone.

Hormone profiles throughout pregnancy vary between species. Progesterone levels do not show a marked increase during pregnancy in several macaque species and baboons. In the common marmoset and the squirrel monkey, however, progesterone and estrogens increase following ovulation and generally remain high throughout pregnancy (Diamond et al., 1987; Chambers and Hearn, 1979). Many NHPs do not require a decrease in progesterone for the onset of parturition; however, the marmoset does experience a decline in plasma progesterone during the last few weeks of pregnancy (Chambers and Hearn, 1979). The hormonal changes associated with female marmosets show marked diurnal variations in urinary estradiol levels (Bos et al., 1993).

Several reports described changes in hormone levels following spontaneous abortion or fetal death. In Bolivian squirrel monkeys, weekly measurement of chorionic gonadotropin (CG), estradiol, and progesterone was used to characterize animals that aborted (Diamond et al., 1985). The authors demonstrated that a gradual decline in serum hormone concentrations to levels at or below 20% of peak values occurred in animals undergoing spontaneous abortion. In rhesus monkeys pregnant with live anencephalic fetuses, estradiol was significantly lower than in pregnant normal controls but estrone was not decreased; following fetal death, both estradiol and estrone decreased significantly (Walsh et al., 1979).

Noninvasive methods for evaluating hormonal dynamics are valuable techniques for monitoring pregnancy, menstruation, and reproductive health in female monkeys. Many investigators have successfully quantitated ovarian steroid hormones in feces and urine (Moorman et al., 2002; Bardi et al., 2001). Ovulation and conception were detected by fecal steroid profiles in a group of wild Japanese macaques (Shimizu, 2005). Matsumuro et al. (1999) successfully used a commercially available radioimmunoassay kit to detect estradiol and progesterone levels in fecal samples from cynomolgus monkeys. The excretion of steroids and steroid metabolites was reviewed by Whitten et al. (1998), and a summary of published reports describing validated applications for quantitating excreted steroids as a measurement of ovarian function and pregnancy is provided in Table 6.14.

6.5.14.3 Prolactin

In females, prolactin is an important regulator of maternal behavior. In some NHP species, particularly marmosets, tamarins, and owl monkeys, both sexes demonstrate a high level of paternal behavior. Dixon and George (1982) originally reported that male marmosets carrying their offspring had prolactin levels that were approximately five times higher than males without infants. Subsequent studies of common marmoset and the cotton-top tamarin males have also associated elevated prolactin with various aspects of parenting behavior (Schradin et al., 2003; Ziegler and Snowdon, 2000). Prolactin is typically measured by immunoassay techniques. Although an earlier study in squirrel monkeys reported insufficient cross-reactivity by using antibodies directed at human prolactin, recent studies have successfully used human assays to measure prolactin in the urine from marmosets and tamarins (Scammell, 1992; Ziegler et al., 1996b; Ziegler and Snowdon, 2000; Schradin et al., 2003). Ketamine anesthesia has been shown to greatly increase prolactin levels in rhesus and squirrel monkeys (Scammell, 1992; Puri, 1981).

6.5.14.4 Chorionic Gonadotropin

By contrast to most nonprimate mammals, CG is present in the serum and urine of pregnant female NHPs (Maston and Ruvolo, 2002). The molecule consists of an α and a β subunits. The structure of the α subunit is highly species specific; the β subunit that characterizes CG is immunologically similar among species. An antibody to the β subunit of ovine luteinizing hormone has been used in a hemagglutination inhibition assay and a radioimmunoassay for pregnancy diagnosis in a variety of NHP species. The duration of the reliable positive reaction is brief; in rhesus monkeys, it occurs on days 20–24 of pregnancy, and in cynomolgus monkeys on days 24–28 (Boot and in't Veld, 1981; Lequin et al., 1981; Yoshida, 1983). Use of the hemagglutination inhibition test in rhesus monkeys was evaluated at 19–21 days after breeding. Pregnant females were identified with an accuracy of 73.3%. Of 104 urine samples from non-pregnant intact females, 11.5% yielded a false positive result. Rarely, urine from males or ovariectomized females yielded false positive results (Naqvi and

Lindberg, 1985). Diamond et al. (1987) reported that an increase in CG can be used in the squirrel monkey to distinguish pregnant from nonpregnant females. In chimpanzees, an increase in CG and estrone conjugates are the earliest hormonal changes associated with pregnancy (Shimizu et al., 2003). Human pregnancy tests based on detection of human CG have been used successfully in chimpanzees for early pregnancy detection.

Serum hormone levels for pregnant cynomolgus monkeys have been investigated. Monkey CG rose sharply with a peak at approximately 20 days, which was quickly followed by a return to very low levels throughout the duration of the pregnancy. Serum estradiol levels started to increase at approximately 4 weeks and continued to rise throughout pregnancy with a sharp peak immediately before parturition. Progesterone initially declined until approximately week 7 and then increased steadily until approximately week 21 at which time the levels began to drop until parturition. Prolactin levels remained relatively low until a gradual increase started at approximately 15 weeks and plateaued the last few weeks of gestation. Serum cortisol levels did not change (Hein et al., 1989).

6.5.14.5 Thyroid Hormones

Serum thyroxine (T_4) and triiodothyronine (T_3) may be assayed by standard human immunoassay methods. Although some standardized human assays for thyroid-stimulating hormone (TSH) will cross-react with NHP species, this is not always the case and the method validation for a particular species should always be performed. Cynomolgus monkeys, rhesus monkeys, chimpanzees, and African green monkeys have similar values for total T_4 and total T_3 (Yoshida et al., 1989). Table 6.15 details reference values for thyroid parameters in chimpanzees, rhesus, cynomolgus, African green, owl, and squirrel monkeys.

In male rhesus monkeys, total T_4 levels decline throughout postnatal development, but a transient T_4 elevation occurs immediately prior to puberty and in concert with the peripubertal increase in testicular size and may contribute to the process of sexual development (Mann et al., 2002). An additional study in male rhesus monkeys demonstrated that the low-protein diets affect the thyroid function by decreasing the total T_4 and free T_4 concentrations and elevating the T_3 levels. These changes may indicate a mild hypermetabolic state with increased conversion of T_3 to T_4 (Portman et al., 1985). The administration of estradiol to intact female rhesus monkeys increased their serum TSH by decreasing its degradation (Scammell et al., 1992).

The effects of aging on the TSH, T_3 , and T_4 were determined in cynomolgus monkeys. In males, T_3 , T_4 , and TSH decreased with age. Although T_3 and T_4 decreased with age in females, TSH remained unchanged. Following thyrotropin-releasing hormone (TRH) administration, the TSH concentrations, but not T_3 and T_4 , were maximally increased in the oldest group. These results suggested that in aging primates either the sensitivity of the thyroid gland to TSH or the releasing capacities for T_3 and T_4 are decreased (Yoshida et al., 1989). Kaack et al. (1979b, 1980) demonstrated that T_4 progressively decreases in maturing squirrel monkeys, while T_3 does not change. Much higher values for both T_4 and T_3 were observed in the Bolivian subspecies of *S. sciureus* than in the Columbian subspecies. Additionally, male squirrel monkeys displayed higher concentrations of T_3 and T_4 prior to the breeding season when the body weight was at its highest (Kaack et al., 1980). The owl monkey has lower levels of T_3 as compared to cynomolgus macaques and many other NHP species. This finding is consistent with the lower metabolic rate of the owl monkeys (Whittow et al., 1979).

Chimpanzees have notable differences in thyroid function as compared to humans. They have lower total T_4 levels but increased free T_4 , free T_3 , total T_3 , and T_3 uptake. Gagneux et al. (2001) hypothesized that a higher affinity of transthyretin and/or T_4 -binding globulin for thyroid hormone may account for these differences.

6.6 BRIEF DESCRIPTION OF COMMON PROCEDURES

6.6.1 EVALUATION OF HYPOTHALAMIC–PITUITARY–ADRENAL AXIS FUNCTION

ACTH stimulation and dexamethasone suppression tests are commonly performed on NHP to assess hypothalamic–pituitary–adrenal (HPA) function. One published method for performing an ACTH stimulation test in cynomolgus monkeys requires an overnight fast followed by an injection of dexamethasone (0.5 mg/kg) in the morning to suppress the HPA axis. Four hours after this injection, blood is collected for a baseline cortisol, and ACTH is administered (i.e., Cortrosyn® 10 ng/kg intravenously). Additional blood samples are collected 15 and 30 minutes post-ACTH for cortisol determination. A modified dexamethasone suppression test for NHP has also been described. A morning blood sample for cortisol is taken and a low dose of dexamethasone (130 µg/kg intramuscularly) is administered 12–14 hours later. The next morning, a second blood sample for cortisol is collected. The difference between the two cortisol levels is used as an indicator of sensitivity to negative feedback (Shively et al., 1997).

An immunoradiometric assay for plasma ACTH concentration was validated for rhesus monkeys by Norman and Smith (1992). A study by Sarnyai et al. (1995) utilized this method to determine that rhesus monkeys have a high-frequency, low-amplitude micropulsatile ACTH release that is very similar to humans. Recently, a commercial radioimmunoassay kit with 100% cross-reactivity with human and murine ACTH was successfully validated for capuchin monkeys, a NW monkey species closely related to marmosets and tamarins (Torres-Farfan et al., 2008).

6.6.2 EVALUATION OF GLUCOSE METABOLISM AND REGULATION

Many of the same assays used to evaluate glucose metabolism in humans can be successfully used in NHP. These include (1) fasted insulin and glucose levels, (2) plasma levels of glycosylated proteins,

(3) the OGTT, (4) the intravenous glucose tolerance test, and (5) the euglycemic clamp. Reference intervals for the gluoregulatory measurements associated with these procedures are provided for baboons, rhesus, and cynomolgus monkeys, in Tables 6.16 through 6.18.

Serum glucose concentration is influenced by numerous factors, including gastrointestinal absorption, insulin, hepatic storage and release, glucagon, somatotropin, epinephrine, and cortisol. Through the latter two hormones, excitement and stress may significantly elevate serum glucose. Variations among primate species with respect to anatomy and transit time of the gastrointestinal tract should be considered in determining the length of fasting required to render an animal non-absorptive. In monkeys that have cheek pouches, such as macaques, the cheek pouches should be manually emptied or the retention of food in cheek pouches should be considered in determining whether animals are nonabsorptive.

Elevated fasting glucose is often an early indicator of type 2 diabetes mellitus. In humans, overt diabetes is defined as a fasting glucose that exceeds 126 mg/dL. The normal fasting glucose level for most NHP is 20–30 mg/dL lower than humans; consequently, a persistent fasted glucose of 100–126 mg/dL that is not attributable to a stress response is more likely to indicate overt diabetes (Wagner et al., 2006). In fasting rhesus monkeys and baboons, Goodner et al. (1977) observed periodic oscillations of insulin, glucose, and glucagon. Glucose and insulin oscillated in phase with each other and out of phase with glucagon. Once a meal was consumed, these cycles were disrupted; however, anticipation of feeding did not affect serum insulin levels in rhesus monkeys (Natelson et al., 1982; Goodner et al., 1977).

6.6.3 FRUCTOSAMINE AND GLYCATED HEMOGLOBIN

The measurement of nonenzymatically glycosylated proteins furnishes a biomarker of long-term glucoregulation that is less subject to artifact than the measurement of blood glucose. Studies have indicated that fructosamine or glycosylated hemoglobin may provide effective and objective measures for monitoring glycemic control of diabetic animals in both the clinical setting and in research studies (Cefalu et al., 1993; Wagner et al., 1996). Significant species differences exist, however, and it is imperative that species-specific reference ranges be established. Cefalu et al. (1993) concluded that the glycosylated hemoglobin values for rhesus monkeys were 40% higher than those of cynomolgus monkeys as determined by automated high-pressure liquid chromatography (HPLC). Varied species RBC life span or age-dependent differences in the rates of hemoglobin glycosylation were suggested as possible causes for this discrepancy. Using HPLC, the extra peak for hemoglobin A1c

(HbA1c) is similar for baboons and humans, and HbA1c can be used effectively to monitor hyperglycemia in baboons (Heffernan et al., 1995). Fructosamine was reportedly increased in diabetic cynomolgus monkeys and along with glycated hemoglobin may play a role in detecting the presence of asymptomatic hyperglycemia in NHPs (Wagner et al., 1996; Cefalu et al., 1993). Normal values for glycated proteins in rhesus and cynomolgus monkeys are provided in Table 6.19.

6.6.4 INTRAVENOUS GLUCOSE TOLERANCE TEST

An intravenous glucose tolerance test (IVGTT) can be used effectively in many NHP species to evaluate the effectiveness of glucose-regulating mechanisms following an intravenously administered dose of glucose (Jen and Hansen, 1988; Wagner et al., 2006). For most NHP, this procedure must be performed under anesthesia. Numerous studies have shown that ketamine hydrochloride has minimal effect on the results of an IVGTT in NHP, specifically rhesus, cynomolgus, and African green monkeys (Jen and Hansen, 1988; Brady and Koritnik, 1985; Streett and Jonas, 1982; Kemnitz and Kraemer, 1982; Castro et al., 1981; Fulmer et al., 1984); however, other investigators concluded that both anesthesia and stress had notable effects on glucose regulation in baboons and squirrel monkeys (Lehmann et al., 1997; Ausman and Gallina 1978). In baboons sedated with ketamine, the first phase insulin secretion, basal insulin, and glucose levels, as well as the glucose clearance, were significantly lower during sedation (Lehmann et al., 1997). Both stress and anesthesia reportedly decrease the glucose assimilation rate in squirrel monkeys, whereas manual restraint, but not ketamine sedation, decreases the glucose assimilation in rhesus and African green monkeys (Fulmer et al., 1984; Ausman and Gallina, 1978).

Many additional variables can affect the results of an IVGTT; consequently, it is important to use a standardized approach. To this end, several methods for performing and analyzing the IVGTT in monkeys have been developed and used successfully for research studies and clinical diagnostics. The most common technique involves the determination of basal glucose and insulin levels following a 12-hour fast. An intravenous bolus of 50% glucose solution dosed at 0.5 mg/kg is injected over a short interval (typically 30 seconds to 3 minutes) and followed by serial blood collections at 3, 5, 10, 20, 30, 40, 50, and 60 minutes from the mid-injection time point. Glucose and insulin are

TABLE 6.19
Normal Values for Glycated Proteins in Rhesus and Cynomolgus Monkeys (Mean \pm SD)

^a Cefalu et al. (1993).

^b Najafian et al. (2010).

determined at each of the time points, and several important parameters are derived from the data. Blood glucose decreases exponentially, and the rate of glucose disappearance can be expressed by the fractional turnover rate (K_G). This rate is determined primarily by the deposition of glucose in hepatocytes under the influence of insulin, but it is also affected by the other factors that regulate serum glucose. This rate of decrease can be calculated by two established methods. The first is $K_G = 0.693/t_{1/2} \times 100\%$ per minute, where $t_{1/2}$ (min) equals the time point at which the glucose concentration drops to one-half of the peak value (Jen and Hansen, 1988). Alternatively, K_G can be calculated by the following formula in rhesus monkeys that represents the log-linear decline of glucose levels (Tigno et al., 2004). The area under the curve for insulin can be calculated by the trapezoidal rule, and it provides a useful assessment of insulin resistance:

$$K_G = \frac{[\ln(\text{glucose at 5 minutes}) - \ln(\text{glucose at 20 minutes})]}{15 \text{ minutes}} \times 100\%$$

The minimal model technique is a modified IVGTT that was initially developed in the late 1970s and has been widely used to determine insulin sensitivity and glucose effectiveness through computer modeling (Pacini et al., 1998). Briefly, this technique started with an injection of glucose followed by an injection of tolbutamide to provoke additional endogenous insulin secretion. Insulin and glucose are then measured frequently for up to 3 hours. The values are then entered into a computer program that compares the prediction of the model with measured values and makes adjustments until it is able to calculate glucose effectiveness (S_G) and insulin sensitivity (S_I) (Bergman, 1989). This technique has been utilized effectively in diabetic and nondiabetic rhesus monkeys (Gresl et al., 2003a, 2003b).

6.6.5 ORAL GLUCOSE TOLERANCE TEST

The OGTT offers little benefit over the IVGTT in NHP. For the test to be performed successfully without anesthesia, the animals would have to be willing to quickly ingest substantial quantities of fluids containing glucose and allow blood to be collected through manual restraint. The alternative, which is to administer the fluids through a stomach tube while under anesthesia, poses certain risks such as regurgitation and aspiration. Streett and Jonas (1982) concluded that ketamine impaired absorption of glucose from the intestine. Additional disadvantages of the OGTT include the variability of intestinal absorption, the gastric emptying rate, and the influence of enteric hormones on assay results (Lehmann et al., 1997). Only a few studies utilizing the OGTT have been reported. Two obese

and one lean chimpanzee had abnormal glucose patterns. One of 17 lean chimpanzees and 2 of 14 obese chimpanzees had significantly abnormal glucose tolerance curves (Steinetz et al., 1996).

6.6.6 EUGLYCEMIC CLAMP

The euglycemic clamp is considered the gold standard for determining insulin sensitivity as well as determining the amount of glucose metabolized following a controlled hyperglycemic stimulus. It has been widely used in obesity and type II diabetes studies in rhesus monkeys and baboons (Chavez et al., 2008; Bodkin et al., 1989; Pender et al., 2002). At the start of the procedure, the plasma insulin concentration is acutely increased and maintained at a predetermined level by a prime-continuous infusion of insulin. A variable glucose infusion is administered concurrently to maintain a constant basal level of plasma glucose. Under these conditions, the glucose infusion rate equals glucose uptake in the body and provides a measure of tissue sensitivity to exogenous insulin (DeFronzo et al., 1979); the lower the glucose infusion rate, the greater the degree of insulin resistance. Although the euglycemic clamp provides excellent test characteristics, the euglycemic clamp also has several disadvantages. It is time consuming, labor intensive, expensive, and requires an experienced operator to manage technical difficulty. Insulin resistance has been effectively demonstrated and monitored in both rhesus monkeys and baboons with the euglycemic clamp (Chavez et al., 2008; Hotta et al., 2001; Bodkin et al., 1989).

6.6.7 RENAL FUNCTION TESTS AND URINALYSIS

Measurements of serum urea nitrogen and creatinine are widely used in NHPs, principally to assess renal function. As in other species, extensive renal disease may occur before significant elevations of BUN and creatinine. In addition, nonrenal factors such as diet and dehydration can cause significant increases in both BUN and creatinine. A slight but progressive increase in creatinine signals progressive deterioration of renal function; thus, an animal's own earlier creatinine values may be of greater importance than the historical reference range in detecting renal dysfunction. In humans and baboons, diurnal variations of serum creatinine, glomerular filtration, and renal excretion of creatinine occur (Gavellas et al., 1987; Bos et al., 1993).

Normal ranges for the following urine measurements of renal function have been established for cynomolgus monkeys: (1) specific gravity, (2) creatinine clearance, (3) osmolality clearance, (4) fractional excretion of electrolytes, and (5) urine pH (Table 6.20). This study also suggested that a desmopressin response test at 4 hours post injection is preferable to a water deprivation test in assessing urine concentrating ability (Weekley et al., 2003). The desmopressin-induced urine concentration was determined by administering 0.3–0.4 µg/kg of 1-(3-mercaptopropionic acid)-8-D-arginine vasopressin (4 mg/mL) subcutaneously and placing a urinary catheter under ketamine anesthesia. Urine samples were collected prior to and 4 hours following drug administration. Urine-specific gravity and osmolality were evaluated. A baseline pH range of 6.4–8.2 has been reported for cynomolgus monkeys; however, this range should be interpreted with caution. Different dietary management strategies may affect the normal pH range, and it is not uncommon for some macaque colonies to maintain a normal pH range from 8.0 and 8.5. Consequently, it may be prudent to establish normal pH ranges for individual colonies or groups of animals.

In some species, the clearance of endogenous creatinine can be used to approximate glomerular filtration rate (GFR). In other species such as humans and rats, creatinine is primarily filtered by the glomeruli but also secreted through the renal tubules. GFR in male baboons (*Papio hamadryas*) was evaluated by Gavellas et al. (1987) using either 24-hour creatinine clearance or inulin clearance. The 24-hour creatinine clearance was established in awake, chair-restrained baboons by collecting urine through an external condom catheter for 24 hours. Creatinine clearance was measured using the 24-hour excretion of creatinine and the mean serum creatinine concentration established from multiple venous blood samples collected at the beginning and the end of the 24-hour urine collection. Inulin clearance was calculated in anesthetized and awake, chair-restrained baboons. In both settings, the baboons

received an intravenous infusion of 0.45% NaCl solution containing inulin (1.3–1.9 mg/min to achieve a blood level of 20–30 mg/dL) with or without creatinine. Three to four urine collections were obtained for clearance measurements after 90–120 minutes of equilibration. Clearance periods were 15 and 60 minutes for anesthetized and awake animals, respectively. Blood was collected at the midpoint of each period. Inulin was measured and renal clearance determined by conventional methods. Through this detailed assessment of GFR, it was found that creatinine clearance overestimated GFR and that the renal mechanisms for excretion of creatinine and inulin are different. Creatinine clearance has also been used to assess kidney function in chimpanzees, and normal ranges are provided in Table 6.21.

6.6.7.1 Urinalysis

In owl monkeys, the urine protein/creatinine (UPC) ratio correlated with 24-hour urine protein loss similar to dogs. Thus, calculating a UPC could replace timed urine collections in most clinical circumstances. In addition, positive linear relationships existed between the following pairs of analytes similar to dogs: (1) urine protein and urine creatinine, (2) urine protein and 24-hour urine protein loss, (3) UPC and 24-hour protein loss, and (5) urine protein and urine-specific gravity. Owl monkeys have a lower urine-specific gravity range (1.002–1.023) as compared to dogs (Weller et al., 1991b). In general, many NHP species including macaques and chimpanzees have a lower urine-specific gravity range as compared to dogs and humans. Reference ranges for normal urinary analytes and selected serum parameters used to assess renal function are provided for *A. nancymae*, *A. vociferans*, and *S. peruviansis*, in Tables 6.22 through 6.25 (Baer, 1994; Weller et al., 1993a, 1993b, 1996).

Weller et al. (1993b) measured urinary alkaline phosphatase (UAP), urinary aspartate aminotransferase (UAST), and N-acetyl- β -D-glucosaminidase (NAG) and calculated enzyme:creatinine ratios. The NAG creatinine ratio was similar to normal values for the dog, man, horse, and cat, whereas UAP and UAST creatinine ratios were significantly higher. These elevations were attributed to either a species difference or a high prevalence of subclinical disease. In addition, the investigators concluded that the measurement of UAP, UAST, and NAG, expressed as IU/g_{Creatinine}, is a more sensitive marker for early renal injury than urinary enzymes alone.

TABLE 6.21
Creatinine Clearance in Chimpanzees (5th to 95th percentile)

Measurement	Unit	Median	Result
Age	years	2	1–9
Body surface area	m ²	0.56	0.4–0.94
Height (head to heel)	cm	54.3	38.6–119
Body weight	Kg	29.6	15.0–38.0
Serum creatinine	μmol/L	95.0	64.5–132.6
Volume of urine	mL/24 hours	850	300–1700
Urinary creatinine	mmol/L	3.79	0.66–11.6
Urinary creatinine	mmol/24 hours	2.94	0.6–5.95
Creatinine clearance	mL/min	22.5	4.0–62.5

TABLE 6.22
Normal Urine Parameters in Owl Monkeys

Parameter	Result
Specific gravity	1.010 ± 0.001 (1.002–1.023)
Volume (mL/kg/day)	9–303
Urinalysis—Dipstick	
Protein	0–3+
Glucose	0–1+
Ketones	0–2+
Bilirubin	0
Urobilinogen	0
Occult blood	0–4+
pH	6–8.5
Appearance—color	Light-dark yellow
Appearance—transparency	Clear-cloudy
Urinalysis—Microscopic	
Red blood cells	Rare-few (3–5/hpf)
White blood cells	Rare-occasional
Epithelial cells	Rare-occasional squamous Occasional renal tubular
Casts	Occasional granular
Crystals	Few-moderate triple phosphate Rare-calcium oxalate

Source: Baer, J.F., *Aotus: The Owl Monkey*, Academic Press, San Diego, CL, 1994.

Chimpanzees, like many primate species in captivity, receive a diet of vegetables, fruit, and processed biscuits that contain primarily soy-based proteins. Consequently, it is common to see a urine pH of 8.5 (Kelly et al., 2004). Small levels of hemoglobinuria and protein are frequently found in urine from normal chimpanzees. These findings may be attributable to the highly alkaline urine,

TABLE 6.23**Urinary Enzyme Concentrations in the Owl Monkey (*Aotus nancymae*)**

Enzyme	Mean \pm SD	Range

which can lead to false-positive proteinuria and hemoglobinuria. Additionally, false proteinuria may result from the contamination inherent in voided samples (Kaur and Huffman, 2004). Chimpanzees undergo a monthly menstrual cycle, and erythrocytes and hemaglobinuria are commonly noted in females during menstruation. The amount of creatinine excreted in the urine of chimpanzees is significantly less than that in the urine of humans. This finding may be an important consideration when following human dosages for drugs that are excreted through the kidneys. The potential for prolonged serum concentration as compared to humans exists (Eder, 1996).

Urine electrolyte values for pregnant female baboons are provided in Table 6.26. Very little information exists in the literature on normal urinalysis findings for marmosets and tamarins. Physiological glycosuria reportedly occurs in normal tamarins (Gatesman, 1986).

6.6.8 MISCELLANEOUS

A noninvasive method was recently developed for measuring urinary levels of two additional hormones associated with lactation and parturition, oxytocin and arginine vasopressin (AVP), in squirrel monkeys. This assay utilized HPLC separation of urine followed by a radioimmunoassay to demonstrate that measurable levels of oxytocin and AVP are present and that these levels may alter with changing social conditions (Seltzer and Ziegler, 2007). Luteinizing and FSHs are high in male rhesus monkeys during the first 3 months of life, decreasing thereafter to low or undetectable levels (Frawley and Neill, 1979).

6.7 SERUM REFERENCE INTERVALS/RANGES FOR SELECT NHP SPECIES

Tables 6.27 through 6.35 illustrate reference intervals/ranges for select NHP species.

ALT, alanine aminotransferase; ALP, alkaline phosphatase; AST, aspartate aminotransferase; BUN, blood urea nitrogen;

CK, creatine kinase; D. Bili, direct bilirubin; GGT, gamma glutamyl transferase; T. Bili, total bilirubin; T. Prot, total protein.

^a All monkeys resided on St. Kitts in the Caribbean.

^b Born in Cuba.

7.1 USE OF HAMSTERS IN BIOMEDICAL RESEARCH

Hamsters comprise approximately 25 species belonging to the class *Mammalia*, order *Rodentia*, suborder *Myomorpha*, superfamily *Muroidea*, family *Cricetidae*, and subfamily *Cricetinae*. The *Cricetinae* include all animals that we recognize as hamsters, often divided among seven genera: *Cricetus*, *Mesocricetus*, *Cricetulus*, *Phodopus*, *Tscherskia*, *Mystromys*, and *Calomyscus*. Syrian, or golden, hamsters (*Mesocricetus auratus*) are the most commonly used in research, representing perhaps 90% of hamsters used in the United States (Hankenson and Van Hoosier, 2002). Essentially, all pet and laboratory Syrian hamsters are descendants of three to four littermates captured in the wild in 1930 (Aharoni, 1932; Gattermann et al., 2001). Other species of hamsters are used in

lesser numbers, notably including the Chinese hamster (*Cricetulus griseus*) and the Djungarian, or Siberian, hamster (*Phodopus sungorus*). Use of hamsters in research in the United States has declined almost steadily from a high of approximately 503,590 hamsters reported used for research in 1976 to approximately 172,498 hamsters in 2007, the most recent year for which the annual United States Department of Agriculture (USDA) figures are available (USDA APHIS, 2008). The single most common use of hamsters is in potency testing for leptospirosis vaccines (Stephens et al., 2002). Syrian hamsters are used in leptospirosis research due to their susceptibility to many strains of *Leptospira*, as well as the reproducibility of studies conducted in hamsters (Haake, 2006). Syrian hamsters are a favored model for yellow fever research for both study of the pathogenesis and investigation of candidate therapeutics (Julander et al., 2007; Sbrana et al., 2006). Syrian hamsters also continue to play a key role in research into lipid and glucose metabolism, aging, skeletal and cardiac muscular dystrophy, oral carcinogenesis, and circadian rhythm. Because of the preponderance of Syrian hamsters relative to the other hamster species used in biomedical research in North America, the term hamster refers to Syrian hamsters in this chapter, unless otherwise specified.

Both the Chinese hamster (*Cricetulus griseus*) and the South African hamster (*Myodomys albicaudatus*) are used as spontaneous animal models of noninsulin-dependent diabetes mellitus (McIntosh and Pederson, 1999). Diabetic lines of Chinese hamsters are now well established, originally selected from individuals exhibiting spontaneous disease. Affected Chinese hamsters are hyperglycemic, glucosuric, and hypercholesterolemic and may become ketotic (Chang, 1978, 1981). Insulin levels vary greatly but decrease with time, suggesting eventual insulin exhaustion. The South African hamster also develops diabetes similarly characterized by hyperglycemia, glucosuria, and ketonuria (Packer et al., 1970; Riley et al., 1975; Stuhlman et al., 1975; Yesus et al., 1976).

The Djungarian, or Siberian, hamster (*Phodopus sungorus*) plays a major role in studies of the metabolic and reproductive effects of photoperiod (Braulke et al., 2008; Challet et al., 2000; Dark et al., 1994, 1999; Larkin et al., 2003; Mercer and Tups, 2003; Zysling and Demas, 2007).

Mutant lines of hamsters have been bred for use in at least two areas of research. Mutant Syrian hamsters available for research include cardiomyopathic, also called dystrophic, and tau mutants. As reviewed in Vainzof et al. (2008), the Bio14.6 inbred hamster and sublimes have a 30-kb deletion in the δ -sarcoglycan gene (Nigro et al., 1997), resulting in an autosomal recessive form of dilated cardiomyopathy and skeletal muscular dystrophy. Affected animals are reported to have elevated creatine kinase, referred to as phosphocreatine kinase in the older literature. Hamsters have long been used in circadian research, in part because of the daily regularity of their wheel running (Elliott et al., 1972). Hamsters with circadian rhythms shorter than the normal 24-hour circadian period were found to have an autosomal mutation in a gene referred to as *tau*. Animals homozygous for the mutation had 20-hour circadian periods; heterozygotes had 22-hour circadian periods (Ralph and Menaker, 1988). The *tau* gene has more recently been identified as encoding for casein kinase 1 epsilon (Lowrey et al., 2000), which is also important in circadian rhythm in *Drosophila*. No reports of genetically modified hamsters could be found at the time of this publication.

7.2 UNIQUE PHYSIOLOGICAL CHARACTERISTICS OF HAMSTERS

Hamsters are nocturnal, that is, they are active primarily during the night or dark period. Nocturnal behaviors that may influence some clinical chemistry parameters include feeding, food hoarding, and wheel running. Relevant aspects are discussed below under the influence of photoperiod and circadian rhythm. An additional important physiologic feature of hamster species is that they may undergo periods of hypometabolism. Syrian, Turkish, and European hamsters undergo hibernation, whereas the Djungarian hamster undergoes daily torpor (Newcomer et al., 1987). The difference between hibernation and torpor, which is sometimes called daily torpor, is the greater degree of duration and extent of metabolic suppression in hibernation; both are qualitatively similar energy-saving metabolic strategies with lowered body temperatures and decreased metabolic rate. Hibernation results from a combination of decreasing length of photoperiod and low temperatures,

whereas torpor follows a circadian rhythm, occurring during the normal resting period, that is, the light period. Hibernation may result in reduction of metabolic rates of more than 95% in the European hamster (Mohr and Ernst, 1987). Torpor in the Djungarian hamster may result in up to a 75% decrease in metabolic rate (Heldmaier et al., 2004). Body temperatures approach ambient temperature for both torpor and hibernation. Despite these changes, the animals are normoglycemic (Newcomer et al., 1987), normoxic, and maintain normal pH (Heldmaier et al., 2004).

During periods of normal physiologic activity, that is, not torpor or hibernation, hamsters have an unusually low half-saturation oxygen tension and Bohr shift (Bivin et al., 1987). Although this might be expected in an animal adapted for hibernation, to permit continued delivery of sufficient oxygen to their tissues, one might also expect high cardiac output. Indeed, hamster has a cardiac output, per kilogram of body weight, which is nearly twice that in the rat.

The cheek pouch of hamsters has traditionally played a role in oncology and carcinogenicity studies. These large buccal pouches, which the hamster uses for transporting food, are easily everted and viewed. Significantly, the pouches lack a lymphatic drainage system and have a decreased number of dendritic cells; thus, they are considered to be “immunologically privileged” and will not reject allografts or xenografts. Formerly, this made hamsters desirable research models for the study of xenografted tumor lines, although this role has been eclipsed by immunodeficient mice. However, chemical induction of squamous cell carcinomas in hamster cheek pouches is still considered among the best models of human oral oncogenesis (Vairaktaris et al., 2008). Hamster cheek pouches are also used to study radiation-induced mucositis (Chung et al., 2009; Sonis et al., 1990).

7.3 METHODOLOGY FOR SAMPLE COLLECTION

7.3.1 BLOOD COLLECTION

A variety of sites are readily available for blood collection from the laboratory hamster. Choice of site depends on quantity of blood required, frequency of collection, training and expertise of personnel involved, and procedural limitations that might be imposed by the Institutional Animal Care and Use Committee. All procedures for blood collection, as for other procedures in hamsters, should be in accordance with the Animal Welfare Act and the Guide for the Care and Use of Laboratory Animals.

7.3.1.1 Blood Volume Limits and Frequency

Because of the small size of the hamster, particular attention needs to be given to the amount of blood removed at single or recurring time points for survival methods. Guidelines for this amount are often established by the Institutional Animal Care and Use Committee, and these guidelines should be strictly followed. Blood volume in veterinary medicine is often estimated at 10% of body weight, and the general rule of thumb is that 10% of blood volume can be safely removed from a healthy, adult animal in an adequate plane of nutrition without significant health consequences (McGuill and Rowan, 1989). However, because in the hamster, blood volume is only 7.8% of body weight, following the typical rule of thumb would actually remove approximately 13% of the hamster's blood volume. This (13%) would be sufficient blood loss to cause a significant cholinergic release and hemodynamic changes (McGuill and Rowan, 1989; Morton et al., 1993). The current standard of practice is that 10% of the blood volume of a healthy, adult animal can be removed once every 3–4 weeks, and that 1% of its blood volume can be removed once daily (Morton et al., 1993). As a reference, Table 7.1 presents recommendations on sample volumes that can be safely taken from laboratory hamsters.

7.3.1.2 Orbital Plexus

The hamster has a large venous sinus occupying the orbital space deep to, and in the caudal one half to two-thirds, of the orbit (Figure 7.1; Timm, 1980). Blood is supplied to the orbital venous sinus by the external ophthalmic artery and is drained by the external ophthalmic veins (Popesko

TABLE 7.1
Blood Volume That Can Be Safely Removed From a Hamster

Body Weight (G)	Estimated Total Blood Volume ^a (mL)	10% Blood Volume ^b (mL)	1% Blood Volume ^c (mL)
50	3.9	0.39	0.039
75	5.9	0.59	0.059
100	7.8	0.78	0.078
125	9.8	0.98	0.098
150	11.7	1.17	0.117

^a Total blood volume based upon 7.8% estimate blood volume for a mature healthy hamster on an adequate plane of nutrition.

^b 10% of blood volume can be safely removed from a healthy hamster once every 3–4 weeks. This is approximately 0.8% of body weight.

^c 1% of blood volume can be safely removed from a healthy hamster daily. This is approximately 0.08% of body weight.

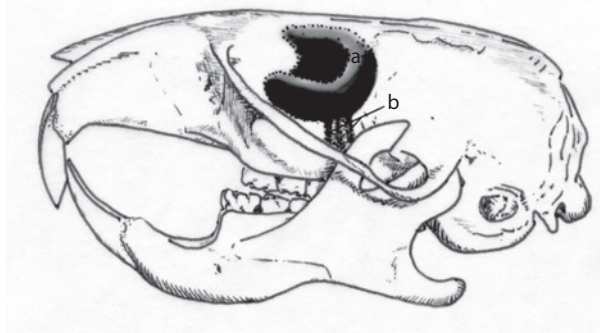

FIGURE 7.1 (See color insert.) Hamster skull—showing location of the orbital venous sinus. Since the orbital venous sinus resides in the caudal one-half to two-thirds of the orbit, the microhematocrit tube should be inserted into the lateral canthus of the eye in a posterior and medial direction. (a) Orbital venous sinus. (b) External ophthalmic veins.

et al., 2002). Two techniques have been described for removing small amounts of blood (less than 0.5 mL) from the orbital venous sinus of the Syrian hamster.

7.3.1.2.1 Micropipette Technique

Accessing the orbital sinus of rodents as a site for blood collection was first described by Stone (1954) and later modified by Sorg and Buckner (1964). A detailed description of this technique in the hamster was published by Timm (1980). Briefly, the anesthetized hamster, for example, with 1%–4% isoflurane (Swindle et al., 2002), is grasped by its head and neck with the thumb and index finger of the nondominant hand. Light pressure is applied to the jugular vein with one finger while lifting the upper eye lid dorsally with the other. Since the orbital venous sinus resides in the caudal one-half to two-thirds of the orbit, a microhematocrit tube is inserted into the lateral canthus of the eyelid in a posterior and medial direction. Gentle pressure is applied, and the microhematocrit tube is rotated as it is inserted. The venous sinus will rupture as it is trapped between the orbit and the microhematocrit tube. Once this occurs, the tube is withdrawn slightly and allowed to fill with blood. Up to 0.5 mL of blood, subject to the limits in blood volume limits and frequency discussed

below, can be collected by this technique if the free end of the microhematocrit tube is directed downward allowing blood to flow into a microcentrifuge tube. Once a sufficient volume of blood is collected, the microhematocrit tube is withdrawn and gentle pressure is applied to the eye to allow blood clotting to occur and to prevent hematoma formation. Since this technique ruptures the tissues overlying the orbital plexus, it can result in leakage of a number of cellular enzymes which may impact the quality of the sample that is obtained. Significantly higher values for aspartate aminotransferase (AST), lactate dehydrogenase (LDH), and creatine phosphokinase (CPK) have been documented using this technique in rats and hamsters when compared to other commonly used methods of blood sampling, such as from the posterior vena cava, which cause less tissue damage (Izumi et al., 1993). Thus careful consideration should be given to the potential experimental impact of sample contamination before using this technique. Additionally, because of the potential for injury to the eye, this technique should only be performed by trained personnel who perform the technique regularly.

7.3.1.2.2 *Syringe*

Blood can also be collected from the hamster's orbital venous sinus using a tuberculin syringe fitted with a 1-cm 23-gauge needle (Pansky et al., 1961). For this technique, the hamster should be anesthetized and placed in ventral recumbency on a flat surface. The thumb and forefinger are used to retract the skin behind the orbit thus lifting the upper eyelid and displacing the eye forward. The tip of the needle is inserted at the midway point of the upper eyelid between the lid and the bulb of the eye; the needle and syringe should be held at approximately 20°–40° from vertical and should be directed ventrocaudally into the back of the orbit. After penetrating approximately 4 mm, the needle will contact the bony orbit after which it should be withdrawn slightly. The tip of the needle should then rest within the orbital venous sinus and blood can be withdrawn by gentle pressure on the plunger of the syringe. This technique can be used for multiple 100–400 μ L blood collections (Pansky et al., 1961; Breckon and Goy, 1979). Pansky et al. (1961) describe using this technique for repeated sampling at 3–4-hour intervals. As previously noted, because of potential injury to the eye, this technique should only be performed by trained personnel who perform the technique regularly.

7.3.1.3 **Saphenous Vein**

Small volumes of blood, 50–200 μ L, can be obtained from the caudal branch of the lateral saphenous vein, which runs dorsally and then laterally over the tarsal joint in the hamster (Popesko et al., 2002). For this technique, the hamster should either be anesthetized or placed, head first, into a restraining tube. If the hamster is small enough, a 50-mL conical tube with a hole cut in the tip works well, thereby allowing access to the hind limb. Shaving the hair over the lower lateral tibia and applying gentle pressure to the lower thigh with the thumb and forefinger will allow visualization of the caudal branch of the lateral saphenous vein. The tip of a small sterile hypodermic needle (23–25 gauge tuberculin needle works well) is then used like a small lance to rupture the vein by holding the needle, bevel up, at a 45° angle and inserting the tip of the needle through the skin until it punctures the superficial surface of the vein. This results in the accumulation of a drop of blood on the surface of the hamster's leg that is collected using a microhematocrit tube. By directing the tip of the microhematocrit tube downward into a microcentrifuge tube, 50–200 μ L of blood can be collected; however, the lesion can clot quickly so anticoagulants should be used in the collection tube (Hem et al., 1998). When blood collection is complete relax the pressure being applied to the thigh and apply gentle pressure to the puncture site with a gauze sponge or cotton ball to potentiate hemostasis and prevent hematoma formation.

7.3.1.4 **Cardiocentesis**

Cardiocentesis can be performed to obtain blood from hamsters as a terminal procedure; however, blood collected by cardiocentesis may be contaminated with muscle enzymes such as creatine

kinase, AST, LDH, or alanine aminotransferase since all of these enzymes, as well as troponins, are found in high levels in cardiac muscle (Thrall et al., 2004). This procedure should only be performed on deeply anesthetized animals. A 20–22 gauge with a 1-inch-long hypodermic needle attached to a 1–5 mL syringe is required, depending upon blood volume to be collected. With the anesthetized hamster in dorsal recumbency, the needle is inserted at a 30° angle just caudal and left lateral to the xyphoid cartilage at the base of the sternum. When the needle is inserted approximately 0.5 inch, gentle aspiration is initiated while insertion of the needle continues. Once blood begins to flow into the syringe, needle insertion is stopped while slow aspiration of blood continues. Depending upon animal size, 2–3 mL of blood can be collected (Donovan and Brown, 2005; Morton et al., 1993). If blood stops flowing, the bevel of the needle should be rotated and the tip redirected until blood flow is reestablished. When blood collection by terminal cardiocentesis is completed, death should be assured by a physical method approved by the Institutional Animal Care and Use Committee, perhaps cervical dislocation or thoracotomy (Morton et al., 1993).

7.3.1.5 Abdominal Aorta or Caudal Vena Cava

Large amounts of blood that is free of contaminating muscle enzymes can be obtained by direct collection from the abdominal aorta or caudal vena cava; however, this is a terminal procedure (Donovan and Brown, 2005; Manning and Giannina, 1966). To perform this procedure, the hamster is anesthetized and placed in dorsal recumbency on a flat surface with the head facing away. A midline incision through the skin, musculature, and peritoneum is made from the xyphoid to the pubis with a scalpel blade or with surgical scissors. With the abdominal cavity opened, the abdominal contents are moved out of the way by reflecting the intestines up and to the left thereby exposing the abdominal aorta and caudal vena cava cranial to the iliac bifurcation and superficial to the lumbar spine (e.g., see Popesko et al., 2002). A 23–25 gauge hypodermic needle or butterfly catheter attached to a 5 mL syringe can then be inserted in a cranial direction, with the needle at a 30°–45° angle, into either the abdominal aorta or vein. For venous collection, a hemostat can be used to occlude the caudal vena cava between to the site of needle insertion and the heart (Manning and Giannina, 1966). For arterial collection, gentle downward pressure at the point of the iliac bifurcation increases the turgor of the aorta (Donovan and Brown, 2005). Gentle pressure is then applied to the plunger to withdraw 3–4 mL of blood, depending upon animal size. At the end of a terminal procedure, death should be assured by a physical method such as cervical dislocation or thoracotomy (Morton et al., 1993).

7.3.1.6 Sample Collection for Blood Gas Analysis

Hamsters are occasionally used for studies that require collection of samples for blood gas analysis. Due to the hamster's small size, direct collection of a sufficient sample for arterial blood gas analysis is difficult; however, samples can be obtained from unrestrained animals by placement of one or more indwelling cannulas. The technique described by Popovic and Popovic, used for cannulation of the aorta, vena cava, or both, in rats and ground squirrels, has been adapted for use in hamsters (Lucey et al., 1980; O'Brien et al., 1979; Popovic and Popovic, 1960). Briefly, the hamster is anesthetized and prepared for aseptic surgery to the left, ventral, cervical region. An incision is made above the left carotid artery, which is then exposed and released from surrounding connective tissue by blunt dissection. The left carotid artery is ligated cranially with a circumferential suture. A caudally directed cannula is then introduced into the artery and advanced until the tip resides within the aortic arch. Next, the cannula is secured to the carotid artery with suture material and the free end of the cannula can be tunneled subcutaneously to the dorsum, exteriorized between the scapulae, and held in place with a suture or wound clip. For a long-term use, the hamster can be fitted with a jacket or harness. The catheter should be flushed and maintained with sterile heparinized saline. A similar procedure can be performed on the right jugular vein to place an indwelling cannula into the right cranial vena cava. Popovic reports that properly maintained cannulae can have

a useful lifetime of 40 days and that cannulae have lasted up to 3 months in hibernating animals (Popovic and Popovic, 1960).

7.3.2 URINE COLLECTION

Hamsters produce approximately 5–8 mL of basic (pH 8.5) urine per day. Urine is often turbid due to the presence of triple phosphate and calcium carbonate crystals. As with many other rodents, hamster urine may have high protein levels. As desert-adapted animals, hamsters can conserve water and concentrate their urine to a specific gravity as high as 1.060. There are a variety of techniques available for collection of urine from the laboratory hamster. Choice of method depends upon quality and volume of sample required, frequency of collection, training and comfort level of personnel involved, and procedural limitations that might be imposed by the Institutional Animal Care and Use Committee.

7.3.2.1 Metabolism Cage

Metabolism cages allow for convenient collection of urine and/or feces over an extended period of time and often allow measurement of water consumption as well. While larger sample volumes can usually be collected, they may be contaminated with feces and are often contaminated with bacteria, which must be considered when results are interpreted. Metabolism cages can be homemade, and a variety of cages are described in a review article (Kurien et al., 2004). Several companies produce well-engineered metabolism cages that allow for reliable collection of urine that is minimally contaminated with feces. Commercial manufacturers should be consulted directly for additional information on their products.

7.3.2.2 Microhematocrit Tube

If a small (25–50 μ L) urine sample is required, there are several methods that can be used to collect voided urine using a microhematocrit tube. Hamsters do not usually spontaneously urinate upon being picked up and restrained as do many other rodents; however, with patience, hamsters will urinate and a microhematocrit tube can be used to collect the voided urine. Alternatively, the hamster can be anesthetized and the bladder can be digitally palpated and gently expressed manually. A microhematocrit tube can then be used to collect the voided urine. Regardless of which method is used to collect voided urine, it should be considered contaminated with bacteria and analyzed in a timely manner.

7.3.2.3 Cystocentesis

Cystocentesis can be used to collect a sterile urine sample from an anesthetized hamster; however, samples collected by cystocentesis are subject to contamination by small amounts of tissue and red blood cells. After the hamster is anesthetized it should be placed in dorsal recumbency. For male hamsters, testicles should be in a scrotal position and should be moved into the scrotum, if necessary, by gentle digital pressure on the lower abdomen. The urinary bladder should be located by gentle palpation and lightly held between the thumb and forefinger. A small (25–27 gauge) needle attached to a tuberculin syringe or butterfly catheter should be inserted in a craniodorsal direction a safe distance away from the trigone (base) of the bladder near the pelvis, but no more than half the distance to the apex. The tip of the needle should not penetrate more than halfway through the bladder lumen, as guided by palpation. Urine collection can then be initiated by applying gentle traction on the syringe plunger. As urine is withdrawn the bladder wall will begin to collapse and eventually occlude the needle. If this happens, the bevel of the needle can be rotated and the syringe angled slightly more toward the spine. When the bladder is evacuated, or a sufficient sample has been removed, the bladder should be released and the syringe carefully withdrawn along the angle of insertion (Breitweiser, 1992).

7.4 PREANALYTICAL SOURCES OF VARIATION

In general, samples from hamsters are subject to the same sources of preanalytical variation as are those from other laboratory rodents.

7.4.1 SEX

Maxwell et al. (1985) found differences in several serum analytes between male and female Syrian hamsters from two sources, Charles River (CR) and Bio Research Laboratories (BR). In Table 7.2, 30 hamsters were sampled per sex from BR and 32 from CR.

Female BR hamsters had lower glucose values than the other three groups (BR males, CR males, and CR females). Female BR hamsters had lower values for triglycerides and higher values for calcium. The CR female hamsters had higher values for cholesterol. Differences between the two strains, as well as some additional possible limitations of the study, are further discussed below. Female hamsters are reported to have circulating levels of amyloid P of 1–2 mg/mL, which are 100–200-fold those in males (Coe et al., 1981).

7.4.2 AGE

As in many mammals, juvenile hamsters have higher serum alkaline phosphatase levels than older animals, 589 ± 105 versus 218 ± 42 in young and mature males, respectively, and 590 ± 75 versus 369 ± 34 in females (Dent, 1977). Young hamsters also have higher serum levels of T3 and T4. Neve et al. (1981) found 3-month-old hamsters to have a mean T4 level of 6.75 ± 0.75 $\mu\text{g/dL}$, whereas 20-month-old hamsters had 3.59 ± 0.16 $\mu\text{g/dL}$, $p < 0.01$. For T3, the 3-month-old group had 62 ± 2 ng/dL, whereas the 20-month-old hamsters had 42 ± 3 ng/dL, $p < 0.001$. Evaluation of clinical chemistry results from aging hamsters should also consider the potential for influences from age-related diseases. Principal causes of mortality in geriatric hamsters include amyloidosis and progressive nephritis (Schmidt et al., 1983), as well as typhlocolitis (Feldman et al., 1982; Nambiar et al., 2005, 2006). Amyloidosis is observed more frequently in female hamsters and affects many tissues, but is most often observed in kidney, liver, and adrenal gland. Early in the disease progression, there are increased serum globulins and decreased albumin, followed by renal glomerular amyloid deposition. With advanced renal amyloidosis, a nephrotic syndrome develops with proteinuria, probable hypoproteinemia (as evident by ascites and anasarca), and hypercholesterolemia. Aging hamsters also have a high incidence of age-related nephrosis resembling that in aging rats (Feldman et al., 1982; Percy and Barthold, 2007). Even with severe nephrosis, blood urea nitrogen is elevated only infrequently, and

TABLE 7.2
Summary of Differences in Clinical Chemistry Between Bio Research and Charles River Hamsters

Analyte	Bio Research Laboratories						Charles River					
	Males			Females			Males			Females		
	<i>n</i>	Mean	SD	<i>n</i>	Mean	SD	<i>n</i>	Mean	SD	<i>n</i>	Mean	SD
Glucose	30	124	31	30	104	25	31	120	34	32	134	38
Bilirubin	30	0.5	0.3	28	0.2	0.1	31	0.4	0.2	31	0.3	0.2
Albumin	30	4.0	0.2	30	4.2	0.3	31	4.3	0.3	31	4.1	0.3
Phosphorus	29	7.5	0.9	28	7.0	1.0	31	8.2	1.1	32	8.3	1.2

serum creatinine has been reported to remain within normal limits (Feldman et al., 1982). The chronic proliferative typhlocolitis can be associated with diarrhea, but the expected changes in serum clinical chemistry have not been described. Aging hamsters also have frequent atrial thrombosis (Hubbard and Schmidt, 1987). Effects of the atrial thrombosis on serum coagulation factors have not been described, but might be considered if unusual results are received from aging hamsters.

7.4.3 STRAIN/BREED

Characteristics of several lines of Syrian hamsters, as well as selected lines of other species, such as the diabetic Chinese hamster, have been described earlier. Differences among Syrian hamsters from different colonies, with regard to various baseline values for clinical analytes, have also been described, as well as differences in response to manipulation. In 1985, Maxwell et al. (1985) compared values for 17 different serum analytes between 64 hamsters from CR and 60 hamsters from BR Laboratories. Hamsters from the two sources were purchased and tested at separate times, but all were approximately 3 months of age and equal numbers of males and females were tested. No health problems were noted, although no laboratory testing for infection was conducted, so differences in obtained values between these sources must be considered carefully. The BR females had higher values for calcium and lower values for glucose and triglycerides than the other groups, and CR females had higher levels of cholesterol. Trautwein et al. (1993) found differences in susceptibility to high-fat-diet-induced gallstones, as well as hepatic cholesterol accumulation and several lipid ratios, among outbred hamsters from CR and Harlan Sprague-Dawley and inbred hamsters from Bio Breeders. Further investigation of changes after feeding a high-fat diet (Dorfman et al., 2003) showed that the outbred CR and the inbred Bio Breeder hamsters had differences in serum total and non-HDL cholesterol, and aortic accumulation of cholesteryl ester.

Only a few examples have been outlined, but they should be sufficient to demonstrate that hamsters obtained from different sources should not be assumed to have the same baseline values or experimental responses. In addition to this caveat, the reader should note that many of the comparisons are old; any divergence between colonies at the time of those studies may not represent variation between the populations with current generations of hamsters, and current equipment may also give somewhat different results. Contemporary control values are strongly encouraged in preference to reliance on decades-old published values.

7.4.4 NUTRITIONAL STATUS

Four-week-old male Syrian hamsters fed a diet containing processed corn starch or rice bran (all diets had the same levels of dietary fiber, fat, and cholesterol) had significantly lower total plasma cholesterol. Diets containing rice bran, in the same study, also lowered low-density lipoprotein cholesterol (Kahlon and Chow, 2000). Although baseline cholesterol levels in hamsters are higher than those in other laboratory rodents, levels increase further with high triglyceride diets (Sullivan et al., 1993). Feeding a diet with 60% carbohydrate as fructose for 2 weeks resulted in significant increases in low density lipoprotein-triglyceride and a corresponding decrease in low density lipoprotein-cholesterol ester. The median diameter of very low density lipoprotein particles was increased, and all high density lipoprotein fractions were elevated. These changes mirror those in humans with an atherogenic lipoprotein profile (Wang and Walzem, 2008). In a lifetime study of the effect of varying levels of dietary protein on the development of age-related nephritis in male and female Syrian hamsters, no differences were found in blood urea nitrogen or serum creatinine, regardless of dietary protein level, 6%, 12%, 18%, or 24% (Feldman et al., 1982). Whether the increased sensitivity of currently available equipment might detect differences, if a similar contemporary study were performed, is unknown.

No specific discussion of the short-term effects of acute fasting is available in the literature. Food deprivation for 27 hours in combination with wheel running markedly reduced plasma glucose in

Syrian hamsters, although plasma glucose was increased by wheel-running in non-fasted animals (Mistlberger et al., 2006).

Feeding a 25% energy-restricted diet to hamsters previously fed a high-fat diet for 7 weeks resulted in significant decreases in serum glucose, cholesterol, and triacylglycerols (Lasa et al., 2007). No influence of long-term dietary restriction on common clinical chemistry parameters without previous manipulation of diet or light cycle is available in the literature, although moderate dietary restriction has been reported to alter adaptability to changes in light cycle in Siberian but not in Syrian hamsters (Challet et al., 2000).

7.4.5 HOUSING ENVIRONMENT (CAGING MATERIALS, LIGHTING, TEMPERATURE, ETC.)

Hamsters, typically bred by vendors with 14 hours of light and 10 hours of dark, are strongly affected by photoperiod. With decreasing daylight, or with steady day length of 12 hours or less, males undergo testicular atrophy and have decreases in circulating testosterone, gonadotropins, and thyroid hormones (Otteweller et al., 1987). The effects of photoperiod changes on body weight are mediated through the hypothalamus by several neuropeptides (Morgan et al., 2003). Increasing photoperiod results in weight gain as a result of hyperphagia mediated by neuropeptide Y (NPY) and Agouti-related peptide (AGRP). In contrast, exposing hamsters to a short photoperiod (8 hours) results in loss of body weight due to anorexia; cocaine and amphetamine-regulated transcript (CART) is one neuropeptide thought to play a key role in this physiologic response.

Group-housed hamsters on an atherogenic diet had higher cholesterol and triglyceride levels than did individually housed hamsters on a similar diet (Yoganathan et al., 1998), although another study found a similar effect only in young hamsters (Smith et al., 1997).

7.4.6 CIRCADIAN RHYTHM—TIME OF COLLECTION

Because hamsters have played an important role in investigation of the circadian clock in mammals, a brief review of the understanding of the clock's mechanism is appropriate. Light interacts with photoreceptors in the retina, which transmits nerve impulses via the retino-hypothalamic tract directly to the suprachiasmatic nucleus (SCN), with glutamate as a neurotransmitter. The SCN is thought to function as the central circadian clock, although peripheral clocks may also play a role. Activation of the glutamate receptors in the SCN leads to a calcium influx and activation of signal transduction pathways that eventually modify clock proteins and expression of genes such as *cfos*, NGF1-A, and the clock genes *Dec1*, *Per1*, and *Per2*. As the central clock, the SCN communicates with peripheral clocks by diffusible factors, of which TGF α and prokineticin 2 have been identified (Albrecht, 2004). Melatonin release from the pineal gland, which was previously thought to be important in circadian rhythm, is not currently considered to play a major role. The effects of circadian rhythm on several serum analytes have been reported in hamsters maintained at standard temperatures, that is, without torpor or hibernation. The hamster adrenal is able to secrete both cortisol and corticosterone, and Albers et al. (1985) found that both glucocorticoids varied significantly over a 24-hour period in hamsters maintained on a cycle of 14 hours light and 10 hours dark. Both hormones rose late in the light phase, reached their acrophase (peak) near the beginning of the dark phase, stayed high until late in the dark phase, then decreased to a nadir early in the light phase. However, corticosterone levels exceeded cortisol when both hormones were at low levels (light phase), whereas cortisol predominated during the daily (dark phase) increases. Chelini et al. (2006) assessed fecal cortisol in 10 mature hamsters for 5 days before and 5 days after the ovariectomy. They found more than 40-fold variation among individuals which may have obscured any changes in fecal cortisol in the days following surgery. They also make the point that total fecal output should be considered in addition to merely evaluating fecal cortisol concentration; that "changes in fecal output, either stress-related or not, affect the concentration of fecal metabolites." As a consequence, they did not feel that fecal concentrations of cortisol, *per se*, were very useful (Chelini et al., 2006). Experimental manipulation of cortisol levels

had no effect on circadian wheel-running rhythm (Albers et al., 1985). Vaughan et al. (1994), found that in male hamsters maintained with 14.5 hours of daylight (6:30 AM–9 PM), serum gonadotropins, T3, T4, and cholesterol all demonstrated significant circadian rhythms, with acrophase occurring at different times for each analyte. Thus, time of collection should be standardized within a study.

7.4.7 ESTROUS CYCLE, PREGNANCY, OR LACTATION

Female hamsters have a 4-day estrous cycle, with development and regression of corpora lutea within a single cycle. In contrast, rats and mice retain corpora lutea for several subsequent cycles (Bivin et al., 1987). Gestation in the hamster is 15–18 days, with parturition usually occurring on the 16th day. Pregnant females have mild hepatomegaly late in gestation, possibly related to reduced bile flow, with a 37% reduction reported at 8 days of gestation and 62% reduction at 14 days. Additionally, decreased cholic acid secretion during pregnancy causes reduced secretion of total bile acids (Bivin et al., 1987).

7.4.8 STRESS

Even mild stressors, such as novelty, may alter sensitive analytes. For example, placing hamsters in an unfamiliar (novel) cage for 15 minutes or more resulted in significant increases in plasma cortisol (Weinberg and Wong, 1986); plasma corticosterone was not measured but both hormones are considered stress-responsive in hamsters, neither is predominant. Being placed in a cage with a large ovariectomized female for 15 minutes (nonreceptive female hamsters will attack males placed into their cage) induced significant increases in ACTH, cortisol, corticosterone, and β -endorphin in submissive males, but not in dominant males. Foot shock induced larger increases than did the novel cage for all of these hormones (Huhman et al., 1990). In contrast to these studies, King-Herbert et al. (1997) found no difference in serum cortisol or corticosterone on the second day, or thereafter, in hamsters immobilized daily for 6 hours in plastic restraint tubes relative to unrestrained hamsters. No serum analytes were assessed prior to the second day. The time of blood collection, from the orbital sinus, during the restraint period was not given. Restrained hamsters did, however, eat and drink less and have lower body weights relative to the unrestrained controls, suggesting some level of stress (King-Herbert et al., 1997).

7.4.9 INFECTION AND DISEASE

Relatively little is known about prevalent infectious diseases of contemporary laboratory hamsters, and even less about effects of these diseases, especially subclinical infections, on clinical chemistry results. A thorough review by Baker (2003) of the effects on research of infectious disease in laboratory rodents reported no specific alterations of clinical chemistry parameters by infectious disease in hamsters. However, Baker frequently referred readers to chapters dealing with more commonly used laboratory species, such as rats and mice. He advises of the possibility that many pathogens, including those that cause subclinical infections, would have similar effects in hamsters as in other laboratory rodents. A number of diseases of infectious or possibly infectious origin may still occur in laboratory hamsters, although prevalence data are not available. These diseases include enteritis including that caused by *Lawsonia intracellularis*, typhlitis, possibly caused by *Helicobacter* (Nambiar et al., 2005, 2006), and demodicosis (Percy and Barthold, 2007). In addition, several *Helicobacter* spp. have been detected in hamsters (Simmons et al., 2000). One of these, *Helicobacter cholecystus* has been associated with lesions of the liver and biliary tree (Franklin et al., 1996) and could possibly alter levels of enzymes, bile acids, and other analytes with a hepatobiliary origin or metabolism. Chronic hepatitis of undetermined cause in Syrian hamsters has been reported to result in increased cholesterol, alanine aminotransferase, and alkaline phosphatase, but not bile acids (preprandial or postprandial) or LDH (Brunnert and Altman, 1991).

A variety of noninfectious diseases are also common in hamsters, including amyloidosis, glomerulonephritis, atrial thrombosis, and polycystic liver disease (Hankenson and Van Hoosier, 2002;

Schmidt et al., 1983; Percy and Barthold, 2007). Effects of these conditions on clinical chemistry parameters are rarely reported, but should be considered when evaluating data from aging hamsters. In addition, many potentially confounding factors can have additive or synergistic influences. For example, age, chronic stress, and cardiomyopathy combine to depress testosterone levels in male hamsters (Ottenweller et al., 1988).

7.4.10 ANESTHESIA

Barbiturate anesthesia in hamsters is reported to elevate glucose for up to 5 hours. Hamsters anesthetized with thiobarbiturate (Inactin[®]) had significantly higher mean blood glucose, 300.1 ± 15.6 mg/dL, than unanesthetized hamsters, 144.8 ± 7.7 mg/dL, ($p < 0.0005$) (Turner and Howards, 1977). Anesthetics are also reported to alter blood gases and blood pH (Reid et al., 1989). A variety of injectable and inhalant anesthetic regimens for hamsters is summarized in Swindle et al. (2002). No specific reports could be found of effects in hamsters of commonly used contemporary anesthetics such as isoflurane gas or ketamine in combination with other drugs on clinical chemistry values. However, one might expect and should be alert to the potential for anesthetics to alter clinical chemistry values in a fashion similar to their effects in other rodent species. For more detail, please see the chapters devoted to mice and rats.

7.4.11 SPECIMEN COLLECTION/HANDLING ARTIFACT

No specific effects of hemolysis or lipemia on clinical chemistry parameters in hamsters have been reported. It is likely, however, that hemolysis can lead to artifactually increased measured levels of serum potassium, phosphorus, and some enzymes and that lipemia can artifactually decrease serum electrolytes in hamsters as in other species of laboratory animals.

As noted in Table 7.1, serial sampling of blood is recommended to be limited to a volume equivalent to more than approximately 0.8% of body weight every 3–4 weeks, or approximately 0.08% daily.

As noted in Section 7.3.1, and consistent with observations in other species, blood collection by cardiac puncture may result in sample contamination with enzymes present in cardiac muscle, specifically CPK, AST, LDH, and alanine aminotransferase (Maxwell et al., 1985; Thrall et al., 2004).

7.5 BRIEF DESCRIPTION OF COMMON PROCEDURES

7.5.1 GLUCOSE TOLERANCE TESTS

Syrian hamsters are widely used as models of experimental pancreatic cancer and diabetes, so glucose tolerance tests are commonly performed in Syrian hamsters. A number of factors including animal age, method of glucose administration, and whether the procedure is performed on awake or anesthetized animals can have a significant effect on results. In one study that compared the oral glucose tolerance test (OGTT) to the intraperitoneal glucose tolerance test (IPGTT), it was noted that saline-administered control hamsters had a significant increase in plasma glucose (McCullough et al., 1987). This effect, likely due to the stress of handling and saline administration, appeared to decrease with age in the OGTT but not the IPGTT treatment group (McCullough et al., 1987). A study comparing IPGTT to OGTT in nonanesthetized hamsters found that OGTT provided more consistent results that varied with the dose of glucose administered (McCullough et al., 1987). Since so many factors can affect the results of the glucose tolerance test in hamsters, it is strongly recommended that the procedure be performed in all animals in a standardized and consistent manner. Animals should be fasted for approximately 18 hours before starting the study, although water should be provided *ad libitum*. A baseline blood sample should be taken followed by glucose administration. Nonanesthetized hamsters should be given 0.75–1.0 gm/kg glucose by oral gavage. Blood sampling should be performed in the least stressful manner possible, for example,

using an indwelling catheter, although consistent results have been obtained by orbital venous puncture. Follow-up blood samples should be taken at 30, 60, and 120 minutes (McCullough et al., 1987).

7.5.2 ADRENOCORTICOTROPIC HORMONE STIMULATION ASSAYS

Adrenocorticotrophic hormone (ACTH) stimulation assays are typically performed in the hamster to probe the adrenal pituitary axis as a part of study protocols for stress, cortisol, and carbohydrate metabolism. The hamster possesses adrenal 17 α -hydroxylase activity and thus responds to ACTH stimulation by producing cortisol (LeHoux et al., 1992). In a basal state, blood corticosterone concentrations were three to four times higher than cortisol concentrations; however, with ACTH stimulation this difference disappeared (Ottenweller et al., 1985). Furthermore, the authors demonstrated that ACTH administration and the application of acute stress elevated plasma cortisol and corticosterone concentrations but only cortisol was increased following chronic stress. They recommended that both cortisol and corticosterone be evaluated when assessing adrenocortical function in the hamster. ACTH stimulation assays can be performed using both short- and long-acting synthetic ACTH. In studies using short-acting ACTH, 2.5 IU of a short-acting ACTH such as Cortrosyn™ is injected intraperitoneally and a blood sample is collected 30 minutes later for analysis (Ottenweller et al., 1985). Synacthen®, a synthetic depot preparation of ACTH, has been used in longer term ACTH stimulation assays in hamsters (LeHoux et al., 1992). In this procedure, 1 IU of Synacthen® is administered intramuscularly every 5 hours until the study is completed (LeHoux et al., 1992).

7.6 SUMMARY

Relative to rats and mice, the number of hamsters used annually in biomedical research is small and declining. Nonetheless, unique characteristics, many of which are related to physiologic adaptations associated with torpor and hibernation, with lipid metabolism and with susceptibility to a few infectious diseases, continue to make the hamster valuable.

8.1 USE IN BIOMEDICAL RESEARCH

The guinea pig (*Cavia porcellus*) has historically been considered a hystricomorph mammal belonging to a family of burrowing rodents (Caviidae) native to the Western Hemisphere. More recently, sequencing of the mitochondrial genome and molecular analysis has indicated the guinea pig should be considered in a separate taxonomic group currently of intermediate rank (Frederiksen and Heeno-Andersen, 2003; Adkins et al., 2000; Konno et al., 1999; D'Erchia et al., 1996; Li et al., 1992). In the wild, guinea pigs live in small groups in the open grasslands of Bolivia, Western Peru, Argentina, Uruguay, and Brazil (Weir, 1974). They have been domesticated and are used as food animals in several South American countries. Guinea pigs were first brought to Europe in the early 1600s, where they were bred for food and as pets. In the early 1900s, they were first used as laboratory animals, primarily in genetic research. Since then, they have proved useful laboratory animal models for research in areas including nutrition, immunology, gastroenterology, cardiovascular disease, audiology, toxicology (including teratology and reproductive toxicology), pharmacology, and infectious disease research, including tuberculosis, listeriosis, and Q-fever.

Since the first addition of this text in 1989, guinea pig use for biomedical research in the United States has declined approximately 64% from 481,712 to 172,864 in 2015, the last year for which figures are available from the United States Department of Agriculture (USDA, 2016). Even though the popularity of guinea pigs in research has declined from a peak in the 1930s, their use as pets has increased.

8.2 UNIQUE PHYSIOLOGIC CHARACTERISTICS

8.2.1 GASTROINTESTINAL SYSTEM

Guinea pigs are monogastric and have a completely glandular stomach in contrast to other rodents such as mice and rats which have glandular and nonglandular gastric components (Hargaden and Singer, 2012). The guinea pig gut flora is predominantly Gram-positive and they are very sensitive antibiotic-induced enterotoxemia (Manning et al., 1984). Like other rodents, guinea pigs practice coprophagy and this activity could result in the recirculation of an array of factors potentially impacting a variety of clinical pathology parameters.

In the guinea pig, as in humans, the intestine is the principal site of cholesterol synthesis, whereas the liver is the principal site in other species. Swann et al. (1975) showed the liver-to-ileum ratio of acetate incorporation into cholesterol is 0.061 in the guinea pig and 1.57 in the rat. All cholesterologenic tissues in the guinea pig are subject to feedback inhibition (Swann et al., 1975; Wriston, 1984).

8.2.2 CARDIOVASCULAR SYSTEM

Brewer and Cruise (1994) outlined the comparative aspects of guinea pig cardiovascular physiology, including the low basal and peak coronary blood flow. There are extensive intracoronary collaterals present in the guinea pigs making it difficult to elicit a coronary infarct compared with other species. The guinea pig's electrocardiogram differs from other rodents in that they have longer S-T segments. Guinea pigs are very sensitive to adenosine and their cardiac tissue is unaffected by vasoactive intestinal peptide, unlike other mammals.

Guinea pigs serve as a model of the circulatory form of pregnancy toxemia, where the aorta caudal to the renal vessels undergoes fetal compression due to the relatively large size of the conceptus as guinea pigs are precocious at birth compared to other rodents. Sequelae-to-fetal compression of the caudal aorta is reduced blood pressure to the uterine vasculature, placental necrosis, ketosis, and death (Percy and Barthold, 2007).

8.2.3 RESPIRATORY SYSTEM

Brewer and Cruise (1997) outlined the comparative aspects of the guinea pigs respiratory system. Alveolar development is nearly complete at birth compared to other rodents. Guinea pigs have a complex pharyngeal anatomy common in hystricomorphs, highlighted by the presence of a palatal ostium which is a small opening in the continuation of the soft palate to the base of the tongue. The palatal ostium makes endotracheal intubation and oral gavage a challenge (Hargaden and Singer, 2012). Access is easily gained to the eustachian tube complex in the guinea pig. Compared to other mammals, guinea pigs have very prominent smooth muscle in the distal bronchi which is arranged spirally (Brewer and Cruise, 1997). Pulmonary serous cells are absent in the guinea pig unlike the rat, whereas goblet cells are common in the guinea pig and rare in other small rodents (Hargaden and Singer, 2012). In the pulmonary capillaries of guinea pigs, neutrophils, not macrophages, adhere to endothelial cells and capture intravascular foreign bodies up to the size of red blood cells (Terada, 1993; Brewer and Cruise, 1997). The neuroendocrine bodies found in the lungs of guinea pigs appear to be a modification associated with their evolutionary development at the high altitude of the Andes Mountains. Percy and Barthold (2007) highlighted unique histological

aspects of the respiratory architecture in the guinea pig, such as pulmonary arterial and arteriolar medial thickening, prevalent Clara cells, perivascular lymphoid nodules, and osseous metaplasia in the lungs. Physiologically, the guinea pig offers a well-characterized airway hyperresponsiveness and reaction model of asthma.

8.2.4 ENDOCRINE SYSTEM

The guinea pig does not require growth hormone for growth, as is the case for other mammals. Pituitary gland removal does not impact growth in this species. Insulin-like growth factor I and II are responsible for growth in guinea pigs (Harkness et al., 2002; Adkins et al., 2000). Guinea pig growth hormone is functional in other species, as it will support growth in hypophysectomized rats. Both growth hormone and the growth hormone receptor have a single amino acid replacement at a functionally significant location, but it is unclear what role this plays.

The alpha (α -) subunit of glycoprotein hormones such as follicle stimulating hormone, luteinizing hormone, thyroid stimulating hormone, and chorionic gonadotropin is produced by the pituitary gland. The guinea pig's common α -subunits of these glycoprotein hormones are not homologous to those in other rodents. Suzuki et al. (2002) speculated that the differences in the guinea pig's common α -subunits was a primary reason that the guinea pig fails to ovulate when treated with human or equine chorionic gonadotropin (hCG or eCG) as routinely used in mice (Suzuki et al. 2002). Instead, they found that ovulation could be induced with human menopausal gonadotropin (hMG) when administered at the appropriate phase of the estrous cycle (Suzuki et al., 2003).

Gonadotropin-releasing hormone (GnRH) is produced in hypothalamus and regulates many aspects of sexual development and reproduction. The guinea pig GnRH receptor differs from most other rodent species in terms of amino acid composition and ligand sensitivities (Fujii et al., 2004). In the female guinea pig (*Cavia aperea*), onset of puberty was dramatically affected by changes in photoperiod (Trillmich et al., 2009). The authors concluded that this effect was due to the ability of melatonin to block GnRH as had been demonstrated in numerous other mammalian species (Jimenez-Linan et al., 1997). Melatonin serves an important function in guinea pigs due to the longer gestation period compared to other rodents. It is believed that this can function as a prenatal mechanism to delay maturity from the pregnant dam to the female offspring in utero (Trillmich et al., 2009). As seen with many other hormones, guinea pig melatonin differs in amino acid structure compared to other mammalian species.

Produced by the mammalian kidney in response to tissue hypoxia, erythropoietin is an essential hormone that controls erythrocyte production. While there is a high degree of sequence homology evidence demonstrating biological cross-reactivity between humans and numerous other species (Wen et al., 1993), guinea pig erythropoietin failed to stimulate mouse or human erythroid differentiation in vitro; however, guinea pig erythroid progenitors were stimulated by human or mouse erythropoietin, suggesting differences in erythropoietin or erythropoietin receptors (Stopka et al., 1998).

Insulin is a highly conserved hormone in numerous species (Jukes, 1979; Smith, 1966). Insulin from hystricomorphs, including guinea pigs, differs from most other species in at least one-third of its amino acid sequence (Beintema and Campagne, 1987; Blundel and Wood, 1975; Jukes, 1979; Smith, 1966). Circulating guinea pig insulin possess between 1% and 5% of the biological activity of insulin from other mammalian species (Zimmerman and Yip, 1974). Circulating guinea pig insulin reacts poorly with standard anti-insulin antibodies, does not dimerize at high concentrations, does not form crystals, and does not bind zinc (Zimmerman and Yip, 1974). The review article by Beintema and Campagne (1987) provides an overview of the molecular evolution of rodent insulin, highlighting the uniqueness of guinea pig.

Guinea pigs produce insulin in small quantities in extrapancreatic tissues; however, this insulin appears to be confined to the cells in which it is produced and has not been detected in the plasma (Rosenzweig et al., 1980). This insulin is as active metabolically as other mammalian insulin but

does not appear to be responsible for controlling variations in plasma glucose levels (Rosenzweig et al., 1980), which is controlled by the less active, pancreatic insulin. Rosenzweig et al. (1983, 1985) proposed that two insulin genes existed in the guinea pig genome; one producing the typical guinea pig insulin in the pancreatic beta cells and the second producing a protein similar to the more conserved mammalian insulin. Chan et al. (1984) contended there is but a single gene. Commercially available insulin radioimmunoassay kits are not valid for measuring plasma insulin levels in the guinea pig but can be used to measure tissue levels of nonpancreatic guinea pig insulin. Some commercial plasma insulin kits utilize anti-insulin antibodies produced in guinea pigs, which further limits their utility in this species. To further complicate the ability to measure guinea pig insulin, de Pablo et al. (1986) determined that protozoa contain materials which can interfere with the guinea pig's insulin radioimmunoassay.

Cortisol is the principal glucocorticoid produced by the guinea pig, in contrast to the rat and mouse, which predominately produce corticosterone. The guinea pig has a high rate of interconversion between cortisol and cortisone (Manin et al., 1982). Garris (1979) described a diurnal cycle with plasma cortisol concentrations increasing from their dark-phase lows, starting at 4 hours prior to the onset of the light phase of the light:dark (14 hours:10 hours) photoperiod, peaking between 4 and 8 hours after the onset of the light phase then followed by a steady decline until reaching basal concentrations prior to the onset of the dark phase. The author suggested that the diurnal cycle of plasma cortisol in the guinea pig resembled what was observed for humans but was in contrast with that seen rats.

Transcortin, or corticosteroid-binding globulin, has been identified in many species and can bind both cortisol and progesterone. The pregnant guinea pig has a second steroid binding protein, progesterone-binding globulin that specifically binds progesterone but not cortisol. Guinea pig transcortin has a much higher affinity for cortisol than for progesterone, in contrast to human transcortin, which has a similar affinity for both steroids. Progesterone-binding globulin appears to be unique to hystricomorph rodents (Wriston, 1984). Guinea pigs, like humans, are able to maintain a pregnancy following ovariectomy in contrast to mice, rats, and rabbits (Zarrow et al., 1963).

Rodriguez et al. (2008) outlined the concept of uterine progesterone receptor localization and its role in various components of parturition, including pubic symphysis relaxation. The article explores the interaction of various hormones involved with the initiation of parturition, including oxytocin, progesterone, relaxin, and estrogen.

Relaxin is a steroid hormone, secreted by the uterus, responsible for interpubic ligament relaxation permitting lengthening of the cartilaginous nonsynovial joint and, in turn, facilitates delivery of the relatively large, precocious young (Hisaw et al., 1944; Rodriguez et al., 2003; Zarrow, 1947). Rodriguez et al. (2008) remarks that the guinea pig interpubic ligament relaxes so markedly that it permits fetal passage where the average head diameter is twice the average pelvic canal diameter. Zarrow (1948) evaluated the role of other hormones in the pubic symphysis relaxation, and Rodriguez et al. (2003) postulated on relaxin's role (and other hormones including estradiol) in the underlying cellular response, a response that resembles inflammation. Relaxin affects corpus luteum function and plays a role in permitting ovulation (Jagiello, 1967), and inhibits guinea pig's myometrial activity; however, total suppression of uterine activity does not occur and myometrial activity is inversely related to serum relaxin levels (Porter, 1971a, b). Furthermore, relaxin has little effect on oxytocin's ability to initiate intrauterine pressure (Porter, 1972).

Zarrow (1947) evaluated relaxin levels in serum, urine, and other tissues. Relaxin was detected in the serum of all guinea pigs by day 21 of pregnancy, peaked by day 28, where it was maintained through gestational day 63 when a sharp drop was noted. A further drop was detected at parturition, most likely due to decreased placenta output. Relaxin's falling serum levels paralleled relaxin's urine levels. Larkin and Reneger (1986) used light microscopy to perform immunolocalization of relaxin. Endometrial gland cells demonstrated high numbers of granules staining positively for relaxin from mid- to late-gestation in the guinea pig.

8.2.5 HEMATOPOEITIC SYSTEM

Guinea pigs have a lower red blood cell count and the largest erythrocyte of the commonly used rodents in biomedical research (Hargaden and Singer, 2012). Lymphocytes are the predominant peripheral blood leukocyte in the guinea pig and they are resistant to the lymphopenic effects of exogenous corticosteroids compared to other mammals.

Foa-Kurloff or Kurloff cells are mononuclear cells containing lymphocyte and monocyte properties (Eremin et al., 1980) and are observed regularly in blood smears of guinea pigs. These cells contain intracytoplasmic periodic acid Schiff (PAS) positive material found in all guinea pigs (rare in newborn animals) with higher numbers seen in females (and estrogen exposed males) they are thought to be the equivalent of natural killer cells. They are believed to prevent maternal rejection of the fetal placenta during pregnancy and have a role in the increased cancer resistance observed in guinea pigs. Kurloff cells are seen in high numbers in the trophoblast region of the placenta during pregnancy.

As mentioned in Section 8.2.3, guinea pig neutrophils adhere to endothelial cells and capture intravascular foreign bodies the size of red blood cells (Brewer and Cruise, 1997). Calcium ions play an important role in normal guinea pig neutrophil functions, including chemotaxis, superoxide anion generation, and granule enzyme release. Azuma et al. (1986) demonstrated that calcium antagonists (including verapamil and nifedipine) interfered with these important neutrophil functions.

8.3 METHODOLOGY FOR SAMPLING COLLECTION

8.3.1 BLOOD COLLECTION

Data regarding the clinical chemistry of the laboratory guinea pig remains sparse. This may be due to the relatively small number of guinea pigs used in research and the difficulty in obtaining blood samples from their peripheral veins, as their deep vessels are often covered with many layers of fat. Methods of obtaining repeated blood samples have been described (see Table 8.1), in addition to

TABLE 8.1
Methods for Obtaining Blood Samples from Guinea Pigs

Method	Comments
Cutting nail bed	Small quantities of blood (<1 mL); may be contaminated
Marginal ear vein	Small quantities of blood (<1 mL); may be contaminated
Dorsal metatarsal vein	Small quantities of blood (<1 mL); may be contaminated
Saphenous vein	Small quantities of blood (<1 mL); may be contaminated
Interdigital vein	Small quantities of blood (<1 mL); may be contaminated
Orbital sinus	Moderate quantities of blood (>2 mL); little contamination; requires anesthesia
Jugular vein	Moderate quantities of blood (>2 mL); not contaminated
Lateral metatarsal vein (vacuum assisted)	Moderate quantities of blood (>2 mL); may be contaminated
Femoral vein	Moderate quantities of blood (>2 mL); not contaminated
Cardiocentesis (cardiac puncture)	Large quantities of blood (>5 mL); not contaminated; cardiac or pulmonary laceration may cause death; must be performed under anesthesia as a terminal procedure
Vena cava or other large internal vessels	Large quantities of blood (>5 mL); not contaminated; must be performed surgically under anesthesia; usually a terminal procedure
Decapitation	Large quantities of blood (>5 mL); usually contaminated; terminal procedure

Source: Shomer et al. (1999) *Contemp Top Lab Anim Sci*. 38(5):32–35. (jugular vein); Clifford, C.B. and White, W.J., In W.F. Loeb and F.W. Quimby [ed.], *The Clinical Chemistry of Laboratory Animals*, Philadelphia, PA, Taylor & Francis, 1999 (all other sites).

single-sample terminal methods such as decapitation or surgical intervention (see Huneke, 2012). With the exception of cardiocentesis (cardiac puncture), femoral venopuncture, and orbital sinus bleeding, sample volumes are usually low and often contaminated; however, cardiocentesis, femoral venopuncture, and orbital sinus bleeding have a low degree of repeatability and may be stressful to the animal. Although the blood volume obtained may be low, advancing analyte technologies makes it possible to obtain more data from smaller volumes. As highlighted in Section 8.5.1, select hormone determination can be made from feces versus plasma, thereby reducing stress and the need to collect blood for some parameters.

Blood and plasma volumes of the guinea pig average 6.96 and 3.88 mL per 100 g of body weight, respectively; although these figures vary considerably with age (Green et al., 1976; Sisk, 1976). They are highest at birth and steadily trend downward until 900 g of body weight is reached, at which point they tend to level out. It is generally considered that not more than 10% of the total blood volume should be collected once every 3–4 weeks and daily collections of no more than 1% can occur without adverse effects. In their publication, Terril and Clemmons (1998) indicated that the guinea pig blood volume averaged 75 mL/kg, thus, 7.5 mL of blood/kg body could be removed once every 3–4 weeks. As a general guideline, the author uses 1.25% (1.25 mL/100 g of body weight) once every 2 weeks for blood collection. However, readers are advised to consult their Institutional Animal Care and Use Committee (IACUC) or Ethics Committee for institutional guidelines on permissible collection volumes and frequency.

When preparing guinea pig serum in plastic rather than glass collection tubes or vials, clotting occurs much more slowly. Since potassium is released from platelets during clotting, the use of plastic tubes, such as the Microtainer® (Becton Dickinson, Franklin Lakes, NJ), results in reduced serum potassium levels and minimizes sample dilution due to the Microtainer's® use of lyophilized or freeze-dried anticoagulants (Caisey and King, 1980; Dyer and Cervasio, 2008). During clotting, guinea pig blood cellular elements release lactate dehydrogenase and gamma glutamyl transferase (GGT) into the serum (Campbell, 2012). The release of GGT into the serum is in sharp contrast to many other mammalian species where GGT release does not occur. Of the common laboratory animal species, only the guinea pig, rabbit, and nonhuman primate had detectable serum levels of GGT; cats, dogs, rats, and mice do not. Guinea pig serum GGT levels are approximately one-sixth of those reported for nonhuman primates, and the release may be associated with blood clotting. The source of both elevated GGT and lactate dehydrogenase in blood clot formation must be considered when evaluating these analytes in guinea pigs. The lymphocytes and granulocytes of guinea pigs and man have alkaline phosphatase (ALP) activity (Sisk, 1976).

8.3.2 URINE COLLECTION

Guinea pig urine is typically yellow to orange in color, with the color dependent on the dietary phytochemicals (as observed in rabbits). Care should be taken not to confuse darker urine caused by these dietary phytochemicals with hematuria. Like other herbivores, the urine pH is normally more alkaline, frequently 8.0–9.0. Crystaluria is uncommon and if found warrants further investigation for urinary calculi.

Urinalysis provides a powerful adjunct to clinical chemistry and other diagnostic modalities in guinea pigs. Urine collection techniques parallel those used in other species and include free catch, ventral midline cystocentesis (25-gauge needle), metabolic caging, or a simple, clean, empty cage (Hrapkiewicz et al., 1998; Riggs, 2009; Fisher, 2006). Clearly, the cleaner the sample, the more profound and robust the urinalysis results, especially when bacterial culture is needed in cases of suspected urinary tract infections. Cystocentesis may be facilitated with sedation and ultrasound. At least 4–6 mL of urine is required for urinalysis; with urinalysis results varying depending on factors such as sex, age, stock/strain, and so on.

8.4 PREANALYTICAL SOURCES OF VARIATION

8.4.1 ANESTHESIA

Anesthesia can be a confounding factor in the interpretation of clinical chemistry analyses of most species including the guinea pig. Inhalant anesthetics are widely used with laboratory animal species. While rarely used now, a large number of publications have demonstrated the hepatotoxic effects of halothane anesthesia (Lind et al., 1987, 1992) including elevated isocitrate dehydrogenase (Lunam et al., 1985). This hepatotoxicity appears to be due to cell-mediated immune mechanisms (Furst et al., 1997). Lunam et al. (1986) identified a genetic predisposition for liver damage (serum alanine aminotransferase, ALT) in guinea pigs but did not exclude the possibility that other factors may be involved. Lunam et al. (1985, 1986, 1989) described a variable percentage of animals affected (~20%–50%), provided a description of the histopathology observed, and compared this with human halothane hepatopathology. Bourdi et al. (2001) linked outbred (Hartley) guinea pig hepatotoxicity to an enhanced hepatic halothane metabolism which formed relatively high levels of trifluoroacetylated protein adducts; cytochrome P450 proteins may have a role in catalyzing the formation of these proteins. Durak et al. (1999) evaluated blood urea nitrogen (BUN) and creatinine levels in animals following exposure with 2% isoflurane (in oxygen) and found no significant alterations over the course of the study. Zheng et al. (2001) evaluated the effects of sevoflurane and its degradation product, fluoromethyl-2,2-difluoro-1-(trifluoromethyl)vinyl ether (Compound A), in guinea pigs and found no significant alteration in BUN, ALT, or creatinine after a 4-hour exposure but did note a humoral immune response by 14 days postexposure.

Injectable anesthetic agents can pose similar concerns. Dang et al. (2008) compared five anesthetic regimens and evaluated blood collected from the anterior vena cava of Hartley guinea pigs. Although complete blood count values did not differ between the regimens, serum clinical chemistry values did; specifically glucose, BUN, phosphorus, and creatine phosphokinase varied between anesthetic regimens. The authors concluded that intraperitoneal ketamine–xylazine was preferred for vena cava blood collection. D'Alleinne and Mann (1982) determined that ketamine–xylazine anesthesia might impact toxicologic parameters. They observed elevations in BUN, creatinine, and ALT for up to 5 days following anesthesia; however, these elevations were not significant. Kim et al. (2006) determined that the reversible cardiac depression seen with ketamine was due to increases of intracellular ionized magnesium concentration and total magnesium efflux.

Etomidate is a safe, short-acting, nonbarbiturate anesthetic agent used for anesthetic induction or constant rate infusion maintenance. Etomidate does not provide adequate analgesia, and guinea pigs had the lowest ED₅₀ of any species studied (Wauquier, 1983; Calvo et al., 1979; Janssen et al., 1975). Use of etomidate is associated with cortisol depletion (Addison's disease), and Boidin et al. (1986) suggested a role for cytochrome P450 and ascorbic acid (vitamin C). Lambert et al. (1983, 1984, 1985, 1986) evaluated various compounds, including etomidate, *in vitro* with respect to biopotency and sites of action of compounds affecting adrenal steroidogenesis. Lambert's group determined etomidate was the most potent of the 12 compounds studied, which included propofol and thiopentone. Etomidate's site of action was the enzyme 11 β -hydroxylase (as is thiopentone's) and propofol acts between adrenocorticotrophin (ACTH) binding and pregnenolone production.

Brown et al. (1989) recently compared blood gas values between resting nonanesthetized guinea pigs and those anesthetized for 30 minutes using various anesthetics. The animals were not intubated but allowed to breathe room air unassisted. As expected, animals became hypercapneic and hypoxic; the effect was slight with ketamine/xylazine anesthesia and pronounced with diazepam/alphaxalone–alphadolone anesthesia. Anesthesia with pentobarbital/fentanyl–droperidol or diazepam/fentanyl resulted in an intermediate degree of respiratory depression.

8.4.2 AGE

Age-related changes in clinical chemistry endpoints have been demonstrated. For example, serum ALP levels in the guinea pig have been shown to decrease with increasing body weight and age during the first year of life, similar to the decrease with maturation in other species (Kitagaki et al., 2005).

Also similar to other species, total protein continues to rise in guinea pigs until it reaches its adult value by 200 days of age; followed by a long steady decline (Kitagaki et al., 2005). In addition, triglyceride levels display a long steady rise between 200 and 800 days of age in guinea pigs (Kitagaki et al., 2005).

Serum cholesterol, BUN, and creatinine levels in guinea pigs demonstrated a rapid increase to ~150 days of age followed by a slow but progressive increase in Weiser–Maples guinea pigs (Kitagaki et al., 2005). Chloride levels decrease briskly over the life of female Weiser–Maples guinea pigs, and sodium levels trend toward a slight increase over the life of male Weiser–Maples guinea pigs (Kitagaki et al., 2005).

Malinowska and Nathanielsz (1974) evaluated plasma aldosterone in neonatal and adult guinea pigs via radioimmunoassay. Neonates (between 6 and 24 hours of age) had peak aldosterone values of 552 pg/mL compared to adult male levels of 72 pg/mL (when collected by cardiocentesis). Interestingly, peak aldosterone levels in adult males were found to be 126 pg/mL when collected via an indwelling arterial catheter. There was no relationship found between aldosterone and glucocorticoid levels in either the adults or neonates.

Rigaudiere et al. (1976) determined testosterone and androstenedione in the plasma and testes of Dunkin–Hartley guinea pigs via gas chromatography in animals that ranged from newborns to animals who were 35 months of age. The authors identified four periods of androgenic activity over this wide temporal range of animal life span:

1. Neonatal period from birth to postnatal day (PND) 16
2. Pubertal period from PND 16 to PND 90
3. Adulthood from 3 to 6 months of age through 24 months of age
4. Senescence between 24 and 28 months of age

The peak testosterone concentration associated with the neonatal period occurs at days 2 and 3 of age and as described in Section 8.2.4, readers are reminded that testosterone is a potent pituitary–adrenocortical inhibitor. Pelardy and Delost (1977, 1978) also observed a transient neonatal testosterone peak and determined light, in addition to testes, played a role in the testosterone peak's occurrence.

8.4.3 STRAIN

Waner et al. (1996) compared the clinical chemistry values of euthymic, normal (haired), and hairless Dunkin–Hartley guinea pigs and demonstrated significant differences in many serum chemistry analytes (Table 8.2).

Kunzl and Sachser (1999) have prepared a review comparing hormonal (cortisol and testosterone) and behavioral differences between the domestic and wild guinea pig.

It is interesting to note that the wild Andean guinea pig hemoglobin oxygen affinity is greater than that observed in either laboratory guinea pigs or rats, yet comparable to the Andean chinchilla, *Chinchilla brevicaudata* (Winslow, 2007; Ostojic et al., 2002).

8.4.4 DIET OR NUTRITIONAL STATUS

Dietary constituents and/or the nutritional status of the animal can have notable effects on clinical chemistry parameters in guinea pigs.

TABLE 8.2
Serum Chemistry Differences in Euthymic Hairless Compared to Normal (Haired)
Dunkin–Hartley Guinea Pigs^a

Analyte	Significant Changes, Increase or Decrease, in Euthymic Hairless vs. Normal (Reported Means)
Alanine aminotransferase (ALT)	↑ (90 vs. 37 IU/L)
Albumin	↑ (3.6 vs. 2.9 g/dL)
Alkaline phosphatase (ALP)	↓ (342 vs. 45 IU/L)
Amylaset	↑ (2,257 vs. 1,117 IU/L)
Asparate aminotransferase (AST)	↑ (83 vs. 183 IU/L)
Blood urea nitrogen (BUN)	↑ (103 vs. 56 mg/dL)
Calcium	↑ (10.7 vs. 10.3 mg/dL)
Creatine kinase (CK)	↑ (412 vs. 183 IU/L)
Creatinine	↑ (0.7 vs. 0.5 mg/dL)
Magnesium	↑ (4.9 vs. 3.8 mg/dL)
Phosphorous	↑ (10.8 vs. 7.1 mg/dL)
Potassium	↑ (6.2 vs. 4.0 mEq/dL)
Sodium	↓ (131.5 vs. 134.2 mEq/dL)
Total protein (TP)	↑ (5.3 vs. 4.7 g/dL)

Source: Adapted from Waner, T. et al., *Vet Clin Pathol.*, 25, 61–64, 1996.

Mammals generally differ in the way they react to dietary cholesterol. For example, in species such as rats, dogs, nonhuman primates, and humans, diets high in cholesterol (1%–2%) do not cause extensive or rapid expansion of body cholesterol pools, and hypercholesterolemia is uncommon in these species (Chantuin and Ludewig, 1933; Wilson and Lindsey, 1965). This is not the case in the guinea pig, rabbit, and prairie dog (Green et al., 1976; Prior et al., 1961; Wagner, 1976). In the guinea pig, hypercholesterolemia is often accompanied by fatty infiltration of many tissues, including the liver. Further, high dietary cholesterol may induce hemolytic anemia in the guinea pig. This anemia is accompanied by splenic enlargement and bone marrow hyperplasia and may lead to death before atherogenic plaque formation (Ostwald and Shannon, 1964; Yamanaka and Ostwald, 1968; Yamanaka et al., 1967). Dietary protein sources impact serum cholesterol levels. For example, soy-based protein sources lower serum cholesterol in contrast to casein sources (Atwal et al., 1997). Furthermore, amino acid supplementation of casein sources may positively impact serum cholesterol and serum cholesterol fractions.

As mentioned in Section 8.4.2, age-related cholesterol changes observed in Weiser–Maples guinea pigs showed a rapid increase in serum cholesterol to ~150 days of age with a slow but progressive increase when fed a standard guinea pig diet (Kitagaki et al., 2005). Guinea pigs fed a normal diet have little if any high-density lipoprotein (HDL) until they are fed cholesterol. The cholesterol bound to this HDL is predominantly nonesterified (Yamanaka et al., 1967). In guinea pigs, as in humans, low-density lipoproteins (LDL) are the predominant lipoprotein fraction, and changes in dietary fiber predominately affect LDL (Fernandez et al., 1997). Similarities to humans in both the “normal” lipid profiles and in the response to dietary modifications have led guinea pigs to be proposed as the most appropriate model for human hypercholesterolemia (Sullivan et al., 1993). However, because dietary cholesterol as low as 0.1% may induce biochemical changes and lesions in the guinea pig, dietary consideration should always be taken into account in interpreting serum levels of lipids and lipoproteins in the guinea pig (Ostwald and Shannon, 1964; Yamanaka et al., 1967).

Guinea pigs are one of a few species that have lost the capability to synthesize Vitamin C (ascorbic acid) and must obtain daily requirements via the diet (Drouin et al., 2011). Conflicting results have been obtained in guinea pigs on the effect of ascorbic acid on serum ALP activity. Degkwitz (1982) demonstrated ascorbic acid deficiency did not increase ALP activity in the guinea pig compared to controls. Whereas, Mahmoodian et al. (1996) demonstrated an 80%–90% decrease in serum ALP activity in scorbutic guinea pigs, specifically due to a loss of bone ALP activity. Fasting and inanition have also been shown to decrease ALP activity (Tsuchiya and Bates, 1994).

Similar conflicting effects on ALP activity have been demonstrated in studies in which guinea pigs were fed diets either deficient in magnesium or zinc. Everson et al. (1959) found no differences in ALP activity in guinea pigs fed a manganese-deficient diet compared to control diet. Everson et al. (1959) also found no differences in ALP activity in preweanling guinea pigs whose dams were fed a magnesium-deficient or control diet, a finding also observed in developing rats (Hurley et al., 1959). In contrast, ALP activity dramatically increased in guinea pigs fed either zinc-deficient (<20 ppm) or magnesium-deficient diets (Alberts et al., 1977; Underwood, 1971).

8.4.5 STRESS

Glucocorticoids are essential for normal neural development. Since guinea pigs give birth to young with advanced neural development and a large proportion of neuroendocrine maturation occurring in utero (similar to humans, and, compared to rats or mice, which have significant postnatal neural development), they have been used in studies examining the effects of glucocorticoids (i.e., stress-related) on hypothalamo–pituitary–adrenal function in prenatal manipulations (Kapoor et al., 2006). Kapoor and Matthews (2005) reported that maternal, gestational stress (and cortisol secretion) impacts male guinea pig testosterone levels (and behavior). Moderate maternal stress (2 hours over 3 days at gestational day 50 and day 60) results in increased basal cortisol level in male offspring and decreased testosterone levels. Kapoor and Matthews (2008) evaluated moderate maternal stress (2 hours over 3 days at gestational day 50 and day 60) in female offspring following prenatal stress exposure. Timing of the gestational, maternal stress exposure, as in males, varied according to when the stress occurred during gestation and elicited a sex bias. Cortisol measurements in this study were salivary cortisol levels versus plasma levels in the Kapoor and Matthews (2005) study. There was no prenatal stress effect regarding basal cortisol levels or an effect related to the reproductive cycle stage. Females exposed at gestational day 50 and 60 had lower salivary cortisol stressor responses during estrous. Gestational day 60 stress-exposed female offspring had lower estradiol levels during the luteal and diminished ovarian weight. Females, as in males, lacked a diurnal cortisol response. In another study, juvenile guinea pigs (both male and female) born to dams exposed to an “adverse event” every other day through the second half of gestation (chronic maternal stress) had elevated basal salivary cortisol levels at PND 25 (Emack et al., 2008).

Sachser and Lick (1989), Sachser and Kaiser (1996), and Kaiser and Sachser (1998) evaluated social stress in guinea pigs and the impact on hormonal activities and animal behavior. Sachser and Lick (1996) determined confrontational stress resulted in extremely high plasma glucocorticoids, creatinine, urea nitrogen, and decreased testosterone in confrontational losers, whereas the confrontational winners did not differ from control animals. Sachser and Kaiser (1996) determined gestational social stress (unstable social environment) masculinized female offspring characterized by male-typical courtship and play behavior, whereas social stress during lactation did not alter behavior. Kaiser and Sachser (1998) determined social instability impacted behavior and hormonal levels. Male-like behavior was once again observed in female offspring exposed to gestational environmental instability with corresponding higher serum testosterone levels and bilateral adrenal tyrosine hydroxylase activity.

8.4.6 SEX

Sexual dimorphism in the plasma cortisol levels of the guinea pig have been observed after 30 days of age, with males having higher levels than females. These differences are related to differences in metabolism and binding of cortisol by transcortin (El Hani et al., 1980). In guinea pigs between 90 and 120 days of age, basal and stress plasma cortisol levels are the same for both sexes, but sexual dimorphism reappears in adult guinea pigs. These changes seem to correspond to changes in testosterone levels.

8.4.7 DISEASE

Shapiro (1993) demonstrated in a chronic renal failure model (one- and two-thirds nephrectomy) that guinea pigs develop abnormal LDL catabolism, related not only to clearance mechanisms, but also suggested functional LDL differences develop in the uremic guinea pigs.

In evaluating a series of serum cytokines using the Hartley guinea pig model of osteoarthritis, the serum level of 18 cytokines was evaluated. Cytokine levels were evaluated for correlation with histopathologic findings. For this condition, it was determined that IL-6 and G-CSF correlated most closely with the histopathologic findings (Huebner et al., 2007).

Collins (2008) indicated ovarian cysts are the most common form of endocrine disease encountered in guinea pigs; cysts (5–7 mm in diameter) are observed in >75% of cavies between 1.5 and 5 years of age. These cysts are frequently bilateral and if functional result in secreting estrogen or progesterone and a bilaterally symmetrical nonpruritic flank to lumbosacral alopecia.

New Zealand guinea pigs exposed to toxic oil (canola oil) experienced elevated urinary protein excretion, creatinine clearance, and urine creatinine concentration compared with control animals over a 28-day period of exposure (Sanchez-Bernal et al., 1993).

Bret et al. (1993) evaluated kidney tubule enzymes in urine sequentially in a mercuric chloride nephrotoxicity model in guinea pigs. Urine was collected in metabolic chambers, centrifuged, and analysis executed on the supernatant. GGT and ALP were released first, indicative of cell membrane/brush border damage. Lactate dehydrogenase emergence is later indicating cellular disruption. Lastly, DNA detection is evidence of cell death resulting from tubule cell necrosis.

Although urolithiasis is rare in guinea pigs, Okewole et al. (1991) described calcium oxalate urolithiasis associated with an outbreak of *Streptococcus pyogenes*. Other reports of urolithiasis in the literature include Sprink (1978) and Stuppy et al. (1979). Holowaychuk (2006) offered a case report where a guinea pig had ingested oxalate-containing plants and was presented for renal failure; however, oxalate crystals were not found in the urine. When the animal was ultimately euthanized the owners declined a diagnostic necropsy.

8.5 METHODOLOGY FOR COMMON PROCEDURES

8.5.1 ADRENOCORTICOTROPHIN STIMULATION TEST

Kapoor and Matthews (2005) and Liu and Matthews (1999) described an Adrenocorticotrophin (ACTH) stimulation test in guinea pigs in which carotid artery catheters were surgically placed and maintained for 3 days after surgery before initiating the ACTH stimulation test. ACTH was administered intra-arterially (2 µg/kg) to male guinea pigs at 1300 hours and blood samples (plasma) collected for cortisol measurements at –30, 0, 30, 60, and 120 minutes. The –30 and 0 time samples were averaged to determine a baseline cortisol level.

Bauer et al. (2008) described an ACTH stimulation test which measured fecal cortisol levels. Guinea pigs were injected subcutaneously with 20 IU Synacthen® depot at 1200 hours. Fecal

samples were collected every 2 hours during the first 24 hours, every 6 hours during the subsequent 24 hours, and every 12 hours during the third 24-hour period. Peak cortisol metabolite levels occur ~18 hours following ACTH administration and are dependent on gastrointestinal transit time. Over the 20-hour gastrointestinal transit time, it is believed the peaks and valleys seen with blood adrenocortical activity are blunted.

8.5.2 CORTICOTROPHIN RELEASING HORMONE STIMULATION TEST

Liu and Matthews (1999) described a corticotrophin releasing hormone (CRH) stimulation test using surgically catheterized (carotid artery and jugular vein), adult, female guinea pigs. Animals were administered human CRH via the jugular vein catheter at 0.2 and 2.0 $\mu\text{g}/\text{kg}$ between 1300 and 1400 hours and blood samples (plasma) were collected via the carotid artery catheter at -30, -10, 0, 5, 15, 30, 60, 90, and 120 minutes for both serum ACTH and cortisol measurements via radioimmunoassay. Peak serum levels were observed at 30 (ACTH) and 60 (cortisol) minutes post-CRH.

8.5.3 ORAL GLUCOSE TOLERANCE TEST

Banerjee and Ghosh (1946) described a technique for the oral glucose tolerance test (OGTT) where after an overnight fast, a (fasting) blood glucose level is obtained and animals are fed 200 mg of glucose per 100 g of body weight of a 50% solution. Blood samples are then taken (45-minute intervals for 280 minutes) for glucose determination. Everson and Shrader's (1968) technique varied slightly in that it is specified the animals are fasted for 20 hours and animals were given the glucose in a 20% solution, fed by a dropper and consumed over 2 minutes. Animals were subsequently anesthetized with pentobarbital and sampled at 30 minutes, 1, 2, 3, and 4 hours.

8.5.4 INTRAVENOUS GLUCOSE TOLERANCE TEST

Everson and Shrader (1968) described an intravenous glucose tolerance test (IVGTT) in the guinea pig using a surgical aortic cannula placement via the carotid artery for serial blood collection. Following 5–10 days recovery (based on the animal's return to normal body weight), animals were fasted 18 hours and a (fasting) blood sample was collected. Over 3 minutes, animals were administered 100 mg per 100 g of body weight of a sterile 40% glucose solution in physiologic saline. Samples were obtained from unrestrained animals at 15, 30, and 45 minutes and 1, 2, 3, and 4 hours, and serum glucose measured.

Kind et al. (2003) described a similar IVGTT whereby jugular vein and carotid artery catheters were placed and approximately 11 days later animal were fasted for 16 hours and 50% dextrose solution (diluted in 0.9% saline) was administered via the jugular catheter (over a 2-minute period) at 500-mg dextrose/kg body weight in a total volume of 2.5 mL followed by 2 mL of 0.9% saline. Plasma was collected for glucose measurements via carotid artery at 2, 5, 10, 20, 30, 40, 60, 80, 120, 150, 180, and 210 minutes.

8.6 CLINICAL CHEMISTRY REFERENCE RANGES FOR THE GUINEA PIG

Data for clinical chemistry serum reference ranges for several guinea pig strains and urine analytes in the guinea pig are shown in Tables 8.3 and 8.4, respectively.

TABLE 8.3
Clinical Chemistry Serum Reference Ranges for Several Guinea Pig Strains

TABLE 8.4
Urine Analytes in the Guinea Pig

Analyte	Results	Reference
Urinary volume	63 ± 8	Duan et al. (1996) and Huerkamp et al. (1996)
Color	Yellow (reddish)	Kraft and Dürr (2005)
Turbidity	Clear-slightly turbid	Kraft and Dürr (2005)
Odor	n.s.	Kraft and Dürr (2005)
Blood	Negative	Kraft and Dürr (2005)
Urobilinogen	Neg-weak positive	Kraft and Dürr (2005)
Bilirubin	Negative	Kraft and Dürr (2005)
Protein	Negative	Kraft and Dürr (2005)
Nitrite	Negative	Kraft and Dürr (2005)
Ketone	Negative	Kraft and Dürr (2005)
Glucose	Negative	Kraft and Dürr (2005)
pH	8.0–9.0	Kraft and Dürr (2005)
Specific gravity	1.000–1.040	Kraft and Dürr (2005)
Leukocytes	Negative	Kraft and Dürr (2005)

ACKNOWLEDGMENTS

I wish to thank Dr. Charles B. Clifford and Dr. William J. White, the previous authors of this chapter, for their vision and contributions to this chapter.

9.1 INTRODUCTION

Domestic ferrets (*Mustela putorius furo*) occupy important niches as animal models in biomedical research. As evidenced by the number of citations in a web-based literature search, their eminent use today is in the field of virology, particularly in influenza-related projects. Ferrets have been represented in influenza research since the 1930s (Smith et al., 1933), but their role has expanded dramatically with concern for a human influenza pandemic from influenza A H5N1 (“bird flu”) and, more recently, from H1N1 (“swine flu”; Garrett, 2009). Several review articles (Maher and DeStefano, 2004; Luke and Subbarao, 2008; van der Laan et al., 2008; Barnard, 2009; Belser et al., 2011) enumerate ferret attributes that make them desirable models for influenza research; highlights are a natural susceptibility to infection and parallels with humans in regard to clinical presentation and pathogenesis.

Ferrets are permissive hosts for influenza types A and B (Kiupel and Perpignan, 2014; Kim et al., 2009), and, unlike mice, prior animal adaptation of the ferret is not required for disease. Potential transmission between humans and ferrets is well recognized, and animal care technicians with flu-like symptoms are asked to forego working with research ferrets. Ferret-to-ferret passage, as well as ferret-to-human, has been documented. A 2009 outbreak of respiratory disease among a large farm colony of ferrets in Iowa underscores the clinical importance of influenza in these animals (Patterson et al., 2009). In the latter case report, histology, immunohistochemistry, and molecular techniques allowed the etiology to be characterized as an H1N1 influenza strain. In the face of this sensitivity, it is critical that ferrets destined for influenza research be assessed in advance for preexisting antibodies (Matsuoka et al., 2009).

Similar to infected humans, ferrets dosed intranasally with benign or seasonal influenza will exhibit self-limiting signs of upper respiratory disease such as sneezing, coughing, rhinitis, anorexia, malaise, and fever. The ferret body size allows these clinical signs to be easily monitored, including temperature variations via a subcutaneous transponder microchip. Their ciliated upper respiratory epithelium is selectively infected, sloughed, and regenerated in most cases, and hemagglutination inhibition assays can be performed to demonstrate antibodies after recovery. However, when ferrets are young, immunocompromised, or exposed to more pathogenic strains, influenza virus can replicate in the lower airways and lungs, causing interstitial pneumonitis and other sequelae with variable lethality. In ferrets exposed to virulent H5N1 isolates, van Riel et al. (2006) found the virus attached to similar cell types as were observed in infected humans. Secondary bacterial infections,

often with *Streptococcus pneumoniae*, can be superimposed and complicate the course of disease in ferrets (Peltola et al., 2006).

Current influenza studies involving ferrets are designed to elucidate viral virulence, pathology, and transmissibility (Zitzow et al., 2002; Jackson et al., 2009; Watanabe et al., 2009; Koster et al., 2012). With early concern regarding its potential global impact, research ferrets were inoculated almost immediately with strains of the novel 2009 A (H1N1) swine influenza virus obtained from human patients (Maines et al., 2009; Munster et al., 2009). Likewise ferrets are suitable for evaluating antiviral therapies and vaccines (Kugel et al., 2009; Shoji et al., 2009). The development of effective vaccine strategies against the H5N1 subtype of avian influenza is a major focus of research using ferrets (Forrest et al., 2009; Middleton et al., 2009; Perrone et al., 2009). An overview of influenza vaccine research by van der Laan et al. (2009) concludes that ferrets will continue to be invaluable experimental subjects, in part because they can be infected with a viral subtype different from that in a subsequent vaccine and develop a heightened response to the vaccine, that is, a “priming” effect, which is a situation analogous to humans. Recent research using genetically modified strains of influenza in ferrets sparked a debate among scientists about whether the published information could be used by bioterrorists (Cohen, 2012; Kuehn, 2012).

Other viruses that attack the human respiratory system are also evaluated in ferrets. Soon after its emergence, ferrets were among the first laboratory animals experimentally infected with the coronavirus responsible for severe acute respiratory syndrome (SARS; Martina et al., 2003). Subsequent reports have validated the ferret SARS infection model (Chu et al., 2008; van den Brand et al., 2008; Danesh et al., 2011). As with influenza-infected ferrets, efficacy of potential treatments and vaccines for SARS has been tested in ferrets (Ter Meulen et al., 2004; Weingartl et al., 2004; Darnell et al., 2007; See et al., 2008). In a summary article concerning animal models for SARS, Roberts et al. (2007) comment that ferrets constitute an outbred species, and the inherent variability between individuals can be a confounding factor in challenge studies. While true, the relative genetic heterogeneity of ferrets is an additional parameter shared with human populations.

Ferrets are exquisitely sensitive to canine distemper virus (Kiupel and Perpinan, 2014) with ongoing, natural infections (Perpinan et al., 2008). Ferrets serve as a model for the related measles virus in humans (Sawatsky et al., 2012). Both morbilliviruses cause respiratory signs, skin rash, fever, neurological sequelae, and severe immunosuppression in their respective hosts. Marine mammal morbilliviruses have also been partially characterized with passage through ferrets (Nielsen et al., 2008). Pillet et al. (2009) provides a review of morbillivirus research applications in ferrets, including the use of ferrets to study the pathogenesis of subacute sclerosing panencephalitis. These authors and others invoke a lack of ferret-specific reagents and adequate knowledge about ferret chemokines and cytokines as a drawback when using ferrets in research areas such as virology; however, investigations have been undertaken that start to address this deficiency (Senchak et al., 2007; Danesh et al., 2008; Ochi et al., 2008; Rutigliano et al., 2008; Svitek et al., 2008).

Other researchers have used ferrets to study henipaviruses (reviewed in Geisbert et al., 2012), respiratory syncytial virus (Colasurdo et al., 1998; Byrd and Prince, 1997), and human metapneumovirus (MacPhail et al., 2004). In addition, aspects of the ferret respiratory system have been exploited for other than viral-based research. For example, ferrets continue to be used as training models for human pediatric intubation (Kircher et al., 2009). Expression of the cystic fibrosis transmembrane conductance regulator (CFTR) gene in ferret airway epithelium and submucosal glands is identical to that in humans (Li and Englehardt, 2003), and researchers have genetically engineered ferrets with a disrupted CFTR (Sun et al., 2008, 2010). This considerable success may lead to cloned ferrets for investigating other genetic diseases. A related technical advance is sequencing of the ferret genome, which has been performed at the Broad Institute (for information see <http://www.broadinstitute.org>).

With a relatively immature nervous system at birth, especially in contrast to cats, ferrets constitute a useful system to investigate neurological development and the influence of experience, or activity (Weliky, 2000; Sur and Leamey, 2001; Sengpiel and Kind, 2002; Dalva, 2010). As the

eyes of ferret kits do not open until they are 32 days old, a popular research paradigm, in “rewired” ferrets, is to induce retinal projections to innervate nonvisual areas of the brain. The effects of lesions created in neural pathways are also studied in adult and immature ferrets (e.g., Fuentes-Santamaria et al., 2007; Gautschi and Clarke, 2007; Allman et al., 2009). Progressive cortical development has been correlated to the appearance of gyri and sulci on the ferret brain surface by using magnetic resonance imaging (Neal et al., 2007), while other neuroscience researchers are using viral vector techniques to label ferret neurons (Jian et al., 2005).

Comparable to *Helicobacter pylori* in humans, *Helicobacter mustelae* (Swennes and Fox, 2014) colonizes the gastric mucosa of ferrets. Ferrets harboring *H. mustelae* can be clinically normal or can exhibit vomiting, weight loss, and other signs associated with gastritis, gastric ulceration, hypergastrinemia, gastric adenocarcinoma, and mucosa-associated lymphoid tissue (MALT) lymphoma. Marini and Fox (1999), Solnick and Schauer (2001), and Whary and Fox (2004) review the use of ferrets as a gastric helicobacter model; Nedrud and Blanchard (2003) present general techniques for infecting ferrets with *H. mustelae*. Due to the high prevalence of *H. mustelae* in ferrets from commercial vendors in the United States, drug therapy to eradicate the organism is required before experimental inoculation. Alternatively, pregnant jills can be treated with antimicrobials and subsequent kits raised *H. mustelae*-free prior to involvement in helicobacter research (Batchelder et al., 1996). Administration of isogenic mutant strains of *H. mustelae* has helped to identify virulence and colonization factors (Andrutis et al., 1997; Patterson et al., 2003). Also, *H. mustelae*-infected ferrets have contributed to efforts in developing a vaccine against *H. pylori* (Sutton and Lee, 2001; Del Giudice et al., 2001).

There are similarities in emesis between ferrets and humans, which has made ferrets suitable as a nonrodent animal in the testing of novel drugs (Ji et al., 2007; Saif et al., 2007; Duffy et al., 2012; Du Sert et al., 2012), as well as for dissecting basic emetic mechanisms (van Sickle et al., 2003; Osinski et al., 2005; Onishi et al., 2007). In nutritional research, the absorption and metabolism of carotenoids in ferrets have been studied (Wang et al., 1993; Lee et al., 1999; Russell, 2004). Ferrets also are used as models for vitamin A metabolism (Raila et al., 2002), including a report on the ability of vitamin A to protect ferrets from clinical disease when exposed to canine distemper virus (Rodeheffer et al., 2007). Ferrets are convenient subjects for reproductive behavior and neuroendocrinology studies; a summary on the importance of olfaction in mate selection among different species, including ferrets, has been published by Baum and Kelliher (2009). Adrenocortical neoplasia in ferrets has been reviewed as a model for the human disease recently (Beuschlein et al., 2012). Cardiovascular researchers have employed ferrets (Morgan, 2014), such as in a comparative study that identifies the extent of collateral coronary circulation (Maxwell et al., 1987). In other instances, cardiac disease is surgically induced in ferrets (Diaz et al., 2004; Graham and Trafford, 2007). Ferrets continue to be used in parasitologic research (Webster and Kapel, 2005); earlier studies are discussed by Eberhard (1998). To a limited extent, ferrets have been exposed during experiments to non-respiratory viruses, such as lyssaviruses (Vos et al., 2004; Hanlon et al., 2005). They have also been shown to be susceptible to the prion that causes chronic wasting disease in cervids (Perrott et al., 2012). Overall it is apparent that, although total animal numbers used per year are less than in certain other laboratory animal species (Ball, 2006), ferrets are highly appropriate small animal models in diverse areas of study.

9.2 UNIQUE PHYSIOLOGICAL CHARACTERISTICS OF FERRETS

As obligate carnivores, ferrets require diets high in meat protein and fats, and low in complex carbohydrates and fiber (Marini et al., 2002). The simple stomach is like that of humans. There is no cecum present, and the transition from ileum to large intestine is indistinct grossly. Transit time through the ferret gastrointestinal tract is relatively rapid, around 3 or 4 hours, and thus the time when an animal is being fasted should be only a few hours. Ferret spleen size can be variable; potential causes for splenomegaly include extramedullary hematopoiesis, lymphoma, and isoflurane

administration. The ferret lung capacity is three times larger than predicted for its body size, and its trachea is long and narrow. These and other characteristics, such as more bronchiolar branching and extensive bronchial submucosal glands similar to the human lung, have made the ferret popular in respiratory research, as described in Section 9.1. Reference values for cerebrospinal fluid in healthy adult ferrets reveal a slightly higher protein concentration than found in dogs and cats (Platt et al., 2004). Because ferret sweat glands are poorly developed, it is important that environmental temperatures for ferrets be less than 85°F–90°F. A distinct musky odor is characteristic of adult ferrets, even when the paired anal scent glands have been surgically removed, because of normal sebaceous secretions (Marini et al., 2002). Proteinuria is not unusual in ferrets, especially in males (Fox, 2014), and urine pH is close to 6.0 when animals are provided a high-quality diet (Quesenberry and Orcutt, 2012).

The most common coat color in commercial ferrets is sable, or “fitch”; however, albino animals and other color variants are also available. Breeding animals and pseudopregnant jills with the two former coat types were used to assist identification of cystic fibrosis clones (Sun et al., 2008). Intact adult male ferrets can be twice the size of adult females (1.0–2.0 kg compared to 0.6–1.0 kg, respectively), and seasonal fluctuations in body fat result in concomitant changes in body weight. Sexual maturity is attained at 4–12 months of age, dependent on photoperiod, and gestation length is 41 ± 1 days (Lindeberg, 2008). In general, female ferrets are seasonal breeders and induced ovulators, with estrus persisting until a female is bred or artificially caused to ovulate. Potentially fatal bone marrow suppression and aplastic anemia can result from estrogen toxicity if estrus is allowed to continue a few weeks, causing some researchers to purchase only male ferrets so as to avoid the complications of estrus in females (Ball, 2006). Distinct blood groups have not been detected in ferrets (Manning and Bell, 1990), which has clinical relevance when repeated blood transfusions are necessary.

The lifespan for a ferret is reported to average 6–8 years. Several neoplastic diseases can develop in adult animals (Li et al., 1998; Miwa et al., 2009); of these, insulinomas are the most common, with presenting clinical signs related to hypoglycemia (Chen, 2008). Adrenal gland disease is unique in ferrets because usually adrenal sex hormones (estradiol, 17-hydroxyprogesterone, androstenedione) are elevated rather than glucocorticoids (Rosenthal and Peterson, 1996; Simone-Freilicher, 2008; Rosenthal and Wyre, 2012), albeit there are single case reports of ferrets with hypercortisolism (Schoemaker et al., 2008) and hyperaldosteronism (Desmarchelier et al., 2008).

9.3 METHODOLOGY OF SAMPLE COLLECTION

9.3.1 BLOOD COLLECTION

Larger blood volumes (1–6 mL) should be collected from the jugular vein or cranial vena cava, using a 1–6-mL syringe attached to a 25–20-gauge needle. Different restraint methods have been described for these venipuncture sites in the conscious ferret (Ko and Marini, 2014; Quesenberry and Orcutt, 2012). For blood collection from the jugular vein with one assistant, the ferret can be wrapped tightly in a towel that restrains the forelimbs caudally (Figure 9.1). The ferret is held in dorsal recumbency by the scruff of its neck while the phlebotomist presses on the thoracic inlet to enhance venous filling and visualization. The jugular veins of ferrets lie between the thoracic inlet and the ear base, and bending the needle slightly can be helpful (Otto et al., 1993). Jugular venipuncture can also be accomplished by holding the ferret in ventral recumbency with its neck extended and forelegs pulled downward over the edge of a table, as is typically done with cats. Some ferret practitioners (Dyer and Cervasio, 2008; Siperstein, 2008) prefer to obtain blood from the cranial vena cava in ferrets, noting that a relatively caudal placement of the heart minimizes the risk of inadvertent cardiac puncture. In this technique, the ferret is placed in dorsal

FIGURE 9.1 (See color insert.) Restraint for blood collection from right jugular vein in an awake ferret. Clipping the hair at the venipuncture site is recommended.

recumbency as described above. A small gauge, 1-inch needle is inserted at the thoracic inlet, at a 45° angle to the body, and pointed toward the opposite rear leg. With gentle suction applied to the syringe plunger, the needle is withdrawn until blood is visible in the hub. This method should be aborted if the ferret struggles.

Cephalic or lateral saphenous veins are accessible when small amounts of blood are needed; tuberculin or insulin syringes with small gauge needles are appropriate for these sites. A number of other ferret bleeding techniques have been described in the literature but are not routinely used now, such as the use of tail vessels, toenail clipping, and cardiocentesis (Ko and Marini, 2014; Ryland and Bernard, 1983); the latter is only acceptable during a terminal procedure in an anesthetized animal. Disadvantages of these methods include small volumes and/or sample variability (Otto et al., 1993), invasiveness, and concerns for animal welfare.

Additional recommendations when collecting blood from ferrets are prior clipping of the venipuncture site if warranted, distracting the ferret with a food treat (which would elevate blood glucose levels), and considering the use of microfuge tubes. Due to the tough skin of adult ferrets, piercing the skin overlying the vessel beforehand with a 20-gauge needle is helpful. Also sedation for a blood draw can be employed regardless of positioning. Routine injectable agents include intramuscular ketamine hydrochloride (30–60 mg/kg) or intramuscular ketamine/xylazine (20–40 mg/kg, 1–4 mg/kg, respectively); yohimbine (0.5 mg/kg) given intramuscularly after sample collection will reverse xylazine-induced bradycardia and decrease recovery time. Intramuscular ketamine (30 mg/kg) mixed with acepromazine (0.3 mg/kg) has also been used successfully (Otto et al., 1993), whereas isoflurane chamber anesthesia is safe for a pregnant animal. Erythron indices, and to a lesser degree plasma protein values, are reduced during ketamine/xylazine sedation, as well as with isoflurane (Ko and Marini, 2014). Similar to other species, total blood volume in ferrets is estimated to be 5%–7% of body weight, and a maximum of 10% of the total blood volume should be withdrawn at any one time in a normal animal, every 2 weeks; thus a 1-kg male could safely have 6 mL of blood collected at one time. To acquire an adequate amount of plasma or serum, it is suggested that up to three times as much blood volume be collected as plasma or serum volume required, and to spin the blood about 20% longer than for other species (Whary, 2014).

9.3.2 URINE COLLECTION

Cystocentesis of a palpable urinary bladder in a well-restrained ferret can yield one or more milliliters of urine; a small gauge needle is appropriate. Also free catch samples are often adequate and easy to procure. A procedure for urinary bladder catheterization has been described (Ko and Marini, 2014).

9.4 PREANALYTICAL SOURCES OF VARIATION

Earlier authors (Thornton et al., 1979; Lee et al., 1982; Hoover and Baldwin, 1988; Fox, 2014) have reported clinical chemistry data from ferrets. However, comparisons of data are difficult because of different ages and sources of animals, anesthetic regimens, and analytical technology. Nevertheless in previous publications, as well as in current serum chemistry data given below that were obtained from Marshall BioResources, an inverse relationship is suggested between ferret age and values for inorganic phosphorous, alanine transaminase, alkaline phosphatase, and creatine kinase. Intact adult females will have sex hormone levels that reflect their reproductive cycle status, which in turn is affected by photoperiod; for example, a nonstimulatory photoperiod (8 hours light, 16 hours dark) coincides with low estradiol and luteinizing hormone levels (Fox et al., 2014). Progesterone secretion by corpora lutea begins at ovulation, and peak levels are reached at about day 15 of pregnancy or pseudopregnancy (Lindeberg, 2008). Neutered ferrets are expected to have low sex hormone levels, with high hormone levels supporting a diagnosis of adrenal gland disease or an ovarian remnant.

9.5 BRIEF DESCRIPTION OF COMMON PROCEDURES

Functional tests carried out in other animal species are performed rarely in ferrets; to a considerable extent this is because such evaluations are not required to diagnose typical disease syndromes. As stated in Section 9.2, adrenal gland disease in adult ferrets, while fairly frequent, normally affects sex hormone instead of cortisol levels. Primary thyroid, renal, and liver diseases are uncommon in ferrets. Infrequent cases of diabetes mellitus are usually iatrogenic sequelae to islet β cell surgery (Chen, 2008); however, two case reports of diabetes mellitus in ferrets unrelated to pancreatic surgery have been published (Boari et al., 2010, Phair et al., 2011). For research purposes in particular, descriptions of adrenal and thyroid assays (Garibaldi et al., 1988a,b; Heard et al., 1990; Schoemaker

TABLE 9.1
Serum Clinical Chemistry Data for Ferrets

Analyte	Units	Age	Male	Female
ALT	IU/L	Young	327.0 \pm 228.1	288.1 \pm 203.1
		Adult	89.7 \pm 17.3	122.3 \pm 19.3

		Adult	147.9 ± 2.0	148.9 ± 2.6
Total protein	g/dL	Young	6.3 ± 0.4	6.1 ± 0.3
		Adult	5.8 ± 0.3	6.2 ± 0.3
Estradiol	pmol/L	Neutered	30–180	103–238
		Intact	109–299	
17-hydroxyprogesterone	nmol/L	Neutered	<0.1–0.8	<0.1–1.9
		Intact	<0.1–20.4	
Androstenedione	nmol/L	Neutered	<0.1–1.5	<0.1–10.8
		Intact	<0.1–30.6	

Note: Values for all analytes except sex hormones (estradiol, 17-hydroxyprogesterone, and androstenedione) are given as mean ± standard deviation. These values were adapted from “The Marshall Ferret Serum Chemistry Data” (Marshall BioResources, Reference Data Guide 2014, available under Reference Data for Ferrets at www.marshallbio.com), as well as unpublished data, using a Vitros 250 analyzer. Young animals (31 males, 31 females) are sexually intact and 12–20 weeks of age; adults (30 males, 30 females) are sexually intact and 1–2 years of age, with females having had at least one litter but “resting” as much as possible, that is, not in visible estrus, pregnant, or lactating, when blood was drawn. All samples were collected under ketamine/xylazine sedation, and were nonhemolyzed.

Ranges for normal sex hormone levels (estradiol, 17-hydroxyprogesterone, and androstenedione) in neutered and intact ferrets were provided by the Clinical Endocrinology Service, College of Veterinary Medicine, University of Tennessee, and Dr. Jack Oliver (unpublished data). The neutered ferret group consists of animals castrated (13 males) or spayed (13 females) early, with a mean age of 1.5 years when hormone levels were measured. The sexually intact males (40 ferrets) and females (40 ferrets) are 6–9 months of age.

ALT, alanine aminotransferase; ALP, alkaline phosphatase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; CK, creatine kinase; GGT, gamma glutamyl transferase.

TABLE 9.2
Urinalysis Data for Adult Ferrets

Parameter	Male	Female
Volume ^a (mL/24 h)	26 (8–48)	28 (8–140)
Sodium ^a (mmol/24 h)	1.9 (0.4–6.7)	1.5 (0.2–5.6)
Potassium ^a (mmol/24 h)	2.9 (1.0–9.6)	2.1 (0.9–5.4)
Chloride ^a (mmol/24 h)	2.4 (0.7–8.5)	1.9 (0.3–7.8)
Specific gravity ^b	1.059 ± 0.007	1.047 ± 0.007
Total protein ^b (mg/dL)	9.6 ± 1.4	7.6 ± 1.2
Protein by strip ^b (mg/dL)	30–100	Trace-30
pH by pH meter ^b	6.2 ± 0.1	6.3 ± 0.3
pH by strip ^b	6.0–6.5	6.0–6.5
Leukocytes by strip ^b	Negative	Negative
Nitrite by strip ^b	Negative	Negative
Glucose by strip ^b	Negative	Negative
Ketone by strip ^b	Negative	Negative
Bilirubin by strip ^b	Negative	Negative
Blood by strip ^b	Negative	Negative-2+ hemolyzed (one case)
Urobilinogen by strip ^b	0.2	0.2
Sediment ^b	Urine sediment from all ferrets had amorphous urates present, and most contained mucous strands and/or protein sheaths. The male urine samples had sperm cells and several samples from both sexes had rare RBCs; both sperm and RBCs resulted from sample collection. Squamous epithelial cells, WBCs, cocci, uric acid, and Ca oxalate crystals were rarely seen.	

Source: Fox, J.G., *Biology and Diseases of the Ferret*, 2014.

^a Values are given as mean (range) and taken from Thornton et al. (1979) (40 males and 24 females).

^b Urine was collected by cystocentesis from eight males and eight females (sexually intact, 1–2 years of age, sedated with ketamine/xylazine as above), and the samples were evaluated by the Diagnostic Laboratory of the Division of Comparative Medicine, Massachusetts Institute of Technology. A refractometer was used to assess urine-specific gravity and total protein, whereas Multistix 10 SG (Siemens) reagent strips provided semiquantitative results. Values are reported as mean ± standard deviation when warranted.

et al., 2002, 2004), as well as inulin and exogenous creatinine clearance measurements to estimate renal function (Esteves et al., 1994), are available.

9.6 REFERENCE RANGES

Serum clinical chemistry data for ferrets and urinalysis data for adult ferrets are available in Tables 9.1 and 9.2, respectively.

10.1 USE OF FISH IN BIOMEDICAL RESEARCH

The zebrafish, *Danio rerio*, is a freshwater fish originally found in South Asia, with distributions ranging from India, Bangladesh, Nepal, Myanmar, and Pakistan (Lawrence, 2007). They are cyprinids omnivorous poikilothermes and have been used in research for the past 100 years but more extensively since the mid-1970s (Lieschke and Currie, 2007; Sullivan and Kim, 2008). The zebrafish shares many biological attributes with other vertebrates, and it is well suited as a vertebrate integrated organ system model.

Due to the zebrafish's biological attributes and the ability to transfer well-established techniques in embryology, genetics, and molecular biology, researchers have used zebrafish to study a wide range of subjects including genetics, vertebrate development, proteomics, behavior, aging, immunology, toxicology, cancer, neurobiology, drug discovery, and infectious diseases (Berghams et al., 2005; Dovey and Zon, 2009; Drabsch et al., 2016; Bambino and Chu, 2017; Matsui, 2017; Gerhard, 2007; Grunwald and Eisen, 2002; Keller and Murtha, 2004; Onnebo et al., 2004; Trede et al., 2004; Alvarez et al., 2007; Lieschke and Currie, 2007; Nakatani et al., 2007; Schilling and

Webb, 2007; Amatruda and Patton, 2008; Barros et al., 2008; Meeker and Trede, 2008; Sullivan and Kim, 2008; Ellett and Lieschke, 2010; Anderson et al., 2011; Chan and Mably, 2011; Löhr and Hammerschmidt, 2011; Sipes et al., 2011; Gaikwad et al., 2011; Goldsmith and Jobin, 2012; Quafe et al., 2012; Genge et al., 2016; Luderman et al., 2017; Schledgel, 2016). They are used in large-scale genetic screens to identify mutants based on identifying abnormal development and phenotypes (Feitsma and Cuppen, 2008; Hao et al., 2010; Wolman and Granato, 2012). Since the model was originally developed, fundamental progress has been made, making the model even more attractive to researchers. For example, some breakthroughs include the Sanger Institute zebrafish genome sequencing project; availability of full-length cDNAs and DNA microarrays for expression analysis; techniques for generating transgenic lines and targeted mutations; and suitability for functional genomic and phenotypic screens.

The first animal model of congenital sideroblastic anemia was the zebrafish mutant, *sauternes* (au), which develops microcytic, hypochromic anemia (Brownlie et al., 1998). The zebrafish is the first genetically accurate model of hepatoerythropoietic porphyria that can be used to study the pathogenesis of uroporphyrinogen decarboxylase (UROD) deficiency (Wang et al., 1998). A zebrafish model for the Shwachman–Diamond syndrome (SDS) has been developed (Venkatasubramani and Mayer, 2008). SDS is characterized by exocrine pancreatic insufficiency, neutrophil defect, and skeletal abnormalities. The use of morpholino-mediated gene knockdown technology lead to the loss of nucleolar protein called the Shwachman–Bodian–Diamond syndrome (SBDS) protein in the zebrafish, generating a model system where gene function and novel therapies can be evaluated (Venkatasubramani and Mayer, 2008).

This field is rapidly evolving and provides fundamental information on the formation and function of vertebrate biology, providing insight into mechanisms of human disease (Grunwald and Eisen, 2002; Ingham, 2009; Löhr and Hammerschmidt, 2011; Genge et al., 2017; Matrone et al., 2017). One of the major advantages of working with zebrafish is that they produce a large number of synchronously developing, transparent embryos enabling real-time imaging of developing pathologies. Zebrafish genome has been sequenced; they have a short generation time; they are easily accessible and are amenable to high throughput analysis, making them suitable for large-scale mutagenesis and screening studies, which are not readily available in other vertebrate systems (Wen et al., 2012; Wittmann et al., 2012). The Japanese medaka, *Oryzias latipes*, is another aquatic vertebrate model which is also a small, egg-laying freshwater teleost. Primary research applications of the Japanese medaka include ecotoxicology, developmental genetics, genomics, and evolutionary biology studies. The genome sequence of the medaka inbred strain, Hd-rR, has been completed (Kobayashi and Takeda, 2008; Takeda, 2008).

The cardiovascular system of the zebrafish has been extensively studied since the heart is easily visualized at 72 hours post-fertilization and many of the molecular, cellular, and electrophysiological mechanisms underlying cardiovascular development and function have been conserved in vertebrate evolution (Baker et al., 1997; Milan et al., 2006; Rubinstein, 2006; Arnaout et al., 2007; Milan and Macrae, 2008). As a consequence, many mutations impacting the cardiovascular system have been studied in embryos, and most of the research focusing on the formation, function, anatomy, hemodynamics, and gene expression of the cardiovascular system has been pursued in both the embryo and adult zebrafish (Genge et al., 2016; Matrone et al., 2017; Saffitz, 2017; Burns et al., 2005; Milan et al., 2006). One classic example is the mutation in the *slow mo* gene in zebrafish where the inwardly directed hyperpolarizing pacemaker current is reduced, leading to bradycardia (Baker et al., 1997; Briggs, 2002).

Zebrafish are oviparous and can easily breed year round in a laboratory setting. Females lay eggs that are then fertilized externally, and the embryos are transparent during organogenesis, enabling visual assessment of their development in real time (Vogt et al., 2009; Yang et al., 2009). Screening for specific phenotypes is possible since embryonic development occurs in full view. Furthermore, they can produce a large number of embryos, and depending on the zebrafish lines,

husbandry practices, and diet, their clutch size can range from 100 to 300 embryos per week (Spence et al., 2008). Their generation time is approximately 3 months (Lieschke and Currie, 2007).

Zebrafish eggs and adults are small. At fertilization, the eggs measure approximately 0.7 mm in diameter, and adults measure approximately <120 mm total length (Spence et al., 2008). They are easy to maintain in laboratory settings, can adapt to a wide range of environmental parameters, and require less space than other *in vivo* models and can be housed at higher densities compared to other research animals. It is estimated that the cost of husbandry when working with mice compared to zebrafish is between 1:100 and 1:1000 (Goldsmith, 2004). There are many zebrafish wild type lines used for research and most are described on the Zebrafish Information Network (www.ZFIN.org; Trevarrow and Robison, 2004).

Clinical chemistry is a diagnostic and research tool commonly used in mammals. Clinical chemistry techniques and values have been established in many different fish used for production or environmental conservation program (Ellsaesser and Clem, 1987; Houston, 1990; Bullis, 1993; Axelsson and Fritsches, 1994; Roche and Boge, 1996; Groff and Zinkl, 1999; Jagadeeswaran et al., 1999; Hrubec and Smith, 1999, 2000, 2004; Black, 2000; Congleton and LaVoie, 2001; Dye et al., 2001; Sakomoto et al., 2001; Harms et al., 2002; Greenwell et al., 2003; Murtha et al., 2003; Asadi et al., 2006; Caldwell et al., 2006; Knowles et al., 2006; Reavill, 2006; Elo et al., 2007; Mauel et al., 2007; Tavares-Dias and Moraes, 2007; Zhou et al., 2009). However, the use of clinical chemistry in the research of laboratory fish such as medaka and zebrafish is not common due to the challenges associated with sample collection, small sample size, and lack of procedural standardization.

Zebrafish physiology is affected by stress, disease, water chemistry, and nutrition (Groff and Zinkl, 1999; Bayne and Gerwick, 2001; Briggs, 2002; Evans et al., 2005; Craig et al., 2007; Ramsay et al., 2006, 2009; Harper and Wolf, 2009; Siccardi et al., 2009; Cachat et al., 2010). This chapter reviews current literature focusing on clinical chemistry values, sample collection techniques, as well as preanalytical sources of variation known to impact fish physiology, clinical chemistry, and genetics. Most of the information gathered for this chapter focuses on freshwater fish in an attempt to highlight the need to establish clinical chemistry baselines to promote good research data, minimize variability, and for health monitoring.

Electrolyte values vary between fish species, health status, and water chemistry. Sodium and chloride in conjunction with a hemogram can indicate the hydration status of the fish (Groff and Zinkl, 1999). Sodium and chloride are important in fish osmoregulation and are found in a 1:1 ratio; however, the concentration of sodium is commonly greater than chloride concentration (Groff and Zinkl, 1999).

10.2 METHODOLOGY FOR SAMPLE COLLECTION

Common procedures used in other mammalian models have not yet been standardized or developed in zebrafish, since the model has been primarily developed to study genetics and gene function in embryos and larvae. Very few articles have been published on clinical chemistry of zebrafish and to date, no publications were found pertaining to adrenocorticotropin hormone (ACTH) stimulation, bile acids, bromosulphthalein (BSP) clearance, insulin clearance, thyroid-stimulating hormone (TSH) stimulation, ammonia tolerance, and dexamethasone suppression test in zebrafish. There are several important reviews which focus on clinical chemistry and procedures in fish (Ellsaesser and Clem, 1987; Houston, 1990; Groff and Zinkl, 1999; Greenwell et al., 2003). Groff and Zinkl (1999) wrote a review of clinical chemistry of cyprinid fish focusing on koi, carp, and goldfish. Since zebrafish are cyprinids, this review highlights some similar patterns between gold fish and carp which are also cyprinids. A review of blood collection techniques for biochemical analysis in adult zebrafish has been published (Pedroso et al., 2012).

10.2.1 BLOOD COLLECTION

Fish clinical chemistry is a valuable tool in disease diagnosis but lacks the nomenclature and procedural standardization that exist with mammalian clinical chemistry. Compared to other mammalian species, clinical chemistry is not routinely performed in fish species; however, significant research has been done to develop the knowledge necessary to collect samples in fish (Ellsaesser and Clem, 1987; Houston, 1990; Bullis, 1993; Axelsson and Fritsches, 1994; Roche and Boge, 1996; Groff and Zinkl, 1999; Hrubec and Smith, 1999, 2000, 2004; Jagadeeswaran et al., 1999; Black, 2000; Congleton and LaVoie, 2001; Dye et al., 2001; Sakomoto et al., 2001; Harms et al., 2002; Greenwell et al., 2003; Murtha et al., 2003; Asadi et al., 2006; Caldwell et al., 2006; Reavill, 2006; Tavares-Dias and Moraes, 2007; Elo et al., 2007; Borges et al., 2007; Pedroso et al., 2012). Although laboratory fish such as medaka and zebrafish are small, phlebotomy can be performed (Jagadeeswaran et al., 1999; Murtha et al., 2003; Onnebo et al., 2004; Elo et al., 2007; Pedroso et al., 2012).

Clinical chemistry in fish can be performed using either serum or plasma. Serum and plasma are the fluid component of blood and the clotting factors are found in plasma and not in serum (Hrubec and Smith, 1999). In mammals, clinical chemistry results from serum or plasma are very similar when samples are handled in a standardized manner. Evaluating the similarity and differences between the use of plasma and serum on the effect on measured blood analytes has not been studied in zebrafish, though. However, it has been assessed in rainbow trout *Oncorhynchus mykiss*, channel catfish *Ictalurus punctatus*, hybrid tilapia *Oreochromis* spp., and hybrid striped bass to name a few (Hrubec and Smith, 1999; Hrubec et al., 2000). Further details pertaining to the differences between plasma and serum on clinical chemistry are discussed in Section 10.3.

10.2.1.1 Primary Sites for Collection

Blood samples can be collected in fish from the dorsal aorta, heart, and caudal vein. The primary site of collection should be determined based on the size of the fish and the sample volume required. In smaller fish such as medaka and zebrafish, blood sampling is a terminal procedure and the common blood collection sites include the dorsal aorta, heart, and caudal vein (Eames et al., 2010; Pedroso et al., 2012). In larger fish, such as salmon, trout, or tilapia, the most common blood collection sites are the caudal vein and heart (Noga, 1996; Jagadeeswaran et al., 1999; Black, 2000).

In zebrafish, blood collection from the dorsal aorta requires anesthesia as discussed in Section 10.2.1.2. The anesthetized fish is placed on a flat surface or restrained in one's hand. A transverse incision measuring 0.3–0.5 cm in depth is made posterior to the dorsal fin by using a sharp pair of scissors (Jagadeeswaran et al., 1999; Murtha et al., 2003; Pedroso et al., 2012). The blood pools from the incision site and it is collected with a micropipette tip or a capillary tube. The risk with this technique is sample contamination from the incision site or a perforated gastrointestinal tract (Jagadeeswaran et al., 1999; Murtha et al., 2003).

In larger fish, collecting blood from the caudal vein is the most commonly used technique and the least traumatic (Noga, 1996; Groff and Zinkl, 1999; Black, 2000). The caudal vessels can be accessed using a ventral or a lateral approach using a 25 or 22 G needle depending on the size of the animal. Pretreating the needle with heparin can minimize coagulation (Reavill, 2006). The needle is inserted ventrally through the skin near the base of the caudal peduncle until firm resistance is felt and then the needle is redirected ventrally and laterally while gently aspirating (Noga, 1996). Depending on the size of the animal, the blood sample can be collected into a syringe or transferred into a heparinized capillary tube from the hub of the needle (Groff and Zinkl, 1999). In contrast, due to the small diameter of the zebrafish caudal vein, the vessel cannot be accessed using a syringe and needle. However, it can be accessed by severing the base of the tail with a scalpel blade in deeply anesthetized or euthanized zebrafish. A heparinized capillary tube is applied on the caudal vessels and blood sample collection is enabled by capillary action (Noga, 1996). Tissue fluid contamination and dilution may impact results if the sample is used for clinical chemistry

(Ikeda and Ozaki, 1981; Noga, 1996; Congleton and LaVoie, 2001). In zebrafish, the blood volume collected from the caudal vein is very small due to rapid clotting.

Black (2000) described a technique for blood collection in very small fish such as medaka or mosquitofish. The fish are anesthetized with MS-222 and submerged with 70% ethanol (Iwama and Ackerman, 1994). The caudal peduncle is severed with sterile scissors. The fish is immediately placed head-up in a 10 mm × 75 mm polyethylene tube (PE) tube with 1 mL sterile physiological saline solution. The blood pools at the bottom of the tube as the tube is delicately swirled. After cessation of the blood flow, the fish is removed with sterile forceps. The content of the tube is then transferred into a conical microcentrifuge tube and centrifuged at 16,000 rpm for 1 minute (Black, 2000). The physiological saline is decanted and the red blood cells (RBCs) are resuspended in 1 mL of physiological saline and centrifuged again at 16,000 rpm. After centrifugation, the supernatant is decanted and the RBC can be used for biochemical analyses such as DNA strand length determination (Black, 2000).

Cardiocentesis (also referred to as cardiac puncture) is another method of blood collection, which has been used to collect blood in small and large fish. This technique should only be used for terminal blood sample collection (Noga, 1996; Black, 2000; Eames et al., 2010; Harper and Lawrence, 2010). The heart is located in the posterior edge of the gills and cardiocentesis is performed in anesthetized animals which are positioned in dorsal recumbancy to access the heart ventrally. Cardiocentesis in larger fish such as catfish and trout can be performed using a 23 G needle attached to a syringe, which is inserted on the linea alba on the ventral midline between the pectoral fins directly into the heart (Black, 2000). Zebrafish hearts are very small. For example, a 1-year-old fish with body length ranging from 3 to 4 cm have hearts 1–2 mm in length with a diameter of 1 mm (Sun et al., 2008).

In small fish, the heart can be exposed by performing a ventral incision between the pectoral fins using scissors (Groff and Zinkl, 1999). This helps in visualizing the heart, minimizes the risk of excessive tissue damage, and reduces contamination of the blood sample with epidermal cells and body fluids that may impact clinical chemistry results. For zebrafish, a micropipette tip is then directly inserted in the ventricle. The blood sample can become hemolysed if the ventricle collapses and air is suctioned into the tip while the sample is being collected (Reavill, 2006).

Alternatively, whole blood can be collected in anesthetized or euthanized zebrafish by decapitation by transecting through the pectoral girdle with scissors. The incision is made immediately anterior to the articulation of the pectoral fin with the girdle that severs the heart, and blood is collected by holding a microcapillary tube adjacent to the heart (Eames et al., 2010).

Serial sampling techniques can be used in large fish species such as salmon, trout, and catfish. Blood can be collected from either restrained or free-swimming fish. In addition to repetitive individual collection of blood samples, several blood vessels in fish can be cannulated for long-term studies which require serial blood collection. Some of the most commonly cannulated vessels include the dorsal aorta, the ventral aorta, and caudal vein (Houston, 1990; Sohlberg et al., 1996; Black, 2000).

10.2.1.2 Methods of Restraint

Optimization of fish blood sampling techniques may require either immobilization under anesthesia and/or the use of physical restraint. Although fish can be restrained physically without anesthesia, the stress associated with the capture, handling, and restraint can affect physiological responses and clinical chemistry values (Torres et al., 1986; Ellsaesser and Clem, 1987; Bullis, 1993; Groff and Zinkl, 1999; Greenwell et al., 2003; Dror et al., 2006; Crosby et al., 2006; Ramsay et al., 2006, 2009; Gravel and Vijayan, 2007; Alsop and Vijayan, 2008; Liu et al., 2008; Cachat et al., 2010). Therefore, the use of anesthesia during phlebotomy is recommended in order to reduce clinical chemistry variables associated with stress.

Fish can be restrained manually or with a device which stabilizes the position of the anesthetized fish by maintaining the animal in dorsal or ventral recumbancy. Depending on the size of

the fish, a sponge or piece of styrofoam with a V-shaped groove can be used to stabilize the fish (Wooster et al., 1993; Harms, 2005; Harper and Lawrence, 2010).

There is a large body of literature which indicates that the use of anesthetics can impact the physiology of teleost fish and clinical chemistry (Randall, 1962; King et al., 2005; Rothwell and Forster, 2005; Rothwell et al., 2005; Crosby et al., 2006; Palić et al., 2006). Further details pertaining to the impact of anesthetics on clinical chemistry are discussed in the “Anesthesia” section of this chapter.

The most commonly used anesthetic in fish is Finquel (Argent Chemical Laboratories, Inc., Redmond, Washington) which is commercially available as TMS. Finquel is also known as MS-222, MESAB, Tricaine, 3-amino benzoic acid ethyl ester, and ethyl 3-aminobenzoate (Brown, 1993; Iwama and Ackerman, 1994). MS-222 is the only anesthetic and sedative agent approved for use with food fish by the US Food and Drug Administration and is recommended by the American Veterinary Medical Association (AVMA) Guidelines on Euthanasia. Although there are many other anesthetics used in fish, they will not be discussed in this chapter (Iwama and Ackerman, 1994; Noga, 1996; AVMA, 2007; NIH, 2009).

A large portion of this section will focus on providing background on MS-222 since it is used by most zebrafish laboratories when collecting blood samples. MS-222 is a benzocaine derivative with an additional sulphonate radical which makes it water soluble and also acidic. It is sold as a white crystalline powder and needs to be reconstituted in water. When working with MS-222 in the powder form, caution must be taken to prevent inhaling the powder, or exposing mucous membranes and eyes. The action of the benzoic acid derivative is affected by both water temperature and water hardness (Houston and Woods, 1976). Its action is decreased in cooler temperatures and in soft water conditions (low alkalinity). MS-222 is absorbed across the gills. In salmonids, MS-222 is metabolized by acetylation and excreted in urine 24 hours after administration and no residues are detectable (Houston, 1990; Burka et al., 1997).

According to the manufacturer (Argent Chemical Laboratory), reconstituted MS-222 stored at room temperature showed no significant loss of potency after 3 days but the potency decreases after 10 days. Many research laboratories reconstitute MS-222 in water and make a concentrated stock solution which is then aliquoted into small vials and frozen, although no published information was found regarding impact of freezing on potency/activity of stock solution. The stock solution should not be buffered with sodium bicarbonate unless it is used immediately as this can cause dissociation of the sulfonate group (Houston, 1990; Noga, 1996). MS-222 is light sensitive, and the solution may change color if it is exposed to light. If this is noted, the solution should be discarded (Iwama and Ackerman, 1994; Noga, 1996). The unbuffered MS-222 stock solution should be stored in an opaque container and then frozen.

One of the critical factors when using MS-222 is managing the buffering capacity of the water. Distilled water and reverse osmosis water have little or no buffering capacity and should not be used when reconstituting MS-222. Water with no buffering capacity has zero alkalinity. Alkalinity is needed to neutralize acid and maintain a neutral pH. Because MS-222 is acidic, water solutions with CaCO_3 levels <50 mg/L should be buffered with sodium bicarbonate. Otherwise the anesthetic or euthanasia solution can lead to acidosis in fish as the water pH can decrease to 5 (Houston, 1990; Noga, 1996). This has a direct impact on the animal's welfare and physiology.

Different buffering agents are suitable and include sodium bicarbonate and sodium hydroxide (Noga, 1996; Rombough, 2007). Sodium bicarbonate should be added to the solution at a ratio of 2:1 [sodium bicarbonate (wt):tricaine (wt)] and adjusted to a pH of 7 (Noga, 1996). The fish are immersed in buffered water with dissolved MS-222, and the water concentration of MS-222 is usually higher than the levels in the fish (Allen and Hunn, 1986; Burka et al., 1997). MS-222 is readily absorbed across the gills and cannot be administered by injection since the MS-222 will be eliminated via the gills (Burka et al., 1997).

Induction and recovery times are inversely correlated with body weight where the effect is greater in smaller fish (Houston and Woods, 1976; Iwama and Ackerman, 1994).

The most common method of euthanasia in zebrafish embryos, larvae, and adults is by immersing the animals in a buffered solution of MS-222. The MS-222 concentration needed for anesthesia or

euthanasia in fish is both species and age dependent (Brown, 1993; Bullis, 1993; Stoskopf, 1993; Iwama and Ackerman, 1994; Masee et al., 1995; Noga, 1996; Rombough, 2007; Westerfield, 2007). The age, species, and duration of anesthetic exposures must be taken into account when using commonly recommended anesthetics in fish (Gilderhus and Marking, 1987; Rombough, 2007; Macova et al., 2008). Euthanasia methods used with laboratory zebrafish should be consistent with the latest AVMA Guidelines on Euthanasia (2007) which recommend a concentrated solution of buffered MS-222 (e.g., 200–500 mg/L) for adult fish for 5–10 minutes following the cessation of opercular movement.

The National Institutes of Health (NIH) has provided a comprehensive review of age-specific euthanasia guidelines for zebrafish (NIH, 2009). For zebrafish older than 8 days post-fertilization (dpf), an overdose of MS-222 (200–300 mg/L) by prolonged immersion for non-survival procedures can be used. The fish should be left in the solution for at least 10 minutes following cessation of opercular movement (NIH, 2009). Necropsy can be initiated 5–10 minutes after cessation of opercular movement.

Another protocol recommended for zebrafish ≥ 8 dpf is anesthetizing the fish with MS-222 (168 mg/L) followed by rapid freezing in liquid nitrogen (NIH, 2009). Zebrafish ≥ 8 dpf can be immobilized for euthanasia by submersion in ice water (5 parts ice/1 part water, 0–4°C) for at least 10 minutes following cessation of opercular movement (NIH, 2009). In any fish where it is difficult to visualize opercular movement, fish should be left in the ice water for at least 20 minutes after cessation of all movement to ensure death by hypoxia. For zebrafish 4–7 dpf, immobilization for euthanasia by submersion in ice water (5 parts ice/1 part water, 0–4°C) for at least 20 minutes can be used to ensure death by hypoxia (NIH, 2009). Another protocol recommended by the NIH (2009) for zebrafish 4–7 dpf is the addition of bleach solution (sodium hypochlorite 6.15%) to the culture system water at 1 part bleach to 5 parts water. They should remain in this solution at least 5 minutes prior to disposal to ensure death. As detailed in the scientific background section of the NIH guidelines, pain perception has not developed at these earlier stages so this is not considered a painful procedure (NIH, 2009). For zebrafish embryos ≤ 3 dpf, development should be terminated using bleach as described with for zebrafish 4–7 dpf (NIH, 2009).

There are other references specific for zebrafish anesthesia and euthanasia. The commonly used MS-222 stock solution concentrations is 4 g/L, and the anesthetic dose is 4 mL of stock solution in 100 mL of water or 40 $\mu\text{g}/\text{mL}$ (Westerfield, 2007). The euthanasia dose for adult zebrafish recommended by Westerfield is 10–20 mL of stock solution in 100 mL water (Westerfield, 2007). Research has showed that zebrafish larvae are more tolerant to the affect of MS-222 than adult fish (Rombough, 2007). The recommended dose for euthanasia for 3–9 dpf zebrafish larvae is 1800 mg/L (Rombough, 2007).

10.2.1.3 Blood Volume—Collection Volume Limits

The blood volume in bony fish (*Osteichthyes*) is small compared to other vertebrates. The total blood volume in fish ranges between 1.5% and 5% of body weight (Conte et al., 1963; Groff and Zinkl, 1999). In carp, blood volume is approximately 5% of body mass, and conservative estimates of blood volumes that can be collected from a 100 g fish is 1.0 mL (Groff and Zinkl, 1999).

Depending on the size of the animal, blood sampling technique, and technical proficiency of the phlebotomist, blood volume collected from one adult zebrafish can range from 1 to 10 μL (Jagadeeswaran et al., 1999; Murtha et al., 2003; Eames et al., 2010). With most blood collection methods in zebrafish, the quantity of blood is most commonly 5 μL , and sample volumes of 10 μL are less uncommon. Blood samples are usually pooled from several zebrafish for analysis. Although small volumes are collected from adult zebrafish, researchers have applied different technologies to meet their research needs. For example, blood glucose in zebrafish has been measured by using glucose meters with various test strip sample volumes (Elo et al., 2007; Eames et al., 2010). These include the following:

- OneTouch Ultra, 1 μL sample (LifeScan)
- FreeStyle Lite, 0.3 μL sample (Abbott)

- Accu-Chek Aviva, 0.6 μL sample (Roche Diagnostics)
- Accu-Chek Compact Plus, 1.5 μL sample (Roche Diagnostics)

10.2.1.4 Blood Storage Recommendations

Fish blood is known to coagulate rapidly and the rate of coagulation increases with stress (Groff and Zinkl, 1999). One of the critical factors when preparing samples for analysis and storage is to process the sample immediately since clinical chemistry values can be altered if blood is kept at room temperature for ≥ 1 hour or after being refrigerated from 1 to 3 hours (Korcock et al., 1988; Houston, 1990; Groff and Zinkl, 1999). Once the blood sample is collected, it should be centrifuged at low temperatures (Houston, 1990; Groff and Zinkl, 1999).

When working with zebrafish or other small fish, whole blood can be pooled from multiple fish. Blood can be pooled in 0.5 mL microcentrifuge tube (OS-pl microcentrifuge tube) and allowed to clot, and spun for 10 minutes at 2,500 rpm. Centrifugation above 2,500 rpm may lead to hemolysis (Murtha et al., 2003). The serum is then pipetted off the top. Serum biochemical values were obtained from the pooled serum of five groups of approximately 50 zebrafish, using the VetScan Diagnostic Profile II (Abaxis, Inc., Union City, California) (Murtha et al., 2003).

The risk of hemolysis increases at room temperature and during storage of sample (Houston, 1990).

10.2.2 URINE COLLECTION

Zebrafish do not have a urinary bladder (Lieschke and Currie, 2007; Harper and Lawrence, 2010). Therefore, there are no easily accessible methods to collect urine in zebrafish. However, urine collection to assess renal function and urinary excretion has been performed in various fish species such as trout, salmon, and catfish using a urethral or urinary bladder catheters (Curtis and Wood, 1991; Black, 2000; McDonald et al., 2002). Many different types of catheters have been used to collect urine in fish. Black (2000) provides a concise summary of materials and techniques which have been developed. Nephrons from freshwater fish work to counteract hypervolemia and salt depletion by producing significant amounts of dilute urine. In freshwater fish, the urine volume ranges from 2 to 6 mL/kg/h (Greenwell et al., 2003).

10.3 PREANALYTICAL SOURCES OF VARIATION IN CLINICAL CHEMISTRIES

Preanalytical sources of variation have been reviewed in many fish species and numerous studies have shown that factors such as age, sex, strain, anticoagulants, anesthetics, environmental conditions, sampling technique, capturing method, analysis techniques, and diet can influence fish blood values (Groff and Zinkl, 1999; Hrubec and Smith, 1999; Sakomoto et al., 2001; Dutta et al., 2005; Asadi et al., 2006; Ramsay et al., 2006, 2009; Harper and Wolf, 2009; Cachat et al., 2010; Goncalves et al., 2012). Some parameters may be affected by multiple factors. For example, glucose values are sensitive to stress, bacterial infection, fish size, fish age, ambient temperatures, water temperature, oxygen levels, nutritional status, fasting, as well as the reproductive stage of the fish (Groff and Zinkl, 1999; Greenwell et al., 2003; Choi et al., 2008). Very little work has been done on assessing sources of variation affecting biochemical values in zebrafish or medaka. In zebrafish, fasting has been used as a research tool to evaluate its impact on behavior, fin regeneration, and gene expression (Novak et al., 2005; Goldsmith, 2006; Amole and Unniappan, 2009; Moss et al., 2009). One can hypothesize that many of the factors affecting blood chemistry in teleost fish also affect zebrafish.

10.3.1 PLASMA VERSUS SERUM

In mammals, the use of plasma or serum does not generate significant differences and both samples are interchangeable (NCCLS, 1990; Hrubec and Smith, 1999). This interchangeability does not seem to exist in fish, and in general, fish plasma is preferred over serum when evaluating clinical chemistry (Ellsaesser and Clem, 1987; Hrubec and Smith, 1999). One of the advantages of working with plasma rather than serum is that there is more yield with plasma, which is important when working with small blood volumes (Hrubec and Smith, 1999; Sakomoto et al., 2001).

Although, evaluating the similarities and differences between the use of plasma and serum on the effect on measured blood analytes has not been studied in zebrafish, it has been assessed in rainbow trout (*O. mykiss*), channel catfish (*I. punctatus*), hybrid tilapia (*Oreochromis* spp.), and hybrid striped bass (*Morone saxatilis*) (Hrubec and Smith, 1999). Findings in all species had significant differences between plasma and serum affecting potassium, magnesium, and phosphorus concentrations. Serum samples yielded lower potassium values and higher magnesium and phosphorus values compared to plasma samples (Hrubec and Smith, 1999). Glucose values in the rainbow trout, hybrid striped bass, and channel catfish were lower in the serum compared to plasma levels. Rainbow trout, channel catfish, and hybrid tilapia cholesterol levels were higher in the serum sample. It has been shown that the blood plasma calcium and magnesium concentrations are maintained within definite ranges in the common roach, a fish in the *Cyprinidae* family (Martem'yanov, 2001). The most likely difference between plasma and serum is during the clotting process where blood constituents are being metabolically utilized (Hrubec and Smith, 1999).

In fish, serum and plasma have many similarities; however, some of the major differences include that plasma contains clotting factors and an anticoagulant that are absent in serum (Hrubec and Smith, 1999). The metabolic mechanism for the differences between plasma and serum in fish is not known (Hrubec and Smith, 1999). In general, processes that can cause differences between plasma samples and serum sample include hemolysis and cellular metabolism affecting analyte levels due to uptake and release of various components in the blood (Hrubec and Smith, 1999).

10.3.2 COAGULATION AND ANTICOAGULANTS

The use of anticoagulants is recommended and many have been evaluated in fish. Examples include heparin, citrate, oxalate, and ethylenediamine tetraacetic acid (EDTA) (Axelsson and Fritsches, 1994; Groff and Zinkl, 1999; Jagadeeswaran et al., 1999; Murtha et al., 2003). Selection of the most appropriate anticoagulant in fish will vary depending on the purpose of the sample. Coagulation is less likely to occur when a plastic syringe is used as opposed to using a glass syringe (Houston, 1990).

Heparin is a commonly used anticoagulant in fish and it is available in different salt forms including sodium, calcium, ammonium, or lithium (Black, 2000). The effective concentrations range from 50 to 100 USP units/mL or 0.30–0.75 mg/mL of sample (Houston, 1990; Groff and Zinkl, 1999). The blood sample acid–base status is not affected by the use of heparin. When evaluating plasma electrolyte levels, sodium or potassium heparin is recommended (Groff and Zinkl, 1999). If calcium ions are being measured from plasma stored in heparin, the concentration should not exceed 100 USP units/mL (Axelsson and Fritsche, 1994; Black, 2000;). Due to low biological levels of lithium, some researchers prefer to use heparin lithium salt as opposed to the ammonium, calcium, sodium salt, which are readily available (Houston, 1990). When evaluating plasma electrolyte levels, sodium or potassium heparin is recommended as an anticoagulant (Groff and Zinkl, 1999). EDTA was the anticoagulant used and serum electrolytes are listed in Table 10.1 (Murtha et al., 2003).

Although heparin has been used as an anticoagulant in glucose studies in zebrafish (Eames et al., 2010), fluoride anticoagulant has been recommended for determining glucose levels in other fish if samples are not processed within 30 minutes of collection since fluoride slows down glycolysis

TABLE 10.1
Clinical Chemistry Data for Zebrafish

Strain	Nonspecified	
	Mean \pm SD	Range
Albumin (g/dL)	3.0 \pm 0.2	2.7–3.3
Alkaline phosphatase (IU/L)	2.0 \pm 4.5	0.0–10.0
Alanine aminotransferase (IU/L)	367.0 \pm 25.3	343.0–410.0
Amylase (IU/L)	2331.4 \pm 520.6	1898.0–3195.0
Total bilirubin (mg/dL)	0.38 \pm 0.1	0.2–0.6
BUN (mg/dL)	3.2 \pm 0.4	3.0–4.0
Calcium (mg/dL)	14.7 \pm 2.3	12.3–18.6
Phosphorus (mg/dL)	22.3 \pm 1.5	20.3–24.3
Creatinine (mg/dL)	0.7 \pm 0.2	0.5–0.9
Glucose (g/dL)	82.2 \pm 12.0	62.0–91.0
Potassium (mEq/L)	6.8 \pm 1.0	5.2–7.7
Total protein (g/dL)	5.2 \pm 0.5	4.4–5.8
Globulins (g/dL)	2.1 \pm 0.6	1.3–2.8

in blood. The disadvantage for using fluoride is that it can affect other enzymatic processes in the serum (Stoskopf, 1993). The recommended anticoagulant for evaluating enzymatic activities and electrolyte levels is ammonium heparin or lithium heparin (Stoskopf, 1993). EDTA should be avoided if the fish are being anesthetized or euthanized with MS-222 since it can often lead to hemolysis. Hemolysis affects clinical chemistry parameters, especially if coloremeteric tests are used to quantify blood parameters (Noga, 1996).

The use of EDTA or heparin can impact the potassium and sodium levels in serum and calcium levels in plasma. These changes occur due to the calcium binding activity of EDTA and due to the potassium and sodium salts found in this anticoagulant (Stoskopf, 1993). EDTA should not be used to determine the concentration of plasma calcium levels in fish (Groff and Zinkl, 1999). EDTA can alter blood–gas tension and can also decrease blood pH (Groff and Zinkl, 1999).

10.3.3 SEX AND AGE

Age-related changes in clinical chemistry has been reported in fish (Groff and Zinkl, 1999; Hrubec et al., 2001; Asadi et al., 2006). However, no publications were found pertaining to the impact of age or sex on the clinical chemistry of zebrafish or medaka. In carp and goldfish, values including glucose, serum amylase, chloride, creatinine, and total protein increase with age. Calcium and alkaline phosphatase levels decrease with age. Serum cholesterol, uric acid, and urea nitrogen decrease initially and then increase with age (Groff and Zinkl, 1999; Stoskopf, 1993). Asadi et al. (2006) have demonstrated that male sturgeons have higher glucose, albumin, globulin, and phosphorus levels as compared to females. In cyprinids such as koi and carp, males have lower plasma protein levels than females (Groff and Zinkl, 1999). In striped bass, clinical chemistry values were significantly different among age groups except for creatinine and potassium concentrations, and the changes reported were similar to those noted in mammals as well as rainbow trout (Hrubec et al., 2001).

10.3.4 DIET, FEEDING, FASTING, AND STARVATION

Dietary composition, insufficiency, or overabundance can impact the physiological parameters, growth, reproduction, and behavior in fish (Post, 1993; Stewart, 1993; NRC, 1999). Nutritional imbalances impact fish health, research, and can also affect blood chemistry parameters (Post, 1993; Stewart, 1993; Siccardi et al., 2009; Trenzado et al., 2009). Dietary requirements and formulations are not standardized in most fish species—most of the research has focused on important aquaculture or ornamental fish such as salmonids and cyprinids. Although zebrafish are currently one of the most important fish biomedical research models, the nutritional requirements for the different life stages of this species have not yet been established. This is unfortunate as the major food source of zebrafish is brine shrimp which has minimal nutritional value when it is fed as a food source without enrichment (Conklin, 2000; Astrofsky et al., 2002; Stoskopf, 2002). Furthermore, storage losses, bioavailability of nutrients, nutritional imbalances and potential contaminants, from both human and natural sources, which are known to affect the health, growth, and reproduction of fish are important factors that are not addressed within zebrafish research.

The clinical chemistry of carp and koi has been studied by comparing parameters from fish that were fed a reduced ration of food with fish that receive a complete ration of food (Groff and Zinkl, 1999). Parameters such as whole blood ammonia, lipids, plasma protein, and glucose differed between groups where fish receiving a complete ration had elevated glucose, lipid, whole blood ammonia, and plasma protein compared to the fish fed a smaller amount of food (Groff and Zinkl, 1999). Starvation can also lead to increased lipid levels (Groff and Zinkl, 1999). This information indicates that food ratio can impact some clinical chemistry parameters in fish.

10.3.5 STRESS

Many different stress factors are known to impact fish such as handling, housing density, capture, restraint, hypoxia, anesthesia, air exposure, disease, and sampling technique. All these factors may therefore impact fish clinical chemistry values (Mazeaud et al., 1977; Ellsaesser and Clem, 1987; Bullis, 1993; Groff and Zinkl, 1999; Bayne and Gerwick, 2001; Greenwell et al., 2003; Dror et al., 2006; Gbore et al., 2006; Ramsay et al., 2006, 2009; Fast et al., 2007; Scott and Ellis, 2007). There are three different phases that occur during a stress response in fish (Barton, 2002). The first phase is a generalized neuroendocrine response where catecholamines (epinephrine and norepinephrine) are released from the chromaffin cells and corticosteroids are released from the interrenal cells (Harrell and Moline, 1992). Increased circulating levels of these hormones trigger a secondary response that involves physiologic and metabolic pathways. Examples of the secondary response include hyperglycemia due to enhanced glycogenolysis and gluconeogenesis, vasodilation of arteries in gill filaments, increased cardiac stroke volume, increased urine production, and immune function depression (Gratzek and Reinert, 1984; Harrell and Moline, 1992; Greenwell et al., 2003). The first and second phases have been described as adaptive responses which enable the fish to adjust to the stress factors and maintain homeostasis. In contrast, the third phase can cause systemic changes which may no longer be able to adapt to stress. As a result, the overall health of the animals may be impacted to the extent that their performance, growth, reproduction, disease resistance, and behavior are adversely affected (Barton, 2002).

Bayne and Gerwick (2001) reviewed the acute phase response and innate immunity of fish and explained how tissue trauma and microbial pathogens change protein and macromolecule concentrations of the body fluids of different teleosts, leading to metabolic changes in several organ systems.

Stress-related diuresis can lead an electrolyte imbalance due to the loss of chloride and other ions in the urine (Greenwell et al., 2003). Stress in carp and goldfish causes decreases in sodium and lipid levels and increases in lactate, potassium, and glucose levels (Groff and Zinkl, 1999). Hyperglycemia can persist for 24–48 hours after the stress factor is removed (Chavin and Young,

1970; Groff and Zinkl, 1999). In contrast, chronic stress was shown to decrease glucose levels (Groff and Zinkl, 1999). Due to the increase in catecholamines that lead to vasoconstriction and hypertension, an increase in branchial perfusion and diuresis follows. The increase in branchial perfusion leads to increase in branchial permeability, causing hemodilution due to an increased water gain. This in turn leads to a loss of electrolytes, which decreases plasma osmolarity because of hyponatremia and hypochloremia (Groff and Zinkl, 1999). Hyponatremia and hypochloremia are exacerbated by diuresis (Mazeaud et al., 1977; Groff and Zinkl, 1999). The impact of stress can be minimized with the use of proper anesthetics and optimal research technique and handling.

Different studies have associated fish handling with an increase in plasma glucose and lactic acid as well as cortisol levels (Bullis, 1993; Fast et al., 2007). Clinical chemistry parameters that are affected by transport stress and handling in channel catfish include glucose, lactate dehydrogenase (LDH), and creatinine phosphokinase (Ellsaesser and Clem, 1987). Other serum chemistry variables that are affected by stress in fish include sodium, CO₂, urea nitrogen, direct bilirubin, cholesterol, creatinine, and protein levels (Ellsaesser and Clem, 1987). Acclimatization prior to sample collection is critical for establishing baseline values and minimizing blood chemistry variables (Torres et al., 1986; Ellsaesser and Clem, 1987; Bullis, 1993; Gravel and Vijayan, 2007).

Serial blood sampling is not recommended in fish due to the stress associated with handling fish and the impact on clinical chemistry results (Torres et al., 1986; Ellsaesser and Clem, 1987; Bullis, 1993; Groff and Zinkl, 1999; Gravel and Vijayan, 2007). The effects of stress on blood values in fish can be extensive and of long duration (Houston, 1990).

10.3.6 WATER CHEMISTRY

Water chemistry parameters have shown to influence urine and plasma composition in freshwater fish (Scherer et al., 1986; Stoskopf, 1993; Hrubec et al., 1997; Greenwell et al., 2003; Bolner and Baldisserotto, 2007).

The plasma NaCl in freshwater fish is hypertonic to the water environment. The approximate ratio is 150 mM to <1 mM (Greenwell et al., 2003). Their body fluids are hyperosmotic compared to the water and favor the influx of water across the gill epithelium. The amount of water influx across the gill can reach approximately 50% of the total body water per hour (Greenwell et al., 2003). Therefore, freshwater fish risk hypervolemia, overhydration, and salt depletion (Greenwell et al., 2003).

Bolner and Baldisserotto (2007) studies showed that water pH affects urinary excretion and plasma ion levels in silver catfish, *Rhamdia quelen*. Urine flow rate as well as urine and plasma pH increase with the increase of water pH. Urinary sodium excretion rate increases and ammonia urinary excretion rate decreases with elevated water pH (Bolner and Baldisserotto, 2007). Plasma ammonia levels decrease when fish are housed in water pH from 4.0 to 8.0. However, in water pH of 9.0 ammonia levels are elevated. The majority of the plasma ions and urinary excretion changes observed in silver catfish exposed to acidic or alkaline water were consistent with the results seen in rainbow trout *O. mykiss* (Bolner and Baldisserotto, 2007). In addition, the kidney and urinary bladder appears to contribute to acid–base balance in silver catfish, because urine pH changed according to plasma pH (Bolner and Baldisserotto, 2007).

Other changes include a decrease in serum sodium and chloride levels with an increase in cortisol levels when fish are placed in acidic environments (Scherer et al., 1986; Stoskopf, 1993). This leads to a shift where sodium reabsorption is decreased and magnesium is secreted as opposed to being reabsorbed in order to facilitate water excretion from the fish (Stoskopf, 1993).

A major source of calcium in teleost fish is either dietary or from the surrounding water. Changes in environmental calcium impact calcium uptake through the gills. In zebrafish and trout, changes in water calcium concentration have a direct impact on the fish's calcium regulation, and gene expression and protein levels are directly influenced (Radman et al., 2002; Craig et al., 2007).

Amino acid metabolism in teleosts generates nitrogenous waste which is excreted as ammonia and is associated with increased susceptibility to disease (Goncalves et al., 2012; Shih et al., 2008). The gills are the major site for eliminating ammonia in exchange for sodium (Shih, et al., 2008). Ammonia excretion through the gills is influenced by water pH and ammonia levels in the water, therefore affecting zebrafish physiology (Shih et al., 2008).

Ammonia ion is the primary constituent of blood ammonia levels, and toxicity levels in fish can be diagnosed when blood values range from 400 to 500 $\mu\text{g}/\text{dL}$ (Groff and Zinkl, 1999). In zebrafish larvae, ammonia is mainly excreted from the yolk sac epithelium (Shih et al., 2008). Elevated ammonia levels from water exposure in zebrafish affects gene expression, whole body cortisol levels, and suppresses the innate immune response (Goncalves et al., 2012).

Zebrafish are commonly acclimated in soft water prior to toxicology studies. Soft water is ion poor similar to reverse osmosis water. Exposing fish to soft water over a 7-day period affects their overall physiology by altering their osmoregulation due to remodeling of the zebrafish gills (Craig et al., 2007). The fish endocrine system may also be influenced by water parameter changes. For example, changes in salinity can upregulate or downregulate endocrine genes such as atrial natriuretic peptide, rennin, prolactin, growth hormone, and parathyroid hormone (Hoshijima and Hirose, 2007).

10.3.7 TEMPERATURE AND SEASONS

The effect of water temperature on physiological, hematological, and clinical chemistry parameters has been evaluated in many different fish species (Ellsaesser and Clem, 1987; Bullis, 1993; Roche and Boge, 1996; Hrubec et al., 1997; Cataldi et al., 1998; Groff and Zinkl, 1999; Little and Seebacher, 2015; Prassack et al., 2001; Sardella et al., 2004; Fiess et al., 2007; Choi et al., 2008). Biochemical parameters which seem to be affected in channel catfish due to seasonal temperature changes include potassium, magnesium, CO_2 , glucose, creatinine, albumin, iron, alkaline phosphatase, and glutamate-pyruvate transaminase (Ellsaesser and Clem, 1987). In zebrafish, most of the work has focused on studying the impact of temperature on cardiac activity, metabolism, and circadian rhythms (Jacob et al., 2002; López-Olmeda and Sánchez-Vázquez, 2009). To date, no reports assessed the impact of temperature variations on clinical chemistry of the zebrafish.

It is well established that temperature can affect the immune function and can lead to stress in fish (Stoskopf, 1993; Prophete et al., 2006; Choi et al., 2008). Fish can be stressed by elevated or low water temperatures as well as by rapid temperature fluctuations without acclimation. Rapid temperature decrease limits a fish's ability to produce antibodies integral to an immediate immune response, and a delay in the immune response may provide sufficient advantage for pathogens, enabling them to colonize, reproduce, and establish an infection (Dror et al., 2006). In cyprinids such as koi and carp, an increase in temperature can lead to altered clinical chemistry parameters such as a decrease in plasma sodium, plasma protein, and whole blood ammonia (Groff and Zinkl, 1999). Thermal stress in sea bass led to increases in plasma glucose (Roche and Boge, 1996).

Many different factors have been reported to affect plasma electrolytes in cyprinids (Houston, 1990; Groff and Zinkl, 1999). Examples include seasonal, diurnal, photoperiod variations as well as temperature cycles (Houston, 1990; Groff and Zinkl, 1999). Electrolytes that seem to be mostly affected include sodium and chloride; however, concentrations of potassium, magnesium, and free calcium seem to be less variable (Groff and Zinkl, 1999). Interestingly, although there are differences between goldfish and carp, they maintain a general overall pattern similar to cyprinids (Groff and Zinkl, 1999).

10.3.8 HYPOXIA

In aquatic environments, hypoxia can occur under different circumstances. Low oxygen levels are most commonly observed when fish are shipped in insufficiently aerated containers, or when

maintained in anoxic conditions where plant and algae overgrow in either natural or captive environments. A decrease in oxygen availability to tissues can lead to necrotic or apoptotic lesions in multiple organs (van der Meer et al., 2005). For example, channel catfish exposed to sublethal hypoxia led to histopathologically evident necrosis, hyperemia (vascular congestion), edema, hemorrhage, hyperplasia, and/or hypertrophy in a variety of anatomic sites including gills, liver, spleen, and anterior and posterior kidney (Scott and Rogers, 1980; Sollid et al., 2003; Almeida et al., 2017).

Certain animals such as some teleost fish, frogs, and insects have the capacity to tolerate or adapt to hypoxia (van der Meer et al., 2005). It has been shown that zebrafish can survive weeks of severe hypoxia as they develop adaptive responses which modulate their behavioral and physical phenotype (van der Meer et al., 2005). Evidence from cDNA microarray technology revealed that hypoxia was associated with changes in gene expression in the gills of zebrafish, in addition to gene repression that impacted protein biosynthesis and metabolic pathways (van der Meer et al., 2005). Chronic hypoxia has been shown to cause various changes in a diverse range of organ systems and fish species, including the hearts of zebrafish and cichlids (*Haplochromis piceatus*) (Marques et al., 2008); the reproductive tracts of Atlantic croaker (*Micropogonias undulatus*) (Thomas et al., 2007); and peripheral blood leukocytes of tilapia (Choi et al., 2008).

Clinical chemistry values of carp and goldfish are affected by hypoxia. Magnesium levels and whole blood ammonia levels are elevated and lipid levels are decreased in hypoxic carp and goldfish (Groff and Zinkl, 1999). Hypoxia increases plasma glucose levels in hypoglycemic fish as well as affects glucose uptake from various organs (MacCormack and Driedzic, 2006). Hypoxia in cyprinids leads to a reduction in glomerular filtration rate which leads to hyperkalemia, hypercalcemia, hypermagnesemia, and hyperphosphatemia (Groff and Zinkl, 1999). Although no published work evaluates the impact of hypoxia on clinical chemistry in zebrafish, work has shown that hypoxia in zebrafish alters gene expression and impacts physiology and cell expression in multiple organs (Roesner et al., 2006; Cossins et al., 2009; Martinovic et al., 2008).

Hypoxia and hypercapnia in fish may alter the distribution of the gill cells such as the pavement and chloride cells which impact the gas diffusion distance between the water and the blood affecting gas exchange and thus fish physiology (Evans et al., 2005). Also, changes in gill surface area can lead to physiological changes. For example, in trout, a 30% decrease in gill surface area led to a significant increase in PaCO₂, which limits O₂ uptake and CO₂ excretion (Evans et al., 2005).

10.3.9 ANESTHESIA

The impact of anesthetics on stress, physiology, plasma cortisol levels, and clinical chemistry parameters has been evaluated in fish, and indicate that there can be significant species differences when using anesthetics such as MS-222 (Houston et al., 1971; Groff and Zinkl, 1999; Small, 2004; King et al., 2005; Crosby et al., 2006; Palić et al., 2006). Physiological changes associated with MS-222 can last for several days after the fish have recovered (Houston et al., 1976; Houston and Woods, 1976; Groff and Zinkl, 1999). Acidosis, ionic imbalance, hemoconcentration, and changes in plasma chemistry parameters have all been reported in carp exposed to unbuffered MS-222 (Groff and Zinkl, 1999). These effects can be eliminated by buffering the water with sodium bicarbonate to neutralize the pH (Groff and Zinkl, 1999).

The use anesthetics while handling fish reduces stress levels and influences plasma cortisol levels (Crosby et al., 2006). For example, plasma cortisol levels increase in fathead minnow, sea bass, and catfish following exposure to stress while anesthetized with MS-222 (Small, 2004; King et al., 2005; Crosby et al., 2006; Palić et al., 2006). However, cortisol levels decrease in gourami exposed to stress while anesthetized with MS-222 (Crosby et al., 2006).

Other changes associated with the use of MS-222 include hypoxia, hypercapnia, hyperglycemia, and increased blood lactate levels (Burka et al., 1997; Houston et al., 1971).

10.3.10 HEMOLYSIS

Hemolysis can lead to inaccurate results in serum chemistry and interfere with colorimetric reactions. Hemolysis in fish can lead to increase in serum aspartate aminotransferase (AST), LDH, and potassium levels (Stoskopf, 1993). Hemolysis can be minimized if the samples are not exposed to moisture or water and by minimizing high-pressure transfer from the needle into the collecting tube (Stoskopf, 1993). The use of MS-222 sedation in conjunction with EDTA can lead to hemolysis (Noga, 1996). It has been reported in different fish species that hemolysis can be reduced if the blood is cooled down to 4°C (Noga, 1996; Groff and Zinkl, 1999). Hemolysis can be prevented by using a large needle, a small syringe and preventing negative pressure when removing the barrel of the needle (Houston, 1990). However, using a large needle size is not feasible when working with small fish. However, preventing the introduction of air in the blood when the sample is collected can minimize the risk of hemolysis.

10.3.11 SAMPLING SITE

Sampling technique can impact serum chemistry (Groff and Zinkl, 1999; Bullis, 1993). There is a difference between blood values depending on whether the blood is collected by cardiocentesis or by severing the caudal peduncle. Muscle damage during sample collection can lead to an increase in creatine kinase (CK) and LDH (Groff and Zinkl, 1999). Samples collected from the caudal vein by severing the caudal peduncle in carp lead to higher levels of alanine aminotransferase (ALT), LDH, creatinine, and phosphorus compared to samples collected by cardiocentesis (Ikeda and Ozaki, 1981; Stoskopf, 1993). Another study working with juvenile salmon found that ALT, LDH, AST, CK, triglyceride, and potassium (K⁺) were increased when the caudal peduncle was severed compared to cardiocentesis and caudal venipuncture (Congleton and LaVoie, 2001). Na⁺ and Cl⁻ levels were decreased relative to values for samples obtained by caudal vessel puncture. Some enzyme activities (ALT, AST, LDH) and K⁺ concentrations were also greater in samples taken by heart puncture than in samples taken by caudal vessel puncture. Of the methods evaluated, caudal vessel puncture had the least effect on blood chemistry values and was the preferred method for blood chemistry studies on juvenile salmonids (Congleton and LaVoie, 2001).

11.1 INTRODUCTION

The liver is responsible for many vital physiologic functions essential for the maintenance of normal homeostatic mechanisms. It has a remarkable capacity for storage, synthesis, and regulation of a wide variety of substances. In addition, the liver has substantial functional reserve and regenerative capabilities. Because of its important role in preservation of a biologic system, it is prone to injury from a wide variety of toxic, infectious, and metabolic disturbances. The changes in liver functional capacity or detection of disease or injury can be determined using laboratory tests. This review is designed for highlighting the major functions of the liver and the clinical chemistry endpoints/parameters used for detecting the liver pathology and/or functional capabilities.

11.1.1 HEPATIC MICROANATOMY

The microscopic structure of the tissues and organization of the liver has been reviewed (Krishna, 2013). Hepatocytes are the principle cell type of the liver and constitute at least 70% of its total volume (Tennant, 1997). Hepatocytes are polar epithelial cells and, like other epithelial cells, have an apical and basolateral surface. The basal surface of the hepatocyte meets the space of Disse (SD). The SD is separated from the blood-filled hepatic sinusoid by a lining of endothelial cells and Kupffer cells, and Figure 11.1 is a schematic presentation of the liver microscopic architecture and demonstrates the arrangement of hepatocytes to the sinusoids. Kupffer cells of the monocyte–phagocyte system are attached to the luminal face of the endothelial cells (Crawford, 1999). The sinusoidal domain is equivalent to the basolateral domain of other epithelial cells. Hepatic sinusoids differ from capillaries. In this case, the hepatocytes do not rest on a conventional basement membrane, however, are separated from endothelial cells by the SD. Substances released from the hepatocyte to the sinusoids should cross the SD and endothelial cells to gain access to the blood (Solter, 2005). This is facilitated by fenestrations in the sinusoidal lining endothelial cells. These fenestrations are attenuations of the endothelial cells whose structures can be altered by blood pressure, vasoactive substances, toxins, or xenobiotics (Wisse, 1970; Solter, 2005). The SD and endothelial cells do not pose great impedance to the passage of solubilized hepatic enzymes. It is the endothelial cell fenestrations that are important for the regulation of passage of large proteins, such as liver enzymes, and cells (Solter, 2005). Measurement of hepatocellular enzyme activities in the blood remains one of the most useful methods for detecting and monitoring liver pathology.

In the apical portion of the hepatocytes and between adjacent hepatocytes, the biliary system starts as the bile canaliculi (Nathanson and Boyer, 1991; Crawford, 1999). The bile canaliculi are 1–2 μm in diameter formed by grooves in the plasma membrane of facing hepatocytes (Figure 11.1). These canaliculi are demarcated from the vascular space on the basolateral side of the hepatocyte by tight junctions. The tight junctions prevent movement of substances between the bile and blood. Bile flow is facilitated by intracellular actin and myosin filaments whose pulsatile contractions propel the bile through the biliary network (Watanabe et al., 1991; Crawford, 1999). Hepatic bile formation serves two main functions: (1) promotion of dietary fat absorption in gut lumen and (2) elimination

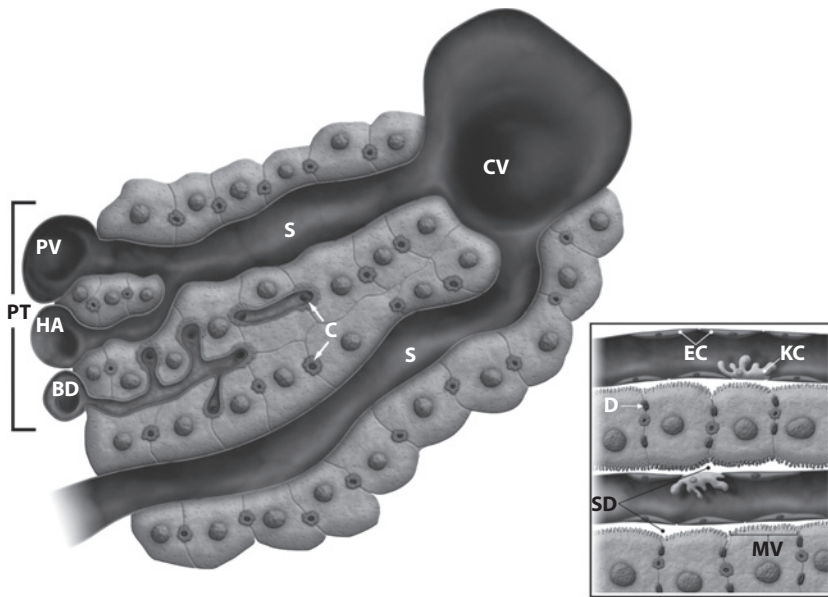

FIGURE 11.1 (See color insert.) Schematic presentation of the liver microanatomy. Hepatic sinusoids (S) are surrounded by one to two layers of cords of hepatocytes. The portal veins (PV), hepatic arterioles (HA), and bile ductules (BD) comprise the portal triad (PT). Blood flows from the portal triad (PV and HA) through the sinusoids to the central vein (CV). Bile flows from the bile canaliculi (C) to the BD of the PT. The inset depicts a close up of the sinusoids lined by fenestrated endothelia (EC) and Kupffer cells (KC). A perisinusoidal space (aka, space of Disse [SD]) is located between the hepatocytes and sinusoids. The basolateral hepatocyte surface has microvilli (MV) that extend into the SD that allows plasma components from the sinusoids to be absorbed by the hepatocytes. Bile canaliculi are formed on the lateral surface of adjacent hepatocytes and the hepatocytes attach to their neighbors with specialized junctions (desmosome; D). Original concept by Chuck Wiedemeyer and Greg Travlos; drawing by David Sabio.

of waste products (Crawford, 1999). Bile flow is the primary method for the elimination of bilirubin, excess cholesterol, and xenobiotics from the liver (Crawford, 1999). Because excretion of bile is one of the main functions of the liver, it is prone to disruption by a variety of hepatic insults. While decreased bile flow, known as cholestasis, can occur as a result of hepatocellular dysfunction, physical obstruction, or other pathologic processes, the exact mechanisms by which biliary constituents enter the blood from the bile are unknown (Solter, 2005). Several laboratory and clinical methods designed for detecting decreases in the bile flow (i.e., cholestasis) will be discussed later in this chapter.

11.1.2 HEPATIC FUNCTION

The liver has many diverse and important physiologic functions. In general, these functions involve storage, synthesis/metabolism, and excretion/transport. The liver plays a large role in the synthesis and metabolism of a wide variety of endogenous and exogenous substances.

11.1.2.1 Protein Synthesis

Hepatocytes are responsible for the synthesis of most plasma proteins including albumin. Albumin is synthesized exclusively in the liver and degradation of albumin occurs in the liver as well as other tissues, including muscle, kidney, and skin (Tennant, 1997; McCuskey, 2006). Degradation of albumin is probably favored in the liver owing to the fenestrated endothelial lining cells that allow access to almost all plasma proteins directly to the SD and to the sinusoidal surface of the hepatocyte under

normal physiologic conditions (Tennant and Center, 2008). The plasma albumin concentration is determined by the hepatic synthetic rate that is normally in equilibrium with degradation. Besides albumin synthesis, the liver is the exclusive site of synthesis of most blood coagulation proteins and most globulins (except immunoglobulins) (Tennant, 1997; McCuskey, 2006; Stockham, 2008). Most protein synthesis is *de novo* from essential dietary amino acids or nonessential amino acids produced by hepatocytes (Stockham, 2008).

11.1.2.2 Carbohydrate Metabolism

An important function of the liver is maintaining blood glucose levels. Through several biochemical pathways and with hormonal influence (e.g., insulin, glucagon), the liver is capable of storing or metabolizing glucose. The liver stores glucose in the form of glycogen and can metabolize the glycogen through glycogenolysis in order to maintain blood glucose levels (Voet D, 1990; McCuskey, 2006). Hepatocytes are also capable of synthesizing glucose from other sugars such as fructose and from amino acids (gluconeogenesis) (McCuskey, 2006).

11.1.2.3 Lipid Metabolism

The hepatocytes are responsible for the synthesis of triglycerides, cholesterol, and fatty acids (Stockham, 2008). The hepatocytes are also important in the production and metabolism of plasma lipoproteins (McCuskey, 2006). The liver is the major source of lipoproteins, excluding chylomicrons, which are synthesized in the intestine. The hepatocytes degrade chylomicrons from the systemic and portal blood and remove remnants of lipoproteins from the systemic blood (Stockham, 2008).

11.1.2.4 Detoxification/Bioactivation

Hepatocytes can detoxify, bioactivate, modify, and degrade a wide range of toxic endogenous and exogenous metabolic byproducts through multiple biochemical processes. Hepatocytes have high constitutive activities of phase I enzymes that convert xenobiotics to reactive electrophilic metabolites (Bishoff, 2007). In addition, hepatocytes have phase II enzymes that are capable of yielding a stable, nonreactive metabolite from the xenobiotic. Many compounds are bioactivated or detoxified by this process (Bishoff, 2007). Endogenous byproducts include uric acid, ammonium from protein catabolism, steroid hormones, and hemoglobin (Stockham, 2008). The role of the liver in activation and detoxification of xenobiotics is of great importance when new compounds are being studied (Cattley and Popp, 2002). The complete cellular mechanisms responsible for detoxification or bioactivation of particular compounds are beyond the scope of this chapter and readers are referred to basic toxicologic and hepatology texts.

11.1.2.5 Storage

Besides storing glycogen, as stated previously, the liver is capable of storing triglycerides and elements such as copper and iron and vitamins (Bishoff, 2007; Stockham, 2008).

11.1.2.6 Excretory

Bile is one of the main substances excreted by the liver and one of its major functions (Pineiro-Carrero and Pineiro, 2004). Bile is produced primarily in the hepatocytes and the composition of the bile is modified in the bile ducts (McCuskey, 2006). The hepatocytes synthesize bile acids from cholesterol for excretion in the bile. Bile is composed of bile salts, bilirubin, glutathione (GSH), phospholipids, cholesterol, proteins, organic anions, metals, and conjugated xenobiotics (Pineiro-Carrero and Pineiro, 2004). Bile serves two different but important functions. First, it is one of the primary routes for excretion of many endogenous and exogenous compounds such as drugs, toxins, and waste products. Second, it supplies bile salts to the intestine for emulsification and subsequent digestion and absorption of dietary lipids (McCuskey, 2006).

11.1.2.7 Mononuclear Phagocytic System

Important non-parenchyma cells within the liver are Kupffer cells. Kupffer cells constitute the largest population of fixed macrophages in most vertebrates (McCuskey, 2006). These cells are part of the mononuclear phagocytic system in the liver and have a wide array of functions. Kupffer cells are responsible for filtering the blood, both systemic and portal, of toxicants (such as endotoxins), damaged cells, organisms, and inflammatory mediators (McCuskey, 2006; Stockham, 2008). In addition, once activated, Kupffer cells secrete a variety of mediators (e.g., reactive oxygen species, nitric oxide, eicosanoids, as well as a myriad of cytokines, including TNF-alpha, IL1, IL6, and others) that affect the function of surrounding cells and produce substances that contribute to host defense (McCuskey, 2006).

11.2 HEPATIC ENZYMES

11.2.1 INTRODUCTION

Activities of liver enzymes in the plasma or serum are used primarily to identify cholestasis or injury to the hepatocyte (Hall and Nancy, 2008; Ennulat et al., 2010a, b). Often referred to as, “liver function tests,” serum or plasma activities of liver enzymes do not provide specific information about liver function. The liver can be markedly dysfunctional without the evidence of increased liver enzyme activity in the plasma. An example would be an animal with liver cirrhosis. An animal with this condition can have severe loss of liver function with concurrent plasma liver enzyme activities within reference intervals. Alternatively, an animal may exhibit very high liver enzyme elevations but still have fully functional hepatic capacity. The reader is referred to Section 11.3.5 for further information.

The degree of liver enzyme activity in serum or plasma is dependent on multiple factors. Most increases in serum liver enzyme activity are caused by increased quantities of the enzymes released into the blood either by leakage from damaged cells or from increased production and release of that enzyme (Thrall, 2004). Other factors that must be considered when interpreting serum liver enzyme activities include liver specificity, intrahepatic, and cellular location of the enzyme, serum half-life, *in vitro* stability, and assay system used for measurement (Hall and Nancy, 2008).

Serum activity of several “liver specific” enzymes is used for detecting and monitoring liver pathology. What makes an enzyme “liver specific” is dependent on the presence of that enzyme in the liver, the concentration of that enzyme in the liver, and the method of release. For example, in dogs, serum alanine aminotransferase (ALT) is a sensitive indicator of hepatocellular damage or leakage because of its high concentrations in hepatocytes (Hoffmann et al., 1999). However, in guinea pigs and large species (e.g., cow and horse) ALT activity in the liver is quite low thus, insensitive indicator of liver damage in those species (Clampitt and Hart, 1978). In addition, the magnitude of increase of a “liver specific” enzyme in serum may not always be a reflection of the quantity of the enzyme in the tissue from which it is derived. The magnitude and rate of enzyme release from the tissue of origin into blood and its subsequent clearance must be considered (Hoffmann et al., 1999; Thrall, 2004). Those tissues with greater concentrations of an enzyme are more likely to contribute more to the serum than those with little or no concentration of that enzyme. However, the magnitude of increase of an enzyme in serum may not entirely reflect the quantity of the enzyme in the tissue from which it is derived. For example, serum γ -glutamyltranspeptidase (GGT) activity can be markedly increased with cholestatic liver disease. However, the greatest concentrations of GGT in the body are found in the kidney and virtually never increased in renal disease (Clampitt and Hart, 1978; Hoffmann et al., 1999; Hall and Nancy, 2008). GGT can be released from damaged tubular epithelial cells but the released enzyme leaks into the urine rather than the serum (Hall and Nancy, 2008).

Another consideration to serum activities of liver enzymes is the normal cellular location of the enzyme within the cell and the mechanisms by which it is released from the damaged cell during a pathologic state. Enzymes that reside within the cytoplasm can be released directly into the

blood through compromised cell membranes of damaged or cells going through necrosis or may be released from viable cells by through blebs that release from the membrane (Gores et al., 1990). Some enzymes whose primary location is in the cytoplasm and tissue of origin does not have direct accessibility to the bloodstream may be released first into interstitial fluid and travel through the lymphatics to the bloodstream. Other enzymes such as GGT, which resides on the cell membrane of the biliary epithelial cells and proximal tubular epithelial cells of kidney do not have direct access to the bloodstream and may be lost in bile or urine.

The effects of drugs, endogenous hormones, or changes in physiology may also play an important role in the serum activity of various enzymes in health and disease. For example, serum and tissue activities of alkaline phosphatase (ALP) isoenzymes can increase in dogs when given exogenous glucocorticoids or under conditions of significantly increased endogenous glucocorticoids (e.g., cortisol) (Hoffmann and Dorner, 1975; Hoffmann, 1976; Wiedmeyer et al., 2002a). Furthermore, the performance of hepatobiliary enzyme biomarkers (including ALT, aspartate aminotransferase (AST), ALP, and GGT) related to drug-induced liver injury has been examined (Ennulat et al., 2010a, b).

Other factors that affect serum liver enzyme activity are rate of clearance (or half-life [$T_{1/2}$]) of the enzyme and different isoforms/isoenzymes that can be found in the serum or plasma of a particular enzyme. The $T_{1/2}$ of an enzyme is important in determining the magnitude and persistence of the enzyme increase. Both $T_{1/2}$ and the different isoforms/isoenzymes found in the serum or plasma will ultimately affect the diagnostic and prognostic value of that enzyme increase. The $T_{1/2}$ of liver enzymes varies from minutes to days depending on the enzyme, the species, and the tissue source. For example, intestinal ALP in dogs is cleared from the blood rapidly ($T_{1/2} < 6$ min) thus offering very little diagnostic information (Hoffmann and Dorner, 1977). However, in rats, intestinal ALP has a longer $T_{1/2}$ thus making it the predominant ALP isoenzyme in serum (Young et al., 1981). Another liver enzyme, sorbitol dehydrogenase (SDH), is cleared quite rapidly from the blood yet remains in blood long enough to allow for detection of acute hepatocellular damage (Hoffmann et al., 1999). Other enzymes such as ALT, with a $T_{1/2}$ in the order of days rather than minutes or hours, offers diagnostic value during and after the initial tissue insult (Ramaiah, 2007; Ozer et al., 2008).

Some liver enzymes exist in plasma in different forms called isoenzymes. These enzymes have identical catalytic activity, however, are produced by different tissues. While commonly referred to as isoenzymes, the term isoform is occasionally used. If different forms of a particular enzyme exist from one gene product, they are referred to as isoforms. Isoenzymes arise from different gene products. For example, the liver, bone, and kidney forms of ALP originate from the same gene (i.e., the tissue nonspecific ALP gene). These isoforms differ only in degree of glycosylation of the core protein. The intestinal ALP form originates from the intestinal ALP gene, and it is considered an isoenzyme when compared to the liver, bone, and kidney forms. Regardless, the isoforms and isoenzymes of ALP have the same fundamental catalytic abilities. Other examples of enzymes that exist as isoenzymes are ALT and lactate dehydrogenase (LDH) (Hoffmann et al., 1999). Although the isoenzymes have the same catalytic abilities, they may or may not differ in $T_{1/2}$. This difference in $T_{1/2}$ usually determines the clinical utility of the isoenzyme.

11.2.2 HEPATOCELLULAR LEAKAGE ENZYMES

11.2.2.1 Alanine Aminotransferase

ALT, formerly known as serum glutamic pyruvic transaminase (SGPT) catalyzes the reductive transfer of amino groups from alanine to α -ketoglutarate to yield glutamate and pyruvate (Hoffmann et al., 1999; Ozer et al., 2008). Enzyme activity can be found in many tissues but the greatest concentration is found within the hepatocyte cytosol (Boyd, 1983; Amacher, 1998). In general, ALT is the most useful enzyme for the detection of hepatocellular necrosis in many species and is the most relied upon liver enzyme to indicate hepatotoxic effects (Amacher, 1998, 2002). However, serum ALT activity is of little value in the large domestic animals (pig, horse, cow, and sheep) and guinea

pigs owing to relatively low hepatocyte concentrations (Clampitt and Hart, 1978). In marmosets, the liver has the highest activity of ALT; cardiac muscle and kidney also had substantial amounts (Mohr et al., 1971).

Both soluble (i.e., cytoplasmic) and mitochondrial isoenzymes of ALT exist. The soluble cytosolic and mitochondrial isoenzymes have been separated by isoelectric focusing (Ruscak et al., 1982). The isoelectric point of the soluble enzyme from rat, guinea pig, human liver, and rat and pig kidney differ dramatically from the mitochondrial ALT from the same organ. Additional differences in the physicochemical and kinetic properties of the two isoenzymes have been reported, which indicate that ALT from mitochondria and cytoplasm are two different proteins (DeRosa and Swick, 1975). The similarity of the cytoplasmic enzyme obtained from different organs indicates that the isoenzymes have no organ specificity but rather are specific for the cell compartment from which they are derived. The differentiation between these isoenzymes may therefore be useful in determination of mechanism of cellular injury.

11.2.2.1.1 *Isoenzymes*

Two ALT isoforms (ALT1 and ALT2) have been identified in humans, mice, rats, and dogs (Yang et al., 2002; Jadhao et al., 2004; Rajamohan et al., 2006). In humans, ALT1 is mainly expressed in kidney, liver, fat, and cardiac tissues and ALT2 is the predominant form in muscle and fat (Yang et al., 2002). It appears the isoforms are conserved across species and display similar tissue distribution. The mouse ALT isoenzymes, ALT1 and ALT2, are highly homologous to the human proteins and show similar tissue distribution (Jadhao et al., 2004). In mice, ALT2 has been proposed as a marker of hepatic steatosis (Jadhao et al., 2004). A novel immunoassay capable of discriminating human ALT1 and ALT2 activities has been developed (Lindblom et al., 2007). To date, assays that discriminate between the different isoforms are not widely available for use in laboratory animals. In the future, ALT isoform specific assays may add information to serum ALT activities and organ specific pathology.

11.2.2.1.2 *Causes of Increased Serum ALT Activity*

11.2.2.1.2.1 *Hepatocellular Damage* By far the main cause for an increase in serum ALT activity is damage to hepatocytes. In fact, increase in serum ALT activity is considered the gold standard clinical chemistry marker for liver injury (Ramaiah, 2007; Ozer et al., 2008). Hepatocyte injury can be caused by a variety of insults such as inflammation, toxicity, hypoxia, or trauma (Stockham, 2008). As stated previously, the largest pool of ALT activity in most species is found within the cytosol of hepatocytes (Clampitt and Hart, 1978; Boyd, 1983). Therefore, simple leakage of cytosolic ALT from compromised hepatocyte membranes or overt hepatocyte necrosis can result in increases in serum ALT activity. Besides leakage and cell necrosis, other mechanisms responsible for the appearance of ALT in the serum have been well described such as induction and cytoplasmic blebbing (Gores et al., 1990; Solter et al., 1994; Solter, 2005). Cytoplasmic blebs are reported to detach from the damaged hepatocyte and allow the cell membrane to reseal without cell death (Lemasters et al., 1983; Gores et al., 1990; Kristensen, 1994). Cell membrane bleb formation has been described in hepatocytes following hypoxic events (Gores et al., 1990; Kristensen, 1994). After detachment, the cytoplasmic blebs reportedly rupture within the SD releasing ALT into the sinusoid (Kristensen, 1994; Solter, 2005). Regardless of the mechanism involved with enzyme release, the magnitude of serum ALT activity is typically proportional to the number of affected hepatocytes damaged (Hall and Nancy, 2008). The greatest elevations result from severe lesions affecting a large portion of the liver. Despite this observation, increases in serum ALT activity have been noted without evidence of histopathologic changes to the liver (Van Vleet and Alberts, 1968; Ozer et al., 2008). The causes for increased serum ALT activity without correlating histopathologic liver lesions may be related to enzyme induction by the particular xenobiotic being studied (Pappas, 1986). Finally, increased serum ALT can be observed with biliary disease or bile duct obstruction

(Hall and Nancy, 2008). Theoretically, the increase in ALT is due in part to the effects of retained bile salts on the hepatic cell membranes and leakage of cytosolic enzymes.

11.2.2.1.2.2 Muscle Damage Besides liver, which has the greatest activity of ALT on a per gram basis in most species, heart, and skeletal muscle have been shown to have significant ALT activity (Clampitt and Hart, 1978). Therefore, muscle damage, when severe and diffuse, can result in increased serum ALT activity in the absence of hepatocellular damage (Watkins et al., 1989; Valentine et al., 1990a; Swenson and Graves, 1997). For example, dogs in a colony with canine X-linked muscular dystrophy and ongoing muscle necrosis all had increased serum ALT activity with no biochemical evidence of hepatocellular damage (Valentine et al., 1990b). Both of these observations support the conclusion that ALT is not truly liver specific and that severe muscle necrosis can contribute to serum ALT activity.

11.2.2.1.2.3 Drug Induction There are numerous drugs that cause hepatocellular damage and release of ALT into serum and the effects of xenobiotics causing liver damage, which are closely monitored through measurement of serum ALT activity. However, there are drugs that cause alterations in ALT activity in liver and/or serum without causing hepatocellular damage. Glucocorticoids have been the most often studied class of drug with regard to induction of ALT, causing an increase in ALT in rat liver tissue following treatment (Rosen et al., 1959a, b; Patnaik and Kanungo, 1977). There is general agreement that glucocorticoids induce the cytoplasmic isoenzyme of ALT. In dogs, increases in serum ALT activity following glucocorticoid administration are commonly observed (DeNovo and Prasse, 1983; Solter et al., 1994). Other studies have shown an association between drugs (e.g., anticonvulsants) and toxins and increases in serum ALT activity due in part to increase in intracellular activity (Solter, 2005; Hall and Nancy, 2008). The increases of ALT activity in the serum from these various compounds is believed to be from *de novo* ALT synthesis but a damaging effect to the hepatocytes could not be ruled out. Finally, low protein diets have been shown to increase serum ALT activity, and the cause is unclear (Rao, 1996).

11.2.2.1.3 Causes of Decreased Serum Alt Activity

Typically, decreases in the serum activity of ALT are insignificant and noted infrequently in toxicologic studies. There have been reports of compounds causing decreased in the liver and serum activities of ALT. It has been reported that microcystin-LR administration can result in significant inhibition of the ALT protein in the liver (Solter, 2000). Moreover, it has been shown that vitamin B6 deficiency can lead to artifactual decreased serum transaminase activity (Ono et al., 1995). In addition, cefazolin treatment of rats results in lowered serum ALT activity, which is associated with lowered ALT activity in the liver, brain, and kidney (Dhami et al., 1979).

11.2.2.1.4 Other Influencing Factors

In monkeys, the use of ALT as a marker of hepatocellular damage can be complicated by the presence of subclinical, enzootic hepatitis A infection (Slighter, 1988). The increase in serum ALT activity appears to be transient and occurs concurrently with seroconversion to the virus. Serum values of up to 300 U/L can be observed in individual monkeys from this phenomenon (Slighter, 1988). Imported cynomolgus monkeys (*Macaca fascicularis*) have displayed increases in serum ALT activities but the cause is unknown (Yoshida, 1981). In addition, multiple administrations of sevoflurane, a rapid-acting halogenated ether, has been shown to increased serum ALT activity in a dose-related manner (Soma et al., 1995). Increases in serum ALT activity in individual mice have been observed including control animals. The cause for sporadically high serum ALT levels in individual mice is suspected to be from physical damage to the liver during handling (Swaim et al., 1985). These spurious findings of high serum ALT activity in mice may complicate interpretation of results of toxicologic studies.

11.2.2.2 Aspartate Aminotransferase

AST, formerly known as serum glutamic oxaloacetic transaminase (SGOT) catalyzes the transamination of L-aspartate and 2-oxoglutarate to oxaloacetate and glutamate (Hoffmann, 2008). AST plays a role in amino acid synthesis and degradation, gluconeogenesis, and serves as a link between the urea and tricarboxylic acid cycles. AST activity is found primarily in heart, skeletal muscle, and liver (Ozer et al., 2008). In rats and marmosets, AST activity can be found in the brain comparable to activity found in the muscle (Mohr et al., 1971; Boyd, 1983). Other soft tissue organs such as kidney and intestine have less AST activity in nearly all laboratory species. Within the cell, AST activity can be found in the cytosol and mitochondria (Ramaiah, 2007; Ozer et al., 2008). In rat hepatocytes, 81%–85% of the total AST activity is found in mitochondria and 15%–19% in cytoplasm (Pappas, 1980, 1986). Nearly 30%–40% of canine liver AST activity is of mitochondrial origin (Keller, 1981). In serum from normal rats, cytoplasmic AST activity accounts for approximately 82% of the total AST activity, and mitochondrial AST activity for approximately 18% (Pappas, 1986). The use of AST activity as a diagnostic enzyme was first reported in 1954–1955, when increases in serum AST activity were described in people with myocardial infarction and viral hepatitis (Keil, 1990; Hoffmann et al., 1999). The lack of organ specificity of AST activity limits its usefulness in diagnostic medicine, but when used in conjunction with other enzymes, it has clinical utility.

11.2.2.2.1 Isoenzymes

The cytoplasmic and mitochondrial isoenzymes of AST are the products of different genes and are therefore separable by immunologic means (Rej, 1980; Pappas, 1986). Both cytoplasmic and mitochondrial AST activity increase significantly until adulthood (Patnaik et al., 1987).

11.2.2.2.2 Causes of Increased Serum AST Activity

11.2.2.2.2.1 Hepatocellular Damage AST activity in serum can increase with hepatocellular damage or leakage from many of the same etiologies as noted with increased ALT (i.e., inflammation, toxicity, hypoxia, or trauma). Increased serum AST activity with liver disease is due to necrosis of hepatocytes and the release of cytoplasmic and mitochondrial AST into lymph and blood (Hoffmann et al., 1999). It has been suggested that because the greatest activity for AST is found in the mitochondria in rats, more severe liver necrosis is necessary for serum AST activity increases when compared to ALT (Ramaiah, 2007). Leakage of AST through the cell and mitochondrial membranes has long been suggested as the mechanism of appearance in blood. However, like ALT, membrane injury sufficiently severe to allow the leakage of proteins from viable cells would surely disrupt cellular electrolyte balance and lead to cell death. The alternative to leakage of enzyme is the formation of cytoplasmic blebs, like ALT (Gores et al., 1990; Solter, 2005). Release of AST into the serum from hepatocytes may also occur during reparative processes of liver disease (Stockham, 2008).

11.2.2.2.2.2 Muscle Damage Because of the high concentration of AST in the skeletal and cardiac muscle, a variety of insults to the muscle can result in increased serum AST levels. General etiologic categories include trauma, degenerative changes as a result of hypoxia, metabolic, neoplastic, nutritional, inherited, or inflammatory insults. In short, many of the same etiologies that can result in an increase in ALT serum activity can cause an increase in serum AST.

11.2.2.2.2.3 Other Causes *In vitro* hemolysis or delayed removal of serum from a clotted sample may result in mild to moderate increases in AST activity (Stockham, 2008). It has been shown that adrenalectomy can result in decreases in hepatic AST activity and hydrocortisone administration increases the hepatic cytoplasmic AST activity in rats (Patnaik et al., 1987). Treatment of rats with glucocorticoids increases cytosolic AST mRNA and activity but has no effect on mitochondrial AST (Pave-Preux et al., 1988). Cytosolic AST activity and mRNA have shown increases of

approximately twofold with no change in mitochondrial AST in rats fed high-protein diets (Horio et al., 1988a). Likewise, an increase in liver cytoplasmic AST activity and mRNA were observed following both feeding of a high-protein diet and glucagon injections with no increase in mitochondrial AST or AST in skeletal muscle and kidney (Horio et al., 1988b). Fasting of rats for 16 hours can result in mild increases in serum AST activity (Matsuzawa, 1994).

11.2.2.2.3 *Causes of Decreased Serum AST Activity*

Like ALT, decreases in AST are usually rarely observed and most likely insignificant.

11.2.2.3 Sorbitol Dehydrogenase

SDH, also known as iditol dehydrogenase, catalyzes a reversible reaction involving conversion of fructose to sorbitol. SDH is a cytosolic enzyme in all cells with the highest concentration of activity on a per gram basis is found in the liver followed by the kidney (Boyd, 1983). SDH mRNA has been detected in all tissues except the small intestine in the rat, with highest concentrations found in the testis, liver, and kidney (Estonius et al., 1993; Lee et al., 1995). Measurement of serum SDH is particularly useful in species whereby serum ALT activity is not liver specific, such as in swine or guinea pigs (Hoffmann et al., 1999). Serum SDH activity has also been demonstrated to be useful in the detection of chemical-induced liver damage in fish (Dixon et al., 1987; Webb and Gagnon, 2007). In rats, plasma SDH activity has demonstrated seasonal variations (Petrovich et al., 2007). Furthermore, excessive dietary intake of the sugar substitute sorbitol induced increased activity of SDH in the liver and plasma (Petrovich et al., 2007). In dogs, serum SDH activity can be used in combination with ALT activity to determine if there is persistent hepatic injury. If serum SDH activity is not increased while ALT activity is markedly increased, it suggests that ongoing liver insult is present (Hoffmann, 2008). This is related to the short $T_{1/2}$ of SDH compared to ALT but proper interpretation of this type of change requires repeated monitoring.

11.2.2.3.1 *Isoenzymes*

Isoenzymes of SDH have not been described.

11.2.2.3.2 *Causes of Increased Serum SDH Activity*

Increases in serum SDH are always related to hepatocellular injury. Administration of certain compounds that cause hepatocellular necrosis results in increased serum SDH activity in a dose-related manner (Blazka et al., 1996; Brondeau et al., 1986; Carakostas et al., 1986; Rikans and Moore, 1988). Because of the short half-life (less than 12 hours in most species), increased serum SDH activity appears early in the course of toxicity and usually returns to baseline levels in a matter of days, depending on the magnitude of the SDH activity increase, the persistence of the toxicity, and the species affected (Hoffmann, 2008). In dogs, SDH activity is less favored for detection of hepatocellular damage than ALT. However, it may be useful in determining if there concurrent hepatocellular damage in cases of traumatic muscle injury where there is also increased serum ALT activity (Hoffmann, 2008). Moreover, the SDH activity measurement in conjunction with ALT may be useful in dogs when attempting to determine if there persists hepatocellular damage. If ALT is markedly increased and SDH activity is not, recovery is likely (Hoffmann, 2008). In mice exposed to certain hepatotoxins, ALT and SDH activities first increase then decrease in parallel (Chapman et al., 1988; Blazka et al., 1996). A review of the results of several toxicologic studies performed in rats found an association between increased ALT and SDH activity and histopathological changes, with SDH activity showing greater positive and negative predictive value than ALT (Travlos et al., 1996). It was found that the SDH activity predicted morphological hepatic change with 75% accuracy. Combining the results of serum SDH activity with ALT activity increased diagnostic accuracy to 100% by 2–3 weeks in repeated dose studies. Nephrotoxicity has not been shown to be a cause for increased serum SDH.

11.2.2.3.3 *Causes for Decreased Serum SDH Activity*

Decreases in SDH activity may occur but are rare, the cause is unknown and most likely insignificant.

11.2.2.4 **Glutamate Dehydrogenase**

Glutamate dehydrogenase (GDH) is a key mitochondrial enzyme in amino acid oxidation and urea production (O'Brien et al., 2002). The enzyme is highly conserved in tissue distribution and function across a wide species range (Schmidt and Schmidt, 1988; O'Brien et al., 2002). The liver has the highest concentration of GDH with lesser amounts in the kidney and small intestine. In the kidney, the activity is found in the proximal and distal tubular epithelium (Kaneko et al., 1997; Ozer et al., 2008). Because of liver has the highest concentration, the serum activity originates solely from this organ.

11.2.2.4.1 *Isoenzymes*

Isoenzymes of GDH have not been described.

11.2.2.4.2 *Causes for Increased Serum GDH Activity*

Similar to ALT and SDH, increases in serum GDH activity are due to hepatocellular damage (Gopinath et al., 1980). Serum activity of GDH is more liver specific than ALT and is not substantially affected by skeletal muscle damage. When compared to ALT activity, GDH elevations under certain hepatocellular damaging events were of greater magnitude and persisted longer in rats (O'Brien et al., 2002). Moreover, in rats, GDH has been used as a plasma marker of alcohol-induced liver injury (Murayama et al., 2009). GDH is not inhibited by compounds that interfere with pyridoxal-5'-phosphate such as isoniazid and lead (O'Brien et al., 2002). Furthermore, GDH activity does not appear to be induced by certain compounds associated with ALT induction (e.g., dexamethasone) (O'Brien et al., 2002). It has been shown that activity of GDH in the serum is more stable than SDH and has a longer half-life in some species (Collis et al., 1979). Use of GDH as a serum biomarker for hepatic injury has been criticized in the past due to technical difficulties with assay procedures (Carakostas et al., 1986). However, advances in commercial assay availability have led to more clinical use (O'Brien et al., 2002; Ozer et al., 2008).

11.2.2.4.3 *Causes for Decreased Serum GDH Activity*

Decreases in GDH activity are most likely insignificant.

11.2.2.5 **Lactate Dehydrogenase**

LDH is a cytoplasmic enzyme that catalyzes the reaction that converts pyruvate to lactate at the end of anaerobic glycolysis (Hoffmann et al., 1999). Although this reaction is reversible, the reduction of pyruvate to lactate is favored and this will generate NAD⁺ under anaerobic conditions so glycolysis can continue. LDH is found in all cells and present in all organs. Liver, heart, skeletal muscle, and kidney contain the highest activity per gram (Clampitt and Hart, 1978; Keller, 1981; Boyd, 1983). While LDH activity can be found in most tissues, the distribution among species varies. In dogs, heart muscle has the highest LDH activity per gram of tissue, followed by skeletal muscle (53%) and liver (41%). Rabbits have a similar distribution, while rats have the highest LDH activity in skeletal muscle followed by heart muscle (77%) and liver (41%). Pigs are somewhat unique in that heart muscle (10%) and liver (5%) have very low activity compared to skeletal muscle (Hoffmann et al., 1999). In laboratory animals, the lack of specificity without isoenzyme analysis and lack of sensitivity for detection of liver disease have reduced the utilization of LDH as part of diagnostic enzyme profiles.

11.2.2.5.1 *Isoenzymes*

Mammals have two different LDH subunits, the H type (heart subunits) and M type (muscle subunits) (Boyd, 1983). These combine randomly to form five tetrameric isoenzymes: H₄, H₃M, H₂M₂, HM₃, and M₄. The electrophoretically slow moving LDH4 and LDH5 (or HM₃, M₄ respectively)

isoenzymes are found primarily in skeletal muscle while the fast moving LDH1 and LDH2 (or H₄, H₃M) predominate in cardiac muscle in laboratory animals (Boyd, 1983). Liver is similar to skeletal muscle in that it contains primarily LDH5 and LDH4 in laboratory animals, but interestingly, in sheep and cattle, liver has an LDH isoenzyme profile more like heart rather than skeletal muscle. In laboratory animals, it is difficult or impossible to differentiate the liver or skeletal muscle as the source of increased LDH5 and LDH4. Use of increased LDH1 and LDH2 to identify experimentally induced myocardial infarction is feasible (Preus et al., 1988). LDH1 and LDH2 isoenzymes predominate in erythrocytes of all the species except the rat, which shows a predominance of LDH5 (Boyd, 1983). LDH1 and LDH2 predominate in the normal serum of all the species except the dog, cat, and rat (Boyd, 1983). Cynomolgus monkeys have five LDH isoenzymes. Isoenzymes 1–3 are the most prevalent, and similar quantities of each are found in serum (~22%–28%); isoenzyme 5 is the least prevalent. The activity of isoenzymes 1 and 2 is high in the myocardium, kidneys, and brain; monkeys also have a high amount of these isoenzymes in red blood cells (Preus et al., 1988). In mice affected with the LDH virus, the infection alters the macrophage population and prevents rapid clearance of LDH5 (Rowson and Mahy, 1985). The macrophages that clear LDH5 have no action of clearance on LDH4 (Rowson and Mahy, 1985). Macrophage clearance of other enzymes such as ALP is not affected with virus infection.

11.2.2.5.2 Causes for Increased Serum LDH Activity

Since LDH is a cytoplasmic enzyme and found in all organs it lacks specificity and sensitivity for assessment of hepatocellular damage, although damage to hepatocytes or muscle is the main reasons for increased serum LDH activity. In laboratory animals, LDH has been used for the detection of experimentally induced myocardial injury (Asha and Radha, 1985; Preus et al., 1988; Takami et al., 1990). To increase the specificity of LDH activity for detection of myocardial injury, determining particular isoenzyme activity (i.e., LDH1 activity) can be determined (Boyd, 1983). LDH activity is increased after exercise in rats with higher activity in males compared to females (Van der Meulen et al., 1991). Mice infected with the lactate dehydrogenase elevating virus (LDEV) can have increases of 3–10-fold in serum LDH activity (Rowson and Mahy, 1985). Serum enzyme levels are not directly related to the level of viral infectivity but are dependent on the rate of clearance of the enzymes (Rowson and Mahy, 1985). Clearance rate depends on the activity of macrophages. This virus is thought to destroy or block a population of macrophages that remove LDH from circulation, resulting in a marked reduction in clearance of either endogenous LDH or exogenously administered LDH (Rowson and Mahy, 1985; Hayashi et al., 1988).

11.2.2.5.3 Causes for Decreased Serum LDH Activity

Decreases in LDH activity are most likely insignificant.

11.2.2.6 Glutathione S-Transferase

The glutathione *S*-transferases (GST) are a complex family of proteins that display various biological functions. The main purpose of GST is the phase II detoxification of xenobiotics (Giffen et al., 2002). GST is capable of the reaction between GSH and electrophilic compounds and carcinogens allowing for their detoxification (Boyer, 1989). The family of GST enzymes is found predominantly in the cytoplasm, and consists of isoforms (alpha, mu, pi, and theta) and a microsomal form (DePierre and Morgenstern, 1983; Morgenstern and DePierre, 1983; Giffen et al., 2002). GST is found in all species and in virtually every organ. In the rat and other species, the liver contains the greatest GST activity (Clarke et al., 1997; Giffen et al., 2002). In the rat, the hepatic GST activity is low at birth and increases progressively until adulthood (Eidne et al., 1984; Harman and Henry, 1987). Erythrocytes of dogs, rats, and mice contain GST activity, which is higher than erythrocyte GST activity found in pigs and rabbits (Vodela and Dalvi, 1997). GST is typically a dimeric enzyme that can be found as a trimer and monomer (Mannervik, 1985; Boyer, 1989).

11.2.2.6.1 Isoenzymes

There have been numerous subunits identified and hence numerous isoenzymes. In the rat, the isoenzymes are dimeric hybrids of identical or dissimilar subunits (Mannervik, 1985). The isoenzymes are grouped into classes referred to as alpha, mu, and pi, based on their isoelectric points, structural, and functional similarities (Jensson et al., 1985; Mannervik, 1985; Mannervik et al., 1985). Rat liver expresses primarily alpha and mu classes of GST, while pi classes are present in minimal quantities (Robertson et al., 1985). The pi class is more prevalent in kidney and pancreas.

11.2.2.6.2 Causes for Increased Serum GST Activity

11.2.2.6.2.1 Hepatocellular Damage In the rat, alpha-GST has been shown to be a valid serum marker of hepatotoxicity (Giffen et al., 2002). Following carbon tetrachloride administration to rats, serum GST increases either in parallel with ALT activity or preceding the increase of ALT and AST activity (Adachi et al., 1981; Aniya and Anders, 1985; Igarashi et al., 1988; Clarke et al., 1997). In addition, when compared to serum ALT and AST activity, GST activity rapidly returns to pretreatment activity, which is consistent with the shorter half-life of GST activity in blood (Adachi et al., 1981). Administration of other hepatotoxic compounds also results in increases of serum GST activity (Aniya and Anders, 1985; Giffen et al., 2002). A marked increase in serum GST activity in the absence of a significant increase of serum ALT activity is observed in baboons following shock-induced hepatic injury, suggesting that serum GST activity may be used as an early marker of posttraumatic hepatic injury (Redl et al., 1995). Unlike ALT and AST, GST is found in high concentrations in the centrilobular cells in the liver and thus may be a more sensitive indicator to injury in the metabolic zone of the liver (Ozer et al., 2008). In most instances, measurement of serum GST offers no advantages over measurement of ALT and AST in detecting either the time of onset, recovery, or severity of hepatic injury (Giffen et al., 2002).

11.2.2.6.2.2 Drug Induction Administration of phenobarbital and several other compounds (e.g., 3-methylcholanthrene, propylthiouracil, and butylated hydroxyanisole) induce increases of hepatic GST activity in rats of all ages (Eidne et al., 1984; Brondeau et al., 1986; Boyer, 1989).

11.2.2.6.3 Causes for Decreased Serum GST Activity

Decreases in GST activity are most likely insignificant.

11.2.2.7 Ornithine Carbamyltransferase

Ornithine carbamyltransferase (OCT) is a mitochondrial enzyme that catalyzes a step in the urea cycle in the liver (Bondy et al., 2000). OCT is an abundant protein found almost exclusively in the liver with very slight activity in the gastrointestinal tract and kidney in dogs and rats (Reichard, 1959; Curtis et al., 1972; Hoffmann et al., 1999; Amacher, 2002). Serum OCT activity in these species is minute (Plaa, 2008). Therefore, serum OCT activity can be considered of hepatic origin. Isoenzymes of OCT have not been described. Methods for determining OCT activity in serum have been developed but may not be available for routine use (Ohshita et al., 1976; Murayama et al., 2006).

11.2.2.7.1 Causes for Increased Serum OCT Activity

Because OCT is found almost exclusively in the liver, it is considered a highly specific serum marker of hepatocellular necrosis and hepatotoxicity (Bondy et al., 2000; Amacher, 2002). Past studies have shown that mitochondria-derived serum markers of carbon tetrachloride hepatotoxicity are less sensitive than cytoplasmic enzymes (i.e., ALT and AST) (Baumann and Berauer, 1985). The cause for this finding is believed to be a result of mitochondrial dysfunction causing cell death rather than a consequence of cell death (Murayama et al., 2008). This suggests that some mitochondria are destroyed prior to plasma membrane disturbances resulting in less activity of OCT in the serum.

following administration of certain hepatotoxins. Several recent reports suggest that changes in serum OCT activity may be more rapid than traditional markers of hepatocellular necrosis from administration of hepatotoxins and alcohol-induced injury (Murayama et al., 2007, 2008, 2009). In spite of these encouraging results, OCT does not appear to be used routinely for diagnostic purposes. This is due in part to analytical assay requirements required for routine screening (Bondy et al., 2000). However, recent developments of ELISA make analysis more practical (Murayama et al., 2006).

Induction of urea cycle enzymes, including OCT, has been shown to occur by glucagon (Snodgrass et al., 1978). De novo synthesis of OCT is induced in rats by increases in protein consumption or administration of the substrate for OCT (Hoffmann et al., 1999). It is likely that OCT can be induced with the need for urea synthesis from ammonia by drugs that cause protein catabolism.

11.2.2.7.2 Causes for Decreased Serum OCT Activity

As mentioned previously, it has been suggested that mitochondria destruction prior to disruptions in plasma membrane may not result in increases in serum OCT activity with administration of certain hepatotoxins (Murayama et al., 2008). However, decreases in OCT serum activity are most likely insignificant.

11.2.2.8 Other Hepatic Leakage Markers

11.2.2.8.1 Arginase I

Arginase I is a hydrolase that catalyzes the hydrolysis of arginine to urea and ornithine (Ashamiss et al., 2004). The enzyme is highly liver specific with most activity noted in the organ with trace amounts found in kidney and erythrocytes (Ashamiss et al., 2004). Serum increases in arginase I have been shown to occur with acute and chronically induced hepatic injury in rats (Murayama et al., 2007, 2008). In comparison to traditional measures of hepatic injury (i.e., ALT and AST), arginase I showed the greatest and earliest increase in the serum in response to acute injury in rats (Ikemoto et al., 2001b; Murayama et al., 2008). Despite the encouraging findings of arginase I as an early marker of acute liver injury the lack of commercially available assays for measurement are lacking. An ELISA for the detection of serum arginase I has been developed and may enhance the use of this enzyme in future studies (Ikemoto et al., 2001a).

11.2.2.8.2 Malate Dehydrogenase

Malate dehydrogenase (MDH) is an enzyme involved with the citric acid cycle and catalyzes the reaction of malate to oxaloacetate (Zelewski and Swierczynski, 1991). MDH is a mitochondrial and cytosolic enzyme with its greatest activity found in the liver followed by heart, muscle, and brain (Ozer et al., 2008). Because activity is found in the cytosol of hepatocytes, the damage to these cells results in release to the serum much like ALT and AST. Increases in serum MDH activity has been shown after dosing rats with hepatotoxins (Korsrud et al., 1972; Zieve et al., 1985). The sensitivity of MDH in detecting hepatocellular necrosis compared to more traditional markers has not been performed to date.

11.2.2.8.3 Purine Nucleoside Phosphorylase

Purine nucleoside phosphorylase (PNP) is an enzyme in the purine salvage pathway (Ozer et al., 2008). PNP is a cytoplasmic enzyme with the greatest activity found in liver with lesser activity in the heart and muscle. In the liver, PNP is found in the cytoplasm of endothelial cells, hepatocytes, and Kupffer cells. Damage to these cells results in the release of PNP into the serum much like the other hepatocellular necrosis markers (Ohuchi et al., 1995). It was shown that dosing rats with endotoxin causes increases in serum PNP activity earlier than increases in ALT activity (Mochida et al., 1999). Because PNP is found in the cytoplasm of endothelial cells in the liver, it has been

proposed as a marker of endothelial cell damage in the hepatic sinusoids (Fukuda et al., 2004). The wide spread use of PNP in laboratory animal species as a suitable marker of hepatocellular damage has not been established.

11.2.2.8.4 Serum F Protein

Serum F protein is a 44-kDa protein involved in tyrosine catabolism. The protein is produced in large amounts in the liver with minor amounts in the kidney and is found in the cytosol (Oliveira, 1986; Foster et al., 1989). Serum contains very little serum F protein in a normal subject. In humans, the measurement of serum F protein in the serum appears to be a more sensitive indicator of hepatic injury than aminotransferases and serum concentrations correlate with histologic lesions in the liver (Foster et al., 1989). Serum F protein is produced by a wide variety of animals (Oliveira and Vindlacheruvu, 1987). However, correlation of increased serum F protein and histologic lesions in laboratory animals has not been performed. The lack of practical, high-throughput assays for the measurement of serum F protein limit its use as a marker of hepatocellular damage in laboratory animal species.

11.2.3 HEPATIC CHOLESTATIC ENZYMES

11.2.3.1 Alkaline Phosphatase

ALP is an enzyme that hydrolyzes a wide range of monophosphates and pyrophosphates at an alkaline pH and physiologic pH but at a lesser rate. ALP activity has been described in a wide variety of organisms from bacteria to mammals (Fernandez and Kidney, 2007). In mammals, ALP activity can be found in most tissues of the body. The organs with the greatest ALP activity on a per gram basis are the intestine and kidney in most species (Nagode et al., 1969; Clampitt and Hart, 1978; Boyd, 1983). Other major organs with ALP activity include the liver, bone, and placenta (Clampitt and Hart, 1978; Boyd, 1983). Despite the relative organ activities of ALP, the total serum ALP activity may not offer a clear reflection of disease states involving a particular organ. For example, in dogs, the liver has less than 1% of the ALP activity of intestine, but most of the serum activity of ALP is from the liver (Hoffmann, 2008). On the contrary, the intestine in the dog has the highest ALP activity on a per gram basis but offers no contribution to serum activity.

Despite being widely studied, the *in vivo* function of ALP is not entirely understood but the role of some isoenzymes has been suggested. ALP found on the canalicular membranes of hepatocytes and luminal surface of the biliary epithelium may be involved in choline transport across cell membranes (Fernandez and Kidney, 2007). On the brush border of the intestinal epithelial cells, ALP may be responsible for absorption of dietary phosphates (Harris, 1990). In humans, a point mutation in the bone isoenzyme of ALP leads to hypophosphatasia, markedly defective bone mineralization, and early death of children. This finding strongly suggests a role of ALP in mineralization of bone (Whyte et al., 1996). The role in of ALP in bone mineralization has been confirmed using knockout mice to create hypophosphatemia resulting in impaired bone development (Anderson et al., 2004). One of the more interesting proposed functions of ALP suggest that the enzyme dephosphorylates bacterial endotoxin and diminishes its toxic effects (Poelstra et al., 1997a, b). Other functions of ALP in different organs have been proposed. However, despite the poor understanding of the physiologic function of ALP isoenzymes, their diagnostic importance for the detection of disease has been recognized for many years. ALP can be found attached to the cell surface anchored by a hydrophobic phosphatidylinositol glycan within the membrane. In the small intestine, ALP is located on the tips of mucosal villi and in the kidney, it is found on the brush border of proximal convoluted tubules (Watanabe and Fishman, 1964; Wachstein and Bradshaw, 1965). In the bone, ALP is found on the surface of osteoblasts and on matrix vesicles produced by osteoblasts (Leach et al., 1995). The liver displays different cellular patterns of ALP activity. In a normal animal, ALP is found located primarily on the bile canalicular surface of hepatocytes. During disease states or

induction by various drugs, both the sinusoidal and lateral surfaces of the hepatocyte show considerable ALP activity (Sanecki et al., 1987; Ogawa et al., 1990; Solter et al., 1997).

11.2.3.1.1 *Isoenzymes*

In humans, four gene loci encode four different ALP isoenzymes, which are named for the primary tissue of expression: (1) the tissue nonspecific isoenzyme that is found in the liver, kidney, bone, and most other tissues, (2) the intestinal ALP found on the brush border of the intestine, (3) a placental isoenzyme expressed in trophoblasts during gestation, and (4) a germ cell or placenta-like isoenzyme expressed in small amounts in the testes and thymus (Harris, 1990). In nonhuman primates, all ALP isoenzymes are expressed except the germ cell isoenzyme (Harris, 1990; Hoffmann, 2008). In other mammalian species, there are two genes expressed for ALP isoenzymes: the tissue nonspecific ALP isoenzyme expressed in liver, bone, kidney, and placenta and the intestinal ALP that is generally specific to that tissue (Harris, 1990). The ALP isoenzymes result from the expression of different gene loci and differ antigenically, enzymatically, and biochemically (Hoffmann, 2008). Different ALP isoforms result from the expression from the same gene, have posttranslational modifications of the enzyme but are antigenically and enzymatically similar (Hoffmann, 2008).

Numerous techniques describing the detection, separation, and characterization of the ALP isoenzymes and isoforms have been published. The primary purpose of these techniques is to enhance the diagnostic usefulness of increases in serum ALP activity or gain an understanding of the mechanisms of ALP activity increase in tissues. The general techniques used for identifying the ALP isoenzymes include electrophoresis, isoelectric focusing, inhibition of enzymatic activity by chemicals and heat, selective recognition by lectins, immunochemistry, and cloning and sequencing of the genes (Fernandez and Kidney, 2007; Hoffmann, 2008). Use of these various techniques enhances the diagnostic utility of ALP isoenzymes and isoforms.

The liver alkaline phosphatase (LALP) isoform is moderately heat labile at 56°C, extremely sensitive to inhibition by levamisole, and relatively insensitive to the inhibition by L-phenylalanine, and the carbohydrate portions of the enzyme are terminated with sialic acid, causing the enzyme to migrate rapidly on electrophoresis (Hoffmann, 2008). In rabbits, liver ALP is composed of two isoenzymes separable by diethylaminoethyl (DEAE)-cellulose chromatography that reflects the expression of both the tissue nonspecific gene and the intestinal gene in the liver (Noguchi and Yamashita, 1987). This pattern of expression of two ALP isoenzymes in the liver has been observed in dogs when treated with glucocorticoids (Wiedmeyer et al., 2002a, b). Expression of an intestinal mRNA in rat liver following fat feeding has also been reported (Goseki-Sone et al., 1996). Bone alkaline phosphatase (BALP) isoform, a product of the tissue nonspecific ALP gene like LALP, has a different carbohydrate composition than LALP. Because of this difference, BALP can be distinguished from LALP by a slower anodal migration on cellulose acetate electrophoresis and susceptibility to heat inactivation (Nagode et al., 1969; Hoffmann and Dorner, 1975). In rats and dogs, BALP is also more susceptible to precipitation by wheat germ lectin than LALP (Sanecki et al., 1993; Hoffmann et al., 1994). Use of wheat germ lectin precipitation or heat inactivation with other techniques allows for determining activity of BALP and LALP in serum. Under normal conditions, the BALP makes up approximately 30% of the total serum ALP activity but a very small percentage of rat serum ALP activity (Hoffmann et al., 1994; Allen et al., 1998). Kidney ALP (KALP), like LALP and BALP, is a product of the tissue nonspecific ALP gene, although KALP can display heterogeneity due to variations in the carbohydrate composition especially sialic acid (Saini and Saini, 1978). In the rabbit, both the tissue nonspecific and intestinal genes are expressed in the kidney (Noguchi and Yamashita, 1987). Activity of KALP is not seen in serum, which is likely due to a short circulating half-life and a proximal tubular location (Hoffmann et al., 1999). Intestinal alkaline phosphatase (IALP) isoenzyme, unlike the tissue nonspecific products, is more heat stable, less sensitive to inhibition by levamisole, and readily inhibited by L-phenylalanine (Nagode et al., 1969; Eckersall and Nash, 1983; Eckersall et al., 1986). IALP has a very low carbohydrate composition compared to

the tissue nonspecific products and considered asialoglycoprotein (though dog IALP does contain a small amount of sialic acid) (Hoffmann and Dorner, 1975). Because of this low carbohydrate composition, IALP does not migrate to the same extent on cellulose acetate or agarose electrophoresis as does LALP (Hoffmann and Dorner, 1975; Sanecki et al., 1990). In rabbits, IALP may be the product of both the intestinal and tissue nonspecific genes (Noguchi and Yamashita, 1987). In rats, two cDNAs have been identified that code for rat IALP: IALP-1 and IALP-2, which produce a 69-kDa and 93-kDa protein, respectively (Engle and Alpers, 1992; Engle et al., 1995). Under normal conditions, IALP comprises the major portion of total ALP serum activity in the rat (Righetti and Kaplan, 1971; Hoffmann et al., 1994). In adult cynomolgus monkeys, the majority of ALP activity in the serum is LALP representing 56%–94% of the total activity (Wiedmeyer et al., 1999). In addition, male monkeys have a higher ALP activity in serum than females (Wiedmeyer et al., 1999). Placental ALP is a product of the tissue nonspecific gene in laboratory species (Goldstein et al., 1982). In dogs, placental ALP appears to be an asialoglycoprotein since it has little anodal migration on cellulose acetate electrophoresis and is unaffected by neuraminidase treatment (Hoffmann et al., 1999). Increases in placental ALP activity in the serum of pregnant cats and cows has been observed but not in other domestic species (Fernandez and Kidney, 2007). A unique ALP isoenzyme can be found in dogs referred to as the corticosteroid-induced alkaline phosphatase (CIALP). CIALP activity can be found in the serum and liver of dogs during conditions of glucocorticoid treatment and cases of hyperadrenocorticism (Dorner et al., 1974; Sanecki et al., 1990; Wiedmeyer et al., 2002a). The isoenzyme is actually a highly glycosylated form of intestinal ALP, since it has been shown to be antigenically similar to IALP with both polyclonal and monoclonal antibody, responds to heat, levamisole, and L-phenylalanine inhibition in the same manner as IALP, and has an identical N-terminal amino acid sequence (Hoffmann, 2008). CIALP has not been reported in any other species.

11.2.3.1.2 Causes for Increased Serum ALP Activity

11.2.3.1.2.1 Hepatobiliary disease/Cholestasis One of the most common disorders in laboratory animals that can cause an increase in serum ALP activity, more specifically LALP, is cholestasis. In dogs and rats with experimentally induced cholestasis through bile duct ligation, there was a marked increase in serum LALP (Noonan and Meyer, 1979; Guelfi et al., 1982; Kaplan et al., 1983). However, the magnitude and time to peak serum LALP activity differ between the two species. In dogs, marked increases in serum ALP activity do not occur until approximately 24 hours following bile duct ligation with maximum increases at 4–7 days (Noonan and Meyer, 1979; Shull and Hornbuckle, 1979; Guelfi et al., 1982). In rats though, significant increases of serum ALP activity occur approximately 6–7 hours following bile duct ligation with maximum increases of 7–10-fold greater than normal at 12–24 hours (Kryszewski et al., 1973; Kaplan et al., 1983). The difference in time of response between the dog and rat is probably a reflection of the absence of a gall bladder in the rat. Cholestasis secondary to other diseases such as hepatic lipidosis, pancreatitis, neoplasia, nodular regeneration, enteric diseases, or hypotension can also result in increases in serum ALP activity (Fernandez and Kidney, 2007). Increases in serum LALP activity either experimentally or from natural disease occur due to increased synthesis or presumably increased shuttling of ALP to the sinusoidal membrane of hepatocytes (Solter et al., 1997; Fernandez and Kidney, 2007). However, the exact mechanism in which LALP activity increases with these conditions and gains access to the blood remains controversial and is most likely multifactorial. Serum LALP isoenzyme activity can be mildly increased with instances of hepatocellular necrosis, but are considered of little predictive value in detecting either centrilobular or periportal hepatocellular necrosis (Noonan, 1981; Guelfi et al., 1982; Carakostas et al., 1986). More appropriate markers of hepatocellular necrosis are ALT and SDH activity. Marked increases in serum LALP activity can also occur with glucocorticoid administration in the absence of other indicators of cholestasis (Solter et al., 1994, 1997; Syakalima et al., 1997; Wiedmeyer et al., 2002b). The effects of other compounds on serum ALP activity shall be discussed later.

11.2.3.1.2.2 Bone Disease Increased osteoblastic activity from osteogenesis or bone pathology can result in increased serum ALP activity, specifically BALP. Thus measurement of serum BALP is considered a marker of metabolic activity of the bone in dogs, cats, and rats and most likely in other species as well (Allen et al., 1998; DeLaurier et al., 2002; Powers et al., 2007). Besides a metabolic marker of bone activity, increases in serum BALP activity can occur from pathologic bone conditions. In dogs, increases in serum BALP can be observed in dogs with hyperparathyroidism, fracture healing, and osteosarcoma (Ehrhart et al., 1998; Komnenou et al., 2005; Hoffmann, 2008). Of these pathologic conditions, the highest observed serum BALP activity has been in dogs with osteosarcoma (Ehrhart et al., 1998). In some cases, serum BALP activity reached 50 times the normal reference range, but being near normal activity in other cases. This suggests that the measurement of serum BALP activity has poor sensitivity for the diagnosis of osteosarcoma. However, it was shown that serum BALP activity is an important prognostic marker for canine appendicular osteosarcoma (Ehrhart et al., 1998; Garzotto et al., 2000; Kirpensteijn et al., 2002). Finally, familial hyperphosphatasemia in a family of Siberian huskies in which the increased serum ALP is a result of increased BALP isoenzyme activity has been observed (Lawler et al., 1996).

11.2.3.1.2.3 Endocrine Diseases In dogs, serum ALP activity can be increased in endocrine disorders such as hyperadrenocorticism, diabetes mellitus, hypothyroidism, and hyperparathyroidism (Fernandez and Kidney, 2007). Dogs with hyperadrenocorticism or following treatment with exogenous glucocorticoids, display increased serum ALP activity that is dominated by the CIALP isoenzyme (Dorner et al., 1974; Badylak and Van Vleet, 1981; Solter et al., 1994). Most clinically normal dogs have serum CIALP activity that is either nonexistent or represents only a few units of the total serum ALP activity. It has been shown that use of serum CIALP activity for the diagnosis of hyperadrenocorticism has high sensitivity but poor specificity (Teske et al., 1989; Solter et al., 1993). Most dogs with diabetes mellitus display an increase in serum ALP activity (Hess et al., 2000). The reason for the increased serum ALP activity with diabetes has not been determined. However, it is suspected that secondary hepatic lipidosis may be responsible (Hess et al., 2000). Moreover, which ALP isoenzyme predominates in the serum of dogs with diabetes is unknown but some studies have shown 40%–80% of these dogs have an increase in CIALP (Oluju et al., 1984). Like diabetes mellitus, the predominant ALP isoenzyme in the serum of dogs with hypothyroidism or hyperparathyroidism is not entirely known.

11.2.3.1.2.4 Diet In adult rats, IALP isoenzyme is the major ALP isoenzyme in the serum and it increases after feeding a fat-laden meal (Eliakim et al., 1991; Alpers et al., 1994; Hoffmann et al., 1994; Yamagishi et al., 1994). A similar finding was observed in humans (Cho et al., 2005). Reduced serum ALP activity, presumably from decreased IALP activity, has been observed in fasted rats or rats with decreased food consumption from illness or toxicity (Waner and Nyska, 1994; Travlos et al., 1996).

11.2.3.1.2.5 Pregnancy Increases in serum ALP activity, specifically placental ALP, have been observed in pregnant cats but not pregnant dogs (Fernandez and Kidney, 2007). Typically, in normal cats, placental ALP activity is nonexistent in the serum. In cats, in late pregnancy, there is detectable placental ALP activity (Everett et al., 1977). In late stage pregnant rats, a decrease in serum ALP activity has been observed but higher serum ALP compared to nonpregnant females in the early stages of pregnancy (Liberati et al., 2004; Honda et al., 2008). It is unknown in these studies if the changes in serum ALP activity are due to changes in placental ALP.

11.2.3.1.2.6 Age In young puppies, serum BALP activity can be up to 10-fold greater than in adult dogs but the activity wanes as the dog matures (Sanecki et al., 1993). An increase in serum BALP activity in young animals can be observed in many laboratory species. In rats, serum IALP activity is greater in young rats than mature rats (Hoffmann et al., 1994). Increases in serum CIALP activity

may occasionally be observed in dogs with chronic and/or inflammatory disease. This appearance in inflammatory conditions is more often observed in older dogs (Teske et al., 1989; Solter et al., 1993, 1997). The cause of increased CIALP activity in dogs with chronic inflammatory disease is not clear. Young healthy dogs used for toxicologic studies usually have no CIALP activity, but serum should still be evaluated for the presence of the isoenzyme prior to the initiation of a study, and those animals with CIALP should be eliminated since they may have underlying disease or possibly skew the data for the study.

11.2.3.1.2.7 Drug Induction Numerous compounds such as cortisol, phenobarbital, theophylline, caffeine, and retinoic acid, and many others have been shown to increase serum ALP activity in rats (Hixson et al., 1979; Hoffmann et al., 1999). Of these many compounds, drugs such as anticonvulsants and glucocorticoids have been shown to induce ALP activity without evidence of pathology (Gaskill et al., 2004; Hall and Nancy, 2008). The effects on ALP of these drugs can be blocked by inhibitors of RNA and protein synthesis (Hoffmann et al., 1999). In dogs, the increased synthesis of both CIALP and LALP in dogs treated with glucocorticoids has been well documented (Dorner et al., 1974; Hoffmann and Dorner, 1975; Solter et al., 1994). Treatment with glucocorticoids induces the presence of CIALP activity in liver and serum but the initial response is a dramatic increase in LALP activity, followed by the appearance of CIALP in 7–10 days after initiation of treatment (Solter et al., 1994). The regulation of both CIALP and LALP is at the gene level (Wiedmeyer et al., 2002b). The cause for the delay in CIALP activity in the serum is unknown. In most cases of compound induced serum ALP activity, an isoenzyme analysis has been done; thus, the tissue of origin of most serum ALP increases is unknown.

11.2.3.1.3 Causes for Decreased Serum ALP Activity

Like most other serum enzymes, decreases in ALP activity are of no diagnostic value (Wolf, 1986). However, decreases in serum total ALP, IALP, and BALP have been observed following hypophysectomy in rats (Yeh et al., 1984). In addition, decreases in serum ALP activity has been observed in rats fasted for approximately 16 hours (Apostolou et al., 1976; Matsuzawa, 1994).

11.2.3.2 Gamma-Glutamyltransferase

GGT has multiple functions including catalytic transfer of γ -glutamyl groups to amino acids (Goldberg, 1980b). It is one of the six enzymes that function in the γ -glutamyl cycle, and GGT is the only one in this cycle that is membrane bound. It plays a major role in the regulation of intracellular GSH which is a major antioxidant. GGT also functions in the GSH transferase/GGT pathway that cleaves γ -glutamyl moieties from GSH conjugates. The role of this pathway is detoxification of xenobiotics and carcinogens by rendering them more water soluble and excreted.

GGT is found in all species with activity in the kidney, pancreas, liver, spleen, lung, intestine, seminal vesicles, mammary gland, and ciliary body (Albert et al., 1964; Clampitt and Hart, 1978). The kidney has by far the greatest activity on a per gram basis (Albert et al., 1964; Clampitt and Hart, 1978). The other tissues have varying activities depending on the species. In guinea pigs, kidney tissue has 15 times the activity of GGT as found in the liver; whereas, the activity in the rat kidney is 200–875 times higher than in the rat liver (Albert et al., 1964; Fiala and Fiala, 1973; Hinchman and Ballatori, 1990). Dogs, mice, hamsters, and rats are similar in that they have lower liver GGT activity than guinea pigs and rabbits (Milne and Doxey, 1985; Sulakhe and Lauth, 1985; Hinchman and Ballatori, 1990). This is most likely the cause for lower serum GGT activity in these species.

GGT is generally membrane bound found on the surface of cells. In rats, the biliary epithelial cells in the portal spaces of the liver display histochemical evidence of GGT activity (Daoust, 1982). In addition, GGT activity has been identified on both bile canalicular and sinusoidal surfaces of rat and guinea pig hepatocytes (Huseby, 1979; Lanca and Israel, 1991). When isolated parenchymal, Kupffer, and biliary cells were examined, it was shown that the biliary epithelial cells displayed

approximately 200 times higher GGT activity than hepatocytes (Huseby, 1979; Parola et al., 1990). In the kidney, GGT is found on the brush border of epithelial cells lining the proximal convoluted tubules (Albert et al., 1964). Because of this location, GGT from the kidney is shed into the urine with proximal tubular damage. In the pancreas, the luminal border of cells lining the acini and the pancreatic ducts display GGT activity (Albert et al., 1964). Serum increases in serum GGT are not generally associated with renal or pancreatic pathology.

11.2.3.2.1 Isoenzymes

Isoenzymes of GGT have not been found but changes in the carbohydrate composition of GGT (i.e., isoforms) have been described. Electrophoretic separation and isoelectric focusing of GGT from the kidney and liver from rats resulted in upward of 12 different bands (Jaken and Mason, 1978). GGT extracted from rat hepatomas and hyperplastic liver nodules have shown to be immunologically identical to rat kidney GGT but have varying sialic acid concentrations (Fischer et al., 1986). Varying sialic acid content has been demonstrated for human liver GGT as well (Mortensen and Huseby, 1997). The existence of a single gene for liver GGT in mice has been shown but with at least seven different promoters (Rajagopalan et al., 1993; Sepulveda et al., 1994). Similar observations have been made in rats, though the number of gene promoters is unknown (Darbouy et al., 1991; Brouillet et al., 1994; Okamoto et al., 1994).

11.2.3.2.2 Causes for Increased Serum GGT Activity

11.2.3.2.2.1 Hepatobiliary Disease/Cholestasis Because GGT is found primarily in the liver on bile epithelium, the serum activity increases are mainly due to cholestatic diseases or biliary epithelial necrosis in all species studied (Leonard et al., 1984; Braun et al., 1987; Boone et al., 2005; Ramaiah, 2007). The serum increases with cholestatic disorders may be secondary to membrane solubilization from increased bile acid concentrations (Braun et al., 1987). In experimental models using bile duct ligation, there are moderate differences in the timeframe of appearance of increased GGT serum activity. Bile duct ligation in dogs and rats consistently causes increased serum GGT activity (Wootton et al., 1977; DeNovo and Prasse, 1983). The initial response to bile duct ligation is an increased serum GGT activity with a corresponding decrease in liver GGT activity. In guinea pigs, bile duct ligation results in a pattern of increased serum GGT activity as well (Huseby and Vik, 1978). However, the rate and sustainable increase in serum GGT activity in guinea pigs is different from the dog and rat. This difference in serum GGT activity between guinea pigs and rats or dogs is most likely due to guinea pigs having much higher liver GGT activities normally than the other two species. Therefore, more GGT is available for release into the serum. Generalized hepatocellular necrosis caused by administration of carbon tetrachloride and dibromobenzene or hepatic trauma result in minimal or no increases in serum GGT activity (Noonan and Meyer, 1979; Guelfi et al., 1982; Leonard et al., 1984; Szymanska et al., 1996). In addition to hepatobiliary/cholestatic diseases, chemical-induced hepatocarcinogenesis has been shown to increase tissue GGT activity (Fiala and Fiala, 1973; Manson and Smith, 1984; Fischer et al., 1986). In general, substantial increases in serum GGT activity is considered a specific diagnostic indicator of cholestatic disease.

Despite the kidney having the highly tissue activity of GGT, there is no evidence to support that renal disease causes an increase in serum GGT activity. The absence of kidney GGT activity in the serum is most likely related to the very rapid clearance of kidney GGT activity from blood by the galactose receptor system and the location of GGT on the brush border of the renal proximal tubular epithelium (Hoffmann, 2008). Under pathologic conditions affecting the renal proximal tubules, the GGT is readily shed into the urine. Hence, urine GGT activity has been used as an indicator of nephrotoxicity.

11.2.3.2.2.2 Drug Induction Increases in the GGT activity in liver and serum as a result of induction of enzyme synthesis have been associated with barbiturate treatment and glucocorticoid administration in multiple species (Tazi et al., 1980; Badylak and Van Vleet, 1981; Roomi and

Goldberg, 1981; Solter et al., 1994). The changes in GGT activity from inducing drugs varies among species. Rabbits respond to phenobarbital with a greater increase in liver and serum GGT activity than do guinea pigs and rats (Roomi and Goldberg, 1981). Additionally, rats show an increase in liver GGT activity with phenobarbital administration but no increase in serum GGT activity (Roomi and Goldberg, 1981). In dogs treated with glucocorticoids, an increase in serum and liver GGT was observed (Solter et al., 1994).

11.2.3.2.3 Causes for Decreased Serum GGT Activity

Decreases in GGT activity are insignificant.

11.2.3.3 5'-Nucleotidase

The enzyme 5'-nucleotidase (5NT) is a glycoprotein that hydrolyzes 5'-nucleotides to their corresponding nucleosides (Sunderman, 1990). More specifically, it hydrolyzes nucleoside 5'-monophosphates to adenosine. The exact role of 5NT in the liver is not completely known. In other tissues and cells, the function of 5NT is varied (Sunderman, 1990; Le Hir and Kaissling, 1993). Activity of 5NT is an ectoenzyme predominantly located in the plasma membrane. 5NT activity can be found in numerous tissues including the liver, kidney, brain, lung, intestine, neutrophils, lymphocytes, and muscle (Hardonk and BDe Boer, 1968). The highest activity is found in kidney and intestinal mucosa (Hardonk and BDe Boer, 1968). Despite the varied tissue distribution of 5NT, serum concentrations are specific for hepatobiliary disease (Bodansky and Schwartz, 1968). In the liver, 5NT activity is located primarily on the bile canalicular and sinusoidal membrane of hepatocytes and on connective tissue in the portal triad (Schmid et al., 1994). In mouse and rat tissues, five different bands of 5NT have been identified by agarose gel electrophoresis (Hardonk and BDe Boer, 1968). However, partially purified 5NT from several tissues from the rat exhibits identical enzymatic characteristics (Sunderman, 1990). These findings suggest that the different electrophoretic bands of 5NT most likely represent isoforms and not distinct isoenzymes. There is no indication that separation of 5NT isoforms improves its diagnostic value.

11.2.3.3.1 Causes for Increased Serum 5NT Activity

Increases in serum 5NT activity occur in animals with hepatobiliary disease or cholestasis (Carakostas et al., 1990; Ramaiah, 2007). The serum changes in 5NT activity in experimental induction of cholestasis are similar to the serum changes in ALP and GGT (Kryszewski et al., 1973). Thus, it is perceived that the measurement of 5NT offers no advantages in diagnosing hepatobiliary disease over the measurement of ALP or GGT. However, one advantage 5NT has over ALP is the fact that 5NT does not increase with osseous growth or lesions suggesting that it has a higher specificity for hepatic disease than ALP (Pagani and Panteghini, 2001). However, the routine use of 5NT has not gained popularity due to the lack of acceptable methodologies for convenient measurement (Ramaiah, 2007).

Compounds such as thyroxin and chronically administered ethanol have been shown for increasing the serum activity of 5NT (Drozd et al., 1975; Nishmura and Teschke, 1982). In contrast, 5NT did increase in the serum of dogs treated with glucocorticoids unlike ALP and GGT (Rutgers et al., 1995).

11.2.3.3.2 Causes for Decreased Serum 5NT Activity

Decreases in serum 5NT activity are most likely insignificant.

11.3 ANALYSIS OF HEPATIC FUNCTION

As described previously, the liver has many diverse physiologic functions. Disturbances in those functions as a result of disease or toxic insult can alter specific serum parameters that are routinely measured by laboratory methods. It is important to note that individual test results may not be

specific for liver functional abnormalities. Other disease processes may cause similar abnormalities. Thus, it is important to assess liver function using multiple laboratory test results, clinical findings, histopathology, and other ancillary parameters such as imaging. It is also important to note that increases in serum activities of liver specific enzymes do not directly indicate the loss of liver function. Liver function can be markedly reduced without increases in serum liver enzyme activities.

11.3.1 BILIRUBIN

Bilirubin is the product of catabolism of the heme molecule within the cells of the mononuclear phagocyte system (Hall and Nancy, 2008). Approximately 85% of serum bilirubin comes from the breakdown of hemoglobin from senescent erythrocytes destroyed by macrophages found in the liver, spleen, and bone marrow (Nuttall, 2001). The remaining 15% is produced from erythrocyte precursors destroyed in the bone marrow or catabolism of other heme-containing proteins such as myoglobin, cytochromes, and catalase (Nuttall, 2001). Bilirubin, released from the macrophages into the circulation where it binds covalently to albumin, is water insoluble and referred to as indirect, unconjugated, or prehepatic bilirubin (Hall and Nancy, 2008; Stockham, 2008). The unconjugated bilirubin is removed from circulation by the hepatocytes that prepare it for removal from the body. Removal of bilirubin from the serum is a stepwise process involving uptake, conjugation, secretion, and excretion (Hall and Nancy, 2008). Uptake of unconjugated bilirubin by the hepatocyte occurs after it dissociates from albumin. Once dissociated, uptake is facilitated across the sinusoidal membrane by an organic anion transport polypeptide, which is a sodium and energy independent process (Tennant and Center, 2008). Upon entry into the hepatocyte, bilirubin binds to ligandin, a cytosolic protein that has transport and detoxification functions. Through binding of the bilirubin to ligandin, efflux back into the plasma is prevented (Tennant and Center, 2008). The bilirubin within the hepatocyte is then conjugated to glucuronic acid producing monoglucuronide and diglucuronide to be excreted into the bile (Nuttall, 2001). Secretion of water-soluble conjugated bilirubin into the bile is an energy-dependent process and the rate-limiting step of the whole process (Hall and Nancy, 2008). Small amounts of conjugated (also known as direct or hepatic) bilirubin escape into the serum. The conjugated bilirubin does not bind to albumin, and it can be freely filtered through the glomerulus (Hall and Nancy, 2008). Most of the conjugated bilirubin filtered through the glomerulus is reabsorbed in the proximal tubules. Conjugated bilirubin is excreted in the bile and stored in the gall bladder or directly into the intestines. When bilirubin enters the intestine, it is minimally resorbed, degraded to urobilinogen, and excreted in the feces (Stockham, 2008).

Serum unconjugated (indirect) and conjugated (direct) bilirubin can be differentiated by using the Van den Bergh assay (Nuttall, 2001). By distinguishing the predominant bilirubin in the serum, clinical judgments as to the cause for the increase in bilirubin may be possible. However, this information needs to be additive to clinical observations, other laboratory data, and gross and histologic pathology findings. Laboratory determination of conjugated and unconjugated bilirubin is not usually necessary or recommended as part of routine toxicologic studies (Hall and Nancy, 2008), and Table 11.1 demonstrates previously expected values for total serum bilirubin of a variety of healthy experimental and domestic species and humans. This is due in part to variation in metabolism of bilirubin among different species (Ramaiah, 2007). Nonhuman primates and mice typically have the highest total serum bilirubin concentrations, while other species have considerably less total serum bilirubin concentrations (Tennant, 1999). In addition, it has been demonstrated that male nonhuman primates (specifically vervet monkeys) have a higher total and direct bilirubin serum concentration compared to females (Sato et al., 2005). If the situation originates where there is an increase in serum bilirubin without evidence of hemolysis or histologic changes consistent with cholestasis, determining the ratio of conjugated to unconjugated bilirubin in serum may be helpful (Ramaiah, 2007).

TABLE 11.1
Total Serum Bilirubin of Experimental Species, Domestic Species, and Humans

Species	Total Serum Bilirubin (mg/dL) \pm SD	Reference
Dog	0.1 \pm 0.1	Klaus (1958)
Cat	0.18 \pm 0.06	Mitruka and Rawnsley (1981)
Rat	0.2 \pm 0.2	Laird (1974)
Hamster	0.4 \pm 0.1	Tomson and Wardrop (1987)
Guinea pig	0.31 \pm 0.07	Mitruka and Rawnsley (1981)
Rabbit	0.19 \pm 0.10	Tennant et al. (1981)
Mouse	0.4 \pm 0.5	Williams et al. (1966)
Cow	0.2 \pm 0.1	Berger (1956)
Sheep	0.1 \pm 0.01	Berger (1956)
Horse	1.1 \pm 0.4	Berger (1956)
Pig	0.2 \pm 0.2	Berger (1956)
Rhesus monkey	0.4 \pm 0.3	Anderson (1966)
Howler monkey	0.75 \pm 0.06	Katz et al. (1968)
Marmoset	0.2 (range: 0.0–0.4)	Deinhardt and Deinhardt (1966)
Human	0.4 \pm 0.2	Powell et al. (1967)

11.3.1.1 Causes for Increased Serum Bilirubin

Conditions that cause increases in serum bilirubin concentration (hyperbilirubinemia) can be classified into those that result in the elevation of primarily the unconjugated form of bilirubin and those that are associated with an elevation of the conjugated or both conjugated and unconjugated forms (Table 11.2). Increases of predominantly unconjugated bilirubin have been related to the overproduction of bilirubin, impaired bilirubin uptake by the liver, or deficiencies of bilirubin conjugation. Increases of conjugated or both unconjugated and conjugated bilirubins have been related to biliary obstruction, hepatocellular diseases/injury, and defective canalicular excretion.

11.3.1.1.1 Decrease in Functional Hepatic Mass

A reduction in functioning hepatocytes can affect several steps in the processing of bilirubin. With a loss of hepatocyte function, alterations in uptake and conjugation of unconjugated bilirubin, as well as, secretion of conjugated bilirubin results in hyperbilirubinemia. Often with impaired hepatic function, conjugated bilirubin is the predominant bilirubin fraction found increased in the serum. However, it is possible with decrease in function to result in serum increases in both conjugated and unconjugated bilirubin. Therefore, it is recommended that increased serum bilirubin information be combined with other laboratory or pathologic data. As stated previously, the use of serum liver enzyme activities may not be appropriate for determining liver functional capabilities. Hereditary defects in bilirubin processing resulting in increases in the unconjugated bilirubin similar to that detailed for Crigler–Najjar syndrome, Type I (Chowdhury et al., 1993; Yamazaki et al., 1995) or conjugated bilirubin similar to what occurs in Dubin–Johnson syndrome (Chowdhury et al., 1993; Yamazaki et al., 1995) have been described in rats.

11.3.1.1.2 Cholestasis

Pathologic conditions that impair bile fluid through the bile canaliculi, bile ducts, or gall bladder can result in hyperbilirubinemia. Typically, conjugated bilirubin is increased over unconjugated bilirubin concentrations. Over time, the increase in conjugated bilirubin can lead to increases in unconjugated bilirubin (Stockham, 2008). The pathologic causes for impaired bile flow are varied

TABLE 11.2
Pathophysiological Mechanisms Responsible for Hyperbilirubinemia

	Plasma Bilirubin		Urine Bilirubin	Urine Urobilinogen
	Unconjugated	Conjugated		
Increased bilirubin production: hemolytic anemia, resorption from hemorrhage, hematoma	↑	N	0	↑
Impaired hepatic uptake of unconjugated bilirubin:	↑	N	0	↓ or N
neonatal hyperbilirubinemia, fasting hyperbilirubinemia, benign unconjugated hyperbilirubinemia of horses, congenital photosensitivity (Southdown sheep)	–	–	–	–
Impaired conjugation of bilirubin: glucuronyl transferase deficiency (Gunn rat), neonatal hyperbilirubinemia	↑	N	0	↓ or N
Impaired biliary excretion of bilirubin: intrahepatic cholestasis, black liver disease (Corriedale sheep), congenital photosensitivity (Southdown sheep), biliary cirrhosis, bile duct obstruction	↑	↑	↑	↑ or 0

N = normal; 0 = absent; ↑ = increased; ↓ = decreased.

and measurement of serum bilirubin usually does not define the pathologic condition. As stated previously, other laboratory and clinical findings are important for determining the exact cause for hyperbilirubinemia. Other clinical laboratory findings that may be altered with cholestatic disease include serum ALP and GGT activities (Fujii, 1997).

11.3.1.1.3 Intravascular or Extravascular Hemolysis

Disorders that result in red cell lysis can cause abrupt increases in serum bilirubin. Destruction of RBC by macrophages in the spleen, liver, and bone marrow cause increases in production of unconjugated bilirubin. If the increase in production and delivery of unconjugated bilirubin to the liver exceeds the uptake capacity of the hepatocyte, hyperbilirubinemia, dominated by unconjugated bilirubin, will occur. The increase delivery of unconjugated bilirubin to the liver with hemolytic disorders can cause increased bilirubin conjugation and secretion. If the formation of conjugated bilirubin exceeds secretion, the conjugated bilirubin can be released into the circulation. Thus, hemolytic disorders can result in hyperbilirubinemia from both unconjugated and conjugated bilirubin. Typically, the concentration of unconjugated bilirubin is markedly increased with hemolytic events.

11.3.1.2 Causes for Decreased Serum Bilirubin

Decreases in total bilirubin are rarely observed but has been associated with test compounds that induce microsomal enzyme production (Goldberg, 1980a).

11.3.1.3 Influencing Factors

Free hemoglobin in a serum/plasma sample from hemolysis and precipitation of immunoglobulins in the sample can falsely increase bilirubin results (Stockham, 2008). In addition, ultraviolet light can degrade bilirubin in a sample and decrease results.

11.3.2 BILE ACIDS

Bile acid metabolism is a major function of the liver and an important component of cholesterol homeostasis (Tolman, 2001). Primary bile acids are synthesized from cholesterol by hepatocytes, conjugated to glycine and/or taurine and secreted into the biliary system (Tennant, 1999; Tolman, 2001; Russell, 2003). In general, two primary bile acids (chenodeoxycholic and cholic acid) are produced by most vertebrate species. However, a variety of molecular forms of bile acids can be synthesized by different species (Hoffmann et al., 2010). For example, while cholic acid commonly occurs as a primary bile acid of mammals, chenodeoxycholic acid (found in rat, human, and hamster) can be replaced to muricholic acid (mouse) or hyocholic and hyodeoxycholic acid (pig) (Russell, 2003; Kandrac et al., 2006). A leading form of bile acids in mice, muricholic acids differ from the more common bile acids, cholic acid or chenodeoxycholic, by having a hydroxyl group at the 6-position instead of the 7-position. Bile acid conjugates to taurine primarily in the dog and rat but in the cat, bile acids conjugate to taurine exclusively (Tennant, 1999). In the rabbit, the conjugating appears to be almost completely specific for glycine (Tennant, 1999). The conjugate bile acids are secreted into the bile canicular system, transported through the bile ducts and stored in the gall bladder. In those species that lack a gall bladder, the bile containing bile acids is continually secreted into the duodenum (Ramaiah, 2007). In the colon, the actions of bacteria modify the structure of primary bile acids to into secondary bile acids. For example, by removal of an α -hydroxyl group at position seven converts the primary bile acids, chenodeoxycholic and cholic acid, to their secondary bile acids, lithocholic and deoxycholic acid, respectively. Figure 11.2 represents the formation of primary and secondary bile acids. Movement of bile acids into the biliary system is an osmotically active process (Handler et al., 1994). Bile acids are considered to be the primary organic solutes responsible for bile flow (Handler et al., 1994). Once deposited in the duodenum, either directly as in the rat or contraction of the gall bladder under the influence of cholecystokinin, bile acids play an important role in the digestion and absorption of dietary fat and other lipids. This digestion process occurs in both the duodenum and jejunum (Tennant and Center, 2008). In the terminal ileum, most of the bile acids are reabsorbed by a highly efficient transport system in the epithelium, and they enter the portal circulation. The portal circulation returns the bile acids to the liver for removal by the hepatocytes and

FIGURE 11.2 Schematic representation of bile acid metabolism in the liver and intestinal tract. Primary bile acids are synthesized in the liver and the secondary bile acids are formed by microbial modification of the primary bile acids in the large intestine.

recycling. A small portion of the bile acids is excreted in the feces. This system is known as enterohepatic circulation and is the method for conserving the bile acid pool of the body (Tolman, 2001).

The predominant bile acid found in bile differs between the species. In mice and rats, the predominant bile acid is taurocholate (Tennant and Center, 2008). In dogs, the predominant bile acid is cholic acid and chenodeoxycholic acid in nonhuman primates (Ramaiah, 2007). In most species, serum bile acids can be easily measured by spectrophotometric assays (Tennant and Center, 2008). In addition, the performance of the bile acids test differs among the species depending on the presence of a gall bladder. In those species with a gall bladder, a serum sample for bile acids analysis is taken after a 12-hour fast. After this baseline sample (i.e., prebile acid) is taken, the animal is fed a meal or injected with cholecystokinin as a method to contract the gall bladder and release of a bolus of bile acids into the duodenum. After a set amount of time (typically 30 minutes to 2 hours) another serum sample is taken for bile acids measurement (i.e., postbile acid) (Bridger et al., 2008; Stockham, 2008). Using this method, hepatic functional ability is assessed by exposing the hepatocytes to an influx of endogenous bile acids (Stockham, 2008). Performance of the serum bile acids test using a pre and postprandial bile acids method increases the diagnostic sensitivity and specificity of the test in the dog (Center et al., 1991). In those species that lack a gall bladder, such as a rat, a serum sample after fasting and measured for bile acid content is valid for diagnostic utility.

11.3.2.1 Causes for Increased Serum Bile Acids

11.3.2.1.1 *Decrease in Functional Hepatic Mass*

Since serum bile acid processing is dependent upon hepatocellular function, bile excretion, and portal blood flow, these processes can be assessed using serum bile acid concentrations. Increased serum bile acids have a high sensitivity for the detection of hepatobiliary dysfunction (Stockham, 2008). However, the cause for the decrease in hepatic function may not be definitively determined and the functional abnormalities can be from primary or secondary insults. Liver toxicity secondary to administration of xenobiotics has the potential to alter multiple steps in the process of bile acid formation and excretion thus causing an increase in serum bile acid concentration (Hall and Nancy, 2008). Other diffuse hepatic pathologic conditions (i.e., chronic or acute inflammation, degenerative disease, metabolic disturbances) can cause sufficient damage to the hepatocytes and alter their functional abilities to produce or clear bile acids.

11.3.2.1.2 *Vascular Shunts*

Acquired or congenital portosystemic shunts result in bile acids absorbed from the ileum to bypass the liver and enter into the systemic circulation. These conditions cause marked increases in serum bile acid concentrations. This pattern of marked serum bile acids increase may be most noticeable following ingestion of a meal (Tennant and Center, 2008).

11.3.2.1.3 *Impaired Bile Flow*

Conditions that cause hepatic or posthepatic impairment of bile flow (i.e., cholestasis) can cause an increase in serum bile acids. Several mechanisms responsible for increase in serum bile acids concentration with impaired bile flow are proposed. With impairment of bile flow, there is a down-regulation of bile acid transport proteins in the canalicular system, which causes hepatocytes to release bile acids in the sinusoidal blood (Stockham, 2008). Also with cholestasis, accumulation of bile acids has been shown to be toxic to the hepatocyte and may cause cell death (Webster and Anwer, 1998; Webster et al., 2002). Damage to the hepatocytes may alter their function and cause the release of bile acids to circulation. With some conditions, cytokines can impair bile acid transport proteins on the canalicular membranes and cause accumulation of bile acids (Whiting et al., 1995; Moseley et al., 1996). As expected with impairment of bile flow, a concurrent decrease in bilirubin excretion is expected but may not be profound enough to result in increases in serum bilirubin (Stockham, 2008).

Despite the clinical utility of using serum bile acid concentrations to identify hepatic disease, its use has not proven effective for the identification of hepatotoxicity (Cheng-long et al., 1992). It does not appear to have advantages over the use of serum liver enzyme activity measurement for monitoring hepatotoxicity (Hall and Nancy, 2008).

11.3.2.2 Causes for Decreased Serum Bile Acids

In humans, approximately 95% of the bile acids secreted during a single pass through enterohepatic circulation are recirculating bile acids (Tolman, 2001). Therefore, a disruption in this cycle can result in a decrease in serum bile acids. In most instances, it is ileal malabsorption of the bile acids that are the cause for abnormal enterohepatic circulation and thus decreased serum bile acid concentrations (Tolman, 2001).

11.3.2.3 Influencing Factors

Free hemoglobin or excessive lipids in the plasma/serum sample can have a negative effect on the spectrophotometric assay (Stockham, 2008). Other factors that may provide unequivocal results, especially with the bile acid challenge test, are spontaneous contraction of the gall bladder prior to feeding, delayed emptying of gastric contents, increased intestinal transit time, and abnormal bile acid absorption in the ileum (Stockham, 2008).

11.3.3 AMMONIUM

The catabolism of proteins and nucleic acids results in the formation of nonprotein nitrogenous metabolites for which one is ammonium (NH_4^+). The majority of the circulating NH_4^+ is produced in the gastrointestinal tract by metabolism of dietary protein by bacteria. The NH_4^+ is transported to the liver via the portal vein and hepatic artery where it is converted to urea in the hepatocytes by the Krebs–Henseleit urea cycle (Newman and Price, 2001). The urea diffuses into the sinusoidal blood or bile canaliculi to be excreted through the kidney or gastrointestinal tract, respectively (Stockham, 2008). NH_4^+ can be excreted through the kidney as well. Typically, ammonium (NH_4^+) is the predominate form found in the plasma compared to relatively little ammonia (NH_3). The ratio of NH_4^+ to NH_3 in the plasma at physiologic pH (i.e., 7.4) is approximately 30:1 (Stockham, 2008). Ammonium does not diffuse across cell membranes whereby ammonia is lipid soluble and rapidly diffuses across cell membranes. As the plasma pH increases, there is a shift of ammonium to ammonia and the rate of entry of ammonia into the cell increases. Therefore, the rate of entry of ammonia into the cells is proportional to the plasma concentration. This shift to ammonia and rapid entry into the cells is most profound in the central nervous tissue whereby ammonia has a toxic effect (i.e., hepatic encephalopathy).

11.3.3.1 Causes for Increased Serum Ammonium

The two main reasons for increase in serum NH_4^+ are similar to those causes for increased bile acids: decrease in functional hepatic mass and portal blood shunting. Intestinal bacteria produce large quantities of ammonium daily that requires clearance from the blood (Stockham, 2008). Those conditions that cause diffuse hepatocellular disease (e.g., necrosis, cirrhosis, toxic) can greatly diminish the liver's capacity to clear ammonium from the blood and convert it to urea. Typically, a loss of 70% of hepatic functional mass is required before baseline ammonium levels are increased (Bain, 2003; McCuskey, 2006). Moreover, as expected, congenital or acquired shunting of portal blood away from the liver can cause marked increases in serum levels of ammonium. Other possible causes for increased serum ammonium levels are congenital deficiencies in urea processing (rare), postprandial increase production of NH_4^+ and strenuous exercise (observed in dogs) (Stockham, 2008).

11.3.3.2 Causes for Decreased Serum Ammonium

Decreases in serum NH_4^+ do not appear to be of clinical significance.

11.3.3.3 Influencing Factors

Timely analysis for serum NH_4^+ is important for gaining accurate values. Once collected into the proper tubes (EDTA or heparin), the samples should be cooled to 4°C and analysis performed within 1 hour of collection. Inadequate sampling handling or delay in analysis can result in altered values (Stockham, 2008). In addition, heme pigment from hemolysis can falsely increase NH_4^+ values (Stockham, 2008).

11.3.3.4 Ammonium Tolerance Test

If a decrease in hepatic function is suspected and other laboratory tests (i.e., bile acids, bilirubin, etc.) are equivocal, an ammonia tolerance test may be performed. The principle of this test is to challenge the liver with a large dose of NH_4^+ via administration of NH_4Cl (either rectally or orally) or feeding a high-protein meal. The methodologies for each are described elsewhere (Stockham, 2008). In conditions of loss of hepatic function or portosystemic shunting of blood, an excessive increase in serum NH_4^+ is observed when the tolerance test is performed accordingly. The ammonium tolerance test is contraindicated when resting hyperammonemia is present as it may contribute to furthering of clinical abnormalities (i.e., hepatic encephalopathy). These tests are performed mostly in dogs but can be used with other species such as the rat (Mito et al., 1979; Sutherland, 1989).

11.3.4 DYE EXCRETION TESTS

Hepatic function can be assessed by excretion tests using two organic anions: indocyanine green (ICG) or bromosulfophthalein (BSP). The use of BSP to assess liver function in humans was introduced over 80 years ago and has been used in animals since the 1950s (Flatland et al., 2000). BSP is administered intravenously and circulates bound to primarily albumin (Cornelius, 1991; Thrall, 2004). The bound BSP is then removed from circulation by the hepatocytes, conjugated and excreted in the bile. Therefore, the BSP excretion test is useful for assessing hepatic blood flow, hepatocellular function, and the biliary system (Cornelius, 1991). A straightforward spectrophotometric to determine plasma concentrations is used to measure BSP plasma concentration to determine clearance. Use of the BSP excretion test has been used in many laboratory species to assess liver function (Cornelius, 1991). However, the test is prone to negative influences by nonhepatic processes such as edema and hypoalbuminemia (Thrall, 2004). In addition, BSP is no longer commercially available and other liver tests that assess liver function (i.e., bile acids, ammonia, bilirubin) have proven to be more sensitive for detecting liver abnormalities (Center, 1990; Flatland et al., 2000). Like BSP, ICG is administered intravenously, protein-bound (primarily albumin and β -lipoprotein), and removed from circulation by hepatocytes (Cornelius, 1991; Thrall, 2004). ICG is excreted in bile in an unconjugated form. Also similar to BSP, the ICG excretion test is capable of assessing liver function, hepatic flow, and the patency of the biliary system. ICG excretion can be influenced by nonhepatic abnormalities, which requires numerous timed samples and is expensive (Thrall, 2004). Therefore, ICG offers no advantage over other hepatic function tests (Thrall, 2004). With the advent of bile acids and other measures of hepatic function such as bilirubin and ammonium, the use of dye excretion tests is infrequently used today.

11.3.5 OTHER TESTS TO ASSESS LIVER FUNCTION

Because of the diverse physiologic roles of the liver, the changes in the concentrations of several plasma analytes may offer clues to the overall assessment of liver function.

11.3.5.1 Albumin

Albumin is the most abundant serum protein and is produced solely in the liver (Eckersall, 2008). As expected, the loss of functional capacity of the liver can result in a decrease in serum albumin concentrations. Typically, 60%–80% of hepatic function must be lost before hypoalbuminemia is noted (Thrall, 2004).

11.3.5.2 Cholesterol

The liver is the chief organ for cholesterol synthesis and catabolism (Bruss, 2008). Bile is the major route of excretion for cholesterol. Therefore, with decreases in bile flow (i.e., cholestasis), increases in serum cholesterol can occur. Since the liver is the main organ for cholesterol synthesis, a loss of function can result in decrease in serum cholesterol (Thrall, 2004). Since the decrease in bile flow and loss of function can occur simultaneously, serum cholesterol may be variable with severe hepatic disease (Thrall, 2004).

11.3.5.3 Urea Nitrogen

As stated previously, the liver converts ammonium from catabolism of proteins to urea via the Krebs–Henseleit urea cycle (Newman and Price, 2001). Subjects with liver failure lack the ability to convert the ammonium to urea thus increasing serum ammonium and decreasing urea concentrations (Newman and Price, 2001).

11.3.5.4 Coagulation proteins

The liver is responsible for the synthesis of most of the coagulation proteins (Stockham, 2008). If any of the clotting factors decrease by less than 30% of normal, a prolongation in coagulation times can be observed (Thrall, 2004).

11.3.5.5 Glucose

The liver plays a key role in glucose metabolism; thus, loss of hepatocellular function can result in decreased serum glucose (Stockham, 2008). However, it should be recognized that numerous nonhepatic conditions can cause hypoglycemia. Therefore, evaluation of glucose for the detection of liver failure should be accompanied by other liver function tests.

11.3.5.6 Triglycerides

The *de novo* synthesis of triglycerides and incorporation into lipoprotein particles is done in the liver in most laboratory animals. Because of this hepatic function, studies have shown that serum triglyceride levels decrease following the experimental toxic insults to the liver in rats (Provost, 2003). The decrease in the serum triglycerides have been suggested to occur due to the increase in the catabolism of the lipids or impairment of synthesis or transport of the triglycerides in the liver (Provost, 2003). Therefore, triglycerides may be used as an early biomarker of toxic liver insults.

11.3.5.7 Cholinesterases

Not considered a traditional enzyme biomarker of hepatic injury or function, cholinesterases (ChEs) have demonstrated some utility evaluating liver impairment. In general, the mammalian liver contains ChEs, catalytic enzymes involved in the hydrolysis of choline esters. There are two main ChEs, acetylcholinesterase (which, most notably, terminates the action of acetylcholine postsynaptically) and butyrylcholinesterase, also known as nonspecific ChE or pseudocholinesterase, (with no clear physiological function). They differ in their substrate specificities and inhibition by selective inhibitors (Chatonnet and Lockridge, 1989).

Clinically, serum and erythrocyte ChEs have demonstrated utility in identifying exposures to anti-ChE agents, some liver disorders, and congenital abnormalities (Wills and Dubois, 1972;

Witter, 1963). In humans, reduced serum butyrylcholinesterase activity has been linked to chronic liver diseases, including cirrhosis, inflammation, injury and infections, and malnutrition (Brown et al., 1981; Santarpia et al., 2013). In laboratory animals, however, evaluation of ChE activity traditionally has been used as a marker of neurotoxicity to examine products or compounds containing organophosphates or carbamates (Hoffmann et al., 1999). Nevertheless, there are studies demonstrating the use of ChE as a marker of altered hepatic function. For example, in rats, García-Ayllón et al. (2006), demonstrated a marked decrease in the acetylcholinesterase levels in rat livers with bile duct ligation- or CCl₄-induced cirrhosis. Furthermore, plasma from the bile duct ligation-induced cirrhosis rats had approximately 45% lower AChE activity than controls. Since liver butyrylcholinesterase was apparently unaffected, the authors suggested this change was specific for acetylcholinesterase. In mice experimentally infected with *Toxoplasma gondii*, Da Silva et al. (2013) demonstrated a significant reduction in serum and liver butyrylcholinesterase activity and an increase in serum ALT activity during the acute phase of the infection. The authors concluded that the reduced butyrylcholinesterase activity was related to the liver damage caused by the parasitism. In dogs, Tvarijonaviciute et al. (2012) demonstrated that serum butyrylcholinesterase decreased during experimentally induced endotoxemia and that choline administration attenuated the response. The reader is referred to Hoffmann et al. (1999) for a detailed discussion of ChEs, their evaluation and substrate specificities in laboratory animals.

12.1 INTRODUCTION

The kidney is a complex organ that is responsive to the changes in the whole organism. As such, kidney function is affected by various hormones, food intake and diet, shifts in acid–base status, and changes in blood pressure and fluid volume. The functional unit of the kidney is the nephron, consisting of two functionally distinct units: the glomerulus, which is basically a vascular bed

TABLE 12.1
Function Specific Regions of the Kidney

Component of Nephron	Action
Glomerulus	Passive formation of ultrafiltrate of plasma devoid of most protein
Bowman's capsule	Collection of glomerular filtrate
Proximal tubule	Active reabsorption of glucose, proteins, and amino acids, vitamins, ascorbic acid, acetoacetate, hydroxybutyrate, uric acid, sodium, potassium, calcium (by PTH), phosphate (by PTH), sulfate, and bicarbonate Passive reabsorption of: chloride, water, and urea Active secretion of hydrogen ion Production of calcitriol
Henle's loop	Generation of medullary hyperosmolality
Descending limb	Passive reabsorption of water Passive secretion of sodium, urea
Thin ascending limb	Passive reabsorption of urea and sodium; impermeable to water
Thick ascending limb	Active reabsorption of chloride and calcium Passive reabsorption of sodium, impermeable to water, potassium
Distal tubule	Active reabsorption of sodium (by aldosterone), calcium, bicarbonate, and small amounts of glucose Passive reabsorption of chloride, water (by ADH) Active secretion of hydrogen ions, ammonia, and uric acid Passive secretion of potassium
Collecting ducts	Active reabsorption of sodium (by aldosterone) Passive reabsorption of chloride and water (by ADH) Active secretion of hydrogen ion Passive secretion of potassium

ADH, antidiuretic hormone; PTH, parathyroid hormone.

serving as a diffusion membrane, and the renal tubule, which selectively processes the glomerular ultrafiltrate and maintains homeostasis of the organism. The renal system accomplishes this function by three general processes: (1) glomerular filtration and tubular secretion of toxins such as blood urea nitrogen (BUN), creatinine, and metabolic waste products, (2) reabsorption and secretion of water, electrolytes, and solutes from the glomerular filtrate to maintain homeostasis and acid–base balance, and (3) biosynthesis involving formation of a variety of hormones and other chemicals which have both local and systemic effects (Table 12.1).

Detailed descriptions of renal anatomy and physiology are beyond the scope of this chapter. However, knowledge of normal renal function is necessary to understand the pathophysiology and to adequately interpret any changes seen in serum and urine analytes resulting from nephrotoxicity or renal disease. Reviews of renal anatomy and physiology are available in the literature (Pooler and Eaton, 2009; Rennke and Denker, 2010; Rose, 2001).

12.2 INTERDEPENDENCY OF RENAL FUNCTION WITH OTHER ORGAN SYSTEMS

Primary or secondary changes in renal function may affect other organs in the body or may result from dysfunction of these other organs. For example, chronic kidney disease (CKD) can result in inadequate formation of erythropoietin (EPO) and 1,25-dihydroxycholecalciferol. EPO is produced by the kidney and acts on the bone marrow to stimulate the production of red blood cells (RBCs), and synthesis of EPO and its constitutive release into the circulation are controlled by the transcriptional activity of the EPO gene. A key regulator of EPO is the hypoxia-inducible

transcription factor (HIF), which essentially triggers EPO production from the cortical interstitial fibroblasts in the kidney (Castrop and Kurtz, 2010). The clinical effect of failure to produce EPO is the nonregenerative anemia of CKD, whereas the clinical impact of inadequate renal production of 1,25-dihydroxycholecalciferol is development of renal osteodystrophy and renal secondary hyperparathyroidism. Both kidney and lungs play major roles in acid–base regulation in vertebrates so that a significant renal tubular defect with loss of electrolytes can result in systemic disease if untreated and/or the respiratory system is unable to correct the imbalance (Rose, 2001; Rothstein et al., 1990). Natriuretic peptides, synthesized in the heart and prostaglandin E2 (PGE₂), synthesized in the kidneys facilitate renal excretion of sodium and water (Bonvalet et al., 1987; Farman et al., 1987). Several other hormones have specific effects on the kidney and its functions. Renin is produced in the kidneys from specialized cells (e.g., granular cells) of the juxtaglomerular apparatus in response to renal sympathetic activity, decreased intrarenal blood pressure at the juxtaglomerular cells, or decreased delivery of sodium and chloride to the macula densa (Kumar and Fansto, 2010). When less sodium is sensed by the macula densa, the juxtaglomerular cells increase renin release. Renin cleaves the peptide bond between the leucine (Leu) and valine (Val) residues on angiotensinogen, creating the 10-amino acid peptide (des-Asp) angiotensin I. Angiotensin I is converted to angiotensin II (AII) through removal of two C-terminal residues by the enzyme angiotensin-converting enzyme (ACE) within the kidney. AII increases blood pressure by stimulating the Gq protein in vascular smooth muscle cells (which in turn activates contraction by an inositol 1,4,5-trisphosphate [IP₃]-dependent mechanism, leading to vasoconstriction).

Aldosterone is the major mineralocorticoid hormone secreted by the adrenal cortex. In the kidney, aldosterone promotes retention of sodium and bicarbonate, excretion of potassium and hydrogen ions, and secondary retention of water. Aldosterone synthesis is stimulated by several factors, including an increase in the plasma concentration of (1) angiotensin III (a metabolite of AII), (2) AII (regulated by angiotensin I, which is in turn regulated by the hormone renin), (3) adrenocorticotrophic hormone (ACTH), or (4) potassium levels, which are present in proportion to plasma sodium deficiencies. Increased potassium regulates aldosterone synthesis by depolarizing the cells in the zona glomerulosa, which opens the voltage-dependent calcium channels. As such, potassium levels are the most sensitive stimulator of aldosterone (Williams and Dluhy, 1972).

Endothelin-1 (ET-1) together with endothelin-2 (ET-2) and endothelin-3 (ET-3) comprise the endothelin family of 21-amino acid peptides produced in various cells and tissues, especially endothelial and epithelial lineages. ET-1 is a key mediator of vascular tone and renal homeostasis through antagonistic vasoactive effects. ET-1 is a vasoconstrictor, but it also induces the production of the potent vasodilator, nitric oxide (NO). Consequently, dysfunctions of ET-1 signaling are associated with cardiovascular, renal, and respiratory diseases, such as high blood pressure, atherosclerosis, and systemic and pulmonary hypertension (Hynynen and Khalil, 2006).

Arginine vasopressin (AVP), also known as vasopressin, argipressin, or antidiuretic hormone (ADH), is a neurohypophysial hormone found in most mammals. Vasopressin is responsible for increasing water absorption in the kidney by inducing translocation of aquaporin–collecting duct (CD) water channels in the plasma membrane of CD epithelial cells of the nephron (Caldwell and Young, 2006; Nielsen et al., 1995). Vasopressin additionally increases peripheral vascular resistance, which in turn increases arterial blood pressure and plays a key role in homeostasis via regulation of water, glucose, and salts in the blood (Loeb, 1998). Renal disease, which can result in imbalances in these hormones, can invoke plasma volume expansion, hypertension, and peripheral edema.

12.3 LABORATORY TESTS OF RENAL FUNCTION AND INJURY

12.3.1 ROUTINE URINALYSIS

Routine urinalysis is an essential part of the laboratory evaluation, and the results should be interpreted along with the results of a chemistry panel. Ideally, urine should be collected at the same

time, or as close as possible to the time of blood collection for hematology and clinical chemistry. This allows for accurate interpretation of renal-associated parameters from the clinical chemistry and/or hematology panel by correlation with findings in urinalysis. For example, a BUN of 100 mg/dL in a dog may be interpreted differently when the urine specific gravity (USG) is 1.006 (polyuric renal failure) versus 1.080 (renal or potential prerenal effects). Alternatively, a nonregenerative anemia (no reticulocytes) may be explained by renal injury affecting EPO production.

12.3.1.1 Urine Sample Collection

Urine collection from animals can be difficult, but many urinary analytes are affected by the method of collection, processing, or storage (i.e., lack of preservation of urine during and after collection). Proper collection is required for quality results. Urine should be collected under refrigeration into a clean, dry, and sterile container that is free of any disinfecting or cleaning chemicals. If urine is allowed to remain in shallow containers at room temperature (RT), evaporation occurs with resultant increases in specific gravity and bacteria, changes in pH, and deterioration of formed elements such as casts and crystals, so that the sample is not useful for evaluation.

Urine can be collected as a timed free-catch collection, via catheterization, or by cystocentesis. The collection procedure that is most commonly used in toxicology studies is a free-catch, timed collection (Kurien et al., 2004). Monkeys, dogs, and rodents are housed in individual cages, frequently metabolism cages, and urine is collected over a certain period of time. This may be referred to as an overnight collection, but is most usually for a period of 12–18 hours. The use of metabolism cages is optimal for collection of urine from rodents, as variations in design of these cages enhance the quality of sample collection by eliminating water spillage and decreasing contact with feces while permitting urine to flow down an incline into a collecting vessel. Several styles are commercially available and Nalgene® has optimized rodent metabolism cages with reusable individual refrigeration units that keep the specimens at an acceptable cool temperature overnight. Both rat and mouse cages are available, and there is a measurable difference in both the urine volume and quality when appropriately sized cages are used for the different species (Matandos and Franz, 1980). For example, when mice are placed in rat metabolism cages for urine collection, the volume produced by mice is so small that much of it can evaporate. Proprietary collection containers could also be used, for example, styrofoam shipping containers can be modified to accommodate the urine collection tubes through a hole cut in the container lid. Crushed ice is packed tightly around the collection tube and the lid is placed over the container. However, no system totally eliminates contact between urine and feces or urine and food, and some may potentially permit some spilling of the drinking water that could cause dilution of the urine specimen. It is therefore essential that experienced animal care staff carefully set up and inspect the metabolic units to be certain the tips of the watering devices allow ready access to water by the animals, but minimize spillage of water and contamination of the urine sample. In most cases, the animals should not have access to food during a timed urine collection in order to avoid food contamination of the urine. The use of preservatives can also affect the measurement of urine parameters and their use is generally discouraged. Sodium azide, however, is frequently used in samples that are being collected for metabolomic analysis and this does not appear to adversely affect routine urinalysis parameters.

Urethral catheterization may be performed in most species, but is more frequently used in larger animal species such as dogs, cats, miniature swine, and nonhuman primates (Ragan and Gillis, 1975). While chemical restraint may be required with some species, gentle physical restraint is generally sufficient for catheterization in many situations. This technique has been described for use in the rabbit, dog, cat, and monkey (Kirk and Bistner, 1969; Loeb, 1964; Moreland, 1965), as well as the rat (Kraus, 1980). Catheterized samples have less contamination from the distal urogenital tract; however, contamination from the urethra may still occur resulting in increased epithelial cells or RBCs. And poor catheterization technique may lead to trauma or, less commonly, infection (Zinkl et al., 1999; Osbourne et al. 1972; Chew and DiBarola, 1998).

Random urine samples may be obtained from many species by cystocentesis and can be performed in most animals without sedation, tranquilization, or a local anesthetic. The animal is usually placed in lateral recumbency, with the hind legs extended caudally. For larger or obese animals, the animal may be positioned in dorsal recumbency with the hind legs extended straight back from the body. Cystocentesis may also be performed with the animal standing. The bladder is located by palpation, and if the bladder is empty or small, then cystocentesis should be delayed until the bladder contains more urine. Alternatively, ultrasonography may be used to guide cystocentesis of small bladders or bladders that cannot be manually located (e.g., obese or tense animals). Hair may be clipped from the proposed entry site of the needle or simply spread apart by wetting with alcohol. If the hair is clipped, then the skin may be prepared using sterile technique. A 3–12-cc syringe attached to a 1.5-inch, 22-gauge needle is guided to penetrate through the paralumbar fossa, with the bladder trapped against the body wall or fixed between the thumb and forefingers when the animal is in lateral recumbency or through the ventral, caudal abdominal midline and directed toward the most bulbous part of the bladder when the animal is in dorsal recumbency. Needle penetration through either location can be used when the animal is standing. If possible, the needle is directed into the ventral or ventrolateral aspect of the bladder at a 45°–90° angle. Aspiration on the syringe should yield urine. If no urine is retrieved, the needle is withdrawn almost to the body wall and carefully redirected.

Alternatively, a random, free-catch urine sample may be collected and many small rodents, such as rats, mice, and hamsters, will often urinate spontaneously when handled allowing collection of small quantities (5–250 μ L) of urine.

Urine should be stored refrigerated (approximately 4°C) after collection, but allowed to return to RT before analysis. Warming to RT allows for any crystals that may have formed under the refrigerated temperature to dissolve and enables the enzymatic assay reactions to proceed at the required temperature. Urinalysis should be performed on samples from individual animals. Pooling of routine urine samples is not generally an acceptable method, as any alteration in analytes cannot be correlated with alterations in individual animal serum parameters. Stability testing should be performed for various analytes that are assessed in urine samples in order to ensure proper storage conditions and testing limitations. Some stability data may be available on the technical insert sheet provided for each assay. However, when possible, it is optimal for each laboratory to establish stability data for all assays conducted. A general guide for stability information (as determined by one laboratory) for many of the most common urinalysis parameters is listed in Table 12.2.

Sample handling for some nonroutine analytes may require special conditions and in order to obtain reliable results, these conditions should be identified and followed. For example, urine for analysis of *N*-acetyl- β -D-glucosaminidase (NAG) in dogs should not be frozen. The recommended storage conditions for analysis of NAG from dog urine is refrigeration of urine samples at 2°C–8°C for up to 72 hours. However, urine for analysis of NAG from rat urine can be frozen at -80°C for up to 90 days, or aliquots can be refrigerated at 2°C–8°C for up to 72 hours (see Table 12.3). Urine collection for assessment of many of the more novel biomarkers should be performed under similar conditions as for the more routine analytes, for example, clean collection and refrigeration during the collection period. However, stability and storage conditions may be specific for different analytes. One consideration is that proteins are, in general, more stable than enzymes. So it is best to analyze urine samples for enzymes within 24 hours or to establish stability and then follow those criteria.

12.3.1.2 Physical Characteristics

12.3.1.2.1 Volume

Accurate measurement and documentation of urine volume are critical to the assessment of renal function. Volume is often utilized in calculating total output or may be used in normalizing the concentration or activity of many urinary constituents. Measurement of volume is also important in

TABLE 12.2
Urine Specimen Stability Reference Guides (Bristol-Myers Squibb)

Species	Storage Condition	Routine Urine Analysis (Volume, Color, Clarity, pH, Sediment Examination)	Urine Chemistry (Na, K, Cl, Ca, Mg, CREA, UTP, PHOS)	Osmolality (Serum and Urine)
Rat	Room temperature	N/A	N/A	≤5 hours
	2°C–8°C	Analytes: ≤48 hours Sediment: ≤4 hours	Perform same day	≤72 hours
	–80°C	<i>Note: Do not freeze</i>	≤90 days	≤30 days
Dog	Room temperature	N/A	N/A	≤5 hours
	2°C–8°C	Analytes ≤48 hours Sediment ≤6 hours	Perform same day	≤30 days
	–80°C	<i>Note: Do not freeze</i>	≤90 days	≤30 days
Monkey	Room temperature	N/A	N/A	Not tested
	2°C–8°C	Analytes ≤48 hours Sediment ≤6 hours	Perform same day	Not tested
	–80°C	<i>Note: Do not freeze</i>	≤85 days Exception: UMTF and PHOS not tested	Not tested

Time period listed for each analyte indicates stability limit at specified temperature. Ca, calcium; Cl, Chloride; CREA, creatinine; K, potassium; Mg, magnesium; Na, sodium; PHOS, phosphorus; UMTF, urine total protein; N/A, not applicable; UA, urinalysis.

determining potential polyuria associated with polydipsia and/or lack of concentrating ability in the animal. Occasionally, urine is contaminated with drinking water and a very dilute specific gravity or osmolality will result. This abnormality can usually be confirmed by the clinical observations.

Because the reference values for urine sediment evaluation are semiquantitative, it is optimal to start with a standard volume of urine to spin down for microscopic examination. Otherwise, the numbers of cells, casts, or crystals, and so on seen per microscopic field would be diluted or concentrated resulting from variations in the volume of urine that is used for examination. In humans, 10 mL of urine is generally used as the standard volume. Because this volume is not practical for most laboratory animals, particularly rodents, the volume obtained from the “overnight” collection can be standardized to 2–3 mL for small animals (i.e., rats) and 5 mL for larger animals. Using this type of standardization, the investigator can be assured that comparisons among animals are being performed in a consistent manner.

12.3.1.2.2 *Color and Clarity*

Observations of color and clarity should be made on the well-mixed urine specimen. Normal mammalian urine ranges from pale yellow to amber, primarily due to the pigment urochrome (a degradation product of heme) (Finco, 1989; Free and Free, 2012), and the degree of color is reflective of urine volume and concentration. Abnormal urine color may result from the presence of blood, bilirubin, myoglobin, hemoglobin, or certain drugs and this abnormal color can obscure some urine test strip results. Normal freshly voided urine is clear, but may become cloudy due to precipitation of salts if allowed to stand or if refrigerated. Microscopic examination is necessary to determine the cause of cloudy urine

12.3.1.2.3 *pH*

The kidneys play a vital role in maintaining acid–base status by regulating blood bicarbonate and hydrogen ion concentrations. The pH of urine is due to many chemical constituents, primarily inorganic phosphates, sulfates, citrate, ammonium salts, bicarbonate, and carbonic acid. These result from metabolic processes that produce nonvolatile acids filtered through the glomerulus in association with cations, such as sodium. In the renal tubules, sodium is selectively reabsorbed and exchanged for hydrogen ions, which are secreted. Processes involving renal tubular excretion and reabsorption affecting pH are covered in more detail in texts of renal physiology (Rose, 2001; Ganong, 2010; Guyton and Hall, 2011; Osborne et al., 1983).

The pH of urine varies considerably with the species, with the animal’s diet, and with acid–base status. For example, animals with diets composed primarily of high protein (meat-based) will have acidic urine due to the production of more sulfates and phosphates. Urine from animals whose diet is more vegetable-based will be more alkaline or neutral (Latimer et al., 2011; Chew and DiBarola, 1998). The pH should be measured on fresh urine, as the urine becomes more alkaline on standing due to the conversion of urea to ammonia by bacteria (if present), and loss of CO₂ (Latimer et al., 2011). Measurement of urinary pH alone is not generally diagnostic, but should be considered in the context of other findings.

Causes of more acidic urine (lower pH) include excessive catabolic states, as with fever, starvation, ketosis, diabetic mellitus, systemic acidosis, or hypochloridemia. Administration of acidifying agents such as D-, L-methionine or ammonium chloride for the treatment of urolithiasis also will effectively lower urine pH (Osborne et al., 1972; Chew and DiBarola, 1998). Urine with high concentrations of glucose may have a lower pH due to bacterial metabolism of glucose and production of ammonia (Latimer et al., 2011). Fanconi syndrome is a disease of the proximal renal tubules of the kidney where glucose, amino acids, uric acid, phosphate, and bicarbonate are passed into the urine, instead of being reabsorbed, and can result in acid urine. This disease may be inherited or caused by drugs or heavy metals. Additionally, various forms of Fanconi syndrome can affect other functions of the proximal tubule resulting in different complications. The loss of bicarbonate results in type 2 Fanconi syndrome or proximal renal tubular acidosis. Alternatively, the loss of phosphate results in the bone disease rickets even with adequate vitamin D and calcium (Magen et al., 2010).. Causes of alkaline urine (higher pH) include bacterial infection with urease-producing bacteria, systemic alkalosis, and administration of alkalinizing agents

such as sodium bicarbonate (Osborne et al., 1972; Chew and DiBarola 1998). Urinary obstruction will also potentially raise urine pH due to prolonged retention of urine in the bladder and decomposition of urea to ammonia while urine exposed to room air for an extended time may be artificially more alkaline due to loss of CO₂ (Latimer et al., 2011; Osborne et al., 1972; Chew and DiBarola, 1998).

Urine pH additionally impacts the formation of urinary crystals and renal calculi. Uric acid, cystine, and calcium oxalate crystals all tend to form in acidic urine. Struvite, calcium carbonate, calcium phosphate, ammonium biurate, and amorphous phosphate crystals tend to form in alkaline urine (Chew and DiBarola, 1998). Certain drug crystals also may be more likely to form at a specific pH.

For a more accurate assessment of urine pH, a pH meter may be used; however, the precision of a pH meter is not usually required for routine analysis, and the use of a urine test strip is generally satisfactory.

12.3.1.2.4 *Solute Concentration*

The ability of the kidneys to concentrate urine is a measure of renal function, and loss of urine concentrating ability is often the earliest sign of renal insufficiency. Urine entering the proximal tubule is at approximately the same osmolality as plasma. Water is reabsorbed at the proximal tubules by osmotic action following sodium, glucose, and other solutes, so that upon entering the loop of Henle, urine is isoosmotic. Urine osmolality then increases in the descending loop of Henle, which is permeable to water, but not solute. The reverse occurs in the ascending loop of Henle, where active transport of chloride occurs, so that urine entering the distal tubule is then hypoosmotic relative to plasma. Water is reabsorbed in the distal and collecting tubules in excess of solute under control of ADH.

Specific gravity and osmolality are often used as measures of the urine-concentrating ability of an animal. USG is dependent on particle size, number, and weight. It is the ratio of the density of urine to that of distilled water, which has a density of 1 g/mL at 4°C (Watts, 1971). Current refractometers use a scale that is corrected for refractive index, so that USG can be read directly. Using urine or centrifuged supernatant from a urine sample, USG is read on the refractometer rather than taken from the urine test strip because there is a limited range of specific gravity on urine test strips. Rodent urine frequently exceeds the upper limit of the specific gravity on urine test strips. Osmolality is dependent on particle numbers in solution and is considered the definitive method for determining the concentration or solute-to-solvent ratios in urine. It is usually measured by freezing point depression and expressed as millimoles per kilogram of water. Both USG and osmolality can be measured using microliter volumes of urine.

12.3.1.3 **Chemical Analysis**

Urine test strips (also referred to as dipsticks) contain pads of various chemical reagents that provide a color change when a particular analyte is present in urine. This color change is converted to a semiquantitative result for the analyte being measured. Urine test strips are available in various configurations, but for animals, the urine test strip may be used to assess pH, protein, glucose, ketones, bilirubin (primarily the conjugated form), and proteins containing a heme group (iron). Protein quantification is most sensitive to albumin, while ketone measurement is most sensitive to acetoacetic acid. USG, nitrate, leukocytes, and urobilinogen pads are also available on urine test strips, but are either not accurate in animals (leukocytes) or do not provide much additional information in animals and are seldom, if ever, reported. Urine test strip analysis should be performed on uncentrifuged urine, unless there is marked hematuria (which may affect interpretation of the color changes on the test strip). If marked hematuria is present, it may be necessary to centrifuge the urine and perform the urine test strip analysis on the supernatant. The package insert contains useful information about test limitations and interfering substances.

12.3.1.3.1 Protein

The glomerular membrane normally prevents large molecular weight proteins from passage into the filtrate, but the size, shape, and charge of proteins also influence their ability to pass through the glomerulus. Urine test strip measurement of protein is most sensitive for albumin, although the high anion content of alkaline urine may result in false positive results using this method. Positive protein results must be evaluated in relationship to clinical observations, method of urine collection, USG, and microscopic sediment examination. Proteinuria may be due to hemorrhage, infection of the lower urinary tract, intravascular hemolysis, or renal disease (Latimer et al., 2011; Osborne et al., 1972; Chew and DiBarola, 1998), and fever and strenuous exercise may produce transient proteinuria. Microscopic examination of the sediment can help determine the source of protein. Hemorrhage is confirmed by a positive occult blood reaction on the urine test strip and the presence of RBCs in the sediment, and intravascular hemolysis will result in hemoglobinuria leading to a positive occult blood test. A urinary infection or cystitis can be confirmed by observing bacteria and white blood cells (WBCs) on sediment examination (Latimer et al., 2011; Osborne et al., 1972; Chew and DiBarola, 1998).

Proteinuria of renal disease may be due to glomerular and/or tubular lesions. While tubular disease may result in decreased reabsorption of intermediate or low molecular weight proteins such as albumin (66 kDa) or β 2-microglobulin (12 kDa), respectively, and may cause increases in levels of these proteins in urine filtrate, overt glomerular disease can also result in large increases in low-, mid- and high-molecular weight proteins in the urine due to increased permeability of the glomerular membrane. If the proteinuria is due to renal disease, the sediment may or may not contain casts. Nephrotic syndrome is caused by various disorders that damage the kidneys, particularly the basement membrane of the glomerulus. This damage causes abnormal excretion of protein in the urine with resultant hypoproteinemia, hypercholesterolemia, hypertriglyceridemia, and generalized edema. Enhanced hepatic synthesis of lipoproteins containing apolipoprotein B and cholesterol is thought to account for most of the increase in cholesterol levels (Appel, 1991; Joven et al., 1990). Protein results must be analyzed with respect to the USG, as "trace" proteinuria (as determined on urine test strips) may represent significant protein loss with low specific gravity but may not be significant when associated with high specific gravity.

Proteinuria is common and considered normal in male rats and mice, due to major urinary proteins such as α 2-microglobulins (small monomeric proteins with a molecular weight of approximately 18,000) that are filtered through the glomerulus (Cavaggioni and Mucignat-Caretta, 2000; Finlayson et al., 1965; Lane and Neuhaus, 1972; Saito et al., 1996; Swenberg, 1993). Proteinuria in rats increases with age and is related to the spontaneous conditions of chronic progressive nephropathy and hyaline droplet formation in the proximal tubules (Hard and Khan, 2004; Casadevall et al., 2005; Corman et al., 1985; Corman and Michel, 1987).

12.3.1.3.2 Glucose

Glucose is freely filtered by the glomerulus but is almost completely reabsorbed by active transport in the proximal renal tubules. Therefore, glucose is usually not detectable in the urine of healthy animals. However, transient glucosuria can be associated with stress. Glucosuria is most often a function of hyperglycemia where urine glucose values exceed the capacity of tubular transport and can be due to diabetes mellitus, diabetogenic drugs, or inborn errors of carbohydrate metabolism. Glucosuria may also be the result of renal tubular damage, with loss of reabsorptive capacity in the proximal tubules. Urine test strips measure glucose levels semiquantitatively using the glucose oxidase method, which can be affected by large amounts of ascorbic acid in the urine of some species, specifically dog and mouse. For precise measurement, which is sometimes necessary in toxicology studies, urine glucose can be measured using the enzymatic reactions on chemistry analyzers.

12.3.1.4 Sediment Examination

Microscopic analysis of the urine sediment for formed elements in the urine including cells, crystals, and bacteria is considered part of the routine urinalysis and can potentially yield additional

information that may help explain changes in other parameters (Schumann, 1980) (see Table 12.4). However, proper analysis and interpretation of sediment findings may require specialized training and is not always performed for routine urinalysis. For this examination, the standard volume of urine is centrifuged at a low speed, the supernatant is decanted, and the urine is gently resuspended, placed on a slide, and examined under a microscope at low and high dry objectives. Depending on preference, the slide may or may not be stained with methylene blue or a variety of commercial stains for urinary sediment.

A minimum of 10 microscopic fields are viewed at low (10×) and high (40×) magnification and the number of formed elements are quantified and reported as the average number per field. Casts and sperm are reported as the average number per low-power field and other elements are reported as average number per high-power field (Tables 12.5 and 12.6).

12.3.1.4.1 Cells

Blood cells may be observed in urinary sediment and can be of diagnostic importance. The number of erythrocytes or leukocytes in “normal” urine is generally considered to be less than five cells per high-power field (Schumann and Colon, 1980). An increased number of blood cells in the urine

is indicative of renal and/or lower urinary tract disease and, when combined with other urinalysis parameters, may help localize the area of disease.

Hemorrhage from the urinary bladder or urethra is the most common source of hematuria in most preclinical species, and is often related to cystitis/urethritis or urolithiasis. In primates, hematuria may also be due to menses. Although the mechanism whereby intact erythrocytes enter the urinary

system from the kidney is not clear (Schumann and Colon, 1980), blood may occur in urine without increased permeability of glomerular membranes or without evidence of renal hemorrhage. Increased erythrocytes in urine of renal origin may occur with acute or chronic inflammatory disease, neoplasms, or renal calculi. Increased leukocytes in the urine may result from the same mechanism as increased erythrocytes. Of these, pyelonephritis is a common renal cause while bacterial cystitis or urolithiasis are predisposing factors for the presence of leukocytes in the lower urinary tract.

Epithelial cells from any segment of the urinary tract may be observed in urinary sediment. Large, flattened squamous epithelial cells with a high cytoplasm-to-nucleus ratio may exfoliate from the urethra, vulva, or vagina while transitional epithelial cells line the urinary tract distal to the renal pelvis. Identification of renal tubular epithelial (RTE) cells in the urinary sediment should be distinguished from epithelial cells of the lower urinary tract (transitional or squamous), because the presence of RTE cells may reflect injury or disease in the renal tubules.

Various benign or malignant cells may be observed in the urinary sediment and the same cytologic features used in differentiating benign from malignant cells in other exfoliative cytologic specimens are used in evaluating cells in the urine. Most carcinomas of the lower urinary tract epithelium are transitional cell carcinomas and these cells may be detected in urinary sediment with appropriate staining (Koss, 1968; Schumann and Colon, 1980). Although most tumor cells found in urine arise from the urinary tract, metastatic malignant cells may also be observed and metastatic tumors of the urinary tract infrequently exfoliate into the urine (Schumann and Colon, 1980). These tumors may also be associated with increased erythrocytes and/or WBCs in the sediment.

12.3.1.4.2 Casts

Accurate identification of casts can be important in the diagnosis and prognosis of renal disease. Fresh urine should be examined for the presence of casts because they may disintegrate after a few hours, particularly in alkaline urine. Casts are more readily detected with phase-contrast microscopy than with bright-field microscopy, but phase-contrast is not routinely employed for urine analysis. Renal casts are shaped by the tubules of the nephrons and are formed when proteins (mucoprotein and glycocalyx) gel in the renal tubules. A primary component of the matrix of renal casts is Tamm-Horsfall glycoprotein (Serafini-Cessi et al., 2003). This protein is present in the urine of several species and, though normally in solution, may precipitate and gel under conditions of altered urine flow, pH, and/or electrolyte concentrations within the kidney. Various cellular constituents may be incorporated when the protein gel forms. In kidney disease, blood protein may be present in the glomerular filtrate and may be incorporated into the mucoprotein and glycocalyx matrix. Renal casts vary considerably in size and composition and may be of significance in detecting active renal parenchymal disease. It is important to distinguish among the various types of casts, particularly those containing cells, as cellular casts are early indicators of tubular toxicity. Hyaline casts are basically protein casts that may form in cases of decreased urine flow, low pH, high solute concentration, or high protein concentration. Granular casts may be either fine or coarse, and although the source of the granules has not been well established, they are probably aggregated plasma proteins or the remnants of disintegrated cells. Although the "normal" number of casts is not well established, a few hyaline or granular casts per low-power field is not considered pathologic. More than a few granular casts per low-power field is probably indicative of renal parenchymal disease and would not be considered physiologic. Casts are relatively frequent findings in aged rodents and are related to the chronic progressive nephropathies.

RBC casts either indicate glomerular damage sufficient to permit erythrocytes to enter the renal tubules or bleeding from the renal parenchyma due to damage to the tubular basement membrane. With either type of injury, fibrinogen and other proteins also escape into the tubules and trap the erythrocytes in a fibrin matrix to form the cast. These casts may be made of degenerated red cells and hemosiderin, resulting in an orange-colored granular cast in unstained wet mounts. In addition to acute glomerulonephritis, red cell casts may be present in acute tubular necrosis, chronic nephritis, renal infarction, or renal hemorrhage of traumatic origin.

Leukocyte casts are indicative of bacterial infections of the kidney, such as pyelonephritis. Neutrophils probably gain access to the renal tubules by their own motility between and through renal epithelial cells rather than through the glomerulus. Leukocyte casts may occur in glomerular disease but generally are associated with tubulointerstitial disease.

Fatty casts are those in which lipid material is encased in a hyaline matrix. Such casts are associated primarily with acute renal diseases and tubular degeneration.

Casts of RTE cells may form any time there is damage to the epithelium with subsequent exfoliation of a large number of cells. Thus, tubular epithelial casts may be observed in acute tubular necrosis, interstitial nephritis, renal amyloidosis, and renal allograft rejection.

Waxy casts represent the ultimate stage in cellular degeneration. They are believed to be the end stage of granular casts that have been retained for a time in the tubules due to localized nephron obstruction (Schumann and Colon, 1980). They are associated with tubular degeneration and are most commonly observed in chronic nephritis.

Casts that contain a combination of various cells and other material are described as mixed casts.

Bacteria or crystals may become trapped within the protein matrix of a hyaline cast. If such inclusions are numerous, the cast is described as a bacterial or crystal inclusion cast.

Pseudocasts composed of fibrin or mucous threads and aggregates of crystals or cells may be confused with casts. True casts are the result of extrusion or formation within a tube, and as such, have the characteristic shape of defined parallel sides, whereas pseudocasts do not have these characteristics. However, mucous threads and squamous epithelial cells that have a cylindrical shape may occasionally be misinterpreted as casts.

12.3.1.4.3 Crystals

Various types of crystals may appear in the urinary sediment. Most are formed from normal constituents of urine and are of no specific diagnostic significance. Others are considered “pathologic” crystals and originate from exogenous compounds, defective metabolism, or abnormal excretion and their presence may reflect the composition of coexistent uroliths.

Crystals that form in normal urine are usually the result of an excessively high concentration of a relatively insoluble substance (e.g., calcium oxalate, uric acid, triple phosphate, calcium phosphate, amorphous phosphates or urates, or certain drugs and their metabolites) that precipitate out in urine. The type of crystals formed in such cases correlates with the urine pH (Bradley and Benson, 1974) or may occur with refrigeration and then dissolve upon warming to RT.

Abnormal or pathologic crystals may be of diagnostic significance and should always be reported. Cystine urinary crystals may be due to a defect in renal tubular reabsorption, even though plasma cystine levels are normal. Genetic defects in amino acid metabolism or severe liver disease interfering with normal amino acid metabolism may result in amino acidemia, with urinary precipitation of cystine, tyrosine, or leucine. Crystals of cholesterol can form in the tubules and may be indicative of renal disease. Multiple drug therapies also have been associated with crystal formation (Fogazzi, 1996). Sulfonamide crystals have historically been observed in urinary sediment after therapy, but the incidence is now lower due to the introduction of more soluble sulfonamides. Ampicillin may occasionally precipitate in urine following large parenteral doses, and crystals of investigative pharmaceutical compounds that are excreted or metabolized in the kidney may be observed in laboratory animals on studies. Use of the x-ray contrast media, meglumine diatrizoate, may also result in compound-related crystals appearing in the urine.

12.3.1.4.4 Infectious Agents

Normal urine is sterile and devoid of microorganisms. However, some bacteria are present in most urine specimens, unless appropriate and exacting techniques, such as catheterization, are employed to exclude contaminants present in the lower genitourinary tract. Even then, positive cultures may be obtained unless the specimen was cultured immediately or refrigerated. The presence of a large number of bacteria in the sediment of a fresh urine sample when leukocytes are also present should

raise the suspicion of a urinary tract infection. The observance of bacteria in an uncentrifuged, fresh urine specimen is presumptive evidence of a urinary tract infection and usually indicates greater than 100,000 organisms/mL (Schumann and Colon, 1980). In such cases, Gram stains and urine cultures are indicated.

Fungi may occasionally be observed in urinary sediment and may be either saprophytes or pathogens. *Candida* species are the most commonly observed yeast form in human urine specimens. Yeast infection may occur in animals with genetic or acquired immunodeficiency or immunosuppressive chemotherapy. Diabetes also predisposes to yeast infections of the urinary tract.

Only a few parasites or ova are specific to the urinary tract of laboratory animals. However, unless care is taken in obtaining the urine sample, it may contain ova and/or parasites from the gastrointestinal (GI) tract, and some ova (e.g., *Capillaria* and *Trichuris vulpis* ova) may be confused with those of urinary tract parasites.

Diocotophyma renale is a kidney parasite that may live in the renal pelvis of the dog and mink. *Stephanurus dentatus* is a kidney worm found in swine and is relatively common in some parts of the United States. *Capillaria* species are nematode parasites found in the urinary bladder and sometimes in the renal pelvis of dogs, cats, and rats. *Capillaria* species are relatively nonpathogenic and rarely, if ever, found in purpose-bred laboratory animals (Flynn, 1973). *Trichosomoides crassicauda* may be present in the urinary bladder wall, ureters, and renal pelvis of rats, but is usually of low pathogenicity (Flynn, 1973; Owen, 1992). *Klossiella* sp. may also be present in guinea pigs and mice (Seibold and Thorson, 1955). Diagnosis of urinary tract parasitism is made by identification of the characteristic ova in the urine sediment.

12.3.1.4.5 Miscellaneous

Lipid or fat droplets may be observed in urine specimens. They are round, highly refractile bodies that must be distinguished from erythrocytes. Under polarized microscopy, they may exhibit anisotropism. Care must be taken in collecting urine specimens to be certain that contaminating fatty substances are not introduced from lubricating agents or unclean glassware. Lipid of urinary tract origin may indicate degenerative tubular disease, pyelonephritis, acute glomerulonephritis, renal carcinoma, or acute nephritis. Lipiduria may also occur in diabetes mellitus.

Chyluria may rarely occur with obstructions of the lymphatic system (Schumann and Colon, 1980). Elevated urine protein levels and lymphocytes in the sediment and a milky appearance of the urine specimen may be important clues in diagnosing chyluria.

Mucus or fibrin threads are commonly observed in urine. Mucus threads, which are composed of precipitated mucoproteins, may form in most urine as it cools. Fibrin threads are the result of glomerular leakage or hemorrhage into the urinary tract.

Fibers from extraurinary sources may contaminate urine specimens and must be differentiated from casts and mucus or fibrin threads. These contaminants may be cotton, wool, synthetic fibers, or hair. Starch granules from surgical gloves may also contaminate urine specimens. Starch crystals may appear round or oval and highly refractive and corn starch is almost always hexagonal with an irregular indentation in the center.

Spermatozoa are common in the urine of males and may be observed in females following mating. Tailless spermatozoa may be confused with bacteria, yeast, or cell nuclei.

12.3.2 SERUM MARKERS OF RENAL INJURY

12.3.2.1 Creatinine and BUN

Creatinine and BUN are the classic serum markers of renal function. Serum markers generally report changes in glomerular filtration rate (GFR) and reflect functional nephron mass. As the kidney has a large functional reserve, such serum biomarkers only change when there is greater than two-thirds renal compromise. Characteristically, these serum markers are small enough to be freely filtered (nonprotein bound) by the glomerulus, released to the plasma at a constant rate,

generally neither secreted nor reabsorbed from the tubule, and minimally influenced by extrarenal disease/physiology. However, the influence by extrarenal changes, such as a change in muscle mass, increased dietary protein, dehydration, or GI hemorrhage, (GFR depends primarily on renal blood flow) does produce some limitations to their use and can result in a wide baseline variation. In addition, plasma levels also are influenced by tubular secretion or reabsorption. Most of the assays for these parameters are also vulnerable to interference, as many are colorimetric and drugs or endogenous substances can interfere with assay performance.

BUN, a product of ammonia metabolism (excretion), is primarily produced by the liver, and >90% is excreted via glomerular filtration. BUN generally underestimates GFR due to reabsorption or equilibration between the intra- and extravascular space as it readily crosses cell membranes/tubules, and significant (up to 70%) tubular reabsorption is possible. Greater reabsorption occurs at low flow rates/decreased renal perfusion (i.e., when function is compromised). Reabsorption from postrenal sources (e.g., peritoneum, urinary bladder) can also be a source for plasma BUN in cases of bladder rupture. Synthesis and plasma release of BUN are not constant and plasma levels also reflect protein intake, liver function, and protein catabolic states including muscle wasting, GI hemorrhage, and corticosteroid administration.

Muscle is the primary source for plasma creatinine, which is nonenzymatically formed from phosphorylcreatine at a rate of approximately 1.6%–2.0%/day (Wyss and Kaddurah-Daouk, 2000). Feedback control of synthesis provides reasonably consistent baseline plasma levels, so that plasma creatinine is less reflective of protein catabolic states than is BUN. Baseline plasma levels of BUN or creatinine, as well as clearance of either endogenous or exogenous creatinine can be used to estimate GFR. However, creatinine concentrations can overestimate GFR, as there is significant tubular secretion in many species (mice, rats, dogs) and frequently in males with larger muscle mass, particularly at low tubular flow rates (i.e., low GFR) (Eisner et al., 2010; O'Connell et al., 1962). It should also be noted that creatinine secretion can be inhibited by some drugs (i.e., cimetidine, trimethoprim, salicylates) resulting in nonrenal increases in plasma levels. In addition, drugs and endogenous substances may also interfere with colorimetric assay methods.

Azotemia occurs when BUN and/or creatinine increase above reference plasma levels. Azotemia can be classified as prerenal, renal, or postrenal. Prerenal azotemia results from dehydration or decreased renal blood flow (e.g., decreased GFR), but the concentrating ability of the kidney is intact. Renal azotemia results in inadequate concentration of the urine secondary to dysfunction of the kidney. Postrenal azotemia occurs from a blockage of urine flow in an area below the kidneys. The urea nitrogen:creatinine ratio is sometimes used to assist in determining which type of azotemia is occurring. If the baseline for both analytes is elevated, renal azotemia is most likely. If the ratio is extremely high, it is more likely of prerenal or postrenal origin. A high ratio due to increased BUN alone is more indicative of GI hemorrhage, a high-protein diet, or tissue catabolism. A low ratio could suggest that an underlying liver disease, low-protein diet, or tissue anabolic states may coexist.

12.3.2.2 Electrolytes

The concentration of serum electrolytes (such as sodium, calcium, potassium, chloride, magnesium, and bicarbonate) can be affected by nutrition, renal disease, and renal response to acid–base status. Tests that measure the concentration of electrolytes are very helpful for the diagnosis and management of renal or endocrine disease, acid–base disturbances, water balance, and many other conditions.

Sodium levels are directly related to the osmotic pressure of the plasma. Because an anion is always associated with sodium (usually chloride or bicarbonate), the plasma osmolality (total dissolved solute concentration) can be estimated. Since water will often follow sodium by diffusion, loss of sodium leads to dehydration and retention of sodium leads to edema. However, conditions that promote hypernatremia do not promote an equivalent gain in water. These conditions include diabetes insipidus (impaired renal water reabsorption), Cushing's disease, and hyperaldosteronism

(increased sodium reabsorption) (Wu, 2006). Many other conditions, such as congestive heart failure, cirrhosis of the liver, and renal disease result in renal retention of sodium, but an equivalent amount of water is retained as well. This results in total body sodium excess, which causes hypertension and edema, but not an increased serum sodium concentration. Hyponatremia may result from Addison's disease, excessive diuretic therapy, the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), burns, diarrhea, or vomiting.

Potassium is an important electrolyte associated with renal failure. Like sodium, potassium is freely filtered by the kidney. However, in the distal tubule sodium is reabsorbed and potassium is secreted. In renal failure, the combination of decreased filtration and decreased secretion combine to cause increased plasma potassium. Hyperkalemia is the most significant and life-threatening complication of renal failure, but hyperkalemia can also be caused by hemolytic anemia (release from hemolyzed RBCs), diabetes insipidus, Addison's disease, and digitalis toxicity. Frequent causes of low serum potassium include alkalosis, diarrhea and vomiting, excessive use of thiazide diuretics, Cushing's disease, insufficient dietary intake, intravenous fluid administration, and SIADH (Wu, 2006).

Renal tubular acidosis involves the failure to secrete acid into the urine. The resultant systemic acidosis produces weakness, headache, nausea, and cardiac arrest. Acidemia, as measured by serum bicarbonate and/or blood pH, is also common in individuals with chronic renal failure. Conversely, alkalosis or a decrease in the acid content of the blood can result from low plasma chloride, for example from loss of hydrochloric acid by vomiting. If severe, alkalosis can cause paralysis (tetany) (Edmondson et al., 1975).

Hyperphosphatemia can result from the failure of the kidneys to excrete phosphate into the urine (decreased GFR), causing phosphate to accumulate in the bloodstream. Hyperphosphatemia can also be caused by the impaired action of parathyroid hormone and by phosphate poisoning (associated with sodium phosphate enemas). Severe hyperphosphatemia can cause paralysis, convulsions, and cardiac arrest. These symptoms result because the phosphate, occurring in elevated levels, complexes with free serum calcium, resulting in hypocalcemia.

12.3.3 URINE MARKERS OF RENAL INJURY

Nephrotoxicity is difficult to monitor noninvasively. As discussed earlier in this chapter, the most widely used parameters to detect and monitor kidney injury include plasma/serum markers such as BUN and serum creatinine (sCr), and urinary markers, such as urinary volume, specific gravity or osmolality, glucose or protein excretion, and sediment examination. Although many of these measurements provide valid indicators of some aspect of kidney function, they lack sensitivity and/or specificity in detecting early stages of injury or disease and in some cases may be influenced by prerenal changes that may confound interpretation.

Over many decades, the potential of a wide variety of urinary proteins to detect and monitor renal injury has been assessed in numerous animal studies. But it is only in recent years that extensive effort involving collaboration among industrial, academic, and regulatory scientists has been applied to the systematic evaluation of the diagnostic utility of these urinary biomarkers. The determination to characterize more reliable renal biomarkers has been given additional impetus by the discovery of a number of potential novel biomarkers through the use of transcriptomic, proteomic, and metabolomic technologies (Amin et al., 2004; Boudonck et al., 2009; Davis et al., 2004; Devarajan et al., 2003; Kharasch et al., 2006; Mendrick, 2008; Thongboonkerd, 2005; Thukral et al., 2005). This has enhanced the prospect of making available a range of sensitive and specific biomarkers which will have real diagnostic utility. These collaborative efforts (Dieterle et al., 2010a; Vaidya et al., 2010; Yu et al., 2010; Harpur et al., 2011) have resulted in the biological qualification of several urinary biomarkers for potential detection of nephrotoxic injury to either the renal tubules or the glomeruli in preclinical safety studies. Some of these biomarkers have been available for years while others are comparatively new. Eight of these biomarkers (albumin, β 2-microglobulin,

total protein, cystatin C, Kidney Injury Molecule-1 [KIM-1], clusterin, trefoil factor 3 (TFF3), and renal papillary antigen-1 [RPA-1]) were judged by regulatory authorities to be acceptable in specified contexts of nonclinical development for detection of acute drug-induced renal toxicity and to provide additional and complementary information to the currently available standard parameters (EMA, 2009, 2010; FDA, 2008, 2010). There are, however, many gaps in our knowledge to be addressed; thus, more data are required to underpin the current conclusions, to expand the context of use (e.g., to other species including dogs and nonhuman primates), and where necessary to provide additional biomarkers to cover all parts of the nephron. Additionally, an increased understanding of the physiological and pathophysiological roles of the biomarkers as well as their behavior during onset and recovery of injury would enhance their utility.

The following is a summary of those urinary biomarkers regarded by regulators to have the potential for detection of renal injury in animals, as well as more novel biomarkers that have been recently evaluated. Urinary endpoints that have been used over many years to detect and assess renal injury are mostly protein in nature and include measurement of total protein, albumin, and numerous low molecular weight proteins.

The biological role of some proteins found in urine is known to be enzymatic in nature and, therefore, this property has been utilized to determine quantitatively their presence in urine (they can be rapidly and easily measured using standard colorimetric or fluorometric techniques). Hence the term “enzymuria” has been in widespread use for many years. However, other than this historical reason related to their biological properties and the mode of their measurement, there is no logical reason to distinguish them from other proteins in urine. Furthermore, for many of the enzymes of interest, for example, the glutathione S-transferases (GSTs), the enzymatic assays have been replaced by more specific immunological assays which, among other things, allow isoenzymes to be discriminated (e.g., α -GST from μ -GST). Therefore, the term urinary protein biomarker is more appropriate. However, because of the historical importance of “enzymuria” to monitor renal injury as well as the fact that some enzymatic proteins remain useful and enzymatic assays are still used (e.g., NAG), the following discussion includes reference to enzymes as a class of urinary biomarker. However, in order to fully interpret an elevated level of protein in urine, in addition to knowing the biological role of the biomarker, it can be equally important to know the physiology around the biomarker. For example, what is the origin of the biomarker—(extrarenal and/or intrarenal)? If the latter, where is it localized in the nephron or within individual cells? What is the mechanism by which its presence in urine is increased? Does it have a high constitutive presence and leak from injured cells (providing information on acute injury, such as α -GST) or is it induced in response to injury and useful to track onset and recovery from injury (e.g., clusterin)?

Although over 40 enzymes have been identified in urine (Raab, 1972) and have periodically been shown to be sensitive and useful for determining the anatomical location of tubular injury (Stonard, 1990), few have seen widespread acceptance or use as renal biomarkers (Price, 1992a). This is likely related to the fact that these biomarkers do not have diagnostic relevance (Stonard, 1990) that may be attributable to inter- and intrasubject variability resulting from both biological variability (age, sex, time of day, and urine flow rate are contributory factors) and analytical variability (Jung, 1994; Stonard, 1990). With regard to the latter, the majority of enzymes exhibit some degree of instability in urine presenting problems with storage. Another source of variability is the presence of endogenous low molecular weight inhibitors which must be removed by dilution, dialysis, or ultrafiltration. Assay interference can also result from the presence of exogenous substances such as the test (pharmaceutical) compounds (or their metabolites) that have induced the renal injury in toxicity studies. The enzymes are known to have different primary locations along the nephron and within individual cells and those that have attracted most attention are localized in the proximal tubule, the region that is particularly vulnerable to drug toxicity (Bonventre et al., 2010).

The circadian pattern of excretion of some urinary proteins is known to differ but in many cases it is an unknown (Jung, 1994). Thus, it is generally recommended to determine the excretion of urinary analytes as amount/unit time. This requires timed urine collection for the same period each day.

Where accurate and complete timed urine samples cannot be collected (e.g., in an outpatient clinic or in animals where ensuring complete bladder emptying at the beginning and end of the collection period is difficult), the quantity of the analyte of interest can be normalized to the amount of creatinine in urine (dividing the concentration of the analyte by the concentration of creatinine in the same urine sample). In human urine, an excellent correlation between the protein content of a 24-hour urine and the protein/creatinine ratio in a single urine sample has been demonstrated (Ginsberg et al., 1983), and it has become standard clinical practice to normalize urinary excretion of many protein biomarkers to urine creatinine in chronic conditions (Goldstein, 2010). In addition, normalization of urine analytes to creatinine has been shown to correct for incomplete timed urine sample collections in rodents (Haas et al., 1997). In dogs, it has been shown that normalization of urinary enzyme activity per unit of creatinine is reasonably well correlated to 24-hour enzyme activity (Grauer et al., 1995). Normalization to creatinine has the additional advantage of adjusting, at least in part, for alterations in urine flow rate and volume (Jung, 1994). Although urine creatinine is sometimes the preferred approach for normalization of a parameter and is frequently a more convenient factor to obtain than total volume, urine creatinine should not be used when there is significant compromise of renal function, as this will not provide an accurate normalization.

Based on review of the literature, regulatory agencies have agreed that normalization of urinary analytes to creatinine is appropriate in biomarker qualification studies (Dieterle et al., 2010b; Harpur et al., 2011). One case where it is not recommended is when the response to injury results in decrease of a urine biomarker as is the case with TFF3. Yu et al. (2010) stated that dividing a low TFF3 level by a low creatinine level diminishes or masks the information inherent in each biomarker; thus, the signal of TFF3 is “somewhat compromised” if TFF3 is normalized to urinary creatinine. While normalization to urinary creatinine is the most commonly used procedure, it is important to realize that creatinine excretion may be impacted by various factors including age, sex, muscle mass, and diet. As such, control animals on toxicity studies should be matched for these characteristics. In toxicologic studies of renal injury, it should be ensured that creatinine excretion has not been altered by the pharmaceutical agent being investigated (Harpur et al., 2011). Recently, Waikar et al. (2010) cautioned against the normalization of urinary biomarkers to urine creatinine in patients with acute kidney injury where creatinine clearance may be unstable giving rise to misleading results. The authors asserted that actual excretion rate of a biomarker over a timed collection period is the most accurate method of quantification, provided the biomarker was stable over the collection period.

12.3.3.1 *N*-acetyl- β -D-Glucosaminidase

N-acetyl- β -D-glucosaminidase (NAG) is predominantly found in the lysosomes of proximal tubular cells but is also found at lower levels elsewhere in the nephron (Bourbouze et al., 1984). NAG is a widely studied biomarker of proximal tubular injury in both animals and humans (Gibey et al., 1981; Marchewka and Dlugosz, 1998; Price, 1992a, b; Stonard et al., 1987; Westhuyzen et al., 2003). Although NAG is present in plasma, this enzyme is too large (140 kDa) to be filtered at the glomerulus unless there is glomerular damage and the presence of low levels of NAG in normal urine samples results from the pinocytotic and exocytotic activity of the tubular epithelial cells. NAG exists in several isoforms. The A form of NAG is found in solution in the lysosome and may be released during the normal process of exocytosis such that the A form of NAG is the predominant form in normal urine. Thus, an increase in urinary NAG can result from a chemically induced alteration in tubular lysosomal function without renal injury (Bosomworth et al., 1999). The B form of NAG is found on the membrane of the lysosome and may only be released when there is injury to the lysosome and/or cellular necrosis (Sanchez-Bernal et al., 1991). However, increased urinary NAG need not necessarily result from a direct toxic effect on renal tubular cells but may also result from protein overload, provoking increased lysosomal turnover, as seen following chemical induction of glomerulonephrosis and proteinuria (Bosomworth et al., 1999). The measurement of NAG isoenzymes may provide additional diagnostic information, particularly concerning the exact site

of injury (Price, 1992a, b). However, it is rarely applied in practice mainly because of the complex analytical methods required for measurement of the isoenzymes and the absence of widely available immunological assays for each isoenzyme. In addition, measurement of NAG isoenzymes does not provide any definitive information on site of injury since (1) no isoenzyme is uniquely located in one tubular segment and (2) the pattern of NAG isoenzymes found in an elevated level of total NAG may reflect the chemical mechanism of renal cell perturbation as much as the site of injury. For example, early increases in the B form of NAG following administration of gentamicin may be attributable to the well-known lysosomotropic effect of the compound with induction of synthesis of the B form of NAG (Gibey et al., 1984).

Cumulative evidence points to urinary total NAG being a robust and sensitive indicator of acute kidney injury in the clinical setting (Ferguson et al., 2008). It is one of several biomarkers able to both diagnose and predict outcome in patients with acute kidney injury (Coca et al., 2008; Liangos et al., 2007; Parikh et al., 2010). However, urinary NAG activity may be inhibited by endogenous substances (such as urea) and exogenous substances (e.g., industrial solvents and heavy metals) and increased NAG levels may be seen in a variety of conditions unrelated to acute kidney injury such as rheumatoid arthritis, impaired glucose tolerance, and hyperthyroidism (for review, see Ferguson et al., 2008). As a result, insensitivity and nonspecificity may limit the use of NAG as a biomarker of nephrotoxicant-induced renal injury in animal species. Furthermore, in recently reported rodent studies (Harpur et al., 2011), although urinary NAG was increased in the presence of both proximal tubule and CD injury, its diagnostic accuracy was no better than BUN or sCr.

12.3.3.2 Brush Border Membrane Enzymes

There are a number of enzymes located on the brush border membrane (BBM) of the proximal tubular cells including alanine aminopeptidase (AAP), alkaline phosphatase (ALP), and gamma glutamyl transferase (GGT). Occasionally, these have been shown to be sensitive markers of proximal tubular injury in animal studies (for review, see Stonard, 1990), although Gibey et al. (1981) found that AAP (in contrast to NAG) had no prognostic value for development of renal failure in patients treated with gentamicin. Furthermore, neither AAP nor GGT showed increased levels in urine, unlike NAG or β 2-microglobulin, in patients treated with the nephrotoxic chemotherapeutic drug cisplatin (Marchewka and Dlugosz, 1998). However, GGT has been advocated as having diagnostic value for renal tubular injury in certain clinical situations, for example, in contrast nephropathy (Donadio et al., 1998) and was found to be an excellent biomarker in clinical acute tubular necrosis (Westhuyzen et al., 2003). Nevertheless, until recently there has been no rigorous analysis of the diagnostic performance of any of the BBM enzymes for detection of nephrotoxic injury in animals using kidney histopathology as the reference standard. Harpur et al. (2011) included GGT in their biological qualification study of renal biomarkers of tubular injury in rats and found no evidence for any diagnostic value of GGT.

12.3.3.3 Glutathione S-Transferases

Until recently, GSTs have rivaled NAG as the most widely used urinary enzymes to monitor renal injury. GSTs are phase II detoxifying enzymes present in the kidney in various isoforms, the distribution and expression of which varies along the nephron and among species (Beckett and Hayes, 1993; Campbell et al., 1991; Harrison et al., 1989; Rozell et al., 1993; Sundberg et al., 1993). In both rats and humans, α -GST is the predominant isoform in the proximal tubule, whereas μ -GST (GSTYb1) and π -GST are the predominant isoforms in the distal tubule of rats and human, respectively. The increased presence of GSTs in the urine after nephrotoxic injury to rats has been known for more than 30 years (Bass et al., 1979) and is attributed to leakage from tubular cells into the lumen, secondary to epithelial cell damage. In studies on the effects of volatile anesthetics on the kidney, Kharasch et al. (1998) reported that urinary excretion of α -GST correlated with the extent of proximal tubular cell necrosis in rats and measurement of the GST isoforms in urine was more sensitive than either BUN or sCr for detection of tubular injury following administration of anesthetics

in a study in human volunteers (Eger et al., 1997). Urinary excretion of specific isoforms of GST has been proposed not only as a marker of renal tubular damage in general but also to provide information on the location of the injury along the nephron (Branten et al., 2000; Eger et al., 1997; Sundberg et al., 1994a, b).

Despite their extensive use, only recently has the utility of urinary GSTs as biomarkers of renal tubular injury in rodents been systematically evaluated (Harpur et al., 2011). Harpur et al. (2011) demonstrated that urinary α -GST had superior diagnostic accuracy to BUN, sCr, and NAG for diagnosis of injury to the proximal tubule in the rat and was most evident with early damage (before regeneration was present). This is consistent with the conclusion of Ozer et al. (2010), who found α -GST to be an excellent biomarker for early tubular necrosis. The potential value of α -GST as a biomarker of proximal tubular injury in preclinical toxicology studies is strengthened by the available clinical data suggesting this may be a translatable biomarker across species. Urinary GSTs are reported to be diagnostic and prognostic markers of acute kidney injury in various clinical situations (Coca et al., 2008; Han and Bonventre, 2004; Westhuyzen et al., 2003).

However, confidence in the utility of α -GST as a reliable biomarker of proximal tubular injury in rodents is weakened by a currently unexplained observation that the urinary levels of α -GST were consistently decreased in the presence of CD injury without evidence of any injury to the proximal tubule. Based on these data, regulatory authorities in the United States and Europe concluded that α -GST could not be qualified at this time because of opposing responses (e.g., increases vs. decreases) of this biomarker in response to proximal tubular and CD injury that may confound interpretation (Harpur et al., 2011). Recent studies, in which the diagnostic performance of a number of traditional and novel biomarkers were evaluated in a cisplatin model of nephrotoxicity in rats, have provided disparate evidence for the utility of α -GST. Togashi et al. (2012) demonstrated that α -GST was among the best early markers of cisplatin-induced tubular injury, whereas α -GST did not show any improvement over sCr or BUN in two other studies (Pinches et al., 2012; Vinken et al., 2012). Vinken et al. (2012) found that α -GST did not respond to injury as rapidly as clusterin or KIM-1 and quickly returned to control levels despite continued cisplatin dosing and progression of the injury as assessed by histopathology. Following acute injury induced by short-term (3-day) gentamicin administration, Rouse et al. (2011) found that both α -GST and μ -GST were elevated in urine at the time of maximum injury but rapidly returned to control levels despite the presence of regressing injury alongside regeneration.

In the rat qualification studies by Harpur et al. (2011), no conclusion could be drawn about the utility of μ -GST for the diagnosis of renal injury. There were few diagnoses of injury to the distal tubule, where this isoform is known to be primarily located, and where diagnoses of distal tubule injury occurred, there was concomitant CD injury in most cases. In human patients in an intensive care unit, π -GST (which has the same localization in the distal tubule as μ -GST in the rat), was shown to be comparable to α -GST in its predictive value for acute tubular necrosis (a condition involving injury to both proximal and distal tubules). In theory, demonstrating a lack of change in urinary μ -GST (or π -GST) could also be useful to confirm a diagnosis of proximal tubule-specific injury based on an increase of α -GST. However, because of both functional interdependencies and proximity of different segments within regions of the kidney, collateral and nonspecific injury to adjacent nephron segments can readily occur with severe nephrotoxicity. As a result, μ -GST may be increased in the presence of predominantly proximal tubular injury with no concomitant diagnosis of distal tubular injury based on light microscopic evaluation (Harpur et al., 2011).

12.3.3.4 Total Protein

Urinary total protein levels reflect both glomerular and tubular function in that the glomerular filtration barrier restricts passage of macromolecules into the glomerular filtrate, while receptor mediated endocytosis in the proximal tubular epithelium mediates tubular reabsorption of filtered proteins (for review, see Stonard, 1990). As such, proteinuria may be indicative of disease or injury to either the glomerulus or the proximal tubule (D'amico and Bazzi, 2003). Dieterle et al. (2010a)

showed that urine total protein was a more specific and sensitive marker than BUN and creatinine to detect glomerular injury with subsequent impairment of tubular reabsorption in rats. Based on these data, urinary protein has been qualified in rats as a biomarker of glomerular injury and/or impaired tubular reabsorption (EMA, 2009; FDA, 2008). However, urinary total protein has been shown to be less sensitive than urinary albumin for the detection of proximal tubular injury induced in rats by cisplatin (Gautier et al., 2010; Tonomura et al., 2010). Moreover, Harpur et al. (2011) found that measurement of protein in urine offered no diagnostic advantage over BUN or sCr for any of the tubular pathologies that occurred in these rat studies. While the separation of urinary proteins according to molecular weight and the determination of the ratio of high to low molecular weight proteins has been used in clinical practice to discriminate primary tubular disorders from glomerular injury (Stonard, 1990), this is not an established practice in animal studies, especially in rodents where the composition of urine proteins is markedly different from that in humans.

12.3.3.5 Albumin

In the clinical setting, proteinuria is a sign of established kidney damage and plays a pathogenic role in the progression of renal and cardiovascular disease, whereas albuminuria, reflects functional abnormalities that are potentially reversible (Ruggenenti and Remuzzi, 2006). In humans, abnormal albuminuria ranges have been set. Microalbuminuria is excretion of albumin at a rate between 20 and 200 $\mu\text{g}/\text{min}$ or between 30 and 300 mg in 24-hour urine collections and is recognized as an early manifestation of renal disease (Ferguson et al., 2008). Macroalbuminuria is defined as urinary albumin excretion of $>200 \mu\text{g}/\text{min}$ or $>300 \text{ mg}$ in 24 hours and identifies the onset of proteinuria and the development of progressive renal and/or cardiovascular disease (Basi et al., 2008; Ruggenenti and Remuzzi, 2006).

Albuminuria is classically considered to arise from damage to the glomerular basement membrane (Haraldsson et al., 2008). However, recent studies have challenged this notion in the rat, demonstrating that albumin is freely filtered through the healthy glomerular basement membrane, and efficiently recycled (and a fraction degraded) by the proximal tubule (Greive et al., 2001; Russo et al., 2007). In experimental glomerulonephritis, albuminuria results not from an increased glomerular sieving coefficient but from inhibition of the uptake of albumin at the BBM of the proximal tubular cells. These studies imply that albuminuria would more commonly reflect proximal tubular damage than glomerular damage. Consistent with that, albuminuria has been reported in humans following administration of nephrotoxic drugs that produce tubular injury (Kern et al., 2000; Koch Nogueira et al., 1998; Tugay et al., 2006). Thus, albuminuria may prove useful as a marker of acute kidney injury and concomitant proximal tubular cell damage (Ferguson et al., 2008).

In rat studies, elevation of urinary albumin has been shown to be a reliable and specific indicator of renal tubular lesions (Yu et al., 2010). Measurement of albumin in urine was shown to have comparable performance to α -GST and clusterin for detection of proximal tubular injury induced by cisplatin in rats (Gautier et al., 2010) and has been qualified as a biomarker of proximal tubular injury in rat studies, outperforming BUN and sCr (Yu et al., 2010). However, the fact that minimal or mild albuminuria can also be a response to a variety of physiological and pathophysiological conditions such as exercise, fever, dehydration, diabetes, or hypertension (Bonventre et al., 2010), or could result from inhibition of albumin uptake by proximal tubule cells without injury (Chana and Brunskill, 2006), complicates the interpretation of urinary albumin as a clinical biomarker of renal tubular injury, particularly in cases where there are only slight changes in urine values.

12.3.3.6 β 2-Microglobulin

β 2-microglobulin is a 12-kDa polypeptide that is synthesized throughout the body and present in plasma. It is filtered by the glomeruli and almost completely reabsorbed and catabolized in the renal tubules so that only a small amount is normally found in normal urine (Dieterle et al., 2010a). Minimal impairment of uptake in the renal tubules can result in a large increase in β 2-microglobulin in urine; thus, measurement of urinary β 2-microglobulin has the potential to be a sensitive indicator

of impairment of renal tubular function (for review, see Ferguson et al., 2008). It should be noted, however, that increased urinary excretion of β 2-microglobulin can result not only from injury to the renal tubules but also from glomerular alterations causing a high protein load in the tubules and competition for tubular uptake. Based on the data of Dieterle et al. (2010a), urinary β 2-microglobulin has been qualified as a biomarker of glomerular injury and/or impairment of tubular reabsorption (EMA, 2009; FDA, 2008). A limitation of β 2-microglobulin in urine is its instability at acidic pH so that alkalinization of urine is necessary (Trof et al., 2006). This is particularly an issue in human urine where measurement of α 1-microglobulin is generally preferred because it is stable at the low pH of human urine (Payn et al., 2002; Weber and Verweibe, 1992). For example, Herget-Rosenthal et al. (2004b) showed that the prognostic accuracy of α 1-microglobulin in predicting those patients with acute tubular necrosis who would require renal replacement therapy was much superior to that of β 2-microglobulin.

12.3.3.7 Cystatin C

Cystatin C is a low molecular weight protein (approximately 13 kDa) that is produced by all nucleated cells throughout the body (Mussap and Plebani, 2004) and is readily filtered through the glomerulus. As mentioned later in Section 12.3.4.2.2, serum cystatin C has been widely studied for use as an alternative to sCr as an endogenous GFR marker in humans (Madero et al., 2006; Shlipak et al., 2006; Slocum et al., 2012; Westhuyzen, 2006) and has been shown to be superior to sCr as a measure of GFR (Dharnidharka et al., 2002).

In rats, filtered cystatin C is almost completely reabsorbed and catabolized in the tubules (Tenstad et al., 1996). Thus, very low levels of cystatin C are normally present in urine and impairment of tubular reabsorption, either through competition with an increased filtered load of protein (as seen with glomerular injury) or through impaired tubular function (as seen with tubular injury) will result in a large increase in the level of cystatin C in urine (Dieterle et al., 2010a). Based on the results reported by Dieterle et al. (2010a), urinary cystatin C has been qualified as a biomarker of acute drug-induced glomerular damage and/or impaired tubular reabsorption in rats (EMA, 2009; FDA, 2008). However, subsequent studies have provided equivocal results. Ozer et al. (2010) reported results indicating plasma cystatin C was superior to sCr and BUN for the detection of nephrotoxicant-induced injury to various parts of the nephron including tubular injury induced by cisplatin and gentamicin, while Pinches et al. (2012) showed inferiority of plasma cystatin C versus sCr and BUN in a cisplatin model of nephrotoxicity. In addition, Tonomura et al. (2010) found no increase in urinary cystatin C in urine from rats with puromycin-induced glomerular injury. However, in this study the injury was slight and an increase might be anticipated with more marked glomerular injury (Tonomura et al., 2010). Tonomura et al. (2010) also found that urinary cystatin C was insensitive, compared with KIM-1, as a marker of cisplatin-induced tubular injury in rats. In contrast, Togashi et al. (2012) reported that urinary cystatin C had comparable sensitivity to KIM-1 and α -GST for the early detection of tubular injury induced by cisplatin. However, in this model of acute tubular injury plasma cystatin C showed little change, underlining its role as a marker of whole kidney function (glomerular filtration). Collectively, these results indicate that more work is required to establish firmly the utility of measurement of cystatin C, either in serum/plasma or urine, for the detection of glomerular and/or tubular injury in animals.

12.3.3.8 Kidney Injury Molecule-1

KIM-1, a transmembrane glycoprotein with a mucin domain in the extracellular region, has been widely studied in both animals and humans for more than a decade. These studies have shown that KIM-1 has great promise as a sensitive and specific marker of renal tubular injury (for reviews, see Slocum et al., 2012; Vaidya et al., 2008). KIM-1 mRNA and protein levels have been shown to be expressed at a low level in normal kidney tissue but markedly increased in proximal tubular cells following ischemic or toxic injury in rodents (Amin et al., 2004; Ichimura et al., 1998). Following tubular injury from a variety of causes, the mucin ectodomain of KIM-1 is shed into the urine where it

is stable for prolonged periods of time (Bonventre, 2008). Following drug-induced or ischemic injury, urinary KIM-1 levels are elevated when other routine urinary or blood-based biomarkers of injury or renal function did not change, showing the potential sensitivity of KIM-1 in monitoring tubular injury (Ichimura et al., 2004; Vaidya et al., 2006). Recent studies have provided evidence that urinary KIM-1 is a highly sensitive and specific biomarker for the early detection of nephrotoxicant-induced proximal tubular injury, regardless of the mechanism underlying that injury (Hoffmann et al., 2010; Ozer et al., 2010; Togashi et al., 2012; Tonomura et al., 2010; Vaidya et al., 2010; Vinken et al., 2012; Zhou et al., 2008). The superior sensitivity of urinary KIM-1 over whole kidney functional assessment by sCr or BUN was shown by Ozer et al. (2010) and Vaidya et al. (2010). Tonomura et al. (2010) found that KIM-1 was the best biomarker for proximal tubular injury based on its early and time-dependent increase as well as the large magnitude of the increase. In addition, the data generated by Vaidya et al. (2010) demonstrated that KIM-1 outperformed traditional markers (sCr and BUN) and enabled regulatory authorities to conclude that KIM-1 was qualified for the detection of acute drug-induced nephrotoxicity in rats (EMA, 2009; FDA, 2008). Changes in urinary KIM-1 may also reflect recovery from tubular injury in rats (Rouse et al., 2011).

Many of the properties of KIM-1 that have been characterized in rodents are also evident in humans. KIM-1 is expressed at high levels in proximal tubular cells and the cleaved ectodomain of KIM-1 can be detected in the urine of patients with acute tubular necrosis (Han et al., 2002). Human studies also indicate the promise of KIM-1 as a diagnostic and prognostic biomarker of acute kidney injury indicating KIM-1 may be a useful translational biomarker for proximal tubular injury (for reviews, see Coca et al., 2008; Slocum et al., 2012; Vaidya et al., 2008).

12.3.3.9 Clusterin

Clusterin, a dimeric glycoprotein, is expressed in the epithelia of many organs (Rosenberg and Silkensen, 1995). In the kidney, it is highly expressed during early stages of development. In contrast, in the healthy mature kidney, clusterin mRNA and protein are not detectable but are upregulated in response to renal tubular injury and in a variety of renal diseases (Rosenberg and Silkensen, 1995). It has been suggested that secreted clusterin suppresses apoptosis and is involved in cell aggregation and attachment (Rosenberg and Silkensen, 1995). Clusterin expression is upregulated in rats following nephrectomy (Correa-Rotter et al., 1992), unilateral ureteral obstruction (Ishii et al., 2007), renal ischemia-reperfusion (Yoshida et al., 2002), or nephrotoxicity (Kharasch et al., 2006; Silkensen et al., 1997) and in dogs with renal papillary necrosis induced by nefiracetam (Tsuchiya et al., 2005). Increased levels of clusterin protein in urine have been detected following ischemic or chemically induced injury in rats (Aulitzky et al., 1992; Dieterle et al., 2010a; Eti et al., 1993; Gautier et al., 2010; Harpur et al., 2011; Hidaka et al., 2002; Hoffmann et al., 2010) and dogs (Tsuchiya et al., 2005). While increased expression of clusterin (mRNA and/or protein) is seen in humans in a variety of renal disorders (Rosenberg and Silkensen, 1995), to date there are no published results demonstrating the use of clusterin as a diagnostic marker of renal injury in humans.

Clusterin was among those urinary proteins shown to outperform BUN and sCr for in the detection of acute chemical-induced tubular injury without specification of the specific segment involved (Dieterle et al., 2010a; FDA, 2008; EMA, 2009). Regulators (EMA, 2010; FDA, 2010) also concluded that the results presented by Harpur et al. (2011) supported the qualification of urinary clusterin by increasing the level of evidence and clarifying the context of its use, namely detection of acute drug-induced renal tubule alterations, particularly when regeneration is present. This is consistent with current understanding of the biological function of clusterin indicating that, in response to injury, clusterin may be involved in cell aggregation and attachment (Rosenberg and Silkensen, 1995). Overall, these results suggest that clusterin may have utility in detecting renal tubular injury and may be particularly useful in monitoring regeneration. This is supported by the finding that urinary levels of both clusterin and NAG rose rapidly following chronic administration of gentamicin over a 2-month period. In contrast, clusterin levels remained significantly elevated over the duration of the experiment while NAG levels were similar to control values within 10 days despite evidence

of persistent tubulointerstitial disease (Eti et al., 1993). Furthermore, Ozer et al. (2010) found that increased urinary levels of clusterin (and KIM-1) persist during regeneration. Based on these data, clusterin may add most value in monitoring chronic-active injury and regeneration.

12.3.3.10 Trefoil Factor 3

TFF3 is a small peptide hormone produced by epithelial cells in multiple tissues and is associated with inhibition of apoptosis and migration of epithelial cells toward lesions that could contribute to restoration of injured epithelial tissue (Yu et al., 2010). As shown by mRNA expression, TFF3 is expressed in the kidney and, although its distribution in the nephron is not well characterized, Yu et al. (2010) presented evidence for its presence in the proximal straight tubules. Both the renal presence of TFF3 (mRNA) and the urinary concentration of TFF3 protein (Ozer et al., 2010; Yu et al. 2010) were found to be decreased following treatment with some nephrotoxics (carbapenem A and gentamicin) but not others (thioacetamide and cyclosporin A). The decreases in urinary TFF3 correlated with the severity of histopathological lesions in the proximal tubule and TFF3 was claimed to be a sensitive and specific biomarker of tubular injury (Yu et al., 2010). This conclusion needs to be confirmed by additional studies in animals; furthermore, at present there is a paucity of information on its potential clinical utility. TFF3 is by far the least studied protein among those evaluated for potential biological qualification for use in rodent toxicology studies. The lack of data on TFF3 is likely related to the lack of a widely available and validated assay as well as the undesirable property (unique among the qualified biomarkers) that its concentration in urine is decreased, rather than increased, in response to renal injury.

12.3.3.11 Renal Papillary Antigen-1

Although the proximal tubule is the most common nephronal segment targeted by nephrotoxic xenobiotics (Bonventre et al., 2010), renal papillary necrosis is caused by an increasing number of pharmaceutical agents, including nonsteroidal anti-inflammatory drugs (Bach and Thanh, 1998). Until recently, there has been no specific urinary biomarker of injury to this region of the kidney. Renal papillary necrosis can be induced experimentally in rats by nonsteroidal anti-inflammatory drugs and chemicals such as 2-bromethanamine or N-phenylanthranilic acid (NPAA), a biphenyl analogue of mefenamic acid (Betton et al., 2005; Price et al., 2010). To develop markers for renal papillary injury, monoclonal antibodies were raised against proteins released in urine from rats treated with nephrotoxics, and the antibodies were screened for those that correspond to segment specific antigens (Falkenberg et al., 1996; Hildebrand et al., 1999). This procedure identified an antigen, RPA-1, which is specifically expressed in the CD. Price et al. (2010) found RPA-1 particularly difficult to characterize but demonstrated that RPA-1 is a very large membrane-bound glycoprotein located specifically within the CD of the rat kidney. They also showed it to be a good early marker of renal papillary necrosis in the rat. RPA-1 was further evaluated by Betton et al. (2012) and Harpur et al. (2011) as a potential urinary biomarker of CD injury. In these studies, RPA-1 was superior to a number of reference biomarkers (BUN, sCr, protein, and NAG) for diagnosis of injury to the CD in the rat. However, no human equivalent to RPA-1 has yet been identified and thus clinical data are unavailable.

12.3.3.12 Neutrophil Gelatinase-Associated Lipocalin

Human neutrophil gelatinase-associated lipocalin (NGAL), also known as lipocalin-2, is a 25 kDa protein located in neutrophil-specific granules and found in many tissues. In rodents, NGAL gene expression is upregulated in the kidney following ischemic/reperfusion and nephrotoxic injury a response which often occurs in parallel with increases in urinary protein (Hoffmann et al., 2010; Mishra et al., 2003; Rached et al., 2008; Rouse et al., 2011; Sieber et al., 2009). Thus, urinary NGAL has been proposed as an early biomarker for diagnosing acute kidney injury in both animals and humans (for review, see Vaidya et al., 2008). As with other exploratory biomarkers, the results of animal studies have provided discrepant results. Following puromycin administration to

rats, urinary NGAL was shown to be increased in the presence of minimal glomerular vacuolation, with no concurrent tubular pathology (Tonomura et al., 2010) and also with glomerular vacuolation accompanied by tubular degeneration (Fuchs et al., 2012). Urinary NGAL increased in response to acute gentamicin-induced tubular injury in rats and was determined to be the most sensitive, together with urinary KIM-1, of a number of novel biomarkers (Sieber et al., 2009). In other studies using gentamicin to induce renal injury in rats, NGAL has been shown to outperform sCr and BUN as a diagnostic biomarker (Hoffmann et al., 2010; Rouse et al., 2011) but it did not prove to be as sensitive as other biomarkers such as KIM-1 or clusterin. Tonomura et al. (2010) found that urinary NGAL was unchanged in rat urine with cisplatin-induced tubular injury. In another study in which rats were given a single injection of various doses of cisplatin and examined over a period of days (Pinches et al. 2012), increases of NGAL in urine were small and seen inconsistently only at the high dose. In a third study in rats, urinary NGAL increased in response to cisplatin (up to 14 doses) but was inconsistent at early time points so that NGAL was judged to show no greater sensitivity compared with standard clinical pathology parameters (Vinken et al., 2012). In contrast, Fuchs et al. (2012) concluded that NGAL had good diagnostic utility based on their observation of a dose-dependent increase in urinary NGAL following administration of cisplatin or vancomycin to rats over 28 days. In summary, these results suggest NGAL may be a useful biomarker in rodents for glomerular injury and, at least some instances, for tubular injury. However, serum levels of NGAL are known to increase in response to infection and inflammation and NGAL filtered by the glomerulus appears in urine. An example of this was observed in a rodent model of carbon tetrachloride liver injury with no injury to the kidney detectable by histopathology (Smyth et al., 2009). Therefore, the specificity of urinary NGAL for diagnosing acute kidney injury has been questioned (Fuchs et al., 2012; Hoffmann et al., 2010; Sieber et al., 2009). However, it needs to be borne in mind that almost all of the animal studies conducted to evaluate the performance of urinary biomarkers did not include measurement of serum or plasma levels of these biomarkers. Furthermore, the growing body of evidence that NGAL is a useful diagnostic and prognostic biomarker for acute kidney injury in humans in a variety of clinical settings (Haase et al., 2009; Mishra et al., 2005; Nickolas et al., 2008; Tuladhar et al., 2009) encourages the prospect that NGAL could be a valuable translational biomarker of kidney injury and merits further study to more fully characterize its behavior in animal models.

12.3.3.13 Experimental Biomarkers

A number of other urinary proteins, such as interleukin-18, cysteine-rich protein, fatty acid-binding protein, and osteopontin, have been proposed as biomarkers of acute kidney injury (for review, see Vaidya et al., 2008). There are variable levels of evidence from human and animal studies for their potential utility as markers of acute kidney injury and these are not established biomarkers for renal injury or disease. Some biomarkers, such as urinary cytokines, may only reflect increased filtration through the glomerulus due to high circulating levels in plasma, and therefore may not actually arise from the site of local renal damage.

12.3.4 GLOMERULAR FILTRATION RATE (CLEARANCE)

GFR is the most clinically useful index of the severity of renal functional loss and progression (Lane et al., 2009). GFR is defined as the renal clearance of a substance that is neither secreted nor reabsorbed in the tubules, metabolized, or bound to proteins and is nontoxic. GFR is expressed as the volume of plasma cleared of the substance over time and may be evaluated indirectly by measuring serum levels of specific endogenous analytes, or more directly by measuring the clearance of substances removed by the glomeruli and not excreted by the tubules. These substances can be endogenous substances such as creatinine or cystatin C or exogenous substances such as inulin or iohexol.

The most widely used indirect method for measurement of GFR is to determine serum concentrations of creatinine and BUN. As discussed in previous sections, however, creatinine concentrations

can overestimate GFR, as there is significant tubular secretion in many species (mice, rats, dogs) (Hackbarth et al., 1981; Eisner et al., 2010; O'Connell et al., 1962), and tubular secretion is greater at low tubular flow rates (i.e., low GFR). BUN generally underestimates GFR due to reabsorption, as it readily crosses cell membranes/tubules and thus significant (40%–70%) reabsorption is possible (Stevens et al., 2006). Greater reabsorption occurs at low flow rates/decreased renal perfusion (i.e., when function is compromised).

Clearance methods are generally more sensitive in estimating GFR than is determination of plasma or urine constituents; however, they are still indirect measurements (Stevens and Levey, 2009). The clearance rate (GFR) of a substance is calculated by the formula (Latimer et al., 2011):

$$Cx = \text{GFR} = \frac{Ux \times Uv}{\frac{Px}{\text{BW}}}$$

where Cx = clearance rate of the substance (mL/min/kg), Ux = urine concentration of the substance (mg/mL), Px = plasma concentration of the substance (mg/mL), Uv = minute urine volume (mL/min), and BW = body weight (kg).

As seen from this formula, reliable clearance measurements depend on a stable plasma level of the indicator substance and precisely timed and complete collection of urine.

12.3.4.1 Exogenous Substances Used to Measure GFR

12.3.4.1.1 *Inulin*

GFR is measured classically as the renal clearance of inulin against which the validity of other substances used to measure GFR is determined. Historically, inulin has been regarded as the substance of choice for reliable determinations of GFR in laboratory species because it is considered to be cleared exclusively by glomerular filtration (Levinski and Lieberthal, 1992). However, the procedures for determining inulin clearance are complex and lack high throughput. As such, inulin clearance is not a useful assay for routine testing of renal function for large-scale screening assays. Because inulin is an exogenous substance, it must be introduced by intravenous infusion to maintain a stable plasma concentration for the test period of about 30–60 minutes. Anesthesia or rigid restraint of the animal is required, as well as complete emptying of the bladder before, during, and at the completion of the test period. The utility of using a single intravenous injection of inulin to estimate GFR has also been explored (Brewer et al., 1990; Brown et al. 1996b; Fettman et al., 1985; Rogers et al., 1991). The use of radiolabeled inulin has simplified the previously demanding chemical assays for inulin (DeWardener, 1985; Thomsen and Olesen, 1981). These radiolabeled materials, ^{14}C -inulin and ^3H -inulin, are commercially available. However, it has been reported that within the same rat, clearance of undecomposed ^3H -inulin and ^{14}C -inulin may differ by 12%, and for this reason should not be used interchangeably as GFR markers (Shalmi et al., 1991).

12.3.4.1.2 *Iohexol*

Another method for determining GFR uses an x-ray fluorescence technique to measure the disappearance of injected iohexol from plasma (O'Reilly et al., 1986). Iohexol is an iodinated, nonionic, radiographic contrast agent. Sterner et al. (1996) and Lundqvist et al. (1995) have shown that a single sample plasma clearance after single injection of iohexol provides a good estimate of GFR. Studies in dogs and cats administered iohexol at a dose of 300 mg/kg body weight showed that GFR could be measured by using a single compartment model for plasma clearance with three blood samples drawn 3–7 hours after administration (Braselton et al., 1997). Iohexol has been used to estimate GFR in man (Brown and O'Reilly, 1991; Lundqvist et al., 1995; O'Reilly et al., 1986; Sterner et al., 1996), dogs (Braselton et al., 1997; Brown et al., 1996a; Gleadhill and Michell, 1996), cats (Braselton et al., 1997; Brown et al., 1996a), sheep (Nesje et al., 1997), swine (Frennby et al., 1996; Lundqvist et al., 1995), and rats (Masereeuw et al., 1996). The iohexol injection plasma clearance method can

substitute for ^{51}Cr -EDTA and inulin for measuring GFR (Brown et al., 1991; Gaspari et al., 1996; Lundqvist et al., 1995). Miyamoto (2001) showed plasma clearance of iohexol can be determined by use of a simple colorimetric assay to provide an estimation of GFR in cats. Inductively coupled plasma-atomic emission spectroscopy and high performance liquid chromatography (HPLC) have also been used to measure serum iodine to determine plasma clearance of iohexol (Braselton et al., 1997; Gaspari et al., 1996).

12.3.4.2 Endogenous Substances Used to Measure GFR

12.3.4.2.1 Creatinine

The most common test used to evaluate glomerular function is the clearance of endogenous creatinine (Rose, 2001). Creatinine levels in plasma are quite constant and not greatly influenced by diet. In addition, GFR estimates using this method do not include the technical issues encountered with inulin clearance studies (Maillard et al., 2010). However, renal tubular secretion of creatinine occurs in some species, such as rats, guinea pigs, and male dogs (Diezi and Biollaz, 1979), and common methods of assaying creatinine also detect noncreatinine chromogens present in plasma that are not present in urine. Tubular secretion of creatinine tends to overestimate GFR, whereas the inclusion of plasma non-creatinine chromogens results in underestimation of GFR. These two opposing effects fortuitously tend to mitigate these effects (Haycock, 1981). Although methods using cimetidine to block renal tubular creatinine secretion are possible, this may be most useful in correction of a particularly high level of creatinine tubular secretion, which possibly could be species-specific (Nickolas et al., 2008; Toto, 1995).

Endogenous creatinine clearance is a relatively easy test to conduct and is adaptable as a screening test for nephrotoxicity following chemical or physical insults. Plasma creatinine is measured at the start and completion of a timed urine collection. The bladder of an adequately hydrated animal should be emptied at the start of the test (discard specimen) and again at the completion of the timed urine collection. It is necessary to accurately measure the collection period, the volume of urine, and the weight of the animal. The creatinine concentration is then determined on an aliquot of the urine and serum samples. The creatinine clearance (mL/min/kg) may be calculated using the following formula where $[\text{creatinine}]_u$ represents creatinine concentration in the collected urine sample, $[\text{creatinine}]_s$ represents creatinine concentration in the collected serum sample, volume_u represents volume of urine collected during the collection period (mL), time represents duration of collection period (minutes), and BW represents body weight (kg) of the animal (Stockham and Scott, 2002):

$$\text{Creatinine clearance rate} = \frac{[\text{Creatinine}]_{\text{urine}}}{[\text{Creatinine}]_{\text{serum}}} \times \text{Volume}_{\text{urine}} \div \text{Time} \div \text{BW}$$

Clearance of exogenous, injected creatinine may also be determined, but it is not well suited for use in large-scale nephrotoxicity studies. In the dog, however, exogenous creatinine clearance correlates more closely to inulin clearance than endogenous creatinine clearance.

A second plasma clearance method that does not require urine collection involves the single intravenous injection of a compound and the clearance from plasma determined from collection of several blood samples. Sapirstein et al. (1955) developed this technique and the calculations necessary to estimate GFR using injected creatinine in the dog. Ohashi et al. (1996) have shown that the plasma clearance of a single injection of iothalamate can be used to estimate GFR in cats. Ronnhedh et al. (1996) have used iothalamate for urine-free estimation of GFR in rats, but the method requires venous and arterial cannulation.

12.3.4.2.2 Cystatin C

A recent marker being utilized for estimating GFR is cystatin C. Cystatin-C is a 13 kDa nonglycosylated protein and cysteine proteinase inhibitor that is used as a clinical marker of kidney function (Stevens et al., 2006). It is released at a constant rate from all nucleated cells, and is freely filtered at

the glomerulus, with significant uptake by the epithelial cells of the proximal tubules in the kidney (99% in rats) (Tenstad et al., 1996). Unlike creatinine or BUN, plasma levels of cystatin C are not influenced by gender, age, or diet, so serum levels are considered a more accurate estimate of GFR (Dharnidhark et al., 2002; Herget-Rosenthal et al., 2004a; Madero et al., 2006; Shlipak et al., 2006). Cystatin C is measured using immunoassay methods (i.e., immunoturbidometric or nephelometric methods) with antibodies that generally cross-react across species; however, some species-specific assays are available. Cystatin C can be measured in the blood or urine and an impairment of proximal tubular function can lead to increases in both blood and urine (Collé et al., 1990; Conti et al., 2006; Herget-Rosenthal et al., 2007; Tenstad et al., 1996). With impaired renal tubular function, urine cystatin C concentrations may increase up to 200-fold (Lisoskwa-Myjak, 2010). Cystatin C has been shown to be a sensitive indicator of kidney dysfunction in humans, such that cystatin C-based estimation of GFR has been considered useful for clinical practice (Cha et al., 2010). Cystatin C may be more sensitive to low-level decreases in GFR than either creatinine or BUN, and as such is also used as a potentially sensitive marker of glomerular injury in humans and animals. Cystatin C may, however, be increased in inflammatory disease, cancer, or hypothyroidism.

12.3.5 TUBULAR FUNCTION TESTS

The renal tubules are frequently the primary target for nephrotoxic chemicals (Bonventre et al., 2010). For a more detailed account of the points summarized below, see Lote (2010). The physico-chemical properties of urine (e.g., volume, osmolality, pH) and the concentration of many substances present in urine such as protein, amino acids, glucose, or electrolytes are influenced by tubular function. For example, normally amino acids and glucose are almost completely reabsorbed in the proximal tubule. For each substance that normally undergoes reabsorption in the tubules, there is a maximum amount that can be absorbed, referred to as the “tubular maximum.” If plasma levels of the substance are elevated or the filtered load is increased by some other mechanism, the tubular reabsorptive mechanism may become saturated with a consequent increase in urinary concentration. If plasma levels are normal, then an increased urinary presence of a substance will, in most instances, reflect an impairment of proximal tubule function. Evidence in initial screening for disturbance of one or more of the normal constituents of urine might prompt more detailed investigation of tubular function using specific methodologies. These methods are not employed routinely but generally only used in the research laboratory or to follow up a primary finding where there is a need to understand mechanism. Therefore, the tests to evaluate the tubular functions will be described briefly.

Tubular function can be estimated by determination of the fractional excretion (FE) of endogenous substances that are reabsorbed or secreted through the tubular epithelium. FE is defined as the fraction of filtered load of a substance that is excreted in the urine, usually expressed as a percentage. Thus, percentage FE_a is calculated as

$$\frac{([U_a] \times V)}{([P_a] \times GFR)} \times 100$$

where $[U_a]$ and $[P_a]$ are the concentrations of substance “a” in urine and plasma, respectively, and V is the urine flow rate in the same units as GFR (usually mL/min). Accurate calculation of FE requires carefully timed complete urine collections and a concurrent assessment of GFR. As accurately timed urine collection and measurement of GFR are both difficult in laboratory animals, an approximate FE value can be calculated based on a single isolated urine collection as follows, where P_{cr} and U_{cr} are plasma or urine creatinine, respectively (Rose, 2001):

$$FE_a = \frac{[U_a] \times [P_{cr}]}{U_{cr}} \times [P_a]$$

Measurement of FE is most commonly applied to electrolytes. A key function of the kidney is maintaining electrolyte and mineral homeostasis in the face of fluctuating dietary intake and body needs. Indeed, because of the large functional reserve of the kidney, a decrease in plasma electrolyte level is usually not detected until the amount of renal functional impairment is marked. Hence, measurement of urinary electrolyte levels together with plasma levels can provide a sensitive index of the functional state of the kidney. In animal studies, the diet is normally controlled thus ensuring a fairly constant intake of electrolytes. Provided there is no compound-induced change in electrolyte intake, for example, through inappetance or loss such as from vomiting or diarrhea, urine electrolyte levels will reflect the effects of the compound on renal electrolyte handling.

FE assessment can be performed for any electrolyte and might be triggered by an observed change in the concentration of an electrolyte in urine or plasma. In humans, measurement of FE of sodium, calcium, and magnesium have been shown to be useful in assessing underlying tubulointerstitial disease in nephrotic patients (Futrakul et al., 1999; Jespersen, 1997), with FE of magnesium being the most sensitive to detect an early abnormality of tubular structure and function. Increases in FE of magnesium and calcium have also been shown to serve as sensitive indices of the effects on renal function caused by aminoglycoside antibiotics without overt renal injury in both rats and humans (Parsons et al., 1997; Elliott et al., 2000). A full examination of the mechanism and site of impairment of tubular absorption of an electrolyte will require specialized techniques such as micropuncture and microperfusion of short lengths of individual nephrons, usually performed in rats (Garland et al., 1992; Parsons et al., 2000).

12.3.6 CONCENTRATION/DILUTION TESTS

The ability of the kidney to concentrate urine above that of the glomerular filtrate is primarily a function of the loop of Henle and the distal tubule. The foundation of testing the ability of the kidney to concentrate the urinary filtrate is based on water deprivation resulting in plasma hyperosmolality. This, in turn, triggers the release of the ADH which acts on the renal tubule cells to cause reabsorption of water and an increase in urine osmolality. Following renal tubular damage, the ability to concentrate urine is variably reduced. A concentration (water deprivation) test may be adapted for use in routine screening studies for adverse effects on the kidney.

The method for the urine concentrating test is to collect a 16–24-hour urine sample for analysis from animals that have free access to water. The animals are then deprived of water and an additional urine collection is made for 12–16 hours. The osmolality of the urine sample is determined and compared with that obtained when the animal was well hydrated.

The ability of the kidney to dilute the urine is also a tubular function. Urine dilution tests require the oral administration of a water load. In man, this test is conducted by ingestion of about 20 mL of water per kilogram of body weight over a 10–20-minute period and collecting urine hourly for 4 hours. With normal renal function, 75% of the ingested volume is excreted during the 4-hour period with a reduced osmolality. The test can also be used in animals by administering a water load by gavage and then making timed urine collections for a period of a few hours. It is generally thought that the dilution test is a less sensitive indicator of renal damage than the urine concentration test.

12.3.7 Measurement of Renal Plasma Flow and Renal Blood Flow

Several techniques are available for determining renal blood flow in laboratory animals. However, none are suitable for routine screening and will not be covered in detail. The techniques are used primarily in laboratories conducting in-depth studies of renal physiology.

Renal blood flow may be determined indirectly by determining the clearance from plasma of a substance that is extensively cleared in a single pass through the kidney and is cleared via the kidney only. The most extensively used compound is para-aminohippurate (PAH), which is both filtered

and secreted and has a renal extraction ratio of approximately 1.0. The technique involves infusion of PAH and, in theory, it is necessary to collect samples from the renal artery and vein and assay the concentration of PAH. This provides an estimate of renal plasma flow (RPF) which is calculated as follows:

$$\text{RPF} = \frac{\text{Amount of PAH excreted per unit time}}{\text{Difference in arteriovenous concentration PAH}}$$

Thus

$$\text{RPF} = \frac{[U_{\text{PAH}}] \times V}{\text{RA}_{\text{PAH}} - \text{RV}_{\text{PAH}}}$$

where U_{PAH} is the concentration of PAH in urine, V the urine flow rate, RA_{PAH} and RV_{PAH} the concentrations of PAH in the renal artery and renal vein, respectively.

If the extraction ratio of PAH were truly 1.0, then it would not be necessary to measure the concentration of PAH in the renal vein, since this would be zero. Thus, the equation would simplify to $\text{RPF} = [U_{\text{PAH}}] \times V / \text{RA}_{\text{PAH}}$. In fact, the concentration of PAH in the peripheral venous blood can be substituted for the concentration in the renal artery and this is done in practice (Lote, 2010). It should be noted that because not all of the blood that enters the kidneys perfuses the glomeruli and tubules (the perirenal fat, the capsule, and the deep medulla are also perfused), the extraction ratio of PAH is approximately 0.9. Thus, this measurement is really an estimate of cortical blood flow and is referred to as Effective Renal Plasma Flow (ERPF). PAH clearance, determined by the conventional method of continuous intravenous infusion with peripheral blood and urine sample collections, is the gold standard for estimating RPF (Toto, 1995).

Renal blood flow (RBF) may be calculated indirectly from ERPF as follows:

$$\text{RBF} = \frac{\text{ERPF}}{(1 - \text{VPRC})}$$

where VPRC is the fractional volume of packed red cells (Lote, 2010).

Total RBF may also be measured directly and noninvasively using Doppler ultrasound probes or invasively using implanted Doppler flow probes or electromagnetic flow transducers. While these techniques allow accurate and reproducible measurement of total RBF, they are of limited use in the determination of regional changes in blood flow within the kidney. A wide variety of methods, ranging from use of inert gases, isotopically labeled tracers, radionucleotide-labeled microspheres to computed tomography and positron emission tomography, are available for measurement of intrarenal blood flow (for review see Young et al., 1996). All of these methods are highly specialized, time consuming and not widely available. While most can be applied to animal studies, they are unsuitable for routine application and are generally used only in research studies.

12.4 APPROACH FOR ASSESSMENT OF RENAL INJURY

Routine urinalysis, as described in the beginning sections of this chapter, is the first step in any assessment of the kidney, and accurate interpretation of these screening data can provide helpful guidance toward selection of additional analysis. Any further diagnostic or investigative studies, with additional biomarkers, can then be conducted to determine their correlation with region-specific kidney injury, function, and/or mechanism of injury. A panel of renal biomarkers provides the best approach to this additional assessment because, much like a panel of clinical chemistry biomarkers, a single renal parameter is not always specific to a particular injury. The choice of which

assay(s) to use for this second phase of testing should be based on the screening findings, location of the lesion as determined by histopathology, and other pathophysiology that may be accompanying the renal findings, for example, bone, hematopoietic, metabolic.

13.1 THE HEART

The cardiovascular system is comprised of three circulatory systems (Stephenson, 2007). The systemic circulation nourishes the body, except for the lungs and heart, which have their own pulmonary and coronary circulations, respectively. Muscular arteries leave the aorta, and branch and narrow into arterioles of the microcirculation. These arterioles branch, narrow, and simplify even further into capillaries whose walls are formed by only the inner vascular lining of the endothelial cells. Here, the passage of blood is slowed and restricted to one blood cell at a time, thereby facilitating nutrient delivery and waste removal. Oxygen is exchanged for carbon dioxide, or vice versa in the lung. Moreover, there is exchange of metabolic substrate and water from metabolic waste products, such as lactic acid. The capillaries then coalesce into venules, which exit the microcirculation by fusing into elastic veins that return blood to the heart by the vena cava for the systemic circulation, or by the pulmonary vein. The high elasticity and low muscularity of veins, compared to arteries, allow them to have approximately 20-fold greater capacity for distension with increasing pressure and to store approximately two-thirds of blood volume.

Blood pressure is the pressure exerted by blood on the vessel walls. It is the potential energy that causes blood flow and is determined by the product of two variables: the cardiac output and the resistance. The former is the product of heart rate and the amount of blood ejected from the ventricle with each beat, the stroke volume. Resistance is largely dependent on arteriolar luminal diameter, which, like cardiac output, is regulated by innervation from the autonomic nervous system and by various circulating hormones. These contract the circumferential, smooth muscle of arteries. An artery's resistance increases inversely with the fourth power of its radius. In a dog, a typical mean arterial pressure is approximately 100 mmHg, the vena caval pressure is approximately 3 mmHg, and the cardiac output is approximately 2.5 L/min. Thus, the total peripheral resistance is approximately 40 mmHg for each L/min of systemic blood flow (Stephenson, 2007).

The renin–angiotensin–aldosterone system (RAAS) is one of the most important regulators of the cardiovascular system (Stephenson, 2007; Bader, 2010). The renal macula densa produces the plasma protease renin, which hydrolyzes angiotensinogen from the liver to release the decapeptide angiotensin I (Ang I), which in turn is hydrolyzed by endothelial, angiotensin-converting enzyme (ACE) to the octapeptide angiotensin II (Ang II). ACE is also known to hydrolyze kinins. Ang II increases blood volume and pressure by multiple actions. It binds primarily type 1 angiotensin II (AT1) receptors to cause blood vessel constriction, sodium, and water retention by the proximal renal tubules, increased thirst, activation of the sympathetic nervous system (SNS), and zona glomerulosa production of aldosterone in the adrenal cortex. The latter acts on renal collecting ducts and enhances sodium retention along with chloride and excretion of potassium.

Local RAAS also occurs in heart, kidney, brain, and vessels enhancing the effects of the circulating RAAS (Bader, 2010). RAAS has important regulatory roles in cardiovascular physiology, but have also been shown to be involved in the pathogenesis of hypertension and of heart failure. Mediators, such as Ang I and II, directly act on cardiomyocytes, cause renal and cardiac fibrosis, and are considered key drug targets for the treatment of cardiovascular disease.

Ang II also binds to type 2 angiotensin II (AT2) receptors that are found only sparsely in healthy vascular, myocardial, or neuronal tissues but are markedly up-regulated following injury. Activation of AT2 receptors antagonizes many of the pathophysiological effects of AT1 receptor activation such as oxidative stress, inflammation, fibrosis, vasoconstriction, and myocardiocyte hypertrophy.

The natriuretic peptides, primarily produced by the cardiomyocytes, are critical in the regulation of fluid balance (van Kimmenade and Januzzi, 2009). Atrial natriuretic peptide (ANP), synonymous with atrial natriuretic factor and atriopeptin, is produced and stored by atria in granules and released in response to increased tension in the atrial walls, owing to increased volume or pressure. Natriuresis and diuresis are produced by an increase in glomerular filtration rate (GFR), affected by dilation of the afferent, with simultaneous constriction of the efferent, glomerular arterioles. These effects are largely due to receptor-mediated activation of guanylate cyclase causing increases in cyclic guanosine monophosphate (cGMP). The diuretic and natriuretic actions are also due to inhibition of sodium resorption in the proximal convoluted tubule and cortical collecting ducts, and of renin, aldosterone, and norepinephrine secretion. ANP has relaxing effects on vascular and myocardial muscle. If the increase in tension in the atrial wall is prolonged, there is marked induction of ventricular synthesis for further increasing the atrial ANP effects.

B-type (formerly called brain-type) natriuretic peptide is largely produced by ventricles in response to myocardial stretch and anoxia. Neuroendocrine factors also provoke its release, such as Ang II, interleukin (IL) 1 β , and adrenergic agents. It has similar effects as ANP on natriuresis and diuresis by glomerular actions and by inhibition of RAAS and the SNS. It also has antiproliferative and antifibrotic effects on the heart, which are protective in heart disease.

There are local or autocrine or paracrine natriuretic peptides. One, structurally similar to ANP, urodilatin, is produced by distal renal tubules and has similar but locally restricted effects on the kidney and adrenals. There is a C-type natriuretic peptide (CNP) found in blood vessels, kidney, central nervous system (CNS), and the pituitary (Archer, 2003). This lacks direct diuretic effect but retains vascular relaxation effects. Moreover, it may serve as a central neurotransmitter and reproductive factor, and may be involved in bone growth. One isoform of CNP is considered the ancestral origin of the natriuretic peptides. CNP is also expressed in macrophages in response to inflammatory mediators and is increased with sepsis (DeClue et al., 2011).

13.1.1 CARDIAC FUNCTION

The heart is a specialized muscle whose primary function is to pump blood through the body with sufficient pressure and volume to provide oxygen for aerobic metabolism (Stephenson, 2007). It does this in a cyclical process of contraction and relaxation during which blood is expelled from, and enters into, respectively, its muscular ventricles. The heart must respond to widely changing demands for oxygen delivery for tissue metabolism. For immediate response to these demands, the heart has high reserve capacity for adjusting the rate and volume of blood ejected. This is highly regulated by a complex, neuroendocrine system. For longer term changes in demand, the heart can additionally adapt its mass and its regulatory system. Thus, the heart rate, stroke volume, and heart-to-body weight ratio vary according to differences in functional demand that are related to species, breed or strain, age, gender, physical activity, nutritional state, endocrine state, and as well, a wide range of pathologies (Martin et al., 1993; O'Brien, 1998).

Across a wide range of mammalian species, logarithms of (log) heart size and stroke volume are proportional to log body size; whereas, log resting heart rate is inversely proportional to log body size (West et al., 1997). However, additional capacity is observed in more athletic species and strains or breeds than would be predicted by this relationship (Weibel et al., 2004; Painter, 2005). In contrast, diminished capacity is found with pathology (Van Vleet and Ferrans, 2007). For example, in healthy, adult, laboratory animals, heart-to-body weight ratio (%) varies from 0.24 in rats, 0.27 in rabbits, 0.35 in cynomolgus monkeys, 0.42 in guinea pigs, 0.46 in cats, 0.58 in mice, to 0.75 in dogs (Joseph, 1908; Gray, 1945; Drevon-Gaillot et al., 2006). Most exceptional of these data is that for the mouse, the smallest of these laboratory animals; it has a considerably higher heart weight than would be predicted by the allometric relationship between heart weight and body size for mammals. Normal heart rates vary substantially. In dogs, normal heart rates vary from 90 beats per minute (bpm) at rest to 270 bpm at maximal exercise, and in mice normal heart rates vary from 160 bpm during

fasting-induced torpor to 500–600 bpm at rest and 840 bpm with maximal exercise (Swoap and Gutilla, 2009). Even greater ranges are achieved in racing greyhounds owing to a significantly greater heart-to-body weight ratio as compared with other dog breeds. Greyhounds can increase resting heart rates from 30 to over 400 bpm (Gunn, 1989; Engleking, 2009).

Capacity for physiological performance of the heart correlates with the activities of three subcellular biochemical systems for contraction, metabolism, and intracellular calcium regulation (Martin et al., 1993). The timing, rate, and degree of the contraction and relaxation cycle of the heart are determined by the timing, rate, and degree of the contraction and relaxation cycle of the contractile myofilaments within the cardiomyocyte (Stephenson, 2007). These in turn are determined by the timing, rate, and magnitude of the intracellular cycle of calcium release and sequestration by the sarcoplasmic reticulum (Martin et al., 1993; O'Brien et al., 1988). An incremental increase in the heart rate of various etiologies is associated with a similar increment in sarcoplasmic reticulum Ca-ATPase activity (O'Brien et al., 1988). Mitochondria provide the energy necessary for these calcium and contraction cycles. Biomarker activities for all three subcellular systems are proportional to cardiac performance across a wide range of species, with adaptation to physiologically increased, functional demand, and with deterioration during various pathological states (Martin et al., 1993; O'Brien and Gwathmey, 1995; O'Brien, 1998).

13.1.2 CARDIAC INJURY

Cardiac injury may arise from a wide diversity of causes including those that affect the heart primarily, but also those that affect other organs or systems and result in secondary injury to the heart (O'Brien, 2006, 2008; Serra et al., 2010). Etiologies for primary cardiac injury include the following: genetic, nutritional, physical trauma, inflammation, neoplasia, infectious organisms, xenobiotics, hemodynamic overload, severe exertion, ischemia and anoxia, old age, or marked stress. Cardiac injury may also occur secondarily to disease affecting another tissue, organ, or system. Secondary causes include various endocrinopathies (e.g., hyperthyroidism, uncontrolled and marked hypercortisolism, or Addison's disease), marked anemia, pancreatitis, renal disease, and metastatic tumors (Serra et al., 2010).

13.1.2.1 Primary Cardiac Injury

Inherited cardiomyopathy is one type of primary cardiac injury. The Sprague–Dawley rat is commonly affected by an age-dependent and gender-modified spontaneous cardiomyopathy (Kemi et al., 2000; O'Brien et al., 2006). This cardiomyopathy is evident from the finding that at 6–8 months of age, Sprague–Dawley male rats have approximately 10-fold greater levels of serum cardiac troponin I (cTnI), a biomarker of cardiac injury, as compared to age-matched female rats and male rats 3 months of age (O'Brien et al., 2006). These age-dependent cTnI increases correlated with minimal-to-mild, degenerative histopathological change. Spontaneous cardiomyopathy is well described in the Syrian hamster and recently described in the cynomolgus monkey (Recchia and Lionetti, 2007; Zabka et al., 2009) while idiopathic cardiomyopathy affects more than half of chimpanzees (Seiler et al., 2008). There are spontaneous hypertensive rats and the Dahl salt-sensitive strain of rats that develop pathological hypertension leading to pressure overload and cardiac failure (Balakumar et al., 2007). Aging also produces cardiac injury, apparently in association with oxidative stress and the formation of lipofuscin pigment, which may cause a brown discoloration of the myocardium and may be observed at necropsy. Moreover, cardiac injury may occur due to primary neoplasia in the heart such as with hemangiosarcoma or heart base tumors (e.g., chemodectomas), as well occurring secondarily owing to metastasis of neoplasia from another organ, such as with lymphoma (Maxie and Robinson, 2007; Van Vleet and Ferrans, 2007).

Primary cardiac injuries are not only characterized by their etiology, but by the associated morphological or functional cardiac changes. For example, cardiomyopathies may be dilated, hypertrophic, or arrhythmogenic. Other categories include ventricular arrhythmia, pericardial

effusion, valvular disease (mitral, aortic insufficiency jet lesions), subaortic stenosis, infarct, and third degree heart block (Serra et al., 2010).

13.1.2.2 Spontaneous Myocarditis

Spontaneous myocarditis is found in preclinical toxicology studies at necropsy in all species, but especially in nonhuman primates. As natural infectious causes of myocarditis are uncommon in nonhuman primates, it is suspected that it may be secondary to stress-induced cardiac injury (Chamanza et al., 2006, 2010). Proinflammatory cytokines such as ILs 1 β and 6, tumor necrosis factor (TNF- α), and interferon- γ impair cardiac function by causing myocardiocyte apoptosis, and cardiac remodeling, hypertrophy, and dilation. These cytokines regulate the expression of matrix metalloproteinases (MMPs) and the tissue inhibitors of MMP (TIMP), as well as the cardiac fibroblast production of collagen and fibronectin (Rutschow et al., 2006).

In nonhuman primates, the incidence of spontaneous myocarditis is approximately 20%, compared to approximately 1% for pericarditis or endocarditis (Chamanza et al., 2006, 2010). Males were about 50% more frequently affected than females, and rhesus monkeys were twice as frequently affected as marmosets and cynomolgus monkeys. Inflammatory infiltrates were predominantly mononuclear cells in the primates, especially lymphocytes, and frequently associated with myocardial degeneration and edema or fibrin deposition. In beagles, the incidence of spontaneous myocarditis is approximately 5% for males and 2% for females (Greaves, 2007). In rats, only occasional cases are seen, and in mice even less (Greaves, 2007).

13.1.2.3 Trauma

Blunt trauma may occur during handling and restraint, especially with small animals, and could cause release of biomarkers of myocardial injury. For example, mild mechanical trauma produced by rotating mice in a drum caused cardiac dysfunction, myocardial cell apoptosis, and mild increases in cTnI, a biomarker of cardiac injury (Tao et al., 2005). Direct, physical injury also occurs during blood sampling by cardiac puncture, and as this is associated with, increases in cardiac injury biomarkers in the sampled blood, it is not recommended as a sampling technique for samples to be analyzed for cardiac biomarkers (O'Brien et al., 1997a). The increase in serum troponin may occur because of contamination of myocardial tissue in the bore of the needle. Presumably, the injury produced by cardiac puncture could also increase circulating injury biomarkers.

13.1.2.4 Infectious Disease

Cardiac injury from infectious or parasitic disease is not common in laboratory animals, but it may occur (Wells and Sleeper, 2008; Serra et al., 2010). For example, in young dogs, parvovirus infection may cause focal myocardial inflammation followed by fibrosis (Gagnon et al., 1980). Myocarditis induced by parvovirus in man causes increased serum cardiac troponin (Baig et al., 2006). Heartworm infections are well described in dogs and cats. Babesiosis (Lobetti et al., 2002), leishmaniasis (Silvestrini et al., 2010), ehrlichiosis (Diniz et al., 2008), leptospirosis (Mastrorilli et al., 2007), foot-and-mouth disease (Tunca et al., 2008), endotoxemia (Peek et al., 2008) have all been identified as causes of myocardial injury, with increases in serum cardiac troponin.

13.1.2.5 Cardiotoxicity

Numerous classes of drugs have been demonstrated to directly produce cardiac injury (O'Brien, 2008). Anticancer drugs are widely associated with cardiotoxicity, including alkylating agents, anthraquinones, anthracyclines, antimetabolites, various monoclonal antibody treatments, and IL-2. Other drug classes causing cardiotoxicity are the sympathomimetics such as adrenergic agonists and phosphodiesterase inhibitors (PDEi), antiretroviral drugs such as the nucleoside reverse transcriptase inhibitors and protease inhibitors, and peroxisomal-proliferator-activated receptor alpha (PPAR α) agonists (Pruimboom-Brees et al., 2006). It is noteworthy, that the latter toxicity is only known to occur in mice and rats. Increased oxidative stress and mitochondrial injury are

frequently involved in the pathogenesis of myocardial toxicity, although the overstimulatory effects of suprapharmacologic doses of sympathomimetics (e.g., ephedrine) may disrupt myocardial perfusion and cause ischemic necrosis. Significant myocardial injury causes necrosis leading to inflammation followed by fibrosis and mineralization. If these changes are extensive, they may lead to compromised cardiac function and heart failure.

13.1.2.6 Hemodynamic Overload

Functional overload of the heart, if excessive and prolonged, may overwhelm adaptive capacity and cause development of cardiac failure (Muders and Elsner, 2000). The overload may be due to increased preload, which occurs with increased volume of blood, or due to increased afterload, which occurs with increased arterial pressure. Less commonly, it may occur due to a chronically increased cardiac rate (O'Brien et al., 1994). The ventricles respond to a chronically increased hemodynamic burden with progressive hypertrophy. With volume overload, hypertrophy is eccentric. Moreover, it occurs with dilatation of the ventricular cavity and an increase in myocardial mass such that the ratio between wall thickness and ventricular cavity size remains relatively constant. With chronic pressure overload, hypertrophy is concentric; it occurs such that the ratio between wall thickness and ventricular cavity size increases (Maxie and Robinson, 2007). Fluid retention and volume overload occur with chronic treatment with thiazolidinedione insulin sensitizers (i.e., glitazones, PPAR γ agonists) and rarely with insulin, producing cardiac hypertrophy that can progress to cardiac failure (Kalambokis et al., 2004; Bas et al., 2010; Chaggar et al., 2009). Systemic hypertension and pressure overload occur with hypercortisolism, and produce cardiac hypertrophy (Reini et al., 2008).

13.1.2.7 Endocrinopathy

Excessive endocrine stimulation may also cause cardiac injury (Van Vleet and Ferrans, 2007). Stress, which occurs with unaccustomed handling or restraint, especially in nonhuman primates, produces cardiac injury owing to the excessive stimulation of SNS and catecholamine release by a mechanism similar to that described above for the sympathomimetics (Akashi et al., 2010). As thyroid and growth hormones are critical growth factors for the heart, hypertrophic cardiomyopathy with progression to heart failure may occur with chronic hyperthyroidism or excessive secretion of growth hormone as seen in acromegaly (Clayton, 2003). Surprisingly, growth hormone releasing hormone may have direct cardioprotective effects after cardiac injury (Kanashiro-Takeuchi et al., 2010). As indicated above, hypercortisolism occurring with Cushing's disease also has a cardiostrophic effect, in part by activation of the mineralocorticoid receptor (Reini et al., 2008). Hypoaldosteronism occurring with Addison's disease results in impaired sodium and water retention and excretion of potassium. The resultant hypovolemia and hyperkalemia and acidosis may result in impaired cardiac activity, brown atrophy, and ischemic injury (Goodof and Macbryde, 1944; Fallo et al., 1999).

13.1.2.8 Nutrient Deficiency

Cardiac atrophy occurs in parallel with body weight loss during inanition due to deficient caloric and protein intake (Keys et al., 1947). Dietary insufficiency of various macrominerals such as calcium, magnesium, phosphate, and potassium has adverse effects on cardiac performance because of the critical role these ions play in regulating activity. For example, calcium influx during the action potential activates myocardium. Its deficiency has negative inotropic effects with compensatory positive chronotropic effects mediated by the neuroendocrine system (Stephenson, 2007). Chronic hypocalcemia, with untreated hypoparathyroidism or vitamin D deficiency, can cause dilated cardiomyopathy (Sung et al., 2010). The action of calcium is opposed by magnesium. Magnesium, along with phosphate, has a critical role in energy metabolism. Potassium is important in maintaining the resting and action potentials, as well as activating key regulatory enzymes of metabolic pathways. In severe potassium deficiency due to decreased intake or pharmacologic antagonists of potassium homeostasis, cardiac output may be impaired and arrhythmias may develop and lead to heart failure

(Serebruany, 2006) and myocardial necrosis (Allen, 1955). Vitamin E and selenium play critical roles in protection from oxidative stress, and deficiencies of these micronutrients are well known to be associated with cardiomyopathy (Green and Lemckert, 1977; Maxie and Robinson, 2007). Thiamin deficiency, because of its critical role in oxidative metabolism, also impairs cardiac function. Moreover, severe deficiency causes wet beriberi with heart failure (Tran, 2006).

13.1.2.9 Ischemia and Hypoxia

Ischemia and hypoxia are common causes of cardiac injury and necrosis and occur with a wide range of pathologies including myocardial infarct, coronary thrombosis, hypovolemia occurring with marked hypoalbuminemia or shock, anesthesia and depression of the respiratory system, or gastric dilation and volvulus (Maxie and Robinson, 2007; Van Vleet and Ferrans, 2007; Serra et al., 2010). The mineralocorticoid receptor is thought to induce cardiac hypertrophy and fibrosis in response to ischemia. Systemic administration of blockers of this receptor has been shown to reduce markers of inflammation and fibrosis (Fallo et al., 1999). Marked anemia, with hematocrits less than 20% are typically associated with myocardial injury, as indicated by increases in blood troponin in dogs and cats (Serra et al., 2010). The cardiac injury is reasonably attributed to anoxia.

13.1.2.10 Pancreatitis

Pancreatitis and the subsequent release of a wide range of degradative enzymes and myocardial depressant factor cause cardiac injury and is associated with impaired cardiac performance and release of myocardial biomarkers into the peripheral blood (Serra et al., 2010).

13.1.2.11 Renal Disease

In human renal failure, myocardial injury occurs with increased short-term mortality (Martin et al., 1998). Apparently, uremia occurring with renal failure causes accumulation of toxic substances in the blood that produce cardiac injury. Recent studies demonstrate that myocardial injury also occurs in dogs that have severe renal disease (Sharkey et al., 2009; Serra et al., 2010).

13.1.2.12 Marked Stress or Exertion

Marked stress may increase catecholamine levels to the point that myocardial necrosis occurs. This has been well described in the stress-susceptible pig (O'Brien and Ball, 2006), but is well known to occur in man (Akashi et al., 2010) and laboratory animals (O'Brien, 2008). Exertional rhabdomyolysis may occur with unaccustomed or extreme levels of exertion such as in racing or capture myopathy; this is a well-known syndrome associated with cardiac injury and is likely associated with tachycardia, hypercatecholemlia, and anoxia, all of which can individually cause cardiac necrosis (Wells et al., 2009).

13.1.3 IMPACT OF CARDIAC INJURY ON OTHER ORGAN SYSTEMS

Failure of the heart causes underperfusion and limited function of various viscera and skeletal muscle. There is loss of muscle mass and aerobic capacity with exercise intolerance (Minotti et al., 1991; Miller et al., 2010). Hepatic passive congestion occurs with impairment of liver function and hepatocyte injury that releases intracellular enzymes, such as alanine and aspartate transaminases (O'Brien et al., 1993). Renal underperfusion causes decreased GFR with increases in urea and creatinine, and other metabolites and ions normally filtered by the kidney.

The decreased cardiac output stimulates activation of central and peripheral mechanisms to restore output and maintains tissue perfusion. Initially, the compensatory mechanisms maintain circulatory homeostasis. There is a balance of salt and water retention by the RAAS and antidiuretic hormone (ADH) with diuresis produced by ANP. There is also a balance of endogenous mechanisms for vasoconstriction, such as the RAAS, SNS, ADH, endothelin, and thromboxanes, and for vasodilation, such as the parasympathetic nervous system (PNS), prostacyclin, ANP, and

nitric oxide. However, in the later phase, there is excessive vasoconstriction, which inhibits left ventricular outflow to reduce cardiac output. The degree of activation of the compensatory mechanisms correlates with prognosis and life expectancy with plasma norepinephrine concentration having one of the highest predictive values (Cohn et al., 1984).

13.1.4 BIOMARKERS OF CARDIAC INJURY

13.1.4.1 Historical Biomarkers (Creatine Kinase and Lactate Dehydrogenase)

Historically, myocardial injury has been assessed by electrophoretic measurement of cardiac-specific isozymes (multiple forms of an enzyme that catalyze the same reaction) of lactate dehydrogenase (LD) and creatine kinase (CK), enzymes important in intermediary metabolism (Archer, 2003; O'Brien et al., 1997a; O'Brien, 2009). Recently, immunoassays have been developed for the assay of the human CK isozyme that is the most specific biomarker for cardiac injury, CK-MB, although these assays are usually not effective for laboratory animal use because of poor cross-species reactivity (O'Brien et al., 1997a). Each of these two enzymes, LD and CK, is coded by two different genes, although CK is a dimer comprised of only two gene products and LD is a tetramer comprised of four gene products. The different isozymes are formed by the random association of transcripts of two genes that are differentially expressed depending on the tissue type. Cardiac muscle expresses far more of its B than its M gene for CK, and far more of its H than its M gene for LD than occurs in skeletal muscle. Consequently, CK-MB and LD-H₄ (i.e., LD1), and LDH₃M₁ (i.e., LD2) are useful biomarkers of cardiac injury. Cardiac disease apparently further increases the myocardial expression of the B gene. The cardiac isozyme of LD can be measured as hydroxybutyrate dehydrogenase (HBDH) by automated assay based on its substrate specificity for hydroxybutyrate. In a study of blunt trauma in dogs, this was found to be more sensitive than CK-MB (Schober et al., 1999).

Several factors have limited the use of CK and LD isozymes as cardiac biomarkers in animals. First, their tissue specificity is not absolute. For example, slow twitch muscle may express cardiac isozymes. Furthermore, in commonly used laboratory animals, liver, erythrocytes, leukocytes, and platelets may express cardiac LD isozymes, so that liver injury, hemolysis and clotting may confound the diagnosis of cardiac injury (O'Brien et al., 1997a; Walker, 2006). In erythrocytes, LD-1 predominates in guinea pigs, LD-4 or LD-5 predominates in rats and mice, and an intermediate LD isozyme predominates in the hamster (Yasuda et al., 1990). In liver, LD-5 predominates for mice, rats, and hamsters, but not for guinea pigs, where intermediate isozymes predominate (Yasudas, 1990). In the rat, platelets contain mostly LD-5 at a similar level of activity as in erythrocytes, but CK in platelets was approximately 30-fold higher than in erythrocytes and found to be exclusively CK-BB (Beck et al., 1997). Leukocytes of dog and rabbit, but not cat, preferentially express cardiac over skeletal muscle LD isozymes (Washizu et al., 2002). Secondly, and more importantly, these isozymes have poor sensitivity. This reflects significant background levels in the blood and relatively low levels in myocardium of the tissue-specific form compared to the total activity (Aktas et al., 1993). Consequently, their release usually causes less than an order of magnitude increase in the blood. Furthermore, the kinetics of their release and clearance are insufficient to cause early and prolonged increases in the blood. For example, after cardiac injury in man, there is a rapid rise of plasma CK-MB levels reaching a peak within 12 hours and baseline levels within 1–2 days due to rapid clearance. Increases in plasma LD levels are slower, peaking within 48 hours and clearing within several days (Babuín and Jaffe, 1995). Finally, species-specific immunoassays for CK-MB and LD isozymes are not commercially available for use in nonhuman species.

13.1.4.2 Myoglobin and Fatty Acid Binding Protein 3

Myoglobin and fatty acid binding protein 3 (FABP3) are important cytosolic proteins in intermediary metabolism of striated muscle and are small proteins that leak out of cardiac muscle rapidly after injury with plasma levels peaking within 6 hours. Because of rapid release from damaged tissue and high cardiac concentrations, myoglobin and FABP3 have the potential to be used as sensitive

biomarkers of acute injury (Mion et al., 2007). However, these biomarkers are cleared by the kidney within 12–24 hours of injury and their effective use as cardiac biomarkers is substantially limited because of their lack of specificity. For example, myoglobin is found in high concentration in aerobic striated muscle (O'Brien et al., 1992). Although FABP3 is preferentially found in cardiac tissue, it is also found in skeletal muscle and kidney. As such, injury to these other tissues should be excluded before they could be used as cardiac biomarkers and their use may be restricted to negative prediction (i.e., exclusion) of peracute myocardial injury. Finally, the use of myoglobin and FABP3 as biomarkers is also limited by the absence of commercially available, species-specific immunoassays.

13.1.4.3 Ischemia-Modified Albumin

Ischemia-modified albumin (IMA) forms in blood of capillaries within minutes of onset of myocardial ischemia due to oxidative stress (van Belle et al., 2010). This causes changes in the amino end of plasma albumin that decreases its cobalt binding activity, which can be measured by an automated clinical chemistry analyzer method. Plasma levels of IMA peak in a couple of hours and return to baseline within 6 hours (Gaze, 2009). In man, it has been recently demonstrated to be increased with myocardial ischemia (Bar-Or et al., 2000), and, in combination with other cardiac biomarkers, it has been demonstrated to provide additional prognostic information for myocardial ischemic patients (Anwaruddin et al., 2005; van Belle et al., 2010). However, despite high sensitivity for myocardial ischemia, IMA lacks specificity, being also elevated with cerebral, mesenteric, skeletal, and pulmonary ischemia, with severe renal and liver disease, and certain neoplasms. Similar to FABP3 and myoglobin, it may also be useful as a negative or rule-out biomarker of peracute myocardial injury. However, its effective use in laboratory animals has not been proven.

13.1.4.4 Cardiac Troponin

Cardiac troponin (cTn) is currently the gold standard biomarker for acute cardiac injury in man (Daubert and Jeremias, 2010). It is extensively used for detection and assessment of active and ongoing cardiac injury in heart disease (Babuín and Jaffe, 2005). In addition, it has been extensively used for clinical assessment and monitoring of cardiac toxicity in humans being treated for cancer (Shakir and Rasul, 2009).

Troponin regulates the interaction of thin and thick contractile muscle filaments comprised of actin and myosin, respectively (Solaro et al., 2008). Troponin is a complex of three, small globular proteins: C that binds calcium (cTnC), I that inhibits actin and myosin interaction (cTnI), and T that binds tropomyosin (cTnT). These proteins have molecular weights of 23, 18, and 37 kDa, respectively. Calcium binding causes sequential conformation changes in cTnC, cTnI, and tropomyosin that cause cTnI to detach from actin and tropomyosin and to roll out of the way of the myosin cross-bridges that pull on the actin filaments to contract muscle (Metzger and Westfall, 2004).

The high sensitivity and near absolute specificity of cTn have made it the preferred biomarker for myocardial infarct in humans (Daubert and Jeremias, 2010). It is used in man for the identification of myocardial injury and risk stratification, as its elevation correlates with clinical severity and life expectancy (Babuín and Jaffe, 2005). Troponin is now used as a biomarker in a wide range of cardiac injuries, including unstable angina and minimal infarct, left ventricular hypertrophy, congestive heart failure, pulmonary embolism, blunt trauma, sepsis, moderate renal disease and renal failure, diabetes mellitus, and cardiotoxicity associated with anticancer drugs and sympathomimetics. Initially, the delayed onset to peak plasma concentrations (up to 12 hours) following cardiac infarct limited the early use of cTn; however, recent high sensitivity assays have been introduced and preliminary studies in humans using these newer assays demonstrate earlier increases in plasma cTn levels following cardiac injury (Keller et al., 2009).

In the last 10 years, several dozen preclinical published studies have directly confirmed the effectiveness of cTn in laboratory animals for the assessment of cardiotoxicity, including identification, quantitation, and prognosis of cardiotoxicity (O'Brien et al., 1997a; Wallace et al., 2004; O'Brien, 2006, 2008; Serra et al., 2010). The cTn response in animal models in which cardiac muscle injury is

induced is similar to the human cTn response to cardiac muscle injury with respect to cardiac tissue specificity, association with cardiac histological change, and the onset, magnitude, and duration of cTn response. cTn is a dose-responsive biomarker of cardiac injury that correlates with severity of injury at the cellular, tissue, physiological, and clinical levels (O'Brien, 2008).

In veterinary medicine, cTn is rapidly emerging as the preferred biomarker for the detection of myocardial injury in more than a dozen mammalian species. There have been approximately 100 reports of its effective use in various disease states, including a wide range of primary cardiac diseases, numerous infectious diseases, severe respiratory disease, trauma, exertion, anemia, pancreatitis, uncontrolled Cushings and Addisons, hyperthyroidism, sepsis, systemic neoplasia, old age, severe colic, and renal failure (O'Brien, 2008; Wells and Sleeper, 2008; Serra et al., 2010).

Cardiac troponin, predominantly cTnI, has essentially replaced all other biomarkers of myocardial injury over the last decade, first in humans and now in veterinary medicine and preclinical and clinical safety studies. This reflects not only its unique and extraordinary myocardial specificity and diagnostic sensitivity for myocardial injury but also its robustness as a biomarker, and the simplicity and accessibility of assays (Table 13.1; O'Brien, 2006, 2008).

The troponins are released from cardiac tissue during the active phase of cell lysis and return to baseline following termination of active pathogenesis. In situations of progressive cell injury, there is a long-sustained increase in serum troponins. In human and animal studies, cTn has been demonstrated to be the first released within minutes of myocardial injury with peak plasma levels occurring as early as 2–6 hours depending on the duration and severity of the cardiac injury. In experimental models of myocardial infarct in dogs in which coronary occlusion was restricted to 90 minutes, peak plasma cTn levels are seen in 3–4 hours (O'Brien, et al., 1997a). In rats treated with a single, subcutaneous toxic dose of isoproterenol, plasma concentrations of cTnI and cTnT peaked within 2–6 hours. In these rat and dog models, cTnI increases correlated with the severity of histopathological cardiac lesions and infarct size at 3 hours (O'Brien et al., 2006). With naturally occurring myocardial infarct in humans, plasma cTn levels typically rise within 4–6 hours and peak at 18–24 hours. At 72 hours, plasma concentrations correlated with scintigraphic measurement of infarct size. In a rat study with cardiotoxicity induced by a single dose of isoproterenol, cTnI was found to increase almost 800 times the minimal detectable concentration and to decrease with a half-life of 6 hours, resulting in an expected return to baseline of 2.5 days (O'Brien et al., 2006).

TABLE 13.1

Advantage of cTn over Other Cardiac Injury Biomarkers

- Tissue specificity—near absolute discrimination from skeletal muscle and other tissue injury
- Cross-species immunoreactivity—highly conserved epitopes
- Diagnostic sensitivity—can detect background levels, minor injury
- Correlation with cytopathologic and histopathologic biomarkers of acute injury, physiological performance indicators, clinical severity
- Prognostic value
- Effective assays and analyzers widely available
- Microvolume assays available (25 μ L sample)
- Kinetics of release and plasma clearance characterized and appropriate: time to peak, half-life
- Inexpensive
- Robust with good storage stability
- Dose responsive
- Translational across species and into humans
- Widely used and characterized—hundreds of publications
- Candidate for qualification by regulatory agencies

Source: O'Brien, P.J., *Expert Rev Mol Diagn*, 6, 685–702, 2006; O'Brien, P.J., *Toxicology*, 245, 206–218, 2008.

Several reports indicate that cTnT may be more sensitive immediately after injury (Christenson et al., 1998; O'Brien, 2006), possibly because the cytoplasmic pool of cTnT is approximately 7%, which is twice that of cTnI, and the cytoplasmic cTn pool is considered to be released earlier than the myofibrillar pool (Bleier et al., 1998). However, approximately 6 hours after injury both troponins provided equivalent information. Furthermore, cTn is released as a ternary complex, consisting of binary complexes of cTnI and cTnC, and as free cTnT.

As for other organ biomarkers, the amount of cTnI release is affected by tissue content. Partial depletion of tissue cTn (as seen with prior injury, inanition and weight loss, and heart failure) may be associated with decreased amounts of release. Body and cardiac weight loss of approximately 25% in rats produced an approximately 50% decrease in cTn content of myocardium (O'Brien, 2006). In heart failure, loss of myofibrillar volume fraction is indicated by an approximately 30% loss of troponin (O'Brien, 1997; O'Brien et al., 1997a).

Cardiac troponin serves as a biomarker of myofibrillar volume fraction not only in cardiac atrophy but also in cardiac hypertrophy (Slaughter et al., 2004). Pressure overload increased myofibrillar density by up to 30%, whereas volume overload decreased myofibrillar density by up to 15%. Growth factor-induced hypertrophy was confirmed to occur by a mixture of processes; while myofibrillar density had increased by 31% at 1 week, it had normalized by 4 weeks. Minoxidil-induced hypertrophy occurred by a mixture of the processes, with myofibrillar density first decreased by 15% at 1 week before normalizing by 4 weeks. Progressive, pathological hypertrophy, as modeled with spontaneous hypertension, was confirmed to be associated with abnormally increased myocardial, myofibrillar density.

Commercially available assays for cTn are robust, simple, accurate, reproducible, inexpensive, and widely available. The analytical performance for most has been recently evaluated for application in laboratory animals and those with insufficient precision, dynamic range, or cross-species reactivity have been identified (O'Brien et al., 2006; Apple et al., 2008). Effective cTn assays have good cross-species reactivity, reflecting the high degree of conservation of cTn structure, although some assays are species restricted because their antibodies target epitopes that are not well conserved (O'Brien et al., 1997b). Also identified were several highly sensitive assays that were able to detect background levels of cTn in laboratory animals. Four cTnI assays (from Abbott, Bayer, Beckman, and Dade analyzers) gave good responses across multiple species (O'Brien et al., 2006; Apple et al., 2008). More recently, a supersensitive assay that uses capillary flow technology and detects single troponin molecules has been described (Todd et al., 2007) and applied successfully in preclinical toxicology studies (Mikaelian et al., 2009; Schultze et al., 2009). It has sensitivity at least an order of magnitude greater than previous assays, and it has been used for detecting drug-induced injury at levels that have not produced histopathological effects on myocardium (Mikaelian et al., 2011).

Whereas there are numerous cTnI assays, patent restrictions limit cTnT assays to one assay for clinical use (Roche Diagnostics, Basel, Switzerland) and one assay for research and preclinical use (MesoScale Discovery, Gaithersburg, Maryland, USA). Recent reports indicate that as cTnT assays have been developed for sensitivity and tissue specificity, and are now in their third and fourth generations, these assays have lost some cross-species reactivity and significant effectiveness for animal applications (Serra et al., 2010).

In a recent comparative study using numerous models of cardiac injury, a new, high-sensitivity generation of one of the four above-mentioned cTnI assays demonstrated the performance across six species (Centaur cTnI Ultra; Serra et al., 2010). This assay generation was found to be an order of magnitude that is more sensitive than the previous assay version (O'Brien et al., 2006), and had higher precision at low cTnI concentrations. The concentration of cTnI in the blood highly correlated with loss of cardiac function, and outperformed other assays tested. It had a dynamic range (maximum divided by minimum value) of almost 7000 and was able to detect cTnI at concentrations as low as 0.006 $\mu\text{g/L}$ (Serra et al., 2010).

Despite the effectiveness of cTnI as a biomarker of cardiotoxicity, there are caveats to the use of cTnI as a biomarker (Table 13.2). Further, similar to other leakage biomarkers used in clinical

TABLE 13.2**Caveats for Use of cTn in Safety Assessment Studies for Detection of Cardiac Effects**

1. Detection of acute and active ongoing injury causing release of intracellular constituents; does not detect past injury, or loss of cardiac function
2. Causes of Increased Background
 - Cardiac pacing of pharmacological studies
 - Blood collection by cardiac puncture
 - Ischemic injury during anesthesia and euthanasia
 - Excessive handling stress, restraint or exertion, or trauma
 - Spontaneous cardiomyopathy, especially male Sprague–Dawley rat
3. Causes of Blunted Increases
 - Choice of assay with insufficient sensitivity, dynamic range, or tissue specificity, or cross-species reactivity
 - Decreased tissue concentration due to past cardiac injury, inanition, heart failure
 - Inappropriate timing of blood collection

Source: O'Brien, P.J., *Expert Rev Mol Diagn*, 6, 685–702, 2006; O'Brien, P.J., *Toxicology*, 245, 206–218, 2008.

chemistry for detection of organ damage, cTnI does not directly measure tissue function nor does it reflect previous tissue injury. There are preanalytical causes of changes in serum cTn. It may be increased by background cardiomyopathy or by procedures used during sample collection, such as extreme stress, ischemic injury, cardiac puncture, or cardiovascular instrumentation. In addition, cTn may be decreased if there is decreased tissue concentration as may occur with previous cardiac injury, inanition, or heart failure (O'Brien, 2006, 2008).

13.1.4.5 Natriuretic Peptides

Congestive heart failure is associated with numerous neuroendocrine changes. Several of these have been utilized effectively as biomarkers of the severity of the cardiac dysfunction. The characteristic increase in peripheral vascular resistance seen with heart failure has been attributed to increases in sympathetic tone, norepinephrine, Ang II, ADH, and endothelin-1 (ET-1). The increased venous pressure is associated with atrial distension that stimulates production and release of ANP and brain natriuretic peptides (BNPs) that are normally produced primarily in the atria (although BNP is produced primarily in the ventricles in heart disease). ANP is stored in atrial granules, whereas BNP is primarily produced on demand by *de novo* synthesis.

The natriuretic peptides of the atria and ventricles, ANP and BNP, are produced as pre–prohormones and released as prohormones. Both forms are inactive. The pre–pro form is converted to the pro form, which is subsequently converted to the active hormone and then to multiple, inactive, degradative products. This conversion process is mediated by various serum proteinases. In the first step, a small signal peptide is cleaved in the myocardial cell from the pre–pro form to generate pro-ANP or pro-BNP. Both peptides are cleared from the blood by multiple pathways. They are bound to their clearance receptor (natriuretic peptide receptor C [NPR-C]), internalized, and hydrolyzed by lysosomal enzymes. They are also cleaved by neprilysin, a membrane-bound, neutral endopeptidase, and metalloproteinase. Propeptides are converted to active peptides by corin and furin. Corin is a transmembrane cardiac serine protease that cleaves pro-ANP to form ANP and NT-proBNP. Both corin and furin cleave pro-BNP into BNP and the twofold larger N-terminal fragment, NT-proBNP (van Kimmenade and Januzzi, 2009). The NT-pro forms of the natriuretic peptides are inactive and cleared passively more than half by the kidney, and a quarter by the liver (Thygesen et al., 2011).

The atrial and ventricular natriuretic peptides produce their effects by binding to natriuretic peptide receptors A and B (NPR-A, NPR-B) that are coupled to guanylate cyclase. BNP mostly binds NPR-A, which increases cGMP that regulates ion channels, protein kinases, and phosphodiesterases.

Both natriuretic peptides act similarly, to promote natriuresis and diuresis, cause vasodilation, and antagonize the effects of the RAAS and SNS (Thygesen et al., 2011). Furthermore, ANP and BNP are neurotransmitters in the CNS, decreasing sympathetic tone and reducing ACTH and ADH secretion thereby reducing salt appetite and drinking. Accordingly, increases in ANP and BNP may accelerate the development of heart failure.

BNP and NT-proBNP have become important cardiovascular biomarkers in humans, especially in diagnosis, prognosis, and monitoring of heart failure, and a wide spectrum of cardiovascular diseases (Thygesen et al., 2011). The use of BNP and NT-proBNP as cardiac biomarkers in humans is affected by noncardiac factors that affect their blood concentration, such as age, gender, decreases with obesity, and increases with renal dysfunction. However, body weight, age, and gender have not been found to be complicating factors in animals (van Kimmenade and Januzzi, 2009). BNP may be early biomarker of the left ventricular dysfunction developing with doxorubicin cardiotoxicity or congestive heart failure or occult dilated cardiomyopathy (van Kimmenade and Januzzi, 2009).

In rats, species-specific BNP and NT-proBNP assays have been used effectively as biomarkers of cardiac dysfunction. Plasma BNP increased approximately twofold within 6 weeks of weekly doses of doxorubicin and correlated with development of cardiomyopathy and deterioration of fractional shortening of the left ventricle (Koh et al., 2004). Drug-induced cardiomyopathy developing over 2 weeks was associated with a threefold increase in NT-proBNP and a one-third increase in cardiac size (Berna et al., 2008). With infarct-induced heart failure, rats progressively developed cardiac dysfunction, which correlated with up to tenfold increases in NT-proBNP (Fu et al., 2009).

Veterinary application of natriuretic peptide biomarkers has been substantially complicated by several factors. The effectiveness of their use in humans has only partially transferred across species. First, there is considerably more rapid clearance of natriuretic peptides in animals as compared with humans. For example, the plasma half-life of BNP is approximately 90 seconds in dogs but approximately 20 minutes in man (Thomas and Woods, 2003). Second, clearance of BNP biomarkers is markedly inhibited in dogs by decreased GFR and azotemia and this decreases in GFR may increase the natriuretic peptides to similar plasma concentrations associated with heart disease or heart failure (Raffan et al., 2009; Schmidt et al., 2009). There is additionally a lack of cross-species homology in peptide structure, especially for canine BNP, whose pre-pro peptide has only half the sequence homology with man as for canine ANP (approximately 45% vs. approximately 90%; Oikawa et al., 1985). Finally, natriuretic peptides have poor storage stability in serum. Approximately 70% deterioration of natriuretic peptides occurs within 24 hours at room temperature; however, the addition of 0.1% formic acid stabilizes the natriuretic peptides for at least 3 months at 4°C (Berna et al., 2008). Thus, BNP assays developed for use in humans, typically do not work effectively in animals, contrasting remarkably with the cross-species reactivity of those cTnI assays that target antigenic epitopes with high sequence homology. There are, however, ANP assays developed for use in humans that are sufficiently cross-reactive for use in dogs (Prosek et al., 2007).

However, species-specific assays have emerged for cardiovascular peptides (Schellenberg et al., 2008) and are showing similar applications as for humans, although with more blunted differences in concentration (Hori et al., 2008). NT-proBNP has been especially successful in differentiating cardiac disease, compared to BNP, or ANP or its precursors (Oyama et al., 2008).

The atrial peptides, ANP and NT-proANP, were first found to be effective biomarkers for heart failure in dogs, being increased up to sixfold in dogs with heart failure as compared to plasma levels in normal dogs. In the same model of heart failure in dogs, BNP was increased only twofold. Concentration of NT-proANP was 40-fold higher than ANP, and both atrial peptides were almost threefold greater in concentration than the ventricular peptide, BNP (Hägström et al., 2000). In another study, BNP was shown to be much more diagnostically effective, being substantially increased in dogs with advanced heart disease, and even more in heart failure (MacDonald et al., 2003). Mean BNP concentration in dogs with congestive heart failure was 10-fold higher than for dogs with noncardiac causes of cough or dyspnea (DeFrancesco et al., 2007). Although, BNP was found to be increased significantly only in dogs with advanced heart disease, NT-proBNP

had greater diagnostic sensitivity and correlated with cardiac dysfunction, cardiomegaly, and heart failure (Oyama et al., 2008). Using a dog model of acute volume overload, it was shown that NT-proBNP was a considerably weaker and slower responder to overload (Hori et al., 2010) than was ANP.

In dogs with heart failure and associated dyspnea, ANP, BNP, and endothelin are significantly higher than occurs with noncardiac causes of dyspnea (Prosek et al., 2007). Highest sensitivity and specificity for differentiating cardiac and noncardiac dyspnea in dogs, is found with a human proANP assay, followed by canine-specific BNP assay, and human ET-1 assay. In cats, NT-proBNP also accurately distinguishes between cardiac and noncardiac causes of dyspnea (Fox et al., 2009). Widespread clinical application of these biomarkers in veterinary cardiology awaits further assay development and characterization of their effectiveness (Boswood, 2009; Sisson, 2009). So far, only a fraction of the success obtained by adopting human cardiac injury biomarkers (i.e., cTn) for use in animals has been obtained by adopting the new human cardiac functional biomarkers (i.e., natriuretic peptides).

13.2 THE VASCULAR SYSTEM

Interest in biomarkers for vasculitis has developed rapidly in recent years primarily owing to the occurrence of mesenteric vasculitis in rats with phosphodiesterase type 4 (PDE4) inhibitors characterized by medial necrosis and hemorrhage with perivascular edema and inflammation (Daguès et al., 2007a,b). This enzyme is the major inactivator of cAMP in inflammatory and immune cells and is important in regulating airway smooth muscle tone. It is targeted for the treatment of asthma and chronic obstructive pulmonary disease. Absence of biomarkers to identify and monitor the possible occurrence of PDE4 inhibitor-induced vasculitis in man has limited the progression of this drug class.

13.2.1 VASCULAR PHYSIOLOGY AND FUNCTION

The primary function of the vascular system is to transport blood to and away from the cells throughout the body. Although the driving force for this is the heart, the blood vessels control the amount, rate, and direction of blood flow to the various tissues. Blood vessels accomplish this by the massive number and surface area of capillaries that reach within 20–30 μm of all cells. This high surface area is critical since it is proportional to the rate of diffusion (Sherwood, 2012).

In a medium-sized dog, one aorta of approximately 2 cm diameter branches out to 50 thousand arteries with an average diameter of approximately 140 μm and subsequently into 20 million arterioles with approximately 30 μm average diameter. These arterioles in turn divide into the 2 billion capillaries from which most chemical exchange between blood and tissue occurs. The capillaries are only slightly wider than an erythrocyte and are about 50 μm long. The capillaries condense into 130 million venules from 70 thousand veins that ultimately flow into the vena cava (Stephenson, 2007).

Tissue blood flow is controlled by the capillary density, and by the degree of contraction of arterial and arteriolar walls and of precapillary sphincters. This capacity for regulating flow is well demonstrated during vigorous exercise. For example, visceral blood flow is reduced by more than a half, while skeletal muscle flow increases by more than 10-fold to support metabolism and contraction, and the blood flow in skin increases several fold to dissipate metabolic heat. The role of the transported blood is to distribute nutrients and their waste products, respiratory gases, regulatory factors for cellular and tissue activity, and protective substances (e.g., cells and factors involved in hemostasis and immunity).

Capillaries are the site for intestinal mucosal absorption or renal reabsorption of fluid and nutrients, and for exchange of nutrients for waste products at capillary beds of metabolic tissues. The exchange is mediated by diffusion along the concentration gradients between capillary blood plasma and tissues. Fluid ultrafiltration through the capillary wall is based mostly on size and is dependent on the semipermeability of the glycocalyx of the endothelial cell membrane. This

filtration is produced by the steric hindrance and electrostatic charge repulsion of the glycocalyx (Reitsma et al., 2007).

Starling's law of the capillaries indicates that transendothelial fluid flux is driven by hydraulic fluid pressure from the arteriolar end of the capillary and by osmotic pressure generated by the substantial plasma protein that has leaked into the interstitium. These pressures are counteracted by the plasma protein osmotic pressure and by the interstitial fluid pressure. Since capillary fluid pressure falls from arteriolar to venous ends of the capillary, fluid is predicted by this model to flow out the arteriolar end and back in at the venous end. Normally, the amount of fluid leaving the arteriolar end of the capillary bed is equivalent to that entering the venule side. Excess filtered fluid is returned to the circulatory system via the lymphatics (Sherwood, 2012).

This model explains the observation of fluid movement from tissue to blood when the vascular compartment volume is reduced, for example, owing to hemorrhage, sweating, or diarrhea. It apparently explains that fluid moves from blood to tissue when there is decreased oncotic pressure from hypoproteinemia, increased capillary permeability, such as with inflammation or trauma, or increased tissue hydrostatic pressure such as with venous or lymphatic obstruction, or congestive heart failure. However, more recently, Starling's principle has been revised based on experimental evidence indicating that the interstitial osmotic pressure effect is overestimated and glycocalyx effects and microenvironment are more important (Levick and Michel, 2010). Furthermore, in inflammation, lowering of interstitial fluid pressure was found to be of greater importance than permeability increase. This decrease in pressure was due to a change in extracellular matrix leading to up take of water by the glycosaminoglycan ground substance (Reed and Rubin, 2010).

Capillaries are of three basic types. The continuous type is uninterrupted with fluid movement only through intercellular clefts at the tight junctions. Fenestrated capillaries have small pores of about 70 nm diameter that are covered by a diaphragm of radial fibers that will allow small molecules and limited amounts of proteins to diffuse. Sinusoidal capillaries have considerably larger pores with 30–40 μm and allow cell and protein movement.

Leukocytes exit the vasculature by diapedesis through gaps between endothelial cells, usually at postcapillary venules, where blood pressure is reduced. This process is controlled by attractant and activating cytokines and chemokines, and cell surface receptors. These cause cell binding, shape change, and transmigration.

The glycocalyx is a carbohydrate-rich layer that lines the lumen of the vascular endothelium. It is comprised of membrane-bound and soluble components. In capillaries, it is 0.5 μm thick, but up to 5 μm thick in arteries. Bound and projecting from the cell membrane are glycoproteins with short, branched carbohydrate side chains, and proteoglycans with long, unbranched glycosaminoglycan side chains. On top of these are plasma and endothelial-derived soluble components, including hyaluronic acid, thrombomodulin, extracellular superoxidized dismutase, and antithrombin III (Reitsma et al., 2007).

The glycocalyx has multiple functions. First, it restricts solutes and cells from reaching the endothelium, thereby providing protective and filtrative roles. It also transmits shear stress of blood flow into biochemical cell signaling that regulates nitric oxide production and vascular tone, cytoskeletal reorganization, and production of glycocalyx components. This layer is also important as a docking station to concentrate specific plasma constituents, for example, growth factors, lipoprotein lipase, and anticoagulants such as antithrombin III, thrombomodulin, tissue factor pathway inhibitor, and heparin cofactor II (Reitsma et al., 2007).

The countercurrent exchange is used for maximizing the transfer of blood constituents by diffusion gradients over vascular circuits in which blood vessels are adjacent but have blood flowing in opposite directions (Robinson, 2007). It is commonly found in various vertebrate, physiological systems in order to conserve one constituent, such as water, heat, or oxygen, while excreting an unwanted constituent, such as nitrogenous waste or salt. This mechanism is found in various organs including the mammalian kidney to concentrate urine, the placenta, the avian salt gland to distill seawater, and fish gills to extract oxygen from water.

13.2.2 ENDOTHELIUM

Vascular endothelium dysfunction is an early event in vascular disorders, reflecting its critical role in regulation of vascular tone, antithrombosis, leukocyte trafficking, and oncotic pressure by production and release or surface expression of various factors (Tefamariam and DeFelice, 2007). As described below, vascular injury is associated with activation or increase of numerous factors that can be used as biomarkers.

13.2.3 VASCULITIS

Vasculitis is characterized by inflammation and fibrinoid necrosis of blood vessel walls. It may be primary, or secondary to infection, malignancy, or immune disease (Guillevin and Dornier, 2007). There are several possible mechanisms by which drugs can cause vasculitis (Louden et al., 2006). Immunologic and vasoactive mechanisms are most commonly implicated. For example, antineutrophil cytoplasmic autoantibody (ANCA) vasculitis is caused by autoantibodies to neutrophil cytoplasm, resulting in neutrophilic attack of small vessel walls, causing purpura in skin, pulmonary hemorrhage, neuropathy, redness and itching of the eyes, and renal disease with hematuria and proteinuria. Necrotizing angitis occurs in drug abusers and is considered to be produced by an immune mechanism possibly in association with toxic injury or infection. Vasoactive drugs may also cause vasculitis. For example, cerebral vasculitis may be produced by sympathomimetics in humans. Furthermore, vascular-targeting drugs used in cancer treatment may have cardiovascular effects.

In laboratory animals, vasculitis is known to be produced by various mechanisms including immune, infection, particles, cytotoxicity, hypertension, and renal failure (Louden et al., 2006). Spontaneous necrotizing vasculitis occurs with aging in rodents, usually sporadically affecting smaller arteries. Although its cause is unknown, its prevalence is affected by nutrition, hypertension, and gender. Vasculitis may also be induced by various substances, including cytotoxins, foreign proteins and immunosuppressive drugs, and antibiotics. Inotropic vasodilators and PDEi produce medial artery necrosis and inflammation in rats apparently by exaggeration of their pharmacologic vasoactivity resulting in injury of smooth muscle of medium-sized arteries of the pancreas, stomach, mesentery, intestine, and kidney (Joseph, 2000; Louden and Morgan, 2001). These targets are also affected by age, hypertension, and renal failure in rats.

In dogs and rats, inotropic amines, PDE3 inhibitors, adenosine agonists, cardiac glycosides, and ET-1 receptor antagonists produce extramural, coronary, segmental, medial necrosis, and inflammation, apparently, because of their exaggerated hemodynamic effect locally or on heart rate and blood pressure (Joseph, 2000; Louden et al., 2006). Similar coronary changes are seen in monkeys with many of the same cardiovascular drugs.

13.2.4 VASCULAR ANALYTES AND LABORATORY TESTS

Blood biomarkers that have been investigated and proposed for the identification of vasculitis include those associated with inflammation or endothelial cell injury (Brott et al., 2005; Louden 2006) (Table 13.3). For example, mesenteric vasculitis in rats owing to PDE4 inhibition produces significant increases in injury biomarkers such as plasma concentrations of tissue inhibitor of metalloproteinase-1 (TIMP-1), vascular endothelial growth factor (VEGF), thrombomodulin, and in inflammatory biomarkers α 1-acid glycoprotein (AGP), C-reactive protein (CRP), haptoglobin, and IL-1 and IL-6 (Daguès et al., 2007a,b; Weaver et al., 2008). Inflammatory biomarkers are also increased in dogs treated with the same PDE4 inhibitor (Hanton et al., 2008).

13.2.4.1 Cytokines

Cytokines can be valuable biomarkers of inflammation, especially IL-6; however, their role is limited by their short half-life compared to acute phase proteins (APPs) (Shaikh, 2011). Cytokines are

TABLE 13.3
Biomarkers for Vasculitis: Acute Phase Proteins (APP) and Endothelial Proteins

Biomarker	MW (kDa)	Species		Major Role
Acute Phase Response				
		Major APP	Moderate APP	–
IL-1	12–15	–	–	Early proinflammatory cytokine
TNF- α	17	–	–	Early proinflammatory cytokine
IL-6	21–29	–	–	Chemoattractant
TIMP	24–31	–	–	Tissue remodeling
C-reactive protein (CRP)	100	C, P, H	–	Opsonin
Serum amyloid A (SAA)	14	E, B, O, H	M	Apolipoprotein
Haptoglobin (Hp)	81	B, O	D, P, M, R	Bind hemoglobin
α 2 macroglobulin (A2M)	720	R	–	Antiprotease
α 1 acid glycoprotein (AGP)	44	–	C, F, B, O, R	Bind drugs
Serum amyloid P (SAP)	230	M	–	Opsonin, amyloidosis
Fibrinogen	340	–	all	Coagulation
Adhesion Molecules				
Von Willebrand factor (vWF)	500–20,000	–	–	Hemostasis
vWF pro-peptide		–	–	Hemostasis
Caveolin-1	21	–	–	Flow sensor Coagulation and fibrinolysis
NO	0.03	–	–	Vasodilator
Endothelin	2.5	–	–	Vasoconstrictor
Circulating endothelial cell (CEC)	–	–	–	Exfoliated cells

Species: C, canine; F, feline; P, porcine; E, equine; B, bovine; O, ovine; M, murine; NHP, nonhuman primate; H, human.

cell signaling and modulating peptides of the immune system and are produced and released by macrophages and lymphocytes, as well as epithelial and endothelial cells. ILs are produced primarily by T helper cells and macrophages. In injury or infection, extracellular and blood concentrations of cytokines may increase up to a 1000-fold. Chemokines act as chemotactic factors and include erythropoietin for red blood cells, thrombopoietin for platelets, IL-8 for neutrophils, eotaxin for eosinophils, and RANTES (CCL5) for leukocytes.

13.2.4.2 Acute Phase Proteins

APPs are produced and released into the blood primarily by hepatocytes in response to the proinflammatory cytokines, IL-1 and IL-6, and TNF- α (Paltrinieri, 2007). APPs are produced and released by macrophages when exposed to foreign antigen at sites of inflammation. Both IL-1 and IL-6 increase the hypothalamic thermostat. IL-1 increases the endothelial adhesion factors for leukocyte migration, stimulates hematopoiesis, and stimulates the adrenocortical axis to produce glucocorticoids. IL-6 is also important in lymphocyte differentiation and proliferation. TNF- α induces peripheral proteolysis in order to increase hepatic supply of amino acids. IL-1 inhibits the synthesis of negative APP, and stimulates positive APP production in the presence of glucocorticoids (Paltrinieri, 2007).

There are four major classes of APPs based on the magnitude of change in blood concentration in response to inflammation (Watterson et al., 2009): (1) major—increasing rapidly 10–1000 folds and decreasing rapidly; includes CRP in man, dog, pig, and mink, serum amyloid A (SAA) in dog, cat, pig, and ruminants, α 2-macroglobulin (A2M) in rats, serum amyloid P (SAP) in mice, and

haptoglobin in ruminants, (2) moderate—increasing 2–10 folds at slower rate but persisting longer in the blood; includes fibrinogen in all species, haptoglobin in dog, rat, mouse, and pig, AGP in dogs and cats and ruminants, (3) minor—increasing slowly to less than twofold but persisting the longest, and (4) negative—decreasing slowly and mildly; includes albumin and binding proteins for thyroid hormone, cortisol, and retinol in all species.

The multiple APP has different properties and functions, and species distribution (Ceron et al., 2005). CRP is a cyclic pentameric pentraxin that exhibits calcium-dependent binding to bacteria and intracellular antigen of damaged cells to facilitate phagocytosis. It also induces anti-inflammatory cytokines and inhibits neutrophil chemotaxis and function. SAP is a pentraxin glycoprotein homologue of CRP that neutralizes lipopolysaccharide of Gram negative bacteria and has been shown to be involved in the pathogenesis of reactive amyloidosis. SAA is a highly conserved apolipoprotein involved in cholesterol transport. It is precursor to amyloid protein A that is found in α -amyloid, which is deposited in amyloidosis. SAA is also chemotactic for inflammatory cells and inhibits myeloperoxidase release and lymphoproliferation. Haptoglobin is a glycosylated tetramer that binds free hemoglobin, thereby reducing its oxidative stress and proinflammatory effects, and restricting availability of iron for bacterial growth. It antagonizes receptor-ligand activation of the immune system and inhibits granulocyte chemotaxis and phagocytosis. Haptoglobin may be increased with hyperadrenocorticism and certain anthelmintics in dogs and guinea pigs (Boretti et al., 2009). A2M is a tetrameric, irreversible protease inhibitor that is adsorbed to the surface of peripheral blood lymphocytes. It traps proteinase within a cavity thereby exposing sites for receptor-mediated endocytosis by macrophages. AGP is a highly glycosylated protein that binds numerous basic and neutral lipophilic drugs and acidic drugs such as phenobarbital. It has antineutrophil and anticomplement activity and increases secretion of IL-receptor antagonist by macrophages.

13.2.4.3 Caveolin

A potential mechanistically linked biomarker of vascular injury is caveolin-1, which is released from endothelial cells into blood with vascular injury (Louden et al., 2006). This protein is a component of caveolae, which are important contributors to the regulation of vascular permeability and blood flow. Caveolae are microscopic, flask-shaped invaginations of cell surface membrane that are found especially in endothelial cells. They have lipid rafts that are enriched in (1) cholesterol for maintaining their structure, (2) sphingolipid for cell signaling, (3) the integral membrane protein, caveolin-1, for structure and for sequestering and inactivating endothelial nitric oxide synthase (eNOS), and (4) albumin, a 60 kDa albumin-binding glycoprotein. Caveolae detect changes in blood flow by mechanosensing shear stress and play a key role in transcellular movement (important in the activation of eNOS, exposing endothelial leukocyte adhesion molecules, transcellular movement of albumin to maintain the oncotic pressure gradient). Caveolae are additionally considered to participate in regulation of adherens junctions between endothelial cells and hence in paracellular movement.

Caveolin-1 inhibits eNOS conversion of L-arginine into nitric oxide (NO), which is an important cause of vascular injury (Govers et al., 2002). Endothelial nitric oxide synthase is induced by proinflammatory cytokines and acts as a messenger in modulating inflammatory responses. This enzyme also has several other functions including vasodilation, inhibition of platelet aggregation, thrombus formation, leukocyte adhesion, smooth muscle cell proliferation, and low density lipoprotein oxidation. Reaction of NO with superoxide anion forms peroxynitrite, a reactive nitrogen species implicated in oxidative stress-induced vascular injury during inflammation. There is rapid, spontaneous inactivation of NO by conversion into nitrite and nitrate (Tesfamariam and DeFelice, 2007).

13.2.4.4 Endothelins

Endothelins are a family of vasoconstrictor peptides produced by endothelial cells. They are key mediators in regulating vascular function, counterbalancing vasodilators such as nitric oxide and

prostacyclin. In cardiovascular diseases such as cardiac failure and pulmonary arterial hypertension, endothelial cell dysfunction occurs causing vasodilator concentrations to decrease and endothelin concentration to increase. Endothelins also produce proinflammatory effects (Kedzierski and Yanagisawa, 2001; Maguire and Davenport, 2014) and have been reported to activate polymorphonuclear cell secretion and adhesion and macrophage activity. Endothelins contribute to extracellular matrix remodeling during tissue repair and thus may participate in intimal damage in vascular diseases. Increased blood concentration of ET-1 and its inactive prohormone, big endothelin-1 (Big-ET) have been found to have prognostic value in cardiac disease in humans (Barton and Yanagisawa, 2008). There is relatively high cross-species homology for these peptides. Assays for these biomarkers in humans have been validated for use in rats and dogs. ET-1 increased several folds during the development of heart failure in rats and dogs (Tonnessen et al., 1997; Prosek et al., 2007). Thus, endothelins have been shown to have similar effectiveness for detection of cardiovascular diseases in dogs as in humans (Schellenberg et al., 2008). Moreover, human endothelins have nearly identical sequence homology with those of dogs, rats, and mice (Biondo et al., 2003).

13.2.4.5 Thrombomodulin

Thrombomodulin has been shown to be mildly increased in vasculitis (Weaver et al., 2008). Thrombomodulin is a cell surface receptor found on and synthesized by vascular endothelial cells (Califano et al., 2000). Its major role is as an inhibitor of coagulation and fibrinolysis. Thrombomodulin functions as a cell surface receptor and an essential cofactor for active thrombin, with which it binds in a 1:1 stoichiometric complex. This complex activates and increases protein C activity by up to a 1000-fold by removing a small peptide by proteolytic cleavage. Thrombomodulin catalyzes the thrombin activation of fibrinolysis inhibitor (TAFI), also known as carboxypeptidase B2. Thrombomodulin is found in plasma and urine after endothelial injury and may predict thrombotic crisis. It is used as a specific biomarker of microvascular endothelial injury and thrombotic events, such as in disseminated intravascular coagulation (DIC) and vasculitis.

13.2.4.6 Adhesion Molecules

Inflammatory cell migration from the vascular space is mediated by adhesion molecules on inflammatory cells and endothelium including vascular cell adhesion molecule-1 (VCAM-1), E-selectin, and intercellular adhesion molecule-1 (ICAM-1) (Lukas and Dvorak, 2004). They are released into the blood following leucocyte and/or endothelial cell activation in various diseases, including autoimmune disease and vasculitis.

13.2.4.7 von Willebrand Factor

von Willebrand factor (vWF) has also been evaluated as a potential biomarker of vascular injury. Hemostatic, platelet-plug formation requires vWF to bridge from platelet glycoprotein IB to exposed collagen in the subendothelium. vWF is also important in the one-to-one stoichiometric transport and stabilization of factor VIII by protecting it from rapid degradation, cellular uptake or from binding to the surface of activated platelets or endothelial cells (De Meyer et al, 2009). The carbohydrate surface of vWF protects it from proteolysis.

A proteolytic, cleavage product of a precursor of vWF may be an effective biomarker of vascular injury. vWF is a polymeric glycoprotein synthesized by endothelial cells and megakaryocytes in a precursor form, pre-pro-vWF. The precursor has a signal peptide that identifies vWF as a protein for secretion. This peptide is removed from pre-pro-vWF by proteolytic cleavage to form pro-vWF. This then forms dimers, and after glycosylation, polymerizes into multimers. Within endothelial cells, these multimers undergo further proteolysis to yield mature vWF multimers and propeptide dimers (vWFpp), both of which are either released constitutively or else stored together in Weibel-Palade bodies. Endothelial vWFpp and VWF are secreted in equimolar amounts, although they are cleared from the blood at several-fold different rates. This differential clearance rate results in their ratio reflecting the time-course of their release (de Wit and van Mourik, 2001). Furthermore,

vWFpp is specific for endothelial cell origin, as it is not cleaved from the pro-vWF precursor in platelets. Blood concentration of vWFpp may increase 100-fold with vascular injury, although it is with a half-life of only hours (Louden et al., 2006).

13.2.4.8 Circulating Microparticles

Circulating microparticles are membranous fragments 0.1–1 μm in diameter that are released from circulating white blood cells and endothelial cells during cell activation or apoptosis (Azevedo et al., 2007). Increased microparticles are found in a wide variety of conditions and are not pathology-specific, including heart failure, sepsis, diabetes, hypertension, renal failure, embolism, and vasculitis. They retain the antigenic signature of the parent cell, and they are formed by the disruption of cytoskeletal structure with formation of the plasma membrane evaginations in a process referred to as budding or blebbing. They are distinct from the larger apoptotic bodies, which are considerably larger cell fragments, and from the small exosomes (0.06–0.1 μm), which are preformed vesicles from the endocytic-lysosomal system and play a role in immune activation and antigen presentation (Azevedo et al., 2007).

Microparticles produce multiple effects from signaling to activation because of their containing surface membrane and cytoplasmic contents of their parent cell. Many of these are proinflammatory, by activating complement, causing chemotaxis and endothelial adherence of leukocytes, and by stimulating cytokine release. They are also procoagulant, by providing phospholipid surface for assembly of clotting complexes or providing activating factors such as tissue factor and factor V.

13.2.4.9 Circulating Endothelial Cells

Circulating endothelial cells (CECs) appear in the blood after injury and in response to inflammatory, immune, and infectious disease. CECs were first described decades ago in rabbits, pigs, rodents, and dogs and have been demonstrated to be increased in shock, endotoxemia, myocardial infarction, hypertension, immunosuppression, and with prostaglandin E inhibition (Erdruegger et al., 2006; Wills et al., 2009; Burger and Touyz, 2012). They are now considered to be sensitive and specific indicators of endothelial cell injury in humans and can be assayed by fluorescence-activated cell sorting (FACS) based on cell surface markers. CECs arise from detachment from the underlying matrix because of impaired adhesion via vitronectin, fibronectin, and vascular endothelial cadherin, which is an endothelial-specific adhesion molecule located at the junctions between endothelial cells. Detachment occurs due to the action of proteases, (as from neutrophils), due to oxidative stress from reactive oxygen and nitrogen species, or by mechanical injury. The CECs are large (10–100 μm) and are intact or anucleate remnants of cells or sheets of multiple cells. They characteristically express vWF and thrombomodulin as well as cluster differentiation antigens CD-31 and CD-146. Endothelial progenitor cells from the bone marrow may be confused with CECs as they have similar cell surface makers. These progenitor cells are involved in vascular repair.

13.2.4.10 Matrix Metalloproteinases

An inhibitor of MMP has been identified as one of the more effective biomarkers of vasculitis (Daguès et al., 2007b). These MMP function in tissue remodeling during diverse physiological and pathological states including morphogenesis, angiogenesis, tissue repair, inflammation, fibrosis, tumor metastasis, and aneurysm (Spinale, 2007). In these processes, they have roles in cell proliferation, migration, differentiation, angiogenesis, apoptosis, and host defense. Their effect is attributable to their endopeptidase activity, which requires zinc as a cofactor at the active site. This degrades extracellular matrix proteins, modulates cell surface receptors and cytokines, and releases ligands (e.g., apoptotic FAS). The MMP are inhibited by one-to-one stoichiometric complexing with specific endogenous TIMP.

13.3 THE RESPIRATORY SYSTEM

13.3.1 PULMONARY FUNCTION AND INJURY

The respiratory system has air conducting and air exchanging zones, served by bronchiolar and pulmonary circulatory systems, respectively (Robinson, 2007). The former zone begins with the nasal cavity and associated sinuses, extends into the pharynx, larynx, and trachea, and ends with the bronchi. The tracheobronchial portion has cartilage for support, and submucosal glands with mucus and serous fluid producing cells. The tracheobronchial lining consists of pseudostratified epithelium, where all cells reach the basement membrane in contrast to stratified epithelium. The lining cells form a mucociliary layer comprised mostly of columnar ciliated epithelial cells, goblet cells, and a mucus layer. This layer moves inhaled particles sized between 2 and 10 μm that are trapped in the mucus by the beating action of the cilia (Lopez, 2007).

There is a transitional zone between the air conducting and exchanging zones that is comprised of the bronchioles. They lack cartilage and glands but have a thick, circumferential layer of smooth muscle in their walls. These bronchioles are lined by ciliated, cuboidal epithelium, and secretory Clara cells, which are not ciliated. They metabolize inhaled xenobiotics by their cytochrome P450 system and produce a bronchiolar lining fluid comprised of glycosaminoglycans, lysozymes, and Clara cell secretory protein (uteroglobin), which has antioxidant, anti-inflammatory, and immunomodulatory functions. Clara cells are also mitotically active and can differentiate into ciliated bronchial cells during repair.

Bronchiolar smooth muscle and therefore bronchiolar diameter, is controlled by opposing signals (Panettieri et al., 2008). SNS norepinephrine activates β_2 receptors and adenylate cyclase to increase cAMP and cause bronchodilation. Increased cAMP may also occur with PDE inhibitors, or by H₂ receptor agonists such as histamine. Decreased cAMP occurs with α -receptor agonists such as phenylephrine, leukotrienes, prostaglandins, or thromboxane. PNS acetylcholine activates M₃ muscarinic receptors and guanylate cyclase to increase cGMP, thereby causing resting tone and bronchoconstriction. Increased cGMP also occurs with H₁ receptor agonists such as histamine, platelet activating factor, or serotonin. Agonists for the H₂ receptor stimulate mucus secretion whereas H₁ receptor agonists stimulate serous secretion (Shimura, 2000).

The respiratory zone contains the respiratory bronchioles that terminate in alveolar ducts that form multiple alveoli lined by the respiring, membranous type I pneumocytes and surfactant-producing, granular type II pneumocytes. Smooth muscle extends down the respiratory tract only to the level of the alveolar ducts. The adjacent alveoli are supported and interfaced with capillaries by a network of connective tissue fibers. To facilitate gaseous exchange, cytoplasm of the type I pneumocytes and endothelial cells of the pulmonary capillaries are on either side of a fused basement membrane over >90% of the alveolar surface area. Adjacent alveoli are connected by pores of Kohn through the septa, which function as collateral ventilation during partial lung expansion and allow the passage of other materials such as fluid and bacteria (Weibel, 2008). The type I cells are thin and flat with a large surface area covering 95% of the alveolar surface. They are replenished by differentiation of the mitotically active type II cells. The type II cells are large and cuboidal, and protrude into the alveoli and have cytoplasmic multilamellar bodies that store phospholipid-rich surfactant. Type II cells are also known to secrete alkaline phosphatase (ALP) along with surfactant (Henderson et al., 1995).

Pulmonary alveolar macrophages (PAMs) are found within the alveolar lumen or on the capillary side with extensions protruding across the intercellular space of the alveolar lining into its lumen (Robinson, 2007). They derive from migrating blood monocytes that have adapted to aerobic metabolism and for phagocytosis of inhaled bacteria, particles less than 2 μm in diameter, erythrocytes from hemorrhage, or neutrophils from inflammation. PAM may also play a role in clearance of surfactant as demonstrated by the accumulation of surfactant with defective PAM, as seen in pulmonary alveolar proteinosis. PAM has abundant, vacuolated cytoplasm rich with mitochondria,

and antioxidant and detoxification enzymes. They migrate with phagocytosed material to the mucociliary layer which traps and moves them up and out of the respiratory tract.

The pleural cavity is the potential space between the parietal pleura lining the inner wall of the thoracic cage and the visceral pleura lining the lungs (Robinson, 2007). It normally contains a small amount of pleural fluid to allow close and effortless sliding of pleura against each other during ventilation, thereby allowing optimal alveolar inflation. The pleura also transmit the chest wall movements during ventilation to the lung. The parietal pleura have sensory innervations and are highly sensitive to pain.

13.3.2 BRONCHOALVEOLAR LAVAGE FLUID

The biochemistry, cytological changes and microbiological changes associated with respiratory disease may be examined by a bronchoalveolar lavage (BAL) in which warmed, sterile, physiological saline is infused and then retrieved from a tube inserted into a bronchus (Henderson, 2005). Although, the BAL is the most reliable method for sampling the lower respiratory tract, it is an invasive technique requiring sedation, limiting its clinical use. Most BAL fluid (BALF) cells are PAM, with smaller numbers of lymphocytes in large animals, and only small numbers of neutrophils and eosinophils (except cats) and few mast cells (Mathers et al., 2007; Burkhard and Millward, 2010; Picinin et al., 2010). The presence of PAM indicates the alveolar origin of the recovered material and the correct interpretation of cell profile, whereas the presence of large numbers of epithelial cells indicates bronchial, nonalveolar material, which hinders the interpretation of total and differential cell distribution. Squamous epithelial cells with bacteria (e.g., *Simonsiella*) indicate oropharyngeal contamination. Changes in differential cell counts on BALF samples may be indicative of different types of disease: (1) Increases in eosinophils in BALF indicate allergic or parasitic disease, (2) increases in neutrophils indicate bacterial or viral infection or cough, (3) increases in mast cells indicate type I hypersensitivity, and (4) increases in erythrocytes and/or PAMs containing erythrocytes or blue-green to black hemosiderin indicate hemorrhage (Burkhard and Millward, 2010).

Toxicological testing of various chemicals and nanoparticles has occasionally included BALF biomarkers for cytotoxicity, inflammation, and oxidative stress (Table 13.4). For example, lung exposure to nanoparticles (particle size <100 nm in one dimension) produces increases in lactate dehydrogenase or decreases in mitochondrial activity due to cytotoxicity, inflammatory mediators and cells due to inflammation, and antioxidant enzymes due to oxidative stress (Carter et al., 2006; Sayes et al., 2007; Warheit et al., 2008).

During collection of BALF samples, recovery of instilled fluid is typically approximately 80% when the dwell times of the lavage fluid are limited to approximately half a minute. However, this recovery can be quite variable, depending on sample handling, lavage volume, number of lavage aliquots, and pulmonary dwell time. Thus, concentrations of endogenous urea or albumin or of dyes added to the instillate, compared to plasma concentration have been used for estimating the degree of dilution of epithelial lining fluid by the instillate (Mills and Lister, 2005). The increased permeability of the plasma-to-airway during pathological conditions can, however, increase the movement of constituents into or out of the instillate causing significant underestimates using the measurement of endogenous substances or overestimates using exogenous substances.

Increases in BALF biomarkers can be used as quantitative and dose-responsive indicators of injury to the respiratory system (Carter et al., 2006). An increase in a BALF biomarker frequently precedes clinical signs and morphological alterations in the lung. Lavages may be repeated to follow a disease process. There are specific biomarkers for inflammation including its early signaling, chemotaxis of the cells involved, and the type and severity of inflammation. Additionally, there are biomarkers for the associated changes including increased capillary permeability, PAM activation, cell lysis, pneumocyte secretion, and oxidative stress.

After cellular elements, inflammatory biomarkers are the most well studied BALF biomarkers. Following stimulation, activated PAM release early proinflammatory cytokines, as described in the

TABLE 13.4
Biomarkers for Pulmonary Disease in BALF

Biomarker	MW (kDa)	Assay	Role
Neutrophils	–	AHA	Inflammation, infection
Eosinophils	–	AHA	Allergy
GSH	0.37	ACCA	Oxidative stress—antioxidant
O ₂ ⁻ , H ₂ O ₂ , NO	0.3	Spec	Oxidative stress—oxidants
GPx, GRx, SOD	84, 100, 33	ACCA	Oxidative stress—enzymatic antioxidants
8-isoprostane	–	ELISA	Oxidative stress—macromolecular (DNA) injury
LD	230	ACCA	Cytotoxicity
ALP	150	ACCA	Increased type II cell secretion or injury
Protein	–	ACCA	Alveolar capillary permeability
Fibronectin	440	ELISA	Chemoattract fibroblasts, endothelial cells, monocytes; acts as fibroblast growth factor
B-glucuronidase	130	ACCA	Lysosomal; macrophage activation
IL1, TNF α	12–17	ELISA	Early proinflammatory cytokines from PAM
IL-6, IL-8	25, 11	ELISA	Chemoattract/activate neutrophils, lymphocytes
MIP-2, MCP-1	8, 12	ELISA	chemoattract and activate PAM
Total phospholipids	–	Spec	Surfactant production

ACCA, automated clinical chemistry analyzer; AHA, automated hematology analyzer; ALP, alkaline phosphatase; ELISA, enzyme-linked immunosorbent assay; GPx, glutathione reductase; GRx, glutathione reductase; GSH, glutathione; H₂O₂, hydrogen peroxide; IL, interleukin; LD, lactate dehydrogenase; MCP-1, monocyte chemoattractant protein-1; MIP-2, macrophage inflammatory protein-2; NO, nitric oxide; O₂⁻, superoxide; PAM, pulmonary alveolar macrophage; SOD, superoxide dismutase; Spec, spectrophotometric; TNF α , tumor necrosis factor alpha.

vasculitis section. These proinflammatory cytokines serve as chemoattractants for inflammatory cells. For example, IL-8 causes chemotaxis and activation of neutrophils, induces the full pattern of responses observed in chemotactically stimulated neutrophils, and is a potent angiogenic factor. Monocyte chemoattractant protein-1 (MCP-1) is chemotactic and is produced by endothelial cells after exposure to cytokines (IL-1 β , TNF- α) and oxidized lipoproteins. MCP-1 attracts and activates monocytes and T cells and regulates the proliferation of vascular smooth muscle cells. Macrophage inflammatory protein (MIP-2) causes leukocyte chemotaxis (Ishida et al., 2006; Carter et al., 2006; Sayes et al., 2007).

Activated PAM also plays a role in chronic lung disease and the development of fibrosis. This reflects their production of growth factors such as transforming growth factor (TGF)- β , a potent fibrogenic growth factor that promotes pulmonary fibrosis by enhancement of transcription for collagen genes, and platelet-derived growth factor (PDGF) that is chemotactic for fibroblasts and stimulates their proliferation.

Oxidative stress plays a major role in pulmonary pathology, especially provided the high oxygen tensions and the heavy use of oxidants in the defensive mechanisms of inflammatory cells. *Ex vivo* production of superoxide, hydrogen peroxide, and nitric oxide from BAL cells is an indicator of inflammatory cell activation and oxidative stress (Jackson et al., 2007). Antioxidant capacity is also a biomarker for oxidative stress and can be assessed by the measurement of several parameters (Tsai et al., 2006; Carter et al., 2006). Glutathione (GSH) is a key component of the antioxidant system by providing a reducing environment. There are also several enzymes that play key roles in oxidative stress including (1) superoxide dismutase (SOD) that detoxifies superoxide, converting it into hydrogen peroxide; (2) glutathione reductase (GR), which maintains GSH in its reduced state; and (3) glutathione peroxidase (GPx), which detoxifies hydrogen peroxide and nitric oxide. These parameters can be readily measured using automated clinical chemistry analyzers (Slaughter et al., 2002).

In chronic inflammation, there is reversible airway obstruction, nonspecific bronchial hyper-responsiveness, and airway remodeling due to basement membrane thickening due to collagen and fibronectin deposition, fibroblast proliferation, airway smooth muscle thickening as a result of both smooth muscle cell hyperplasia and hypertrophy, and excessive production of mucus glycoproteins.

Fibronectin concentration in BALF has been used effectively as a biomarker of lung remodeling and pulmonary fibrosis, with its concentration increasing up to 100-fold (Trifilieff et al., 2000; Tsai et al., 2003). Fibronectin is a dimeric glycoprotein found in the epithelial surface of airways and in the interstitial parenchyma of the lung. It is chemotactic for fibroblasts, endothelial cells, and monocytes and is apparently a growth factor for fibroblasts. Fibronectin is a major component of extracellular matrix, binding collagen, fibrin, and heparan sulfate proteoglycans and mediating the attachment of fibroblasts to the extracellular matrix.

Total phospholipid content of BALF is an indication of surfactant production. Total phospholipid content may be decreased with chronic inflammatory disease and increased with acute disease (Russo et al., 2002); however, the cause of an increase or decrease in total phospholipid content is not always clear.

In contrast, mucus hypersecretion and mucus metaplasia of airways apparently contribute to structural changes occurring in chronic disease. Mucus production is increased by Th2 cells largely by an IL-13-mediated pathway. The Th2 cells also increase eosinophils in allergic airway disease and they in turn produce cytokines that stimulate mucus production.

14.1 INTRODUCTION

Skeletal muscle is a complex organ composed of an intricate array of specialized contractile proteins, conductile membranes with ion channels, and pumps, together with their associated vascular and nerve supply. It represents approximately 40%–50% of the body's weight, and besides its general function in body movement and posture, skeletal muscle contraction is important in heat production, temperature homeostasis, and metabolism. Because skeletal muscle participates in the function of virtually all organ systems in the body, its function should not be overlooked when evaluating other body organs or systemic disorders (Dukes and Reece, 2004; Valberg, 2008). For example, skeletal muscle plays a critical role in the control of diabetes. By increasing the production of glucose transporter protein (GLUT4), the uptake of glucose into muscle cells is improved by exercise and so the progression of the disease may be retarded (Stehno-Bittel et al., 2008). Also, muscle-derived cytokines called myokines appear to have important anti-inflammatory, metabolic, and physiologic roles, which may explain how regular exercise helps to protect against chronic disorders such as cardiovascular disease, type 2 diabetes, dementia, and depression (Pedersen et al., 2007; Pedersen and Febbraio, 2005). Myokines released from contracting skeletal muscle play important roles in lipid and glucose metabolism in other metabolically active tissue such as liver and adipose tissue and can decrease body fat mass and improve whole body metabolism, which may be valuable in the treatment of obesity and cardiovascular-related disorders (Febbraio and Pedersen, 2005; Hittel et al., 2009; Izumiya et al., 2008; Walsh, 2009).

The regulatory pathways, hormones, growth factors, and key molecules that signal skeletal muscle growth or atrophy or satellite stem cell self-renewal are being deciphered (Carlson et al., 2009; Evans, 2010; Lee, 2007; Welle, 2009; Zammit, 2008). Knowledge of these factors is critical to the development of therapeutic approaches to hereditary muscle diseases such as Duchenne's muscular dystrophy, muscle repair, and muscle loss from cachexia, sarcopenia, and inactivity.

14.2 MUSCLE STRUCTURE

Skeletal muscle is composed of extremely elongated multinucleated cells (up to 30 cm) referred to as muscle fibers or myofibers. A whole muscle consists of a bundle of longitudinally arranged muscle fibers that are made up of myofibrils formed from thick (myosin) and thin (actin) myofilaments organized into repeating subunits along the length of the myofibril. These repeating subunits are called sarcomeres and form the basic contractile unit of muscle. Muscle fibers are filled with numerous myofibrils, mitochondria, sarcoplasmic reticulum (SR), Golgi apparatus, and liposomes. The

sarcoplasm is the cytoplasm and the SR is a structure that is similar to the endoplasmic reticulum in other cells. Variation in skeletal muscles results from their different constituent myofiber populations and the vascular and nerve supply.

14.3 SUBCELLULAR MUSCLE PROTEINS

Myofibrils are made up of still finer thick and thin myofilaments. The thick filaments consist almost exclusively of myosin molecules (molecular weight 460,000 Da), whereas the thin filaments are composed of actin (molecular weight 43,000 Da), tropomyosin (molecular weight 70,000 Da), and troponin (Hill et al., 2008; Ruckebusch et al., 1991). Troponin is composed of three subunits (troponin I, troponin T, and troponin C) with a molecular weight ranging from 18,000 to 35,000 Da.

Each myofibril consists of a series of sarcomeres that run parallel to each other on the long axis of the cell. Sarcomeric subunits of one myofibril are almost perfectly aligned with those of the myofibrils next to it. The optical properties of this alignment result in the striped or striated appearance of skeletal muscle (see Figures 14.1 and 14.2).

The characteristic cross-striations of skeletal muscle caused by differences in the refractive indexes of various parts of the muscle fiber are identified by letters referring to the optical properties of living muscle as demonstrated using polarized light microscopy. I (isotropic) bands appear lighter because these sarcomeric regions contain mainly thin actin filaments, whose smaller diameter allows the passage of light between them, whereas A (anisotropic) bands contain mostly larger diameter myosin filaments that restrict the passage of light. The Z line (from the German *zwischen-scheibe*, the band in between the I bands) is a dark line found in the center of the I band. Within the A band is a brighter central region called the H zone from the German *helle*, meaning bright. No actin–myosin overlap occurs in this zone in a relaxed muscle. Finally, the M-line (from the German *mittel* meaning middle) is a dark central line that bisects the A band (see Figure 14.1). The heads of myosin molecules projecting from the ends of the thick filaments contain catalytic sites that hydrolyze adenosine triphosphate (ATP) and sites that cross-link to actin. A sarcomere is defined as the area between two adjacent Z lines and functions as a contractile unit. Nebulin and titin are structural proteins that help stabilize the actin and myosin filaments in the sarcomeres, whereas the dystrophin–glycoprotein complex strengthens the muscle by connecting the fibrils to the extracellular environment (Hill et al., 2008).

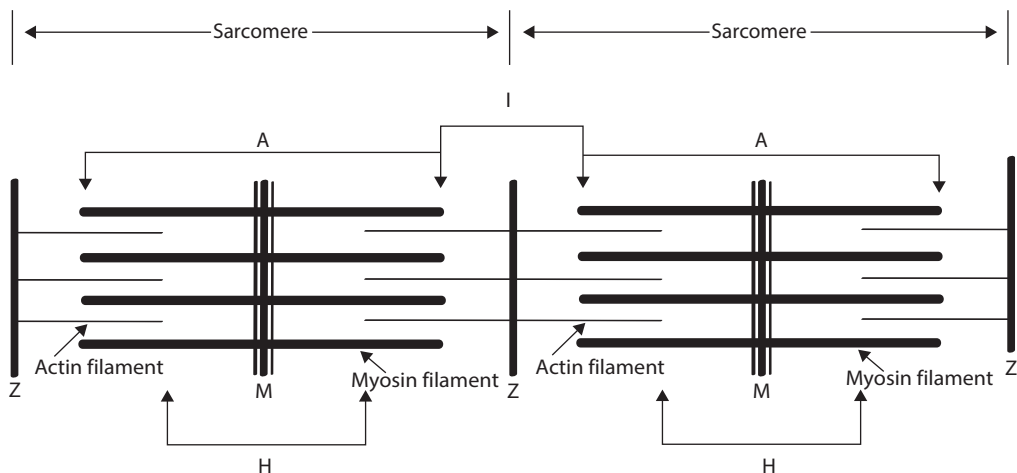

FIGURE 14.1 Diagram of two relaxed sarcomeres of skeletal muscle. The arrangement of the thick myosin and thin actin filaments is identified by letters. The light I band is divided by a dark Z line to which the actin filaments are attached. The dark A band has a lighter H band in the center that is transected by an M line. A sarcomere is defined as the area between two adjacent Z lines. (Courtesy of Cari Grindem-Corbett.)

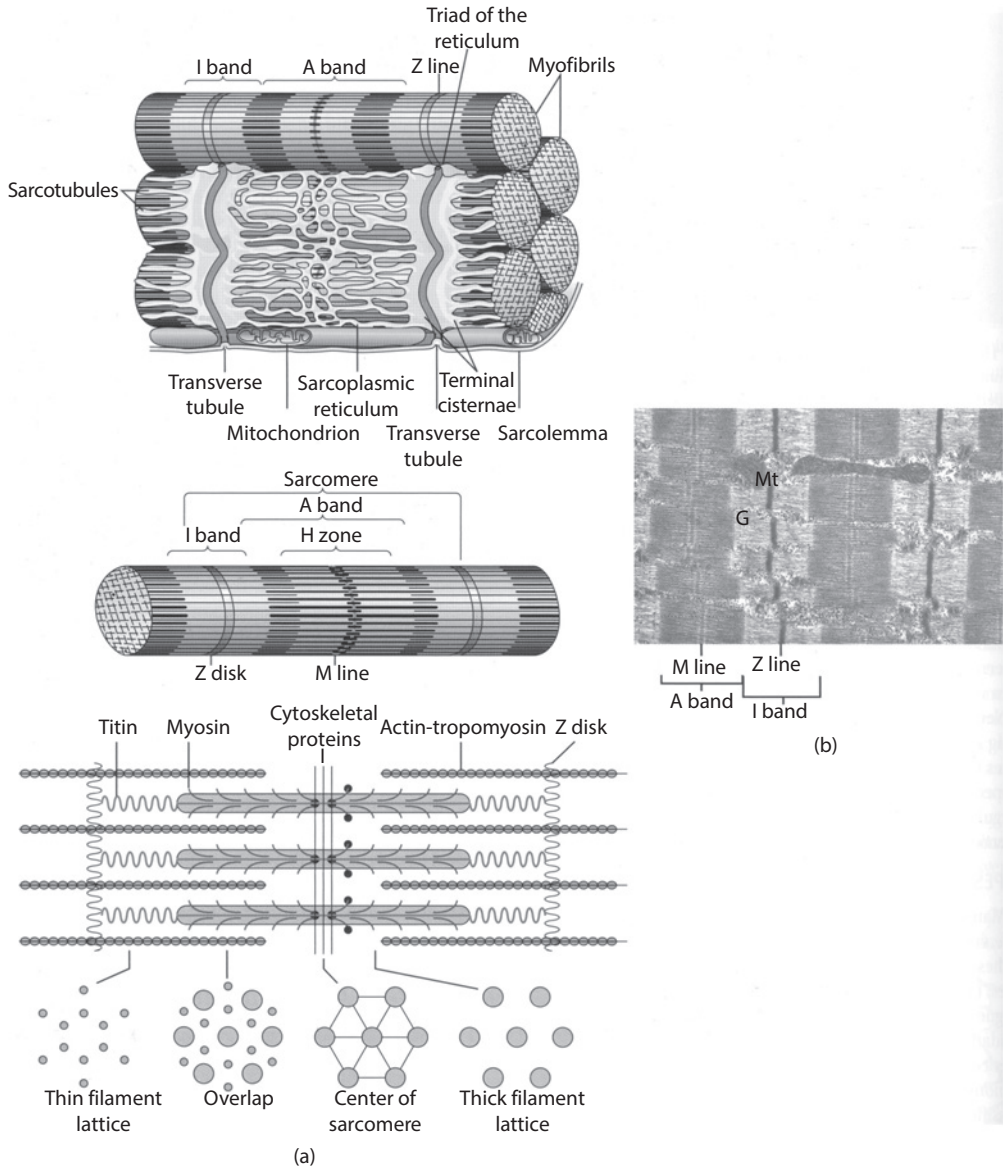

FIGURE 14.2 (See color insert.) Myofiber structure. (a) Schematic representation of myofiber orientation, secondary organelles, and ultrastructural arrangement of cytoskeletal proteins within sarcomeres. (From Copstead-Kirhorn, L.E. and Banasik, J.L., *Pathophysiology Biological and Behavioral Perspective*, Saunders, St. Louis, 2005.) (b) Skeletal muscle, longitudinal section, normal mammalian skeletal muscle. Sarcomeres are defined by Z lines, A bands composed of thick myosin filaments, and I bands composed of thin actin filaments. Dense M lines with adjacent clear H zones occur in the center of the A band. Mitochondria (Mt) and glycogen (G) are interspersed between the myofibrils. Transmission electron microscopy (TEM). Uranyl acetate and lead citrate stain. (Courtesy of Dr. BA Valentine, College of Veterinary Medicine, Oregon State University). (Reprinted from *Pathologic Basis of Veterinary Disease*, 4th edition, McGavin, M.D. and Zachary, J.F, 976, Copyright (2007), with permission from Mosby Elsevier.)

14.4 SARCOLEMMMA AND TUBULAR SYSTEM

The sarcolemma surrounding each muscle fiber is a specialized plasma membrane that contains ion channels along its length and is designed to receive and conduct stimuli. It is composed of two

layers, an inner plasma membrane proper and an outer basement membrane rich in glycoprotein and thin collagen fibrils. T tubules are tubular extensions of the sarcolemma that penetrate the myofibers at the junction of the A and I bands (mammals and reptiles) or at the level of the Z line (amphibians) allowing rapid penetration of the wave of depolarization into the muscle fiber (Hill et al., 2008).

The basement membrane consists of two layers, the outer *reticular lamina* and the inner *basal lamina*. The outermost layer of the sarcolemma (the *reticular lamina*) is composed of the proteins fibronectin, type I collagen, and a high-salt soluble protein, and it fuses with the tendon fibers that form tendons at the ends of the muscle. The tendons, in turn, are attached to the bone. The inner basal lamina contains the proteins laminin, fibronectin, and type IV collagen. Surrounding each individual muscle fiber is the endomysium, a dense connective tissue layer composed of collagen fibrils. A similar thick connective tissue layer called the perimysium divides the muscle fibers into large bundles; this layer also contains loose connective tissue through which arterioles, venules, and nerve branches run. The epimysium is a thick, dense connective tissue layer that covers the entire muscle belly and separates it from other muscles. The reticular lamina and endomysium blend with the perimysial sheaths at the myotendinous joints. Pericytes (satellite cells), located within the basal lamina, may represent precursors of muscle cells, differentiating in response to muscle damage (Dukes and Reece, 2004; McGavin and Zachary, 2007). Alterations in the sarcolemma membrane stability can result in muscular dystrophy. For example, muscular dystrophy results from a lack or defective function of dystrophin. Dystrophin is a cytoplasmic protein that is a critical part of a protein complex (dystropin-associated protein complex), which connects the myofibrils to the extracellular matrix through the sarcolemma.

The sarcotubular system is made up of the SR and the transverse tubular or T system. The T system functions in the rapid transmission of the action potential from the cell membrane to all fibrils in the muscle. The SR is a complex network of channels that completely surrounds the muscle fiber and is related to calcium movement and muscle metabolism. It functions in the uptake and storage of calcium within its lumina and in the release of calcium into the sarcoplasm bathing the myofilaments and organelles. The T tubules form narrow, perpendicular channels around the muscle fiber, and where the T tubules intersect the SR, the SR forms sac-like structures called terminal cisternae on either side, which serve primarily to store and release calcium. This structure of the T tubule with two terminal cisternae is called a triad.

14.5 MOTOR UNIT AND NEUROMUSCULAR JUNCTION

A motor unit is defined as one motor neuron with all of its branches and all the muscle fibers that it innervates. The ratio of nerve-to-muscle fibers varies with muscle function.

Muscles requiring fine movement have a higher nerve-to-muscle ratio. Motor axons terminate at skeletal muscle sites called neuromuscular junctions. At these locations (usually near the middle of the muscle fiber), the sarcolemma is modified to form a motor end plate, which contains numerous surface folds indenting the muscle fiber. Motor neuron axon terminals lie in these folds and have numerous transmitter vesicles containing acetylcholine (ACh) (see Figure 14.3). Selective and nonselective transport of Na^+ , K^+ , Ca^{2+} , and Cl^- across neuromuscular membranes is essential to initiation and propagation of action potentials. Action potentials in the motor axon result in activation of voltage-gated Ca ion channels in the presynaptic membrane. The Ca influx initiates a calcium-dependent release of ACh by exocytosis into the synaptic cleft between the presynaptic axon terminal of the motor neuron and the postsynaptic skeletal myofiber. The synaptic cleft is filled with basal lamina containing acetylcholinesterase (AChE) (Hill et al., 2008). The ACh diffuses across the sarcolemma of the motor end plate and attaches to phasic ACh receptors (AChR) initiating increased membrane permeability to Na^+ , K^+ , and Cl^- . The increased diffusion of ions depolarizes the motor end plate membrane. When the amplitude of depolarization exceeds the threshold, depolarization of adjacent sarcolemma produces a muscle action potential (MAP).

FIGURE 14.3 Transmission of an action potential at a neuromuscular junction. An action potential depolarizes the presynaptic axon terminal and opens voltage-gated Ca²⁺ channels resulting in vesicle fusion and release of acetylcholine (ACh) into the synaptic cleft. ACh diffuses across the synaptic cleft and binds to ligand-gated channels (ACh receptors) in the postsynaptic membrane. Receptor channels open allowing ion exchange. Na²⁺ influx results in an action potential that spreads causing depolarization and initiation of muscle contraction. Acetylcholine esterase (AChE) in the synaptic cleft and at the postsynaptic membrane hydrolyzes ACh into choline and acetate terminating the action potential. Choline is actively transported into the motor neuron for resynthesis of ACh. (Courtesy of Cari Grindem-Corbett.)

The action of ACh is terminated by enzymatic degradation by AChE in the sarcolemma of the motor end plate. AChE hydrolyzes ACh into acetate and choline. Choline is actively transported back into the motor axon terminal for the synthesis of ACh.

The action potential can be inhibited at multiple stages. Magnesium or other divalent cations can partially block the voltage-gated Ca ion channels in the presynaptic membrane. *Clostridium botulinum* toxin attaches to axon terminals and prevents release of ACh resulting in skeletal muscle paralysis. In contrast, the neurotoxin alpha latrotoxin found in the venom of black widow spiders (*Latrodectus*) stimulates the release of ACh from motor nerve terminals resulting in depletion of ACh and skeletal muscle paralysis (Dukes and Reece, 2004; McGavin and Zachary, 2007).

14.6 MUSCLE CONTRACTION

Skeletal muscle contraction is initiated by release of acetylcholine resulting in depolarization of the muscle cell that spreads across the entire muscle cell membrane (sarcolemma). T tubules transmit this potential down deep into the myofilaments. The T tubules form an intimate and complex association with the adjacent terminal cisternae of the SR (triads) (see Figure 14.4). A quaternary protein complex composed of ryanodine receptor (the major mediator of calcium-induced calcium release from the SR) together with triadin, junctin, and calsequestrin proteins (important regulators of ryanodine receptor function) in the SR interacts with a voltage-sensitive dihydropyridine receptor (DHPR) in the sarcolemma at the junctional triads to regulate Ca²⁺ storage and release. Simplistically, depolarization results in the release of Ca²⁺ from the terminal cisternae of the SR into the sarcoplasm, which triggers muscle contraction. The released Ca²⁺ binds to troponin causing a conformational shape change of the troponin molecule. This results in an orientation change of the tropomyosin molecule exposing a myosin-binding site on the actin filament. Cross-bridging of myosin to actin pulls the thick and thin filaments toward each other shortening the length of the sarcomere and causing the muscle to contract. Additionally, ATP is released. It is the cleavage of the high-energy phosphate bonds of ATP that provides the energy required for muscle contraction. Muscle contraction ceases as the calcium ions are rapidly pumped back into the sarcomplasmic reticulum by an active calcium-ATPase membrane pump located in the SR.

14.7 ENERGY METABOLISM

Hydrolysis of ATP provides the energy required for muscle contraction. ATP must be continually resynthesized by muscle fibers because only small amounts can be stored. Creatine phosphate (CP—phosphorylcreatine), another high-energy compound present in small amounts, supplies the energy for resynthesis of ATP. Muscle utilizes free fatty acids for energy during periods of rest or light exercise. Carbohydrates become the predominant energy source during times of intense exercise. During aerobic glycolysis, pyruvate is formed by degradation of glucose and glycogen and enters the citric acid cycle where it is metabolized to CO₂ and H₂O generating large quantities of ATP from adenosine diphosphate (ADP). Insufficient O₂ supplies result in anaerobic glycolysis; pyruvate must then be converted to lactate rather than entering the citric acid cycle. This results in the production of only small quantities of ATP.

Muscle fatigue results when the body is unable to supply sufficient energy or metabolites to the contracting muscles to meet the increased demands of the muscle. Metabolic acidosis develops, which further disrupts metabolic pathways. Lactic acid build-up was once believed to cause muscle fatigue but currently its role in muscle fatigue is uncertain and it may actually help to reduce muscle fatigue (Cairns, 2006). Although lactate production is a good indirect marker for exercise-induced metabolic acidosis, the cause of the metabolic acidosis appears to be increased nonmitochondrial ATP turnover (Robergs et al., 2004).

14.8 MUSCLE ADAPTATION

Muscle is remarkably adaptive to a wide range of physiologic and pathologic stimuli. Responses include atrophy, hypertrophy, necrosis, regeneration, elongation, shortening, and fiber-type conversion (Charge and Rudnicki, 2004; McGavin and Zachary, 2007). Muscle cells regenerate by

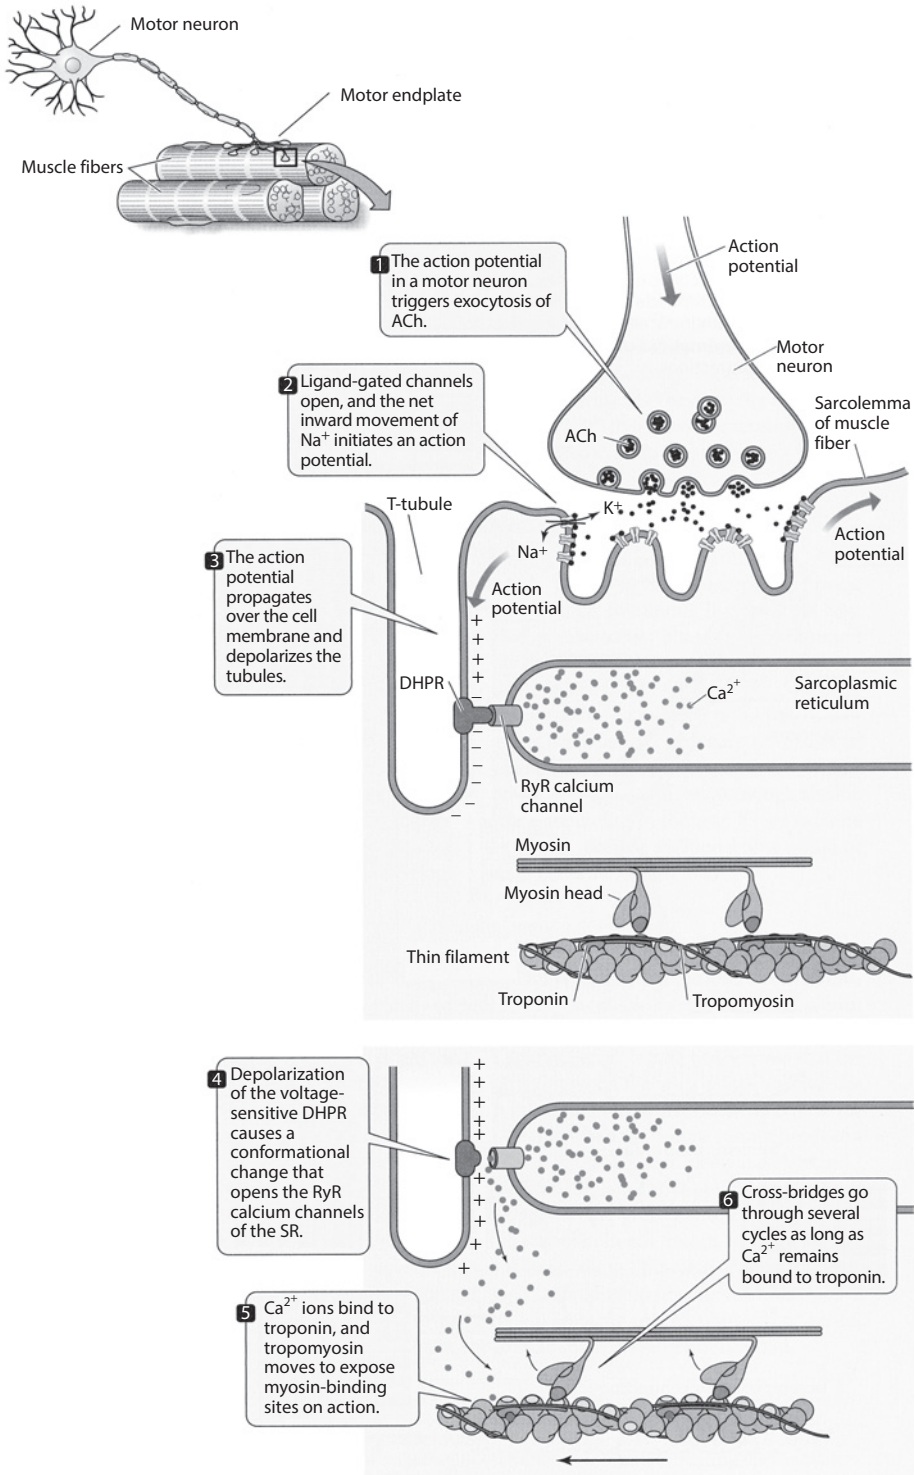

FIGURE 14.4 (See color insert.) Excitation–contraction coupling is accomplished by the interactions of components in two intimately associated membrane systems: the transverse tubular system and the sarcoplasmic reticulum. (After Silverthorn, D.U., *Human Physiology: An Integrated Approach*, Pearson/Benjamin Cummings, San Francisco, 2004; Reprinted from Hill, R.W. et al., *Animal Physiology* Sinauer Associates, Sunderland, 2004, 471. With permission.)

activation of a quiescent population of undifferentiated muscle stem (satellite) cells. Mechano growth factor (MGF) derived from alternate splicing of the insulin-like growth factor-I gene is expressed by active muscle cells and appears to be important in the activation of satellite cells (Hill et al., 2008). Although muscle stem cells are relatively resistant to aging, they are strongly influenced by aging changes in their microenvironment. Exposure of old satellite cells to young systemic factors enhances their regenerative capacity (Carlson et al., 2009). The pathways and factors that regulate muscle stem cells and regeneration are complex but are being delineated and include Wnt, Notch, transforming growth factor-beta (TGF- β), phospho Smad3 (pSmad3), and pair box protein Pax-7 (Carlson et al., 2009; Zammit, 2008). If the basal lamina remains intact, muscle regeneration is orderly and forms a cylindrical structure; otherwise the regenerative process is more disorganized and includes more fibrosis. Lack of a viable blood supply or intact motor nerves will inhibit optimal regeneration. Areas of severe muscle damage or large devascularized areas will heal by scar tissue formation.

Exercise-induced skeletal muscle adaptation varies with training duration, intensity, and frequency and is also influenced by nutritional state, age, and degree of physical fitness. The major metabolic change that exercise induces is an increase in the oxidative capacity to utilize fat, carbohydrate, and ketones (Ruckebusch, Phaneuf, and Dunlop, 1991; Bruss, 2008). Endurance training elicits mitochondrial biogenesis (increased mitochondrial density and enzyme activity), fast-to-slow fiber-type transformation, and changes in substrate metabolism. This contrasts with heavy resistance training, which stimulates the synthesis of contractile proteins responsible for muscle hypertrophy and increases the maximal contractile force output. The molecular and genetic mechanisms of adaptation are distinctly different between these diverse exercise modes (Coffey and Hawley, 2007).

By increasing fat oxidation, enhancing lactate kinetics, and inducing greater type 1 fiber (slow twitch) volume, endurance training results in increased muscle glycogen stores and glycogen sparing. It also increases capillary and mitochondrial density. Additionally, altered gene expression results in altered muscle phenotype with improved resistance to fatigue. In skeletal muscle, mitochondria are the main subcellular structure determining oxidative capacity and resistance to fatigue. Mitochondrial protein can be increased 50%–100% with continuous endurance training; however, with a protein half-life of about 1 week, continuous training is necessary to maintain elevated mitochondrial content (Coffey and Hawley, 2007).

Improved endurance is mainly associated with mitochondrial biogenesis, although enhanced oxygen kinetics, substrate transport, and buffering capacity are contributing factors. Mitochondrial biogenesis is complex, but upregulation of peroxisome proliferator-activated receptor γ coactivator-1 α (PGC-1 α), a coactivator of the peroxisome proliferator-activated receptor (PPAR), is a critical regulator. Increased PGC-1 α -PPAR-mediated transcription is important for establishing an endurance, but not a resistance, training phenotype. Increased gene expression of metabolic proteins (hexokinase, lipoprotein lipase, and carnitine palmitoyltransferase) also promotes an endurance phenotype (Coffey and Hawley, 2007). Ras-extracellular signal regulated mitogen-activated protein kinase (MAPK/Erk), phosphatidylinositol 3' kinase (P13K)-Akt1, p38 MAPK, and calcineurin pathways are the key signaling cascades for skeletal muscle phenotype. Functional genomics using microarray technology and proteomics are increasing our understanding of the molecular determinants of muscle phenotype (Chang, 2007).

Resistance exercise increases muscle cross-sectional area and alters neural recruitment patterns. Adaptation changes induced by resistance training include increased protein synthesis and production of muscle cells. Compensatory hypertrophy increases ribosomal protein synthesis and induces activation and differentiation of nonspecialized satellite cells into new muscle cells.

Muscle loss occurs with aging (sarcopenia), inactivity (atrophy), and disease (cachexia) and is characterized by protein degradation in excess of protein resynthesis (Cohen et al., 1999, Evans, 2010). Proteolysis is regulated by at least three systems: ubiquitin-proteasome, lysosomal, and calpain (Jackman and Kandarian, 2004; Kandarian and Jackman, 2006). Two recently characterized

markers of skeletal muscle atrophy are muscle-specific E3 ubiquitin ligases muscle RING-finger 1 (MuRF1) and muscle atrophy F-box (MAFbx; also called atrogin-1), which are upregulated in rodent and human models of skeletal muscle atrophy (Trendelenburg et al., 2009). Myostatin is a negative regulator of skeletal muscle size and inhibits muscle cell differentiation (Lee, 2007; Trendelenburg et al., 2009; Welle, 2009). Elevated circulating levels of myostatin observed with obesity and insulin resistance may contribute to the systemic metabolic deterioration of skeletal muscles in type 2 diabetes (Hittel et al., 2009). Animals treated with follistatin, a myostatin inhibitor, or animals lacking myostatin have increased muscle mass (Lee, 2007). The capacity of exercise to delay, reverse, or exacerbate atrophy is unclear. Swim training in one rat study did not minimize the deleterious effects of immobilization (Nascimento et al., 2008).

14.9 CLASSIFICATION OF SKELETAL MUSCLE

Mammalian skeletal muscles are composed of different muscle fiber types, which express distinct sets of structural proteins and metabolic enzymes. Myofibers have been classified by both histochemical and immunohistochemical methods. Because the methods are different, the classification schemes are not identical, which can cause some confusion.

Skeletal muscle fibers can be broadly grouped into type I and type II fibers based on histochemical myosin ATPase staining. Type I fibers are slow contracting and slow fatiguing, and have oxidative metabolism, numerous mitochondria, and low myosin ATPase. Type II fibers are fast contracting and more easily fatigable, and have glycolytic metabolism, fewer mitochondria, and higher myosin ATPase. Type II fibers can be further subdivided based on ATPase activity following preincubation in acid and alkaline media into type IIA, IIB, and IIC (see Tables 14.1 and 14.2). Most muscles contain both type I and type II fibers. Red muscles (slow, oxidative, and more vascular) contain many type I fibers and are primarily associated with muscles that maintain posture and slow locomotion. White muscles (fast, glycolytic, and less vascular) contain mostly type II fibers and are used for sprinting. The proportion of these muscle fibers varies among animal species and even between breeds (Burke et al., 1971; Dickinson and LeCouteur, 2002; Valberg, 2008). For example, the proportion of type I fibers is 3% in greyhound dogs, 31% in mongrel dogs, and 12% in thoroughbred horses (Ruckebusch et al., 1991).

TABLE 14.1
Characteristics of Skeletal Muscle Fibers

Factor	Type I	Type IIA	Type IIx
Contraction rate	Slow	Intermediate	Fast
Oxidative capacity	High	Intermediate	Low
Fatigue resistance	High	Intermediate	Low
Glycolytic capacity	Low	Intermediate	High
Vascularity (redness)	High	Intermediate	Low
Myoglobin content	High	Intermediate	Low
Nuclei location	Peripheral	Peripheral	Central
Mitochondrial density	High	High	Low
Fiber diameter	Small	Intermediate	Large
ATPase pH 4.5	High	None	Low
ATPase pH 9.4	None	High	Low
Major storage fuel	Triglycerides	Creatine phosphate, glycogen	Creatine phosphate, glycogen
Function	Aerobic (posture)	Long-term anaerobic (walking, standing, repetitive movements)	Short-term anaerobic (burst of high-speed locomotion)

TABLE 14.2
Selected Histologic and Histochemical Stains Employed in the Evaluation of Muscle Biopsy Specimens

Histologic or Histochemical Stain	Normal Features	Disease Features
Hematoxylin eosin	<ul style="list-style-type: none"> • General histopathologic features 	<ul style="list-style-type: none"> • Basophilia of degenerating/regenerating fibers • Necrotic fibers pale
Modified trichrome	<ul style="list-style-type: none"> • General histopathologic features • Contents of intermyofibrillar space (red) (sarcoplasmic reticulum, mitochondria, lysosomes, lipid, glycogen) • Intrafascicular nerve branches (myelin red) • Muscle fibers (blue) • Connective tissue (blue green) 	<ul style="list-style-type: none"> • Aggregates and vacuoles, “ragged red” fibers, nemaline rods • Loss of myelinated nerve fibers • Fibrosis
Myofibrillar adenosine triphosphatase (ATPase) pH 9.8	<ul style="list-style-type: none"> • Differentiation of type 1 and 2 myofibers • Dog Type 1 Light <ul style="list-style-type: none"> • Type 2A Dark • Type 2C Dark • Cat Type 1 Light <ul style="list-style-type: none"> • Type 2A Dark • Type 2B Dark • Type 2C Dark 	<ul style="list-style-type: none"> • Type 1 and 2 myofiber atrophy in denervation • Selective myofiber type atrophy (various) • Fiber type grouping
ATPase preincubation pH 4.3 (reversal)	<ul style="list-style-type: none"> • Differentiation of Type 2A, 2B, and 2C myofibers • Dog Type 1 Dark <ul style="list-style-type: none"> • Type 2A Light • Type 2C Intermediate • Cat Type 1 Dark <ul style="list-style-type: none"> • Type 2A Light • Type 2B Light • Type 2C Intermediate 	
ATPase preincubation pH 4.6	Differentiation of Type 2A and 2B myofibers Cat Type 1 Dark <ul style="list-style-type: none"> • Type 2A Light • Type 2B Intermediate • Type 2C Intermediate 	Not required in dog because of lack of type 2B fibers
Periodic acid–Schiff–hematoxylin	External lamina, glycogen, and myelin are positively stained (magenta)	Glycogen storage disease (vacuoles/accumulations) Loss of myelinated nerve fibers
Oil red O	Intermyofibrillar lipid inclusions and fat cells in myofascial connective tissue (orange/red)	Lipid storage myopathies Increased staining, often predominantly type 1 myofibers
Nicotinamide adenine dinucleotide–tetrazolium reductase	Mitochondrial oxidative enzyme	Mitochondrial and sarcoplasmic reticulum aggregates Pyknotic nuclear clumps stain darkly Atrophied myofibers may stain darkly Target myofibers
Succinate dehydrogenase	Mitochondrial oxidative enzyme	As for nicotinamide adenine dinucleotide, mitochondrial specific

Immunohistochemical staining using antibodies against myosin heavy chain (MHC) has identified 10 isoforms of MHC in mammalian muscle, each with its own characteristic mATPase activity (Dickinson and LeCouteur, 2002; Peter et al., 1972; Smerdu et al., 2009; Weiss and Leinwand, 1996; Weiss et al., 1999). Myosin isoforms include slow-twitch M I (type I), several specialized isoforms (neonatal, jaw muscle, and extraocular muscle), and three or four major fast-twitch MHC adult mammalian isoforms (IIa, IIx [also known as IId], IIb). The fast-twitch isoforms expressed vary with species and within different muscles. Small mammals like rodents and lagomorphs, in addition to domestic pigs and llamas, express MHC IIa, IIx, and IIb. Humans and some other domestic animals such as dogs, cats, goats, and horses express only two, MHC IIa and IIx (Brooke and Kaiser, 1970; Schiaffino and Reggiani, 1994; Smerdu et al., 2009).

In general, the histochemically classified type I and IIa fibers correspond to MHC I and IIa (see Table 14.1). The histochemical type IIB fibers express MHC IIx. Hybrid fibers coexpress more than one MHC isoform simultaneously, for example, IIC express MHC I and IIa isoforms. MHC isoforms correlate with mATPase activity, fatigability, and also maximum shortening velocity. Different fast and developmental MHC isoforms can be coexpressed in muscle fibers in development, regeneration, transformation, and some normal adult muscles (Smerdu et al., 2009; Schiaffino and Reggiani, 1994).

14.10 LABORATORY EVALUATION

Routine laboratory evaluation of neuromuscular disorders primarily focuses on the measurement of serum enzyme levels as indicators of myocyte damage or necrosis. The activity or concentration of the muscle enzymes in serum is usually low because of their intracellular location within healthy myofibers. Necrosis of myofibers with disruption of cell membranes results in diffusion of cellular contents, including enzymes, into lymphatics or circulation. Other factors that may influence the activity of muscle enzymes include permeability of the cell membrane, rate of enzyme production, alternate sources of enzyme excretion or degradation, and variation in enzyme removal or inactivation (Dunlop and Malbert, 2004; Latimer et al., 2003). Leakage of enzymes, especially

cytosolic enzymes, does not require cell death and, therefore, does not indicate irreversible damage. However, the magnitude of the enzyme elevation generally relates to the number of cells damaged. Magnitude and persistence of enzyme elevation are important parameters in monitoring myocyte injury. Decreased muscle enzyme levels are usually of no clinical significance but may occur with decreased muscle mass, interfering substances, and laboratory errors.

Creatine kinase (CK) is the most commonly used, muscle-specific enzyme to detect and monitor muscle damage. However, it is limited by its relatively short half-life (0.6–9 hours) in most species (Boyd, 1983; Stockham and Scott, 2008; Walker, 2006). Other enzymes such as aspartate aminotransferase (AST), lactate dehydrogenase (LDH), and alanine aminotransferase (ALT) have longer half-lives but lack the specificity of CK. Therefore, if these later enzymes are used to evaluate muscle damage, they must be used in combination with other tests, clinical information, and/or histopathologic evaluation that rule-out nonmuscle causes of enzyme elevation. For example, AST could be used in combination with CK and sorbitol dehydrogenase (SDH) or glutamate dehydrogenase (GLDH) to conclude that an elevation in AST is from muscle rather than liver. Aldolase (ALD) is also used as a biomarker for skeletal muscle injury, especially in the rat. Use of CK isoenzymes also increases muscle specificity but this has limited availability and limited application especially regarding skeletal muscle. Serum CK isoenzyme profiling, most often used for evaluating cardiac injury, has largely been replaced by cardiac troponins (Apple et al., 2008; O'Brien, 2008; Panteghini and Bais, 2008; Walker, 2006). In certain diseases such as progressive muscular dystrophies, tissues may fail to mature normally or maintain normal state of isoenzymes. The distribution of isoenzymes of CK, LDH, and ALD in muscle of progressive muscular dystrophy patients is similar to fetal muscle. The abnormalities of the isoenzymes in this disease are interpreted as a failure to reach or maintain a normal degree of differentiation. Isoenzyme patterns of regenerative muscle may also have fetal distribution patterns (Panteghini and Bais, 2008; Wilson, 2008).

Additional tests to evaluate muscle include proteins (troponin, myoglobin, fatty acid binding protein-Fabp3), antibody titers (immune-mediated diseases such as myasthenia gravis [MG] and masticatory myositis, and infectious diseases), lactate and pyruvate levels, electrolytes, hormones (thyroid, adrenal, sex), metabolic testing, and genetic testing. Of these, troponin and myoglobin are of limited value for investigating skeletal muscle disorders as their use is more applicable to cardiac muscle. “Omics” is a rapidly growing technology that focuses on large-scale and holistic data to understand life through the various “omes.” For example, transcriptomics is the study of the entire set of mRNA in an organism, tissue, or cell and is becoming an integral tool for research as well as for the identification and potential therapy of neuromuscular disorders. Specialized electrodiagnostic tests include electromyography (EMG), evaluation of sensory and motor nerve conduction velocity measurements, and evoked MAPs.

Myofibers can be dysfunctional without exhibiting elevations in serum muscle enzyme concentrations. Therefore, histopathology, immunohistopathology, and/or ultrastructure of skeletal muscle and nerve biopsies are necessary for the investigation of neuromuscular conditions lacking enzyme changes or for a definitive morphologic diagnosis. The focus of this chapter is the basic clinical pathology tests used to diagnose and monitor muscular disorders. Some newer technologies or technologies used less frequently will be briefly discussed.

14.11 PREANALYTICAL AND ANALYTICAL VARIABLES

Identifying or controlling preanalytical variables is important for the interpretation and reproducibility of laboratory data. This is especially critical for research of neuromuscular disorders, testing the myotoxicity of different drugs, or evaluating therapeutic responses (emerging gene therapy). Individuals interpreting data from animals in neuromuscular studies or with neuromuscular disorders should be aware of the following: sample type (plasma or serum, whole blood); how and into what type of tube was the sample collected; specimen handling prior to analysis (stored at room, refrigerator or freezer temperature; separated immediately, within X hours); bleeding site;

recent handling of the animals and their level of acclimation to handling; any history of recent surgery or injections; any confounding factors (lipemia, hemolysis, icterus, drugs); and use of species specific assays and/or reference intervals (Hall, 2007; O'Brien, 2008). Serum or plasma can be used for many of the tests, but the results will vary slightly, and the anticoagulant can make a difference. Platelets, which contain CK and potassium in some animals, may also influence results (Aktas et al., 1993; Stockham and Scott, 2008). Age, sex, and breed/strain may affect the reference interval (Aktas et al., 1993; Honda et al., 2008; Matsuzawa et al., 1993; Walker, 2006; Waner et al., 1991). If anesthesia is used to collect the sample, it may have an effect, especially if any injections or recent surgeries (such as placement of catheters) have been performed. Research animals should be acclimated to handling techniques prior to study initiation. The need for acclimating laboratory animals to handling techniques is well documented in muscle research (Hall, 2007; Goicoechea et al., 2008; Lefebvre et al., 1992). For example, handling mice increases their serum ALT, AST, and LDH levels (Hall, 2007). Many examples of the effect of conditioning of animals exist. Aerobic exercise (swimming) protected the heart from ischemic/reperfusion injury in research rats and was associated with lower CK and LDH values after injury compared with sedentary rats (Zhang et al., 2007). Similarly, endurance training (swimming) in mice was protective for doxorubicin injury and decreased the elevation in cardiac troponin (Ascensao et al., 2005). Conditioned dogs, such as sled dogs, field trial dogs, and racing greyhounds, also appear to have fewer changes in analytes with exercise (McKenzie et al., 2007; Steiss and Wright, 2008).

Sample handling is very important for the accurate interpretation of both neuromuscular biopsies and serum enzyme levels. Serum is the preferred sample for enzyme analysis. Some enzymes, especially AST and LDH, can escape from erythrocytes, and if the serum is left in contact with the clot for a long time or if hemolysis occurs, AST and LDH levels can increase significantly.

For accurate interpretation, reference intervals must be established for each laboratory (Evans, 1996; Mitruka and Rawnsley, 1981). Additional recommendations are necessary for animal toxicologic and safety studies. Kinetic spectrophotometric assays are often preferred over colorimetric, end point, or fluorometric methods for measuring enzymes in experimental safety studies. Better linearity and less interference with endogenous pyruvate or drugs, metabolites, or other chemicals have been reported (Dooley, 1979, 1984). Reference intervals for each strain, sex, and age group or a matched control group are usually required (Keller, 1981; Loeb and Quimby, 1989). For example, genetic variation of CK, LDH, and ALD occurs in mice; and CK and LDH isoenzyme profiles change as gestation progresses. CKBB (CK₁) and LDH₅:MMMM predominate in the embryonic mouse heart muscle, whereas CKMB (CK₂) and LDH_{1 and 2} (HHHH and HHHM) predominate at birth (Loeb and Quimby, 1989). Routine measurement of CK and LDH activities has not been recommended for animal toxicology and safety studies (Weingand et al., 1992, 1996).

14.12 PROTEINS AND ENZYME MARKERS

14.12.1 CREATINE KINASE

CK (EC 2.7.3.2; ATP:creatine *N*-phosphotransferase) catalyzes the reversible phosphorylation of creatine by ATP.

14.12.1.1 Tissue Distribution and Isoenzymes

In all species including cat, dog, horse, ox, man, marmoset, pig, rabbit, rat, and sheep, CK is in the highest concentration in skeletal muscle followed by cardiac muscle, brain, and intestine (Boyd, 1983; Wyss and Kaddurah-Daouk, 2000). CK consists of three dimeric cytoplasmic isoenzymes (CKBB-CK₁, CKMB-CK₂, and CKMM-CK₃) and one mitochondrial isoenzyme (CK-Mt). The

molecular weight for all four isoenzymes is approximately 80,000 Da (Panteghini and Bais, 2008). The cytosolic isoenzymes are dimers of two subunits called M and B. CKBB predominates in the nervous tissue but is also found in the thyroid, kidney, intestines, and smooth muscle of the lungs; CKMB is mainly found in heart muscle where it represents 10%–20% of total CK, but is also present in the diaphragm and esophagus. In skeletal muscle, this isoenzyme represents only 2%–5% of total CK (Panteghini and Bais, 2008). CK-Mt is in mitochondria from many tissues (Stockham and Scott, 2008).

CKMM is the most common isoenzyme and is present in all tissues, especially skeletal muscle. Skeletal muscle from dogs has nearly 100% CKMM; heart muscle has about 98% CKMM and 2% CKMB; brain has about 8% CKMM and 90% CKBB; and intestine has approximately 12% CKMM, 35% CKMB, and 53% CKBB (Kikuta and Onishi, 1986). CK activity in skeletal muscle varies depending on breed (greyhounds > mongrels) and muscle type (fast acting muscles > slow) (Guy and Snow, 1981; Lindena et al., 1982). Dog plasma contains 30%–86% (usually 40%–55%) CKMM, 4%–45.5% (usually 30%–45%) CKBB, and 0%–18% CKMB (Loeb and Quimby, 1999; Voss et al., 1995). Rat myocardium has about 67% CKMM, 16% mitochondrial CK, 15% CKMB, and 2% CKBB. In rat plasma, 5%–10% of CK activity is CKBB with virtually no CKMB (Loeb and Quimby, 1999; Fontanet et al., 1988). In pigs, 4%–5% of the total myocardial CK activity is CKMB (Thoren-Tolling and Jonsson, 1983). Similar to humans, CKMB comprises about 20% of the total CK activity in the myocardium of baboon making baboons potentially a better model for human cardiac disease than dogs, which have only 2%–3% CKMB (Yasmineh et al., 1976). CK isoenzyme distribution patterns change with gestational development, disease states, and training, but the CKMM isoenzyme remains the predominant isoenzyme (Loeb and Quimby, 1999; Schultz et al., 1996).

On electrophoresis, the CKBB isoenzyme migrates most rapidly and is consequently found in the prealbumin area, CKMB has intermediate mobility and migrates to the α 2-globulin region, and CKMM is the slowest and migrates to the γ -globulin zone. CKMB is relatively specific for myocardial infarction but measurements of CKBB and CKMM are of little clinical utility. Techniques for isoenzyme separation include electrophoresis or immunoassay using specific antibodies (Panteghini and Bais, 2008; Wilson, 2008).

CKMB and CKMM isoforms have been described in the dog and have been studied in experimental acute myocardial infarction (AMI). Proportions of the various isoforms have been used to estimate duration and progression of the lesion (Billadello et al., 1989; George et al., 1984).

14.12.1.2 Effect of Disorders and Exercise

Elevations in CK can be caused by skeletal and cardiac muscle damage, intramuscular (IM) injections, exercise, shivering, seizures, hypokalemia, or hypothyroidism (Valberg, 2008; Chanoit et al., 2001). Intramuscular injections can cause variable to marked increases in CK activity, peaking at 4 hours and persisting for 24–72 hours (Aktas et al., 1995; Klein et al., 1973; Lewis and Rhodes, 1978). CK activity can increase secondary to myocardial disease in dogs with dirofilariasis and parvovirus but may remain unchanged in dogs with hypertrophic cardiomyopathy (Loeb and Quimby, 1999). In contrast to humans and dogs, hypothyroid rats do not have elevated CK activity (Nuttall, 1968; Rossmeisl et al., 2009). Low CK values probably have no meaning but may reflect either small muscle mass, and/or sedentary lifestyle or marked muscle atrophy. Lack of CK elevation does not rule out muscle disease. Because of the relatively short half-life (0.6–9 hours), persistent elevations indicate ongoing injury or decreased clearance. Monkeys infected with simian immunodeficiency virus can have 10–15-fold increase in CK early in the disease but during the chronic cachectic phase muscle phosphocreatine levels are decreased (Dalakas, 1993; Hack et al., 1997). Syrian hamsters with hereditary myopathy have increased CK (Eppenberger et al., 1964).

Exercise-induced increases in CK have been reported in dogs (13-fold increase in greyhounds and huskies) and rats especially males or ovariectomized females (Amelink et al., 1988; Ilkiw et al., 1989; McKenzie et al., 2007; Ready and Morgan, 1984).

Serum CKMB has been used as an indicator of myocardial injury in experimental rodent models of AMI (Loeb and Quimby, 1999). Severe skeletal muscle injury (trauma, surgery, etc.) can also elevate serum CKMB. Persistent elevations of total CK and CKMB are diagnostic challenges and occur in muscular dystrophy, end-stage renal disease, or polymyositis, and in healthy subjects undergoing extreme exercise or physical activities, but cardiac troponin should be normal if the myocardium is not injured (Panteghini and Bais, 2008). Cardiac troponin I or T has largely replaced CKMB testing in the human field.

CKBB has been used as a marker of intestinal infarction in an experimental rat model, in which total CK activity increased 14-fold and CKBB activity increased 12-fold (Loeb and Quimby, 1999; Roth et al., 1989).

14.12.1.3 Diagnostic Testing and Sample Handling

Serum or heparinized plasma is the preferred sample. CK activity is unstable; if samples cannot be analyzed immediately (<4 hours), they should be refrigerated (5–7 days) or frozen (1–2 months, possibly longer at -80°C). The addition of sulfhydryl agents restores the original activity but the mechanism is unknown (Aktas et al., 1993; Panteghini and Bais, 2008).

Interferences include hemolysis (>39 mg/dL due to adenylate kinase), exposure to direct sunlight, or fluorescent light (due to loss of CO_2 which causes a slight decrease in CK), very high or low Mg levels, and contamination with oxidizing agents such as hypochlorite (cause slight decrease in CK). Drugs reported to cause interference include amphotericin B, ampicillin, anticoagulants, aspirin, dexamethasone, furosemide, lithium, morphine, and anesthetic agents (Wilson, 2008). Bilirubin, lipemia, and heparin cause little to no interference (Aktas et al., 1993; Wilson, 2008).

CK can elevate with restraint and handling animals for sample collection. Therefore, in some species like mice and monkeys, CK may be an insensitive test with wide reference intervals. Fasting can increase CK in pigs (Baetz and Mengeling, 1971). Male rats have higher CK values than females, whereas a sex difference is controversial in dogs but larger dogs have lower CK activity (Aktas et al., 1993, 1994; Goicoechea et al., 2008). CK activity decreases with age (Aktas et al., 1993; Shibata and Kobayashi, 1978). During the first few months it decreases dramatically then stabilizes during adulthood (Aktas et al., 1993). Platelets are a source of CK and contribute to the higher serum than plasma levels of CK (Aktas et al., 1994; Shibata and Kobayashi, 1978).

14.12.1.4 Serum Half-Life

In general, CK has a short half-life of 2–4 hours; elevates in 4–6 hours and peaks in 12 hours (Stockham and Scott, 2008). Half-life of total CK in the dog has been reported as <2 hours (Rapaport, 1975), 2.6 hours (Aktas et al., 1993, 1994), 4.7 hours (Boyd, 1983), and 0.6–16.2 hours (Lindena, et al., 1986); 9 hours in the rabbit (Lefebvre et al., 1993); 34 minutes in rats (Friedel et al., 1975; Lindena et al., 1986), and 5.2 hours in pigs (Boyd, 1983). In the dog, the half-life of CKMB is 1.3–8.1 hours (Lindena et al., 1986). In humans, the CK half-life is slightly longer at 13–20 hours (Janssen et al., 1989).

14.12.2 ASPARTATE AMINOTRANSFERASE

AST (EC 2.6.1.1; L-aspartate:2 oxoglutarate aminotransferase) catalyzes the transamination of L-aspartate and 2-oxoglutarate to oxalacetate and glutamate.

Addition of pyridoxal-5'-phosphate (P5P) is recommended for the measurement of total enzyme activity. Both AST and ALT can occur in apoenzyme forms that have no catalytic activity. Addition of exogenous P5P activates any available apoenzyme and therefore may increase measured AST and ALT activity (Mesher et al., 1998; Stokol and Erb, 1998; Wan et al., 1993; Waner and Nyska, 1991).

14.12.2.1 Tissue Distribution and Isoenzymes

AST is located in the cytoplasm and mitochondria of hepatocytes, skeletal myocytes, cardiac myocytes, and erythrocytes. It has two isoenzymes, one mitochondrial and one cytosolic with 50% identity and 80% identity, respectively, between different species (Pavé-Preux et al., 1988). Both isoenzymes play a role in amino acid synthesis and degradation, as well as in the link between the urea and the tricarboxylic acid cycles (Pavé-Preux et al., 1988). AST has a molecular weight of 100 Da.

14.12.2.2 Effect of Disease or Tissue Injury

AST is a nonspecific analyte; serum values are increased mainly with liver, muscle, and erythrocyte damage. It can increase up to eight times the upper reference value with muscular dystrophy and dermatomyositis, but is usually within reference interval in neurogenic muscle disorders (Panteghini and Bais, 2008; Wilson, 2008). Its half-life is longer than CK but shorter than ALT. AST should be interpreted together with CK or ALD (as well as liver enzymes) for the evaluation of muscle damage, although, in the absence of liver disease (elevations in liver enzymes and/or histopathologic findings) and hemolysis, increased AST is indicative of muscle damage. In laboratory animals, muscle injury is more likely to elevate AST than ALT, whereas ALT is generally preferred over AST for the evaluation of liver injury.

14.12.2.3 Diagnostic Testing and Sample Handling

AST is stable at room, refrigeration, and freezer temperatures (Latimer et al., 2003). Hemolysis causes an increase in AST levels. Apoenzyme and P5P levels have also influenced AST activity in dogs and rats (Meshar et al., 1998; Stokol and Erb, 1998; Wan et al., 1993; Waner and Nyska, 1991). Addition of P5P to an AST assay resulted in a median decrease of -6.3% (range -33.3% to 25%) in 80 dogs (Meshar et al., 1998). Site of venipuncture in rats also has an impact on the enzyme activity and is markedly elevated in the serum from retroorbital and ventral aorta venipuncture compared with activity in serum obtained from jugular vein and heart (Friedel et al., 1975). AST levels may be increased by the following drugs: acetaminophen, allopurinol, antibiotics, ascorbic acid, methyl-dopa, morphine, phenothiazines, pyridoxine, salicylates, sulfonamides, and vitamin A. Drugs that can decrease AST levels include metronidazole and trifluoperazine (Wilson, 2008). Cephalosporin treatment in rats also resulted in decreased AST activity (Dhami et al., 1979).

14.12.2.4 Serum Half-Life

AST has a short half-life; less than 12 hours in cats (Nilkumhang and Thornton, 1979), 12 hours in dogs (Boyd, 1983), 3.3–4.4 hours (Evans, 1996) and 18 hours in pigs (Massarrat, 1965), 1.6 hours (Friedel et al., 1979) and 2.3 hours in rats (Evans, 1996), and 2.5 hours in rabbits (Amelung, 1960; Boyd, 1983).

14.12.3 ALANINE AMINOTRANSFERASE

ALT (EC 2.6.1.2; L-alanine:2-oxoglutarate aminotransferase) catalyzes the reversible reaction of deamination of L-alanine to pyruvate. Pyridoxal-5-phosphate (P-5'-P) is the main cofactor for ALT and affects its activity (Stockham and Scott, 2008).

ALT activity is measured by absorbance of NADH, which is directly proportional to ALT activity. It is recommended that P-5'-P is added to the reaction so that all of the enzyme activity is measured. Adding P-5'-P resulted in an increase in ALT activity in dogs (median of 9.6% , range -7.1% to 46.5%) and in manatees (Meshar et al., 1998; Harr et al., 2008).

14.12.3.1 Tissue Distribution and Isoenzymes

ALT is a nonspecific analyte abundantly expressed in liver, but is also present in muscle. ALT has two isoenzymes: ALT₁, which is a cytoplasmic protein, and ALT₂, which is located in the mitochondria. ALT₁ has a longer half-life (about 36 hours) than ALT₂ (about 3 hours) in humans, dogs and Sprague–Dawley rats (Dooley, 1984). ALT₁ appears widely expressed in different tissues, whereas ALT₂ expression is more restricted and mainly found in muscle and liver. ALT₂ gene expression is higher in male than in female rats (Yang et al., 2009). In rats and pigs, ALT₁ is the predominant isoenzyme in skeletal and cardiac muscle, but the cytosolic ALT concentration varies from species to species (DeRosa and Swick, 1975).

Tissue distribution of ALT within organs can also vary. For example, periportal hepatocytes in rats may contain five times more ALT activity than centrolobular hepatocytes but unfortunately this cannot be used clinically to localize intrahepatic lesions (Dooley, 1984).

14.12.3.2 Effect of Disease

ALT is primarily used to identify liver disease or injury, but it can increase with severe muscle damage, especially in pigs where its activity is higher in cardiac and skeletal muscle than in liver (Markert, 1984). In mice, handling them by the body compared to the tail resulted in a fourfold increase in ALT activity (Swain et al., 1985). Increased serum ALT can also be induced by anticonvulsants (phenobarbital, phenytoin and primidone), glucocorticoids (prednisone, prednisolone), and thiacetarsemide (Latimer et al., 2003).

In horses, ruminants, pigs, and birds, hepatic ALT is very low and serum increases are the result of muscle damage. In dogs, cats, and most laboratory animals, ALT increases are usually associated with liver disease but can increase with some muscle diseases including muscular dystrophy and acute rhabdomyolysis (Stockham and Scott, 2008). Up to 25-fold increases in serum ALT have been reported in dogs with muscular disorders (Swenson and Graves, 1997; Valentine et al., 1990). In the guinea pig, rabbit, monkey, and baboon, ALT has little to no organ specificity with similar tissue concentrations in heart muscle and liver (Hall, 2007; Loeb and Quimby, 1989; Clampitt and Hart, 1978). Decreased serum activity of ALT and/or AST are occasionally observed in toxicology studies and may relate to decreased hepatocellular production or release, assay interferences, enzyme inhibition, or decreased coenzyme (P-5'-P) activity. Decreased ALT activity does not appear to be pathologically significant. Many drugs are reported to cause increases or decreases in ALT levels in humans (Fischbach and Dunning, 2004). Cephalosporin treatment in rats resulted in decreased ALT activity (Dhami et al., 1979).

14.12.3.3 Diagnostic Testing and Sample Handling

Serum is the preferred sample. Some anticoagulants such as citrate and fluoride should be avoided because they can inhibit the enzyme activity. ALT is stable for 2 days at 25°C, 1 week at 4°C, and unstable at -25°C; -70°C is recommended for longer storage. Up to a 25% decrease in activity was observed in manatee plasma stored for 1 month at -70°C (Harr et al., 2008). Interestingly, rat erythrocytes contain significant ALT activity but hemolysis does not cause a problem, possibly because ALT binds more strongly to erythrocyte membranes than other enzymes (Dooley, 1984). Icterus does not interfere with ALT measurements but lipemia can decrease ALT values. Diet and sex can influence ALT activity in rats. Female rats fed NIH-07 diet had lower ALT values than female rats fed NTP-2000 or male rats fed either diet (Rao, 1996). In rats, ALT is slightly increased when serum is obtained from the retro-orbital venous plexus and markedly increased when obtained from the ventral aorta, as compared with jugular vein and heart (Friedel et al., 1975). Numerous drugs may increase ALT levels and include acetaminophen, anticonvulsants,

antibiotics, nonsteroidal anti-inflammatory drugs (NSAIDs), lipid-lower agents, salicylates, and thiazine (Wilson, 2008).

14.12.3.4 Serum Half-Life

The clearance half-life in dogs is 60 hours, increasing 12 hours postinsult and peaking at 1–2 days and then declining (Latimer et al., 2003) and has also been reported as 2.5–60.9 hours (Evans, 1996). In rats, the clearance $t_{1/2}$ has been reported as 4.5–8 hours (Loeb and Quimby, 1989), 3 hours (Boyd, 1983), and 4.4 hours (Evans, 1996); in rabbits 5 hours (Amelung, 1960) and 5.1 hours (Boyd, 1983); and in pigs 51 hours (Boyd, 1983).

14.12.4 LACTATE DEHYDROGENASE

LDH (EC 1.1.1.27; (S)-lactate:NAD⁺oxidoreductase; LD) is a cytoplasmic hydrogen transfer enzyme that catalyzes the reversible conversion of L-lactate to pyruvate with mediation of NAD as a hydrogen acceptor (Panteghini and Bais, 2008).

LDH activity is measured spectrophotometrically at 340 nm by following either the oxidation of NADH with pyruvate or reduction of NAD⁺.

14.12.4.1 Tissue Distribution and Isoenzymes

LDH is a tetramer and has two subunits, M for muscle and H for heart. The DNA encoding these subunits are LD-A and LD-B, respectively (Rossignol et al., 2003). There are five recognized isoenzymes, based on their electrophoretic mobility:

- LDH₁: HHHH
- LDH₂: HHHM
- LDH₃: HHMM
- LDH₄: HMMM
- LDH₅: MMMM

LDH₅ or electrophoretically slow moving isoenzyme is the main isoenzyme in skeletal muscle. Isoenzyme patterns vary between species but LDH₅ and LDH₄ are the primary isoenzymes in serum with lesser but variable amounts of the other isoenzymes (Preus et al., 1989). LDH₁ and LDH₂ are the main isoenzymes in the heart and may be helpful in monitoring cardiac damage in experimental models of heart disease (Preus et al., 1989).

14.12.4.2 Effect of Disease

Serum LDH has been used for diagnostic purposes for many years. Increased levels are associated with many diseases, in particular those involving the heart or skeletal muscles, liver, erythrocytes, and tumors (Skillen, 1984). LDH activity can be found in all tissues, but the main serum sources are muscle, liver, and erythrocytes. Without isoenzyme analysis, the measurement of LDH is not organ specific. The arterivirus, mouse LDH elevating virus (LDEV or LDV) is associated with chronic elevations of LDH, AST, isocitric dehydrogenase, malic dehydrogenase, and phosphohexase isomerase in infected mice (Notkins, 1965; Riley, 1974). The increased enzyme activity in these mice is due to a decreased rate of endogenous clearance. Any disorder, infection, or chemical that damages cells and releases endogenous enzyme will result in prolonged enzyme elevations. Decreased plasma protein turnover has also been observed in these LDEV mice (Riley, 1974).

14.12.4.3 Diagnostic Testing and Sample Handling

The preferred specimen is serum. Platelets contain high concentrations of LDH and serum values of LDH are higher than plasma (Shibata and Kobayashi, 1978). Hemolysis can contribute significantly to elevations in serum LDH. Ethylenediaminetetraacetic acid (EDTA) inhibits the enzyme, perhaps by binding Zn^{2+} (Panteghini and Bais, 2008). LDH is stable for 3 days at room temperature, stable in refrigeration, and unstable when frozen (Panteghini and Bais, 2008). Drugs that may increase LDH include anabolic steroids, anesthetics, antibiotics, aspirin, and NSAIDs, whereas ascorbic acid and oxalates may decrease LDH levels (Wilson, 2008).

14.12.4.4 Serum Half-Life

The half-life is different for each isoenzyme, but it is approximately 1.6 hours in dogs (Evans, 1996). LDH₅ has a half-life of 0.6 hours in rats (Friedel et al., 1979) and 2.5 hours in rabbits. In pigs, the half-lives for LDH_{1, 2, 3, 4, and 5} are 40, 27, 12, 5, and 3 hours, respectively (Boyd, 1983). In dogs, the half-lives for LDH_{1 and 5} are 3.3 and 0.8 hours, respectively (Bär et al., 1972/1973). In rats, the site of venipuncture has an impact on LDH activity and is markedly elevated in serum from retro-orbital and ventral aorta venipuncture compared with activity in serum obtained from jugular vein and heart (Friedel et al., 1975).

14.12.5 ALDOLASE

ALD (EC 4.1.2.13 D-fructose-1, 6-bisphosphate D-glyceraldehyde-3-phosphate-lyase) catalyzes

the reversible reaction that splits D-fructose-1, 6 diphosphate to D-glyceraldehyde-3-phosphate (GLAP) and dihydroxyacetone-phosphate (DAP) in the glycolytic breakdown of glucose to lactate (Panteghini and Bais, 2008; Sherawat et al., 2008).

14.12.5.1 Tissue Distribution and Isoenzymes

ALD is present in skeletal muscle, liver, and cardiac muscle. In addition to its enzymatic activity, ALD plays a structural role in binding and polymerization of actin in the cytoskeleton (Kao et al., 1999). ALD is a tetramer with numerous isoenzymes. ALD-A₄ is found primarily in skeletal muscle, ALD-B hybrids in liver, ALD-A-C hybrids in heart muscle, and ALD-C₄ in brain and embryonic tissue (Andrews et al., 1961; Loeb and Quimby, 1989).

14.12.5.2 Effect of Disease or Tissue Injury

ALD activity has been used to help distinguish neuromuscular atrophies from myopathies in combination with CK and AST. Generally, there is no advantage in measuring ALD compared to more readily available enzyme assays such as CK, AST, and LDH. However, ALD was once the muscle-specific serum enzyme of choice and is still used in some toxicology studies (Dare et al., 2002; Loeb and Quimby, 1989).

14.12.5.3 Diagnostic Testing and Sample Handling

ALD is stable for 2 days at 25°C and 4°C and unstable at -25°C. A sex and age differences have been reported in human reference intervals (Panteghini and Bais, 2008). Hemolysis may falsely increase ALD. Drugs that may increase ALD levels are corticotrophin, cortisone acetate, and hepatotoxic drugs. Phenothiazines may decrease levels (Wilson, 2008).

14.12.5.4 Serum Half-Life

A muscle half-life of 20 days has been reported in the rat (Segal and Kim, 1963).

14.12.6 TROPONIN

Troponin is the contractile regulatory protein of skeletal muscle. Three troponin subunits form a complex that regulates interactions of actin and myosin in muscle contraction. Troponin C is the calcium-binding component, troponin I is the inhibitory component, and troponin T is the tropomyosin-binding component. Troponin is located primarily in myofibrils (94%–97%) with a small cytoplasmic fraction (3%–7%). Cardiac troponin (cTn) subunits I and T are encoded by different genes and have amino acid sequences that differ from troponins found in skeletal muscle (Panteghini et al., 2008). cTnT is not expressed in normal or diseased skeletal muscles; however, in regenerating rat skeletal muscle, a small amount of cTnT is expressed and has been reported in fetal and diseased human skeletal muscle (muscular dystrophy, polymyositis, dermatomyositis, and end-stage renal disease) (Panteghini and Bais, 2008). cTnT produced by these aberrant skeletal muscles does not react with newer generations of cardiac troponin diagnostic immunoassays (Wilson, 2008). Troponin C is not specific for heart muscle and, therefore, is not used as a cardiac marker. Cardiac troponin levels are generally not affected by skeletal muscle damage, that is, intramuscular injections, trauma, strenuous exercise, or medications. Human cardiac troponin I (cTnI) and T (cTnT) immunoassays have been used with variable success in animals (Burgener et al., 2006). Species-specific differences exist but it is apparent that cardiac troponin can be used as a marker of myocardial damage in large and small mammals and possibly birds (Apple et al., 2008; Fredericks et al., 2001; O'Brien, 1998). cTnI is a more sensitive and specific marker of myocardial ischemic injury than CKMB or myoglobin (Feng et al., 1998).

Troponin I increases in 3–6 hours, peaks at 14–20 hours, and returns to normal at 5–7 days (Wilson, 2008). Recently, drug-induced skeletal muscle injury in the rat was assessed through The Critical Path Institute's (C-Path) Predictive Safety Testing Consortium Skeletal Muscle Working Group (Burch et al., 2016). Evaluations determined through this consortium demonstrated that, for the diagnosis of drug-induced skeletal muscle injury, the biomarkers skeletal troponin I (sTnI), myosin light chain 3 (Myl3), CKMM, and fatty acid binding protein 3 outperformed assays of AST and CK with greater sensitivity and specificity in rat toxicology studies. Further, in the dog, findings have demonstrated that sTnI, Myl3, CKMM were sensitive early leakage biomarkers of skeletal muscle injury showing their translational utility beyond the rat in preclinical studies (Vlasakova et al., 2017).

14.12.7 MYOGLOBIN

Myoglobin is a heme and oxygen-containing cytoplasmic protein in skeletal and cardiac muscle and resembles a single hemoglobin subunit containing one heme per molecule (Drabkin, 1950; Kagen, 1978; Lawrie, 1950; Poel, 1949). Myoglobin can function as an oxygen carrier and can use the bound oxygen for mitochondrial function during hypoxia, but does not display the property of cooperative binding seen in hemoglobin due to the single binding site. It is a 17,800-Da protein with rapid plasma clearance. Gene-knockout mice lacking myoglobin exhibit normal exercise capacity and response to hypoxia indicating adaptation (Ordway and Garry, 2004).

Serum increases in myoglobin occur after injury to either skeletal or cardiac muscle, and myoglobin molecules from both tissues are identical. Myoglobin appears to increase earlier than CKMB after AMIs; this may relate to its low molecular weight and cytoplasmic location. However, even minor injury to skeletal muscle can result in increased serum myoglobin, and this can be mistaken for myocardial injury. Myoglobin is rapidly (8.9 ± 1.5 minutes) cleared by the kidney (Klocke et al., 1982). In humans, serum concentrations usually increase with age and men have higher concentrations than women. Myoglobin concentrations also can vary with the different fiber type composition of muscle and variation among species and ages of animals is reported (Meng et al., 1993). Rapid and quantitative commercial assays that incorporate monoclonal antibodies are available, but results vary with different assays. Test validation is necessary for each species for these commercial myoglobin assays due to the use of species-specific reference material (Walker, 2006). Myoglobin lacks specificity as an indicator of cardiac injury, but because it rises as early as 1 hour after myocardial infarction, it may be useful in the early detection of myocardial infarction before CK₂ or cardiac troponin increase. Therefore, myoglobin could be used as an early negative predictor of cardiac injury (Panteghini and Bais, 2008).

Myoglobin is readily filtered by the kidney at concentrations $>15\text{--}20$ mg/dL. Myoglobinuria is associated with brown colored urine and elevated serum CK levels. Although both myoglobinuria and hemoglobinuria can cause grossly brown urine with a positive occult blood reaction on the urine dipstick, lack of red cells in the urine sediment and lack of a pink colored serum help to distinguish myoglobinuria from hemoglobinuria. Additionally, myoglobinuria can be differentiated from hemoglobinuria by the ammonium sulfate precipitation test; hemoglobin, but not myoglobin, will precipitate out with the addition of saturated ammonium sulfate. Other methods such as ultrafiltration and isoelectric focusing in polyacrylamide gel have been used to differentiate the two. Myoglobin and hemoglobin may contribute to the impairment of renal function.

Hemolysis will interfere with myoglobin testing and drugs such as statins and theophylline will increase myoglobin levels (Panteghini and Bais, 2008).

Myoglobin increases in 2–5 hours, peaks at 8–12, and is back to normal within 24 hours in humans with muscle damage and has a reported half-life of 20 minutes to 20 hours (Panteghini and Bais, 2008). Statins and theophylline may increase myoglobin levels (Wilson, 2008). In dogs, the peak activity after artery occlusion was reported as 20–40 minutes with a half-life of 38 ± 3 minutes (Klocke et al., 1982; Ellis et al., 1985).

14.12.8 CARBONIC ANHYDRASE III

Carbonic anhydrase III is a cytosolic enzyme released from injured skeletal muscle in a fixed ratio with myoglobin. Unlike myoglobin, CA-III is not found in cardiac muscle (McGavin and Zachary, 2007). The combination of myoglobin and CA-III increases the specificity of myoglobin for the early detection of AMI. In one study, MYO-CAIII was significantly more sensitive than CK-MB but equally specific for the early diagnosis of AMI (Brogan et al., 1996; Mion et al., 2007).

14.12.9 FATTY ACID BINDING PROTEIN 3

Fatty acid binding protein 3 (Fabp3) is a member of the family of carrier proteins for fatty acids and other lipophilic substances. These proteins are thought to facilitate the transfer of fatty acids between intra- and extracellular membranes. Fabp3 is in the highest concentration in cardiac and skeletal muscles with type I fibers. Skeletal muscle necrosis can be an adverse reaction from drugs (statins) used to treat hyperlipidemia. Compared to CK, AST, and ALT, in one rat study Fabp3 had a higher concordance, sensitivity, positive, and negative predicative values and false negative rate for skeletal muscle necrosis. Additionally, Fabp3 and AST were found to be more specific biomarkers

of skeletal muscle damage than CK₃ and AST (Pritt et al., 2008). Heart-type fatty acid-binding protein has been used in the early detection of AMI (Pritt et al., 2008).

14.12.10 MYOKINES

Myokines are muscle-derived cytokines that are released with muscle contraction. Myokines possess important metabolic and anti-inflammatory properties and can act in an autocrine, paracrine, or endocrine way (Brandt and Pedersen, 2010; Scheele et al., 2009). IL-6 was the first and most extensively described myokine. Data suggest that exercise-induced acute increases in IL-6 are beneficial by increasing lipolysis, glucose availability, and being anti-inflammatory (Brandt and Pedersen, 2010). Regular exercise appears to offer protection against such chronic disorders as cardiovascular disease, type 2 diabetes, dementia, and depression; myokines may provide an explanation on how regular muscle activity positively influences mood, performance, and cognitive function (Pedersen and Febbraio, 2005). Brain-derived neurotrophic factor (BDNF), IL-8, IL-15, leukemia inhibitory factor (LIF), fibroblast growth factor 21 (FGF21), and follistatin-like-1 (FSTL1) are members of the growing list of myokines (Brandt and Pedersen, 2010).

14.13 MISCELLANEOUS TESTS OR MARKERS

14.13.1 ANTIACETYLCHOLINE RECEPTOR ANTIBODY TEST

Antiachetylcholine receptor antibodies are antibodies against the nicotinic AChR. Elevation of these antibodies is diagnostic for acquired MG (Le Panse et al., 2008). MG is a disease that displays fluctuating muscle weakness. Muscles most often involved include those of the eyes, face, neck, and limbs, and those used for chewing, swallowing, vocalization, and breathing. There is minimal muscle atrophy and no sensory abnormalities (Shelton, 2002). Acquired and congenital forms of naturally occurring MG exist but the congenital forms are rare. Experimental models of the disease have also been described in rodents and rabbits (Shelton, 1999). Acquired MG is the most common neuromuscular disorder diagnosed in dogs and can occur, but is less common, in cats. Acquired MG results from autoantibody-mediated destruction of AChR at the neuromuscular junction. Clinical presentations vary from focal MG associated with regurgitation, to generalized weakness with or without associated megaesophagus or thymoma, to acute fulminating MG. The disease course is variable and unpredictable (Shelton, 2002).

The gold standard test for the diagnosis of acquired MG is the immunoprecipitation radioimmunoassay for the detection of antibodies against AChR. About 98% of dogs with generalized MG are seropositive. A serum sample collected prior to corticosteroid therapy is the specimen of choice. Antibody titers greater than 0.6 and 0.3 nmol/L are considered diagnostic of acquired MG in the dog and cat, respectively. Potential causes for negative titers in MG patients include corticosteroid therapy, antibodies directed at other areas of the neuromuscular junction (muscle-specific kinase—MuSK), and low-affinity anti-AChR antibodies (Eymard, 2009).

A pharmacological test (Tensilon[®] also known as edrophonium chloride) can be used as a presumptive diagnosis of MG. This drug is a rapidly acting, reversible AChE inhibitor with a short duration of action. It functions by competitively inhibiting AChE thereby increasing the available supply of acetylcholine at sites of cholinergic transmission. A positive test result is a dramatic increase in muscle strength after an intravenous (IV) injection (0.1–0.2 mg/kg) (Shelton, 2002).

14.13.2 ANTITYPE 2M ANTIBODY TEST

Antitype 2M antibody testing is used to confirm masticatory muscle myositis, which is an autoimmune inflammatory myopathy characterized by jaw pain or inability to open the jaw (trismus).

Limb muscles are unaffected (Shelton, 2007). Historically, this disease has been called eosinophilic myositis or atrophic myositis, which probably represents the acute and chronic phase of the disease, respectively. The masticatory muscle (temporalis, masseter, pterygoid, and digastricus) has a unique isoform of myosin (type 2M fibers). In masticatory myositis, antibodies are produced specifically against these myofibers. A specific (100%) and sensitive (85%–90%) enzyme-linked immunoabsorbent assay (ELISA) test measures the antibody titers from serum samples collected prior to corticosteroid therapy (Melmed et al., 2004).

14.13.3 LACTATE AND PYRUVATE

Lactate and pyruvate concentrations are recommended for the evaluation of muscle disorders especially those with exercise intolerance and a suspected underlying metabolic myopathy such as mitochondrial abnormalities. Pyruvate is produced from the aerobic metabolism of glucose. Under aerobic conditions, it is converted into acetyl-coenzyme A and enters the Krebs cycle but under anaerobic conditions lactate is produced. Lactic acidosis can be associated with a variety of conditions including systemic disorders (severe hypotension, shock, malignant hyperthermia), extreme muscular activity, or a primary enzyme defect (e.g., pyruvate dehydrogenase, pyruvate decarboxylase, enzymes of the respiratory chain or enzymes of the Krebs cycle). Concurrent measurement of lactate and pyruvate and comparing the ratio of the two can help differentiate various enzyme defects (Houlton and British Small Animal Veterinary Association, 2006; Matwichuk et al., 1999). For example, a defect in pyruvate dehydrogenase has elevations in both lactate and pyruvate with a normal ratio, whereas pyruvate carboxylase deficiency or mitochondrial electron transport chain defects have increased lactate and an increased lactate to pyruvate ratio. Pre- and postexercise lactate and pyruvate samples are ideal for evaluation of metabolic myopathies. Collection techniques and sample handling can affect results of lactate and pyruvate measurements. Therefore, contacting the laboratory for correct specimen handling is recommended (Pang and Boysena, 2007). Lactate samples should be analyzed immediately. Alternatively, samples for lactate can be collected into sodium fluoride/potassium oxalate anticoagulant tubes, cooled, and centrifuged within 15 minutes and analyzed immediately or plasma can be stored at -20°C for up to 30 days. Point of care testing has made lactate measurements more readily available in the clinical setting (Matwichuk et al., 1999; Karagiannis et al., 2006). Pyruvate is more difficult to handle as samples must be diluted with an equal volume of 10% perchloric acid prior to centrifugation. Immediate analysis is preferred but plasma can be frozen at -20°C until analyzed (Olby, 2005).

14.13.4 METABOLIC TESTING

Metabolic testing of urine and plasma can be performed to identify inborn errors of metabolism that result in impaired energy production. Metabolic myopathies are a heterogeneous group of muscle disorders characterized by defects in glycogen, lipid, adenine nucleotide, and mitochondrial metabolism (Preedy and Peters, 2002; Shelton et al., 1998). Mitochondrial myopathies, fatty acid oxidation defects (FAODs), and glycogen storage diseases (GSDs) are the three main categories. Although many medications can impair muscle intermediary metabolism (e.g., statins), they are generally grouped with the toxic myopathies category. Many metabolic disorders result from carnitine deficiency (van Adel and Tarnopolsky, 2009).

14.13.5 GENETIC TESTS

Genetic testing to detect mutant alleles is available for a variety of muscle diseases and can be used to identify both carriers and affected animals. DNA for analysis can be collected from

blood, cheek swabs, or hair. Polymerase chain reaction technology is the basis for many genetic tests.

Molecular defects have been identified and animal models are available for many muscular disorders (Shelton and Engvall, 2005; Wells, 2005). Genetic testing is becoming more available. For example, in dogs, genetic testing is available for the following muscular disorders: phosphofructokinase deficiency (Smith et al., 1996), pyruvate dehydrogenase I deficiency (Cameron et al., 2007), centronuclear myopathy disease (Pelé et al., 2005), Duchenne's muscular dystrophy (Collins and Morgan, 2003; Feron et al., 2009), and myotonia congenital (Finnigan et al., 2007).

14.13.6 ELECTROLYTES AND HORMONES

Containing approximately 60%–75% of total body potassium, skeletal muscle is the largest single pool of K⁺ in the body (DiBartola, 2005). Potassium is the major or primary intracellular cation and is critical in the maintenance of polarized muscle and nerve membranes. Both hyper- and hypokalemia can have significant effects on muscle function. Hyperkalemia decreases the resting potential of muscles and initially makes the cell hyperexcitable; conversely hypokalemia increases the resting potential and hyperpolarizes the cell. Extensive muscle necrosis in conditions such as exertional rhabdomyolysis or arterial thromboembolism can cause dangerous elevations in serum potassium. Hypokalemia (2–3.0 mEq/L) can also cause generalized muscle weakness, elevations in CK, and rhabdomyolysis. Hypokalemia can occur with dietary insufficiency, renal loss, diuretics, diabetic ketoacidosis, and as an inherited disease (Stockham and Scott, 2008). Flame photometry and ion-selective potentiometry are methods commonly used to measure electrolytes. Hyperlipemia or hypergammaglobulinemia can cause errors (i.e., pseudohypokalemia) in flame photometry and indirect potentiometry by exclusion of electrolytes from the solid (lipid and protein) portion of plasma. Depending on the species and breed, hemolysis may cause pseudohyperkalemia. Pigs, rabbits, guinea pigs, hamsters, rats, some breeds of dogs (Asian breeds such as Akita and Shiba Inu), and humans have high intracellular potassium (Hall, 2007; Harvey, 2008). Potassium can also leak from platelets and leukemic cells (Stockham and Scott, 2008).

Ionized calcium affects the threshold potential of membranes. Ionized hypocalcemia lowers the threshold and increases membrane excitability while ionized hypercalcemia increases the threshold. Therefore, hypercalcemia counteracts hyperkalemia but hypocalcemia exacerbates the effects of hyperkalemia on membrane excitability (DiBartola, 2005).

Epinephrine, norepinephrine, insulin, and thyroid hormones all influence the basal activities of skeletal muscle Na⁺-K⁺-ATPase (Dukes and Reece, 2004). Myopathies associated with hypothyroidism and hyperadrenocorticism result from reduced repair and replacement of muscle protein, and progressive loss of skeletal muscle from enhanced catabolism and inhibition of myofibrillar protein synthesis, respectively (Shelton and Cardinet, 1987). Additionally, impaired insulin action that occurs in hypothyroidism and glucocorticoid excess may contribute to muscle atrophy as insulin is a potent anabolic hormone in muscle (Shelton and Cardinet, 1987).

14.14 HISTOPATHOLOGY, HISTOCHEMISTRY, AND IMMUNOHISTOCHEMISTRY

Muscle and nerve biopsy is often the best way to definitively identify a neuromuscular disorder. Conventional muscle biopsies using formalin fixation provides limited information. Frozen unfixed muscle biopsies are the “gold-standard” for evaluation of muscle disorders (Dickinson and LeCouteur, 2002). Specialized immunohistochemical and histochemical techniques using frozen skeletal muscle biopsies have greatly enhanced our understanding of muscle physiology and pathology. Histochemistry or immunohistochemistry stains used on muscle biopsies include hematoxylin

and eosin (H&E), modified Gomori's trichrome, PAS, alizarin red S, alkaline phosphatase, acid phosphatase, nonspecific esterase, lipid stains (i.e., oil red O), nicotinamide adenine dinucleotide dehydrogenase tetrazolium reductase (NADH-TR), succinate dehydrogenase (SDH), ATPase at pH 9.8, 4.3, and 4.6, and cytochrome oxidase (Dickinson and LeCouteur, 2002; see Table 14.2). Staphylococcal protein A and horseradish peroxidase (SPA-HRPO) can be used to localize immune complexes associated with muscle disorders (Shelton et al., 1985).

Immunohistochemistry is available for the detection of many proteins that result in muscular dystrophy including dystrophin, sarcoglycans, laminin α 2, dysferlin, α - and β -dystroglycans, utrophin, and spectrin (Shelton and Engval, 2002).

Frozen muscle biopsies require meticulous handling. Briefly, the muscle of interest is biopsied, the specimen trimmed to 0.5-cm blocks and mounted on thin cork squares with muscle fibers vertical to the cork (facilitating transverse sectioning), snap frozen in isopentane precooled with liquid nitrogen, sectioned in 10- μ m consecutive sections with a cryostat, and stored at -80°C (Dickinson and LeCouteur, 2002).

14.15 OMIC TECHNOLOGY

Omics refers to a field of biologic study ending in the suffix -omics, such as genomics (de Koning et al., 2007), proteomics (Doran et al., 2007, 2009), transcriptomics, interactomics, localizomics, metabolomics (O'Connell et al., 2008), and glycomics (Mahoney and Tarnopolsky, 2008). These studies assay an entire level of biological information; for example, transcriptomics evaluates the mRNA complement of an entire organism, tissue type, or cell. The advantage of omics is that it allows scientists to make thousands or even tens of thousands of measurements in a single experiment that would take months to years to generate using more conventional techniques.

Transcriptomic technology has been the major omic in the study of muscle damage. A transcriptional stimulus from muscle damage alters the expression of many genes. These genes are primarily involved in recovery from and adaptation to the damage. Adaptation can be divided into repeated-bout effect and training-induced adaptation. Two broad categories of transcriptomic technology offer rapid, efficient whole-genome transcriptional profiling. Closed techniques (complementary DNA [cDNA] and oligonucleotide arrays) have become the assay of choice because of increased availability of sequence information from major genomic studies. Closed techniques require sequence knowledge of the genome under study but are less expensive and less labor intensive than open techniques that do not require previous genomic sequence information. Open techniques include differential display (DD), serial analysis of gene expression (SAGE), and massively parallel signature sequencing (MPSS) (Mahoney and Tarnopolsky, 2008).

Proteomic profiling of animal models of skeletal muscle disorders has been valuable in understanding the molecular pathogenesis, and the effectiveness of drugs, genetic modifications, or cell-based therapies on disease progression (Doran et al., 2007). Proteomics of aging skeletal muscle is valuable in identifying the major pathophysiological pathways responsible for fiber aging and may translate into better treatment options (Doran et al., 2009). Age-related muscle wasting can be partially, but not fully, counterbalanced by exercise programs and nutritional supplements. Therefore, once these pathways are known, alternative or additional therapeutic strategies based on pharmacological interventions, cellular therapies, or gene transfer techniques can be considered for our aging population.

Omic technology combined with nonomic technology will allow researchers unprecedented knowledge to understand muscle damage, repair, recovery, adaptation, and response to therapy (Patterson et al., 2008).

14.16 ULTRASOUND, MAGNETIC RESONANCE IMAGING, ELECTROMYOGRAMS

Ultrasound and magnetic resonance imaging (MRI) are noninvasive diagnostic tools that are being used for the early diagnosis, evaluation of disease extent, therapeutic monitoring, and guidance for biopsies in skeletal muscle disease. Although histopathology is necessary for a definitive diagnosis, ultrasound and MRI have assumed a major role in the evaluation and management of many disorders such as the inflammatory myopathies. MRI is sensitive in detecting acute muscle inflammation, edema and fatty infiltration (Curiel et al., 2009). Contrast-enhanced ultrasound, which can measure perfusion, is a useful diagnostic tool in diagnosing acute inflammation in idiopathic inflammatory myopathies (Weber, 2009).

TABLE 14.3
Selected Myopathies in Animals

Classification of Disease	Examples	Animals Affected or Models
Ion channel myopathies	Acetylcholine ion channel—myasthenia gravis	Dog
	Sodium channels—periodic paralysis (HyPP)	Horse
	Chloride channels—congenital myotonia	Adr mouse, miniature schnauzer dogs
	Chloride channels—myotonic dystrophy	Various transgenic mice, horse
	Calcium channels—malignant hyperthermia	Pigs, dogs, horses
Muscular dystrophy	Dystrophin deficiency (Duchenne muscular dystrophy—DMD)	Mdx mouse, golden retriever and other dogs, cat
	Limb girdle muscular dystrophy	Various knockout mice
Disorders of glyco (geno)lysis	α -1,4 glucosidase deficiency (GSDII), Pompe's disease	Knockout mice, cattle, Japanese quail, sheep, cat, turkey
	Debranching enzyme deficiency (GSD III)	Dog
	Branching enzyme deficiency (GSD IV)	Cat, horse
	Myophosphorylase deficiency (GSD V), McArdle's disease	Cattle, sheep
	Phosphofructokinase deficiency (GSD VII)	Dog
Mitochondrial myopathies	Polysaccharide storage myopathy	Horse
	Respiratory chain complex I (NADH ubiquinone oxidoreductase deficiency)	Horse
	Cytochrome <i>c</i> oxidase deficiency	Dog
	Lipid storage disorders	Dog
	Adenine nucleotide translocator (Ant 1) deficiency	Knockout mice
Toxic/iatrogenic myopathies	Transcription factor A disorder	Tfam knockout mice
Immune-mediated myopathies	Drugs—zidovudine (AZT), chloroquine, ethanol, statins (cerivastatin), monensin, snake venom, toxic plants	
	Immune-mediated canine masticatory myositis	Dog
	Acquired autoimmune myasthenia gravis	Dog
	Experimental autoimmune myositis (EAM)	Transgenic mice

(Continued)

TABLE 14.3 (Continued)
Selected Myopathies in Animals

Classification of Disease	Examples	Animals Affected or Models
Infectious myopathy	Bacterial— <i>Clostridial</i> spp., <i>Pasteurella</i> spp., <i>Leptospira</i> spp. Protozoal— <i>Toxoplasma gondii</i> , <i>Neosporum caninum</i> , <i>Hepatozoon canis</i> , <i>Trypanosoma cruzi</i> , <i>Sarcocystis</i> spp., <i>Hammondia</i> spp. Nematode— <i>Trichina spiralis</i> , nematode larva migrans Cestode— <i>Taenia solium</i> (cysticercosis) Rickettsial— <i>Ehrlichia canis</i> Viral—Simian immunodeficiency virus (SIV), feline immunodeficiency virus (FIV)	
Endocrine myopathies	Hyper/hypoadrenocorticism myopathy Hyper/hypothyroid myopathy	Dog Dog
Nutritional myopathies	Selenium/vitamin E deficiency	
Miscellaneous/second myopathies	Renal disease Collagen IV deficiency (Bethlem myopathy) Malignant hyperthermia Ischemia—vascular, thromboembolism, hypotension Rhabdomyolysis (trauma, exertion, malignant hyperthermia) Electrolyte disorders—hypo/ hyperkalemia, hypocalcemia, hypomagnesemia	Mice Pig

14.17 NEUROMUSCULAR DISORDERS AND ANIMAL MODELS

A variety of neuromuscular diseases have been reported in animals (McGavin and Zachary, 2007; de Sousa-e-Silva et al., 2003; Evans, 2004; Shelton and Engvall, 2005). Neuromuscular diseases are disorders of muscle, motor, or sensory nerves or both muscle and nerves. Myopathies are due directly to skeletal muscle abnormalities. Neuropathies are disorders of the nerve innervating the muscle but they can produce secondary changes in the skeletal muscle such as atrophy. A select list of some of the more common diseases with a focus on myopathies is presented in Table 14.3. Diagnostic tests useful in distinguishing these disorders include genetic testing, metabolic testing for enzyme defects, antibody titers for infectious, and immune-mediated diseases, endocrine testing, evaluation of calcium, magnesium, and potassium concentrations, and muscle and nerve histopathologic biopsies (Olby, 2005; Shelton and Cardinet, 1987).

Animal models for myopathies provide vital information related to the pathophysiology of muscular diseases, the physiologic effects of exercise and aging on muscle and the efficacy and toxicity of therapeutic modalities (Shelton and Engvall, 2005; Warren and Palubinskas, 2008; Wells, 2005). Duchenne's muscular dystrophy is the most common inherited myopathy of children and two good animal models that lack dystrophin are the mdx mouse and the golden retriever muscular dystrophy dog (GRMD also known as CXMD) (Shelton and Engvall, 2005; Wells, 2005). Myotonic dystrophy is the most common human inherited adult myopathy. It is due to expansion of a triplet (CTG) repeat in the 3' untranslated region of a protein kinase gene called dystrophia myotonica protein kinase (DMPK). Transgenic mice have enhanced our understanding of this disease. Spontaneous and genetically engineered animal models are available for many of the ion channel, mitochondrial and metabolic myopathies (Coulton et al., 1988; Wells, 2005; see Table 14.3). An experimental autoimmune myositis produced by injecting homogenates of skeletal muscle and adjuvant into animals is a model of human inflammatory muscle disease. Animal testing has enhanced our understanding and reduced the risk of toxic myopathies in humans. Drugs such as zidovudine (AZT), chloroquine, ethanol, and some statins can produce skeletal myopathy (Sieb and Gillessen, 2003; Wells, 2005).

Rodents are and will continue to be extremely important models for basic research into the pathophysiology and treatment of muscle disorders. Additionally, intermediate to larger animal models are emerging as desirable models for preclinical drug trials.

APPENDIX 14.1
Tissue Source and Species Half-Life Comparison

Analyte	Tissue Source(s)	Cellular Location	Circulating half-life					Pig
			Rat	Mouse	Dog	Rabbit		
Aldolase	Skeletal and cardiac muscle, liver		20 days ^b					
ALT	Liver, skeletal muscle	Cytosol, mitochondria (minor)	4.5-8 h ^c 0.9-3 h ^d		48-72 h ^e 149 min ^{-1/f} 59 ± h ^g 3-60 h ^{f/h}	5 h ⁱ 5.1 h ^d		
AST	Liver, skeletal and cardiac muscle, RBCs	Cytosol, mitochondria	1.6 h ^{d/i}		263 min ^k 22 ± 1.6 h ^{l/g/h}	2.5 h ^{d/j}	18 h ^j	
CK	Skeletal, cardiac and smooth (minor) muscle	Cytosol, mitochondria	0.5-1 h ⁱ		< 2 hr 2.61 hr ^r 1-3 h ⁱ 4.7 h ^d	9 h ⁱ	5.2 h ^{d,o}	
CK isoenzymes	MM – Skeletal muscle MB and MM – Cardiac muscle BB – Brain				CKMM: 77 min ^p			

(Continued)

APPENDIX 14.1 (Continued)

Tissue Source and Species Half-Life Comparison

Analyte	Tissue Source(s)	Cellular Location	Circulating Half-Life				
			Rat	Mouse	Dog	Rabbit	Pig
LDH	Liver, skeletal and cardiac muscle, RBCs		0.6 h ^d			2.5 h ^d	
LDH isoenzymes	LDH-1: Cardiac muscle, RBCs and brain LDH-2: Reticuloendothelial system LDH-3: Lung LDH-4: Kidney, LDH-5: Liver and skeletal muscle			LDH-1: 3.3 h ^{o,g} LDH-5: 0.8 h ^{o,g}	LDH-5: 0.8 h ^d		LDH-5: 3 h ^g
Myoglobin	Skeletal and cardiac muscle; not found in smooth muscle				8.9 ± 1.5 min ^f 5.5 ± 0.2 min ^p		
Troponin	Skeletal and cardiac isoforms; not found in smooth muscle		Cardiac troponin I: 6 h ^a , 0.8 h ^b Skeletal troponin I is thought to have similar characteristics as cardiac-type ^u	Cardiac troponin I: 1.9 h ^c			

APPENDIX 14.1 (Continued)**Tissue Source and Species Half-Life Comparison****Tissue Source (Cellular/Subcellular Location) and Species Half-Life Comparison for Skeletal Muscle Analytes^a**

15 Evaluation of Bone Function and Injury

Holly L. Jordan and Bruce E. LeRoy

CONTENTS

15.1	General Concepts.....	515
15.2	Cellular and Molecular Mechanisms of Bone Physiology and Pathophysiology	516
15.3	Biochemical Indicators of Bone Formation and Resorption	517
15.4	Biochemical Markers of Bone Injury	519
15.4.1	Calcium	519
15.4.2	Phosphorus	522
15.4.3	Magnesium	524
15.4.4	Parathyroid Hormone	525
15.4.5	Vitamin D.....	527
15.4.6	Calcitonin	528
15.4.7	Alkaline Phosphatase, Bone Isoenzyme	529
15.4.8	Osteocalcin.....	531
15.4.9	Molecules Associated with Collagen Maturation and Degradation: Propeptides; Cross-Linked C- and N-Telopeptides; Pyridinoline, Deoxypyridinoline	532
15.4.10	Tartrate-Resistant Acid Phosphatase Isoform 5b	535
15.4.11	Cathepsin K.....	536
15.4.12	Matrix Metalloproteinases and Tissue Inhibitor of Metalloproteinases.....	536

15.1 GENERAL CONCEPTS

The skeleton has a key role in locomotion, protecting vital organs, and regulating calcium and phosphorus metabolism. A wide range of disorders may perturb bone metabolism and/or affect mineral ion concentrations, particularly nutritional, renal, endocrine, or neoplastic etiologies. Markers of bone status are valuable not only for clinical appraisal in human and veterinary medicine, but also as endpoints in the experimental animal models of human bone disorders, such as osteoporosis, metastatic bone disease, and fracture healing, and in identifying the toxic effects of novel xenobiotics on bone during preclinical evaluations.

Biochemical assessment of skeletal system injury may include quantification of serum and urine mineral ions such as calcium, phosphorus, and magnesium; evaluation of circulating hormones involved in bone metabolism, such as parathyroid hormone (PTH) and vitamin D; and evaluation

of other biological molecules reflecting the balance of bone formation and resorption, the so-called “bone turnover biomarkers,” for example, bone alkaline phosphatase (BALP), osteocalcin (OC), and collagen telopeptides (Herrmann, 2011). In clinical practice, fluid markers provide useful adjuncts to more cumbersome or invasive measures of bone health, such as bone density measurement by dual-energy x-ray absorptiometry (DEXA) and bone biopsy. However, because fluid biomarkers tend to reflect the whole-body balance between bone formation and resorption only at the time of sampling, serial measurements may be necessary to detect progression of disease or response to interventions. Bone turnover markers are available for use in humans and many other species; most are measured in serum, plasma, and/or urine by immunoassay methods, for example, ELISA, RIA, and/or chemiluminescence. It is essential to verify that the biomarkers of interest are validated for the species under consideration, as not all markers or reagents are appropriate across species. In addition to species-specific factors, application of these markers requires consideration of preanalytical factors, such as sample handling, gender, age, diet, and cyclical influences (Cremers and Garner, 2006).

15.2 CELLULAR AND MOLECULAR MECHANISMS OF BONE PHYSIOLOGY AND PATHOPHYSIOLOGY

Bone is a dynamic tissue. Even in adult animals, the skeletal system undergoes constant remodeling. Basic multicellular units (also called bone remodeling units) intricately regulate the formation and resorption of bone in response to load stresses and metabolic demands (Seeman and Delmas, 2006). In people, resorption requires approximately 3 weeks per site and rebuilding bone requires 3–4 months (Rodan and Martin, 2000). At the start of the resorptive phase, osteoclasts are recruited from hematopoietic stem cell precursors. Under the influence of macrophage colony stimulating factor and receptor activator of nuclear factor kappa B ligand (RANK-ligand or RANK-L), these precursor cells differentiate, mature, and fuse into multinuclear osteoclasts with ruffled borders that form sealed resorption lacuna. Into these spaces, osteoclasts secrete hydrochloric acid, cathepsin K (CTSK), and other factors that dissolve mineral and degrade the extracellular matrix. With cessation of resorption, osteoclasts undergo apoptosis and bone formation is initiated by osteoblasts recruited from mesenchymal stem cells. Osteoblasts produce collagen type I, alkaline phosphatase, OC, and other components, leading to the formation of an extracellular matrix that subsequently mineralizes. After bone formation, the osteoblasts undergo apoptosis or they become incorporated within bone as osteocytes, which function as mechanosensors (Herrmann, 2011; Sorensen et al., 2007).

The specific molecular mechanisms regulating bone remodeling are very complex, and this field is rapidly evolving. Three important mediators are members of the tumor-necrosis factor family: RANK, RANK-L, and osteoprotegerin (OPG) (Boyce et al., 2008). Upon stimulation by PTH, the active form of vitamin D (1,25(OH)₂D also called calcitriol), parathyroid hormone-related protein (PTHrP), and other cytokines and hormones, the osteoblasts upregulate the expression of RANK-L, which stimulates the resorption by mature osteoclasts and the recruitment of osteoclast precursors (Ralston, 2009). Matrix-embedded osteocytes and chondrocytes are also a major, if not the major, source of RANK-L in bone and can stimulate osteoclastogenesis as well (Xiong et al., 2011). OPG is a decoy or “pseudo-receptor” for RANK-L. It is secreted by osteoblasts and acts as an osteoprotector or negative regulator of bone resorption (Boyce et al., 2008; Herrmann, 2011). Soluble OPG captures and inactivates RANK-L in the osteoblast membrane, preventing it from coupling with RANK on osteoclasts. This leads to inhibition of osteoclast function and survival (Capen and O’Brien, 2004). Osteoclasts, in turn, promote bone formation by modulating osteoblast function through the release of bone matrix-embedded growth factors during resorption, such as insulin-like growth factors, transforming growth factor- β , fibroblast growth factors, and bone morphogenetic proteins, which stimulate differentiation and activation of osteoblast precursors (Kraenzlin and Seibel, 2006).

While PTH and 1,25(OH)₂D upregulate bone resorption and circulating calcium concentrations, other mediators, such as calcitonin, inhibit osteoclastogenesis and reduce free calcium. Both PTH and

calcitonin modulate $1,25(\text{OH})_2\text{D}$ concentrations through regulation of the renal 25-hydroxyvitamin D_3 1α -hydroxylase gene. During normocalcemic states, calcitonin predominates, whereas PTH predominates in hypocalcemic states (Zhong et al., 2009). Both factors as well as fibroblast growth factor 23 (FGF23), decrease renal resorption of phosphorus (Capen and O'Brien, 2004).

Maintaining whole-body bone mass depends not only on healthy function of the skeletal system, but also on coordinate pathways in other systems and organs, including the nervous system and adipose tissue. For example, the adipose hormone, leptin causes bone loss via a hypothalamic/sympathetic nervous system signaling pathway, which inhibits osteoblast proliferation and stimulates RANK-L-mediated osteoclastic bone resorption (Karsenty, 2006). Hyperinsulinemia due to impaired hepatic insulin clearance is associated with decreased bone turnover in mice (Huang et al., 2010). Bone tissue can mediate metabolic pathways as well via the osteoblast-derived uncarboxylated form of OC, which modulates insulin production and glucose metabolism (Wei and Ducy, 2010). The full implications of the complex interactions between bone, adipose, pancreas, and other tissues are still being defined.

15.3 BIOCHEMICAL INDICATORS OF BONE FORMATION AND RESORPTION

Perturbations in some bone turnover markers may correlate with the presence of histologic changes in many bone diseases, such as osteoporosis and bone malignancies (Allen, 2003; Cremers and Garnero, 2006; Brown and Chow, 2009), although the premonitory value of currently available bone markers has been somewhat limited. In many instances, these markers are not sufficiently sensitive or specific to serve as independent diagnostic endpoints and must be combined with additional disease markers, functional parameters, and/or imaging modalities (Coleman et al., 2011). Serum and urine markers have been used to monitor responses to therapeutics, to identify patients at risk of fracture, and to identify patients that are most likely to benefit from antiresorptive therapy. Table 15.1 outlines key characteristics of commonly used biomarkers of bone formation and resorption. Select markers have been used for prognosticating bone metastasis with some success, for example, procollagen type I N propeptide (PINP) and BALP (Joerger and Huober, 2012; Selvarajah and Kirpensteijn, 2010).

Concentrations of bone formation markers may vary with the stage of bone formation. For example, BALP is a characteristic marker of osteoblast proliferation; PINP and procollagen type I C propeptide (PICP) characterize the matrix maturation phase; and OC is primarily expressed during mineralization (Herrmann, 2011). Therefore, evaluation of bone turnover should include at least one marker of bone formation and one marker of bone resorption (Herrmann, 2011). Bone resorption is characterized by constituents synthesized by osteoclasts (i.e., tartrate-resistant acid phosphatase 5b [TRACP5b] and CTSK) or released from the extracellular matrix by osteoclasts (i.e., cross-linked N-telopeptide [NTX-1] and C-telopeptide [CTX-1]). Indeed TRAP5b and CTSK concentrations correlate with osteoclast numbers, while CTX-1 and NTX-1 reflect resorptive activity (Herrmann, 2011).

Variability in bone biomarkers owing to factors such as age and cyclical rhythms have been investigated in some common laboratory animals (Allen et al., 1998). Similar to humans, nonhuman primates have high intra- and interindividual variability for most bone markers (Legrand et al., 2003). Diurnal variation in bone turnover markers has been described in rats (Muhlbauer and Fleisch, 1990), mice (Tonna et al., 1987), rabbits (Hansson et al., 1974), and dogs (Ladlow et al., 2002). Dogs show significant diurnal variation in serum concentrations of OC, BALP, pyridinoline cross-linked carboxyterminal telopeptide of type I collagen (ICTP), and urinary deoxypyridinoline (DPD) (Ladlow et al., 2002). Interestingly, there is no significant difference in bone marker concentrations between normal toy and giant breed dogs (Breur et al., 2004). Owing to dynamic changes in bone markers during growth, age and gender-specific reference intervals are essential. Human reference intervals for serum OC, BALP, PINP, and collagen degradation products are highest during childhood and gradually decline with age (Huang et al., 2011). Legrand et al. (2003) reported

TABLE 15.1
Bone Turnover Biomarkers

Bone Formation	Abbreviation	Comments	Species for Which Assays Are Available
Bone isoenzyme of alkaline phosphatase	BALP (serum)	Produced by osteoblasts; marker of osteoblast differentiation	ELISA: mouse, rat, dog, and monkey Wheat-germ lectin precipitation: dog and monkey
Osteocalcin	OC (serum)	Osteoblast-derived protein released into the bone matrix and the circulation; fragments released during bone resorption from the extracellular matrix, thus reflects bone turnover rather than simply formation, unless assay measures the intact form. Also important in energy metabolism	Mouse, rat, dog, monkey, rabbit, and guinea pig
Procollagen type I C or N propeptide	PICP, PINP (serum)	Released from newly synthesized procollagen prior to incorporation of collagen into bone matrix; marker also of collagen type I formation	Mouse, rat, dog, monkey, rabbit, guinea pig, and pig
Bone Resorption			
C-terminal cross-linking telopeptide of collagen type I collagen	CTX-1 (serum or urine)	Released during osteoclastic bone resorption by cathepsin K	Mouse, rat, dog, monkey, rabbit, guinea pig, and pig
N-terminal cross-linking telopeptide of type I collagen	NTX-1 (urine)	Released during osteoclastic bone resorption by cathepsin K	Mouse, rat, dog, monkey, rabbit, guinea pig, and pig
C-terminal cross-linking telopeptide of type I collagen generated by MMPs	CTX-MMP	Released during pathologic bone resorption by matrix metalloproteases	Mouse, rat, dog, and sheep
Urinary hydroxyproline	Urine HYP	Released from collagen triple helix during bone resorption	Not species specific
Urinary pyridinoline and deoxypyridinoline	Urine PYD Urine DPD	Released from mature collagen during bone resorption	Mouse, rat, dog, monkey, rabbit, guinea pig, pig, and sheep
Cathepsin K	CTSK	Essential protease for collagen degradation that is mainly produced by osteoclasts; marker of osteoclast number	Mouse, rat, dog, rabbit, and pig
Tartrate-resistant acid phosphatase 5b	TRACP5b	Enzyme produced by osteoclasts that is involved in intracellular processing of degraded organic bone matrix; marker of osteoclast number, bone resorption	ELISA: mouse, and rat Enzymatic test (TRAP): all species

similar trends in cynomolgus monkeys. In addition, concentrations in males are generally higher than female monkeys.

Sample handling can be an important factor with more labile markers such as OC, which requires rapid processing and freezing for long-term storage. To avoid the effect of transient changes in urine concentration or dilution, urine marker concentrations should be normalized to urine creatinine concentration as a ratio (i.e., urine NTX-1/creatinine) or urine markers can be measured from samples collected over an extended period and reported as the total amount excreted during that collection period (i.e., urine volume \times urine NTX-1 concentration = total amount of NTX-1 excreted/collection period). Indeed, total excretion/collection period may be more accurate in situations where urine creatinine is altered by significant renal injury or changes in muscle mass. For analytes that can be measured in both serum and urine “spot” samples collected simultaneously (usually calcium, phosphorus, or electrolytes), fractional excretion (FE) calculations based on serum and urine creatinine may be applied when overnight collections are not feasible (Stockham and Scott, 2008b). While the routine clinical use of FE tests is limited in veterinary medicine, they have shown value in evaluating mineral deficiencies, in toxicology studies, and in endocrine/renal research (Lefebvre et al., 2008).

15.4 BIOCHEMICAL MARKERS OF BONE INJURY

15.4.1 CALCIUM

Physiology, function, and half-life: The majority of the body’s calcium is in the inorganic portion of the skeleton, which serves as a reservoir for maintaining circulating free (ionized) calcium within a very narrow critical range (approximately 1.1–1.6 mmol/L depending on species) under the influence of mediators such as PTH, vitamin D, and calcitonin (Capen and O’Brien, 2004). Maintenance within this range is essential given the central role that free calcium plays in signal transduction throughout the body and the detrimental effects that can result from dysregulation, such as seizures, tetany, and heart dysfunction. Blood calcium is present in three forms. In mammalian species tested to date, approximately 50% is in the free form (the biologically active ionized form or iCa), 40%–45% is bound to serum proteins (pCa), principally albumin, and the remainder is complexed with citrates, lactate, and other diffusible anions (cCa) (Stockham and Scott, 2008a). Although complete fractionation data is limited for most laboratory animals, serum calcium fractions have been evaluated in healthy dogs, cats, and horses: in these species, pCa is 56%, 40%, and 47%, respectively; iCa is 34%, 52%, and 49%, respectively; and cCa is 10%, 8% and 4%, respectively (Schenck et al., 1996; Schenck et al., 2005; Lopez et al., 2006).

Circulating calcium is maintained via ingestion and uptake in the intestine and through resorption from bone and renal tubules. This relies on a complex network of receptors and transporters (O’Toole, 2011). Within the gut of most mammals, 1,25(OH)₂D is required to induce intestinal epithelial cell uptake of calcium (Perez et al., 2008). Calcitonin and PTH act indirectly on the intestine by stimulating 1 α -hydroxylase in the kidney, which increases 1,25(OH)₂D production. It has been suggested that calcitonin is the predominant mediator during normocalcemia and PTH predominates during hypocalcemia (Zhong et al., 2009); PTH also stimulates calcium resorption from bone and distal renal tubules in response to hypocalcemia. 1,25(OH)₂D stimulates calcium release from bone by inducing osteoclastogenesis. In the kidney, nonprotein-bound calcium is freely filtered at the glomerulus and most is passively resorbed in the proximal tubules and thick ascending loop of Henle via paracellular pathways. Active uptake occurs primarily in the distal tubules under the influence of PTH (Allgrove, 2009; O’Toole, 2011).

Total calcium is commonly measured in serum, lithium heparinized plasma, and urine by spectrophotometric methods using metallochromic dyes. Atomic absorption methods are more accurate, but less accessible for most laboratories. Plasma anticoagulants containing chelators, such as EDTA or citrate, should not be used because these will falsely decrease calcium concentrations. To avoid

the effects of urine concentration or dilution, it is best to normalize urine calcium concentration to urine creatinine concentration as a ratio (calcium in mmol/L/creatinine in mmol/L). Total urine calcium excreted over a defined collection period (usually 12–24 hours) may also be used to assess renal handling of calcium.

As it is the biologically active form, the measurement of iCa by ion-specific electrode is often recommended for accurately assessing the abnormalities in blood total calcium (Schenck and Chew, 2005). Concentrations of iCa are influenced by temperature and pH (iCa concentration and pH are inversely related) and there is debate on optimal sample and handling regimes. Each laboratory should determine the appropriate handling and storage conditions for the species of interest in the context of their specific methodology. In general, serum or lithium heparinized whole blood is preferred over plasma (Krahn and Lou, 2008; Unterer et al., 2004). Samples should be collected anaerobically to prevent pH changes; some investigators recommend placing whole blood samples on ice until analysis (Boink et al., 1992). Serum should be separated immediately to prevent lactic acid production by erythrocytes, which can cause artifactual increase in iCa. Analysis should be performed within 8 hours, if samples are at room temperature (Unterer et al., 2004), although Schenck et al. (1995) found canine serum samples were stable for up to 72h. If necessary, serum can be stored at -20°C for up to 6 weeks (Boink et al., 1992).

Because of the close correlations between blood concentrations of total calcium, iCa, and albumin, formulae have been proposed for some species in an attempt to adjust or “normalize” total calcium results that are low due to decreased albumin concentrations and to attempt to predict iCa status without performing direct measurements (Meuten et al., 1982; Siggaard-Andersen et al., 1983). Studies have refuted the accuracy of this practice (Schenck and Chew, 2005). While the interpretation of total calcium changes should take into consideration qualitative changes in serum albumin and protein concentrations, strict reliance on calculated/adjusted values for total calcium or for prediction of iCa is discouraged (Schenck and Chew, 2005).

Significance of increased concentration/activity: Causes of elevated serum calcium (hypercalcemia) include elevated PTH or PTHrP (i.e., primary hyperparathyroidism, paraneoplastic hypercalcemia), hypervitaminosis D (i.e., dietary supplementation, toxic plants containing vitamin D₂, rodenticides containing cholecalciferol, paraneoplastic hypervitaminosis D, granulomatous disease), decreased renal excretion of calcium (i.e., renal insufficiency, diuretic drugs, hypoadrenocorticism), hypomagnesemia, steroid hormones, and hyperproteinemia (Lumachi et al., 2011; Stockham and Scott, 2008a; Raisz et al., 1977). High serum calcium concentrations can lead to organ dysfunction secondary to mineralization of soft tissues, particularly in the kidney and cardiovascular system. Hypercalcemia may also interfere with normal receptor-mediated cell signaling and cause loss of urine concentrating ability and clinical changes such as altered mentation, and constipation. In people, hypercalcemia is most frequently due to increased secretion of PTH or PTHrP (Lumachi et al., 2011). PTH-secreting parathyroid adenomas are the most common cause in human outpatients (Gopinath and Mihai, 2011). PTHrP is a hormone secreted by tumor cells that mimics PTH. In canine patients, common etiologies of hypercalcemia are paraneoplastic secretion of PTHrP (most commonly associated with lymphoma and apocrine gland carcinomas of the anal sacs), renal failure, hyperparathyroidism, and hypoadrenocorticism (Messinger et al., 2009; Rosol and Capen, 1992). In Fisher 344 rats, hypercalcemia has been associated with testicular interstitial tumors (Rice et al., 1975). Activated macrophages expressing extrarenal 1α -hydroxylase can produce hypercalcemia due to hypervitaminosis D (Christakos et al., 2010). Thus, hypercalcemia may be observed with granulomatous disorders such as sarcoidosis and disseminated fungal infections (Jacobs and Bilezikian, 2005).

Hypercalciuria occurs with a variety of conditions, including congenital defects in calcium-sensing receptors and transporters (Stechman et al., 2009), primary hyperparathyroidism, renal tubular acidosis, hypervitaminosis D, diabetes, and with certain drugs, such as, furosemide, acetazolamide, ammonium chloride, and others (Ordóñez et al., 1998; Foley and Boccuzzi, 2010).

Unlike most laboratory animals, rabbits normally excrete large amounts of calcium in their urine with mean fractional excretion of approximately 45%, compared with <2% in most other species (Buss and Bourdeau, 1984).

Significance of decreased concentration/activity: Decreased serum calcium (hypocalcemia) can be caused by hypoalbuminemia (factitious), decreased PTH activity (i.e., primary hypoparathyroidism, pseudohypoparathyroidism, hypomagnesemia), insufficient mobilization of calcium from bone or intestinal absorption (i.e., hypovitaminosis D, vitamin D receptor abnormalities, lipid malabsorption, exocrine pancreatic insufficiency, pregnancy, lactation, hypercalcitoninism, nutritional hypocalcemia, oxalate toxicity), excess renal calcium excretion, calcium-binding anions (i.e., EDTA, citrate, oxalate, tetracycline), renal failure, myopathies, and urinary tract obstruction [Stockham and Scott, 2008a]). Clinically, hypocalcemia can result in diseases such as rickets with attendant lameness and deformity, altered myocardial contractility, dystocia, tetany, and/or seizures, depending on the species. The threshold for manifestation of clinically evident signs varies in dogs, although signs usually manifest when serum free calcium is <0.8 mmol/L and include muscle tremors, fasciculations, facial rubbing, cramping, aggression, stiff gait, and seizures (Schenck and Chew 2008).

Low serum protein, particularly hypoalbuminemia (80% of protein-bound calcium binds albumin versus 20% to globulins) is a very common cause of low total calcium concentration. Thus, disorders associated with loss or impaired synthesis of serum proteins (i.e., renal injury, protein-losing enteropathy, malabsorption, hepatic failure, etc.) may be accompanied by low serum total calcium. Because iCa is unaffected by decreased serum albumin alone, animals with low serum/plasma albumin do not manifest clinical signs of hypocalcemia. PTH deficiency is a cause of hypocalcemia and may be observed with parathyroid gland injury (i.e., inflammation, trauma, surgery, neoplasia) or due to inadequate release of PTH. Aberrant PTH receptor activity on target tissues, or pseudohypoparathyroidism, is a rare cause of hypocalcemia. Hypomagnesemia can result in hypocalcemia due to apparent refractoriness of bone and kidney to PTH (Yamamoto et al., 2011). Hypocalcemia due to hypovitaminosis D can have multiple underlying causes, including renal injury, fat malabsorption, dietary deficiency, and protein-losing enteropathy. For example, dogs with inflammatory bowel disease may become hypocalcemic (Gow, et al., 2011). Minipigs subjected to subtotal gastrectomy develop transient decreases in serum calcium, which normalizes by 12 months postoperatively (Maier et al., 1997). Primates fed diets low in vitamin D, housed indoors and not provided artificial sunlight, or fed diets with high phosphorus content may develop hypocalcemia and nutritional secondary hyperparathyroidism (commonly referred to as cage paralysis, simian bone disease, or osteomalacia) (Capen and O'Brien, 2004). Rats administered a calcium-deficient diet have decreased serum total calcium, although iCa is usually normal due to heightened serum vitamin D and PTH concentrations leading to increased bone resorption (D'Amour et al., 2011). Decreases in blood calcium concentrations may also occur with excess urinary calcium loss secondary to metabolic alkalosis, antidiuretics (e.g., furosemide), and renal toxins (e.g., ethylene glycol) (Stockham and Scott, 2008a).

Influencing factors (sources of error, interferences, dietary/fasting, etc.): Sources of error in total or iCa determination include using an inappropriate anticoagulant, such as those containing EDTA, oxalate, or citrate. Even heparin, which is an anion, binds calcium to some extent and heparin concentrations should be limited to 15 U/mL of blood when measuring iCa (Stockham and Scott, 2008a). Analytical errors in iCa measurement occur if pH is altered through excessive exposure to air (a vacutainer or capped syringe is recommended) or due to lactic acid from erythrocytes, which occurs when serum is not separated from the clot within 1 hour of collection. Fasting is recommended to limit effects of dietary calcium intake and postprandial alkalosis (Stockham and Scott, 2008). Serum separator tubes are not recommended for determination of iCa due to the presence of calcium-containing material and acidifying products. However, the clinical impact is small; iCa is approximately 0.02 mmol/L higher than when collected in plain serum tubes (Larsson and Ohman, 1985). When measuring calcium concentrations in urine, it has been recommended that samples be acidified to dissolve

precipitated calcium (Foley and Boccuzzi, 2010). However, the difference between calcium concentrations in acidified and nonacidified samples from human volunteers is actually quite small (Feres et al., 2011) and in the absence of clinical impact, some investigators refute this requirement, unless urine samples must be stored 12 hours or more at 4°C prior to analysis (Sodi et al., 2009).

Age, gender, and strain differences in serum total and ionized calcium have been observed in mice (Frith et al., 1980; Leiben et al., 2012; Barrett et al., 1975; Tordoff et al., 2007; Champy et al., 2008; Mazzaccara et al., 2008). Serum free calcium increases with age in rats and is higher in females than males (D'Amour et al., 2011). Pregnant rats have higher total calcium than nonpregnant cohorts (Liberati, 2004). Lactation reportedly lowers total calcium in sows (Lauridsen et al., 2010). Circadian rhythm in total but not free calcium concentration has been noted in macaques likely due to albumin fluctuation (Hotchkiss and Jerome, 1998). Fasting may decrease not only free calcium, but also total calcium concentrations in some species, such as the pig (Baetz and Mengeling, 1971). In rabbits, increased dietary calcium can markedly increase serum total calcium concentration (Redrobe, 2002) while calcium restriction initially causes an increase, followed by decreases, in intestinal calcium absorption (Barr, 1991).

15.4.2 PHOSPHORUS

Physiology, function, and half-life: Phosphorus is the second most abundant mineral in the body next to calcium and the majority of phosphorus (85%) is complexed with calcium in hydroxyapatite in the skeleton (Khoshniat et al., 2011). In soft tissue, phosphate has a structural role in cell membranes, nucleoproteins, and nucleic acids. It is also vital in cellular energetics, cell signaling, muscle and nerve function, tissue oxygenation, and lipid metabolism (Khoshniat et al., 2011). In plasma, inorganic phosphate is present as monovalent (H_2PO_4^-) and divalent (HPO_4^{2-}) anions; the ratio of the monovalent and divalent forms is pH-dependent varying from 1:1 in acidosis, 1:4 at pH 7.4 to 1:9 in alkalosis. In people, most plasma phosphate is free (55%), 35% is complexed with sodium, calcium, or magnesium and 10% is protein-bound. Serum phosphate reference intervals for adult humans are in the range of 0.8–1.5 mmol/L (Penido and Alon, 2012); for adult dogs, the range is 0.8–1.8 mmol/L (Bates, 2008). Primary mediators of phosphate homeostasis include dietary phosphate, 1,25(OH)₂D, PTH, and phosphate regulating factors or phosphatonins, such as, secreted frizzled related protein-4, matrix extracellular phosphoglycoprotein, and particularly FGF23. Although, it is found in many tissues, FGF23 is primarily expressed in bone where it is produced by osteocytes and to a lesser extent, osteoblasts. Its expression is triggered by hyperphosphatemia, increased dietary phosphate concentrations, and increased 1,25(OH)₂D concentrations (Prié et al., 2009; Alon, 2011). Upon ingestion, phosphate is absorbed primarily in the ileum. Intestinal uptake is regulated by dietary phosphate content and 1,25(OH)₂D, although it is also affected by epidermal growth factor, glucocorticoids, estrogens, metabolic acidosis, FGF23, and other phosphatonins (Marks et al., 2010). Excretion occurs via the kidney where phosphate is freely filtered by the glomerulus and can be resorbed in the proximal tubule via sodium-dependent phosphate cotransporters under the tight regulation of PTH and FGF23, which act as phosphaturic agents (Lee and Partridge, 2009). In concert with its cofactor, Klotho, a transmembrane protein highly expressed in the kidney and to a lesser extent in the parathyroid glands, FGF23 stimulates proximal renal tubule cells to downregulate phosphate reabsorption and vitamin D production and suppresses PTH secretion by the parathyroid glands (Alon, 2011). In the skeleton, phosphorus mobilization is promoted by PTH, vitamin D, and FGF23. Increased plasma inorganic phosphate concentration in turn inhibits osteoclast differentiation and bone resorption (Khoshniat et al., 2011).

Significance of increased concentration/activity: General causes of increased phosphate concentrations in blood (hyperphosphatemia) include decreased urinary phosphate excretion, increased phosphate absorption from the intestine, and shift of intracellular phosphate to the extracellular

fluid. Common etiologies of reduced renal excretion include prerenal, renal, and postrenal conditions that reduce glomerular filtration rate, such as dehydration, kidney injury, urinary bladder obstruction or rupture, primary hypoparathyroidism, pseudohypoparathyroidism, and acromegaly (Bates, 2008). Elevated intestinal uptake of phosphate is seen with phosphate-containing laxatives or enemas, phosphate-containing therapeutics, conditions associated with excess vitamin D, and diets with a low Ca:P ratio. Myopathies and tumor lysis syndrome can cause increased blood phosphate concentrations due to release of intracellular phosphate. Lactic acidosis, respiratory acidosis, untreated diabetic ketoacidosis, and hyperadrenocorticism may also be associated with elevated serum phosphate (Burtis et al., 2006; Stockham and Scott, 2008a). Clinically, a rapid rise in plasma phosphate may be associated with a concomitant decrease in calcium and manifestations of hypocalcemia (tetany, seizures, etc.). Protracted hyperphosphatemia can lead to secondary hyperparathyroidism and soft-tissue mineralization.

Significance of decreased concentration/activity: General causes of decreased phosphate concentrations in blood (hypophosphatemia) include increased urinary phosphate excretion, decreased intestinal phosphate absorption, shift of phosphate from the extracellular compartment to the intracellular compartment, and defective mobilization of phosphate from bone. Excessive urinary phosphate loss occurs with prolonged diuresis due to therapeutics or tubular defects, genetic defects, and increased PTH or PTHrP activity (Aono et al., 2009). Uptake of phosphate can be limited by malabsorption, vomiting/diarrhea, vitamin D deficiency, phosphate-binding agents, and phosphate-deficient diets. Hyperinsulinemia, glucose infusion, hyperalimentation, and respiratory alkalosis result in decreased phosphate blood concentrations due to a shift of phosphate from the extracellular fluid into cells. Insulin promotes transport of phosphate and glucose into cells. Respiratory alkalosis causes increased intracellular CO₂ and pH, which stimulates the glycolytic pathway, particularly phosphofructokinase and the production of increased intracellular sugar phosphates drives phosphate into cells from the circulation (Amanzadeh and Reilly, 2006). Severe catabolic states (e.g., thermal injury, diabetic ketoacidosis, and severe emaciation) have been associated with hypophosphatemia. Severe hypophosphatemia (<1.0 mg/dL or 0.3 mmol/L) can cause hemolysis due to ATP depletion and increased red blood cell fragility. Low phosphorus concentrations may also lead to decreased production of erythrocyte 2,3-bisphosphoglycerate resulting in exacerbation of tissue hypoxia (Harvey, 1997). Although rare, prolonged dietary phosphorus deficiency can cause rickets due to resorption of both calcium and phosphorus from bone stores (Capen and O'Brien, 2004).

Influencing factors (sources of error, interferences, dietary/fasting, etc.): Serum inorganic phosphate concentration is often referred to as “phosphorus” concentration, although phosphorus actually circulates in the form of inorganic and organic phosphate, not the elemental form. The concentration of circulating phosphate is usually expressed in terms of circulating inorganic phosphorus concentration (mg/dL; 1 mg/dL of inorganic phosphorus is equal to 0.32 mmol/L of phosphate) (Stockham and Scott, 2008a). Most assays use ammonium molybdate, which reacts with inorganic phosphate in serum, heparinized plasma, or urine to form a colored phosphomolybdate complex that is detected by spectrophotometer. Some methods use vandate–molybdate and enzymes (Burtis et al., 2006). Anticoagulants containing EDTA, citrate, and oxalate should not be used due to interference with complex formation. When measuring inorganic phosphorus in the urine, samples should be acidified to solubilize precipitated forms. Hemolysis, icterus, and lipemia can cause interference with these assays. Hemolysis releases intracellular phosphate in some species and can falsely elevate measurements (Capen and O'Brien, 2004). High serum immunoglobulins concentrations may also give falsely elevated results with some methods due to precipitation of the immunoglobulins (Bowles et al., 1994). Serum phosphate concentrations may be influenced by age, strain, gender, and pregnancy (Barrett et al., 1975; Champy et al., 2008; Mazzaccara et al., 2008; Liberati et al., 2004). Generally, growing animals have higher concentrations that decrease with age (Wolford et al., 1986; Russo and Nash, 1980; Buchl and Howard, 1997; Penido and Alon, 2012) and

concentrations decrease during pregnancy and lactation. In rats, serum phosphate decreases with age and is higher in males than females (D'Amour et al., 2010). Seasonal variation in serum phosphate has been reported in dogs (Southern et al., 1993). Concentrations may be increased postprandially depending on the diet (Shuto et al., 2009). High-meat diets may increase serum phosphate due to phosphate content; whereas, high-carbohydrate diets are associated with lower concentrations due to intracellular shift in response to glycolysis (Capen and O'Brien, 2004).

15.4.3 MAGNESIUM

Physiology, function, and half-life: Bone contains approximately two-thirds of the body's magnesium: 20% is in muscle and 11% in other soft tissues. High concentrations are present in the cytosol of most cells (second only to potassium), reflecting its role as a cofactor for ATP and glycolytic enzyme function as well as for proper functioning of ion channels. Similar to circulating calcium, there are three magnesium fractions in blood: protein-bound (albumin and globulins), free (biologically active form), and complexed to anions (i.e., citrate and phosphate). Only free magnesium concentrations represent overall magnesium status (Alfrey et al., 1974; Arnold et al., 1995; Fiser et al., 1998).

In healthy dogs, these fractions are approximately 31%, 63%, and 6%, respectively (Schenck et al., 2005). Normal total serum magnesium concentration in people is 0.7–0.9 mmol/L (Kaplinsky and Alon, 2013); in 2–6 month old rats, it is approximately 0.8 ± 0.08 mmol/L (Rude and Gruber, 2004); in normal adult dogs, it is approximately 0.8–1.0 mmol/L (Martin et al., 1994); and in adult (5 month old) pigs, it is approximately 1.2 mmol/L (Ullrey et al., 1967). Plasma free magnesium concentrations in dogs are in the range of 0.25–0.41 mmol/L (Fincham et al., 2004). Dietary magnesium is absorbed primarily in the jejunum, ileum, and colon down an electrochemical gradient via passive paracellular pathways and to a lesser extent, regulated transcellular pathways. Paracellular absorption is affected by water reabsorption and chronic diarrhea results in malabsorption of magnesium (Kaplinsky and Alon, 2013). Steatorrhea also reduces absorption due to formation of nonabsorbable magnesium lipid salts. Transcellular transport is mediated by the transient receptor potential melastatin (TRPM)-6 channel on the apical intestinal epithelium. TRPM-7 and members of the solute carrier family 41 also play a role in magnesium transport (Arnaud, 2008a). Absorption is enhanced by PTH, vitamin D and high dietary calcium or phosphate (Stockham and Scott, 2008). In people, the majority of plasma magnesium is filtered by the glomerulus and in health, 15% is reabsorbed by the kidney, mostly by the thick ascending loop of Henle (Saris et al., 2000). PTH, antidiuretic hormone, glucagon, aldosterone, calcitonin, and β -adrenergic agonists promote renal magnesium resorption (Stockham and Scott, 2008). Very little is known regarding the molecular basis of magnesium storage or mobilization in the skeletal system. It is unclear if transporters such as TRPM-6 and 7 are also expressed in bone cells.

Significance of increased concentration/activity: Causes of elevated circulating magnesium (hypermagnesemia) include decreased renal excretion, which can occur with renal injury and other causes of reduced glomerular filtration rate, increased PTH, and increased ingestion of magnesium-containing foods, de-icing chemicals, or drugs such as laxatives and antacids. Renal disease must be severe to cause hypermagnesemia as the normal kidney is capable of rapid excretion of large amounts of magnesium. High concentrations of magnesium interfere with neuromuscular transmission and release of acetylcholine, which results in symptoms of weakness, decreased reflexes, hypotension, cardiac arrhythmias, and decreased alertness, and if severe, it can result in respiratory paralysis, CNS depression, and coma (Fung et al., 1995; Schaer, 1999). In experimental situations, supraphysiologic concentrations of magnesium result in marked increases in calcitonin secretion similar to the release induced by hypercalcemic states (Capen and O'Brien, 2004).

Significance of decreased concentration/activity: For human patients, Kaplinsky and Alon (2013) recommend measuring the fractional excretion of magnesium [FEMg: (urine Mg/urine

creatinine) \times (serum creatinine/serum Mg) \times 100] to obtain an indication of the source of low blood magnesium concentrations (hypomagnesemia). Causes include extra-renal etiologies (FEMg < 2%: e.g., hypoalbuminemia/hypoproteinemia, dietary deficiency, malabsorption syndromes, enteric disease, chronic diarrhea, and protein-losing enteropathy) and renal etiologies (FEMg = 2%: e.g., impaired renal tubular resorption, osmotic diuresis, and loop diuretics) (Bush et al., 2001; Stockham and Scott, 2008b; Kaplinsky and Alon, 2013). Hypomagnesemia is not uncommon in hospitalized human patients, especially those in intensive care (Herroeder et al., 2011) and many conditions have been associated with low magnesium in veterinary patients as well (Bateman, 2008). Dogs with diabetic ketoacidosis have lower plasma ionized magnesium concentrations than healthy dogs or dogs with uncomplicated diabetes mellitus (Fincham et al., 2004). Functionally, rodent models of severe dietary magnesium deficiency manifest decreased bone magnesium content, abnormalities of growth plate and cartilage, as well as reduced bone strength and trabecular bone mass (Rude et al., 2009). Reductions of dietary magnesium in rats and mice causes decreased osteoblast function and bone formation, which is reflected by reductions in serum and bone ALP activities and serum calcium, vitamin D, PTH, and OC concentrations. However, osteoclast activity and numbers are increased (Rude and Gruber, 2004) suggesting an uncoupling of bone formation and resorption. In most species, including humans, magnesium deficiency causes impaired PTH secretion and/or resistance to PTH (Rude and Gruber, 2004).

Influencing factors (sources of error, interferences, dietary/fasting, etc.): Similar to calcium, total magnesium is measured by spectrophotometric methods using metallochromic dyes. Atomic absorption can also be performed. Free magnesium is measured by ion-specific electrodes, although is rarely done clinically. Calcium ions interfere with magnesium-ISEs, and correction for this must be taken into account (Rayana et al., 2008). Erythrocyte magnesium content has been used as a surrogate of magnesium status; however, this is discouraged due to inaccuracies (Basso et al., 2000). Serum or heparinized plasma samples are preferred; some anticoagulants cause false reductions (i.e., EDTA, citrate, oxalate). Fasting can reduce serum magnesium in pigs (Baetz and Mengeling, 1971). Hemolysis leads to release of intracellular magnesium from erythrocytes and may falsely increase serum magnesium concentrations (Stockham and Scott, 2008a).

15.4.4 PARATHYROID HORMONE

Physiology, function, and half-life: Derived from its precursor, preproPTH, the 84-amino acid active PTH peptide is secreted by parathyroid chief cells in response to decreases in circulating free calcium or increases in circulating phosphate. In humans, PTH has a half-life of 2–3 minutes (Gopinath and Mihai, 2011). PTH maintains calcium and phosphate homeostasis on a minute-by-minute basis by acting at two primary sites, the kidney and bone, and secondarily in the intestine (Capen and O'Brien, 2004). Calcium-sensing receptors on chief cells are activated when circulating free calcium declines. When circulating calcium concentrations are high, intracellular calcium rises inhibiting the secretion of preformed PTH from storage granules. Magnesium is important for normal secretion of PTH due to the magnesium dependency of the adenylate cyclase pathway that facilitates PTH secretion (Allgrove, 2009). Magnesium deficiency can lead to hypoparathyroidism and secondary hypocalcemia (see Section 15.4.3).

In response to hypocalcemia, PTH restores circulating free calcium by mobilizing calcium from bone, increasing renal tubular calcium resorption, and accelerating formation of vitamin D in the kidney, which enhances calcium absorption in the gut. PTH also decreases phosphate resorption in the kidney. Circulating phosphate in turn affects PTH secretion, in part via hypocalcemia that results when serum becomes saturated with the two ions (Capen and O'Brien, 2004), and Khoshniat et al. (2011) proposed the presence of a phosphorus-sensing mechanism that is independent of serum calcium. PTH has direct effects on osteoblasts and renal tubular epithelial cells through the G-protein coupled receptor, PTH receptor type 1 or PTHR (also called PTH/PTHrP receptor)

(Gensure et al., 2005). In the skeleton, PTH demonstrates biphasic activity: under continuous infusion, it catabolizes bone; whereas, intermittent injection results in anabolic bone formation by a mechanism that is unclear (Lee and Partridge, 2009). Administration of intermittent low dose PTH has been utilized to treat osteoporosis (Canalis et al., 2007).

There are multiple circulating forms of PTH; intact PTH (1–84) is the primary active form in blood (Capen and O'Brien, 2004). Recent studies with PTH fragments, such as C-terminal PTH, suggest these may play a role in renal failure and other disease states (D'Amour et al., 2011). PTHrP is a paracrine hormone with actions similar to PTH, including stimulating bone and renal calcium resorption. Although PTHrP binds the N-terminal of PTHR in tissues, it does not cross-react with native PTH and it is not detected by endogenous PTH immunoassays. PTHrP has a high level of sequence homology across species. It is involved in normal fetal development and in development of bone, heart, and mammary gland, however very little is produced by healthy cells after birth. Excessive production of PTHrP by tumor cells is a common mechanism of humoral hypercalcemia of malignancy (Capen and O'Brien, 2004).

Significance of increased concentration: Elevated PTH concentration (hyperparathyroidism) may be caused by primary disorders of the parathyroid gland that result in excessive PTH secretion (primary hyperparathyroidism) or secondary conditions, such as calcium-restricted or deficient diets (nutritional secondary hyperparathyroidism), renal disease or hypovitaminosis D (Gow et al., 2011). Hyperparathyroid gland lesions are usually chief cell adenomas, although chief cell hyperplasia or carcinoma can also occur. In chronic kidney disease, increased serum concentrations of PTH and accompanying decreases in vitamin D 1,25-dihydroxyvitamin D₃ can lead to renal osteodystrophy. Data suggests that PTH (7–84) may interfere with expression of the PTHR and with binding of the intact form (1–84), leading to a state of functional PTH resistance. Increased serum PTH develops in growing rabbits fed a calcium-deficient diet (Gilsanz et al., 1991). Dogs with hypocalcemia and vitamin D deficiency due to inflammatory bowel disease also develop high serum PTH (Gow et al., 2011). Marmosets given bisphosphonates show increased PTH likely secondary to decreased serum calcium (Angeliewa et al., 2004). Clinical changes in hyperparathyroidism are attributed to skeletal weakening and calcium imbalance: lameness, loose teeth, vertebral compression fractures with motor or sensory dysfunction, anorexia, vomiting, constipation, depression, and muscle weakness.

Significance of decreased concentration: Low circulating PTH (hypoparathyroidism) may be caused by primary hypoparathyroidism, hypercalcemic conditions, hypovitaminosis D, or hypomagnesemia. Primary hypoparathyroidism can result from parathyroid gland inflammation, damage (i.e., as a result of thyroid surgery), or metastasis/neoplastic invasion. Idiopathic lymphocytic parathyroiditis occurs in dogs and is considered to have an immune basis. Agenesis of the glands is a rare defect in dogs and humans (Thakker et al., 1990; Capen and O'Brien, 2004). Clinically, hypoparathyroid animals may be nervous, restless, or ataxic, eventually developing tetany and seizures. Laboratory abnormalities may include hypocalcemia due to decreased bone resorption and hyperphosphatemia as a result of reduced renal excretion.

Influencing factors (sources of error, interferences, dietary/fasting, etc.): Two-site immunoassays are recommended to measure serum intact PTH and to avoid cross-reaction with PTH peptide fragments (Capen and O'Brien, 2004). The relative concentrations and functions of PTH fragments, especially in renal failure, is an active area of research (D'Amour et al., 2011). For PTHrP measurement, a similar platform (2-site IRMA) is recommended using EDTA plasma samples with protease inhibitors, such as aprotinin (Capen and O'Brien, 2004). Age and gender can influence circulating concentrations of PTH. In rats, plasma PTH concentration increases with age in males and females, although PTH concentrations do not change with age in female and male rhesus monkeys (Black et al., 2001) or in dogs (Lawler et al., 2007). PTH concentrations tended to decrease in female Gottingen minipigs over time (Scholz-Ahrens et al., 2007). Gender influences PTH fragment ratios in growing

rats (D'Amour et al., 2010). PTH concentrations may also vary with strain. For example, F344 rats have considerably higher PTH concentrations than Wistar or Sprague-Dawley rats (Kalu and Hardin, 1984).

15.4.5 VITAMIN D

Physiology, function, and half-life: Vitamin D is a seco-steroid (steroid with an open B-ring) that is essential for uptake of dietary calcium and phosphorus and for normal bone formation and growth. It is also involved in such diverse processes as regulation of cell proliferation and differentiation, maintaining immune system homeostasis, and regulation of non-bone-related hormone secretion (Bikle, 2009). Vitamin D is obtained by ingestion of vitamin D₂ (ergocalciferol) and D₃ (cholecalciferol) and synthesized endogenously in the skin via the ultraviolet-light dependent conversion of 7-dehydrocholesterol into vitamin D₃. Vitamin D₃ is converted to 25-hydroxyvitamin D₃ (25(OH)D₃) in the liver by cytochrome P₄₅₀ and a second hydroxylation step by 1 α -hydroxylase (CYP27B1) occurs in the kidney. The resulting form, 1,25-dihydroxyvitamin D₃ [1,25 (OH)₂D₃ or calcitriol] binds the vitamin D nuclear receptor and is biologically active. There are species differences in these processes. Unlike rats, ultraviolet light exposure does not significantly increase vitamin D₃ in the skin of dogs. Consequently, dogs do not show seasonal variation in serum vitamin D concentrations (Laing et al., 1999).

Rabbits normally have higher serum total calcium concentrations than most other mammals and excrete significant quantities of calcium in their urine. Still, they have less reliance on vitamin D for intestinal uptake of calcium, as feeding a vitamin D-deficient diet has minimal effect on serum calcium concentrations (Eckermann-Ross, 2008). In contrast, C3H/HeJ mice, which have high tibial mineral bone density compared to C57BL/6 mice, are considered to have enhanced calcium transport/availability due to increased sensitivity of intestinal cells to vitamin D activity (Armbrecht et al., 2002; Chen and Kalu, 1999). There is some evidence that female mice have enhanced intestinal vitamin D-mediated calcium absorption and gene expression compared to males (Song and Fleet, 2004).

Significance of increased concentration/activity: Increased circulating vitamin D (hypervitaminosis D) may be caused by excessive vitamin D intake through over-supplementation or ingestion of vitamin D-containing rodenticides, granulomatous disease, and paraneoplastic secretion by various cancers. Cholecalciferol has been used in rodenticides and ingestion causes increased absorption of calcium and phosphorus with subsequent hypercalcemia and hyperphosphatemia. Vitamin D-induced skeletal disease is infrequent since calcium and phosphorus are derived primarily from the intestine and not through bone resorption; however, soft-tissue mineralization, cardiac effects, and renal failure can be life threatening. Although total calcium concentrations are not different, vitamin D (calcitriol) concentrations are increased 1.5-fold higher in growing rabbits fed a calcium-deficient diet relative to those consuming a calcium-replete diet (Gilsanz et al., 1991). New world monkeys have higher plasma concentrations of vitamin D, versus other animals, which may indicate a natural degree of vitamin D resistance. As such, they require exposure to artificial sunlight and/or dietary supplementation with vitamin D₃ (Lowenstein, 2003; Adams et al., 2003).

Significance of decreased concentration/activity: Low circulating vitamin D (hypovitaminosis D) may be caused by dietary vitamin D deficiency, severe renal disease [due to decreased activity of renal 25(OH)D-1 α -hydroxylase], insufficient exposure to sunlight in some species, and genetic diseases. Vitamin D deficiency causes impaired mineralization during endochondral ossification resulting in osteomalacia or rickets. Animal models of rickets have been reviewed by Dittmer and Thompson (2011), including mouse knockouts for 1 alpha-hydroxylase, vitamin D receptor and vitamin D-binding protein. Rats fed a vitamin D-deficient diet have low serum 1,25(OH)₂D,

decreased total and free calcium, normal phosphate, and high PTH (D'Amour et al., 2011); growing animals develop irregular thickened epiphyses due to failure of the cartilaginous matrix to mineralize properly. Deficiency of 1α -hydroxylase can also cause rickets (type 1) and congenital defects in this enzyme have been described in pigs and humans (Capen and O'Brien, 2004). Type II rickets is found in some New World primates, such as the common marmoset and is due to calcitriol resistance or to overexpression of vitamin D response element-binding protein, which interferes with vitamin D transactivation (Dittmer and Thompson, 2011). These animals develop osteomalacia, hypocalcemia, and secondary hyperparathyroidism in the presence of high calcitriol concentrations. Dogs with inflammatory bowel disease may have low 25-hydroxyvitamin D concentrations (Gow et al., 2011). Genetically modified mice that either lack the vitamin D receptor (VDR) and have elevated calcitriol concentration, or that lack renal 25-hydroxyvitamin D- 1α -hydroxylase and have increased concentrations of 25(OH)D₃ and low calcitriol concentration become hypocalcemic, and develop elevated serum PTH concentration and elevated serum ALP activity (Hendy et al., 2006).

Influencing factors (sources of error, interferences, dietary/fasting, etc.): Excessive exposure of the sample to ultraviolet light may result in falsely decreased measured concentrations. Concentrations are influenced by age, gender, and diet. In rats, vitamin D increases with age and is higher in females than males (D'Amour et al., 2010). Black et al. (2001) found that serum 25-hydroxyvitamin D concentration decreases with age in female rhesus macaques while PTH and 1,25(OH)₂D concentrations did not change. A similar age-related change in 25-hydroxyvitamin D concentration was not evident in males (Black et al., 2001; Colman et al., 1999).

Vitamin D enhances calcium uptake in the intestine by upregulation of the epithelial calcium channel, transient receptor potential vanilloid 6 (TRPV6), and the intracellular transporter, calbindin D. In concert with PTH, it accelerates calcium retention by the kidney through TRPV5 and calbindin transport in the distal tubule. It also promotes phosphate absorption by the intestine and kidney and suppresses PTH synthesis and secretion by the parathyroid gland. In bone, 1,25(OH)₂D₃ mediates osteoclastogenesis and calcium mobilization by stimulating RANKL (receptor activation of NF- κ B ligand) on osteoblasts. RANKL then binds RANK on osteoclast progenitor cells inducing their differentiation and maturation (Dittmer and Thompson, 2011).

15.4.6 CALCITONIN

Physiology, function, and half-life: Calcitonin is a member of the functionally diverse calcitonin gene-related peptide superfamily. This superfamily includes amylin, adrenomedullin, calcitonin receptor-stimulating peptide, and other peptides (Katafuchi et al., 2009). Calcitonin is a 32-amino acid calcitropic peptide hormone produced primarily by the medullary C (parafollicular) cells of the thyroid gland in response to high calcium concentrations (de Paula and Rosen, 2010). It can also be triggered by pentagastrin, growth hormone releasing hormone, beta adrenergic agonists, gastrointestinal peptides, and other factors (Elisei, 2008). Calcitonin receptors are located on mature osteoclasts, epithelial cells in the distal nephron, the placenta, and other tissues (Zhong et al., 2009).

Although its functions have yet to be fully defined, it has been proposed that calcitonin protects against hypercalcemia or "calcemia stress" during such physiologic states as pregnancy, lactation, and during early development (Zhong et al., 2009). It suppresses bone resorption by osteoclasts and decreases calcium resorption in the renal tubules. It also inhibits prolactin secretion and affects the maternal–fetal calcium exchange (Zhong et al., 2009). Thus, during normocalcemic states, calcitonin serves as a primary regulator of renal 25-hydroxyvitamin D₃ 1α -hydroxylase gene expression, whereas PTH is the predominant mediator during hypocalcemia (Zhong et al., 2009). Indeed dogs with drug-induced renal failure, secondary hyperparathyroidism, and low serum calcium exhibit normal calcitonin concentrations (García-Rodríguez et al., 2003). Despite limited sequence homology within the calcitonin gene-related peptide family across species (Katafuchi et al., 2009), there

are some shared functional domains. For example, oral salmon calcitonin has been used to treat osteoporosis in postmenopausal women (Karsdal et al., 2011). Interestingly, this oral form has recently been shown to improve glucose homeostasis and weight in a rat model of obesity (Feigh et al., 2011) indicating that calcitonin has effects beyond bone and calcium metabolism.

Significance of increased concentration/activity: In normal individuals, circulating calcitonin is usually low to undetectable. Increased serum calcitonin concentration has been associated with medullary thyroid carcinomas, nonthyroidal neoplasms, C-cell hyperplasia, thyroid nodules, hypercalcemia, renal failure, and chronic administration of some drugs (i.e., beta-blockers, glucocorticoids, and potential secretagogues) (Toledo et al., 2009). In bulls, particularly those ingesting a high-calcium diet, C-cell neoplasms are not uncommon (Capen, 2007). C-cell tumors have also been described in Fisher 344 rats and Balb/c mice (Haseman, 1998; Van Zwieten et al., 1983). Interestingly, humans and dogs with medullary thyroid carcinoma and hypercalcitoninemia, show minimal effect on calcium concentrations (Elisei, 2008; Feldman and Nelson, 2003). Sepsis upregulates calcitonin gene expression in multiple tissues in hamsters (Müller B et al., 2001). Supraphysiologic doses of magnesium can result in marked increases in calcitonin secretion (Capen and O'Brien, 2004). Calcium or pentagastrin administration can be used as a provocative test to stimulate calcitonin release in patients suspected of having medullary thyroid neoplasia (Elisei, 2008).

Significance of decreased concentration/activity: normal animals usually have undetectable circulating calcitonin. Animals with hypocalcemia or lacking a thyroid gland have undetectable serum calcitonin. Knockout mice lacking calcitonin or calcitonin receptor show increased bone formation due to inhibition of osteoclast activation (Martin et al., 2009).

Influencing factors (sources of error, interferences, dietary/fasting, etc.): Calcitonin is typically measured by immunoassay. False elevations can occur due to heterophilic antibodies. For assays that lack sufficient specificity, calcitonin precursors may cross-react causing false increases (Elisei, 2008). Serum calcitonin increases with age in rats, in contrast to humans in which it decreases with aging. Strain differences in baseline calcitonin have been reported in rats (Peng et al., 1976). Kmiec et al. (2001) reported no difference in serum calcitonin in fed and fasted rats, although refeeding resulted in elevated concentrations in aged rats and reduced concentrations in young rats.

15.4.7 ALKALINE PHOSPHATASE, BONE ISOENZYME

Physiology, function, and half-life: Alkaline phosphatases catalyze the alkaline hydrolysis of many naturally occurring and synthetic substrates. The bone isoenzyme of alkaline phosphatase (BALP; also referred to as bone-specific ALP or BSAP) is produced by osteoblasts through posttranslational modification of the tissue nonspecific ALP gene product (TNSALP), which is also the source of the intestinal and liver ALP isoenzymes. Several isoforms of BALP with distinct glycosylation and catalytic properties have been identified in the circulation of humans and there is some evidence that their expression may be influenced by disorders such as chronic kidney disease (Linder et al., 2009). In bone, BALP mediates hydrolysis of pyrophosphate (a potent inhibitor of mineralization), which releases inorganic phosphorus for incorporation into hydroxyapatite and generates extracellular inorganic phosphate (Harmey, et al., 2004; Coulibaly et al., 2010). Thus, BALP is essential for normal mineralization of skeletal osteoid and mutations of the TNSALP gene can result in bone disorders such as the osteomalacic disease hypophosphatasia (Whyte, 2008).

Circulating (serum or plasma) BALP can serve as a marker of bone formation in humans and many laboratory animal species, including dogs (Sanecki et al., 1993), rats (Hoffmann et al., 1994;

Powers et al., 2007), mice (Huang et al., 2010), minipigs (Scholz-Ahrens et al., 2007), guinea pigs (Li et al., 2005), rabbits (Southwood et al., 2003), cynomolgus macaques (Wiedmeyer et al., 1999), and rhesus macaques (Kramer and Hoffman, 1997). It has been used as a bone turnover marker in assessment of osteoporosis, fractures, antiresorptive therapy, osteomyelitis, malignancy, and other bone disorders (Coleman et al., 2011; Liesegang et al., 2007; Philipov et al., 1995; Southwood et al., 2003; Vasikaran et al., 2011b). The half-life of BALP in human serum is approximately 40 hours (Seibel et al., 2006). The half-life of canine serum BALP is approximately 72 hours, similar to that of the hepatic and corticosteroid isoenzymes (Kramer and Hoffman, 1997). In most species, BALP activity may be influenced by factors such as circadian rhythm, age, gender and hormonal status (Seibel et al., 2006).

Significance of increased concentration/activity: increased BALP activity is associated with bone formation and osteoblastic activity, that is, growth in young animals, metabolic bone disease (i.e., osteomalacia), bone neoplasms (i.e., osteosarcoma or metastasis to bone), endocrine diseases (i.e., hyperparathyroidism), traumatic bone injury, and inflammatory bone disease (i.e., osteomyelitis) (Fernandez and Kidney, 2007). Congenitally increased BALP activity (benign familial hyperphosphatasemia) has been identified in Scottish Terriers (Nestor et al., 2006) and Siberian Huskies (Fernandez and Kidney, 2007). BALP is highly correlated with periosteal ALP activity, a tissue-based marker of bone formation, in a rat model of orchietomy-induced bone loss (Powers et al., 2007). BALP is considered a useful marker of bone metastasis in men with castration-resistant prostate cancer (Coleman et al., 2011). BALP and total ALP were significantly increased by 1 week after experimental radial fracture in dogs and remained elevated 4 weeks postsurgery (Mohamadnia et al., 2007).

Significance of decreased concentration/activity: Decreased serum BALP is associated with reduced bone formation and osteoblastic activity. An alkaline phosphatase knockout mouse model with mutations in TNSALP recapitulates many of the features of human infants with congenital hypophosphatasia, including growth deformities and osteomalacia (Fedde et al., 1999). In an ovariectomy-induced bone loss model in cynomolgus monkeys, decreases in both total and bone-specific alkaline phosphatase were highly correlated with decreased bone mineral density (Legrand et al., 2003).

Influencing factors (sources of error, interferences, dietary/fasting, etc.): BALP activity can be measured by physicochemical methods such as heat or urea inactivation, levamisole inhibition, differential binding to wheat germ lectin or electrophoresis (Itoh et al., 2002). Less cumbersome immunoassays are now available to measure BALP protein in some species. Cross-reactivity with the liver isoenzyme has been reported in some human immunoassays (Vasikaran et al., 2011a). BALP is influenced by many factors, including age, gender, hormonal status, and diet. In rats and mice, BALP shows little circadian variation (Herrmann, 2011). BALP is generally higher in immature animals than older animals (Hatayama et al., 2012; Legrand et al., 1993; Tsutsumi et al., 2004 a and b). Indeed, BALP is the predominant isozyme in rat serum through at least 19 weeks of age (Hatayama et al., 2012). BALP declined in female minipigs tested for up to 76 months after birth (Tsutsumi et al., 2004a). Itoh et al. (2002) found that BALP represents 65% of total ALP activity in dogs less than 1 year, 31% in dogs 1–7 years and 16% in dogs >7 years. Male cynomolgus monkeys have slightly higher BALP activities than females (Wiedmeyer et al., 1999). Significant diurnal variation in serum BALP occurs in dogs (Ladlow et al., 2002), but not female Göttingen minipigs (Tsutsumi et al., 2004b). Relative to non-lactating females, lactating cynomolgus monkeys have increased BALP, as well as increased OC, PYD, and DPD likely due to mobilization of bone calcium (Lees et al., 1998). Marked increases in total ALP activity were found in juvenile rhesus macaques with nutritional metabolic bone disease, presumably due to elevated BALP (Wolfensohn, 2003).

15.4.8 OSTEOCALCIN

Physiology, function, and half-life: OC is a small (5.8 kD) peptide produced by osteoblasts, hypertrophic chondrocytes, and odontoblasts. It is the most abundant noncollagenous protein in bone matrix (Coulibaly et al., 2010). OC is also known as bone γ -carboxyglutamic acid (Gla) protein due to the presence of three Gla residues, which bind calcium. Similar to coagulation factors II, VII, IX, and X, the formation of the glutamic acid residues on OC is vitamin K-dependent. OC has carboxylated and uncarboxylated forms that have unique properties. The carboxylated form has a high affinity for minerals, such as calcium, binds hydroxyapatite and is incorporated into the extracellular bone matrix. The uncarboxylated form released into the circulation mediates energy metabolism through effects on insulin and insulin sensitivity (Confavreux, 2011) and plays a role in vascular calcification (Kapustin and Shanahan, 2011). Mice deficient in OC have increased cortical bone thickness and density with improved mechanical properties, but they also develop hyperglycemia, hypoinsulinemia, low beta cell mass, increased fats mass, and decreased energy expenditure (Ducy et al., 1996; Ducy, 2011).

During bone formation, osteoblasts secrete OC and measurement of serum concentration can be a sensitive and specific indicator of bone formation. Intact OC is susceptible to proteolysis, and there can be considerable variability in interlaboratory results (Seibel, 2005). In resorptive states, OC fragments may be released into the plasma, and the measurement of individual fragments may provide information on the status of bone resorption (Kraenzlin and Seibel, 2006). Thus, if an assay does not measure intact OC, OC is more appropriately considered to be a marker of generalized bone turnover rather than either formation or resorption specifically. Serum OC has been used as a bone turnover marker in osteoporosis and fracture, but it is also influenced by non-bone disorders, such as diabetes, stress, corticosteroids, heart disease, and renal disease (Ducy, 2011; Olmos et al., 2006).

The half-life of OC in human beings is approximately 20 minutes. When stored at room temperature, serum OC concentration may decrease by 20% within a few hours due to protein degradation. This may be avoided by assays that measure intact OC as well as OC fragments. The addition of protease inhibitors may prevent degradation of the intact molecule. OC has been measured in rats, mice, dogs, cynomolgus macaques, rhesus macaques, rabbits, and minipigs. It has been used as a marker of bone turnover in disorders such as osteoporosis (Garnero, 2008), bone lengthening (Theyse et al., 2006), and osteomyelitis (Philipov et al., 1995). It is influenced by age, gender, hormonal status, renal function, and other factors.

Significance of increased concentration/activity: Serum OC increases with bone formation, osteoblastic activity, and bone resorption. As OC is eliminated via glomerular filtration, circulating concentrations may increase in renal failure in the absence of bone formation (Seibel, 2005). OC increases in rats given daily PTH injections (Han et al., 2007). It rises with progression of osteoporosis in women and in some animal models of the disease: ovariectomy causes increased serum concentrations in rhesus monkeys (Keller et al., 2000); transient elevations were seen in an orchidectomized marmoset model (Seidlov-Wuttke et al., 2008). Osteomyelitis was associated with increased OC in dogs (Philipov et al., 1995). Concentrations are typically higher in younger animals than older animals (Colman et al., 1999).

Significance of decreased concentration/activity: OC is decreased with decreased bone formation during physiologic and pathologic conditions. From postweaning to adulthood, rats may experience an approximately 50% decrease in serum OC concentration. This decrease is associated with increasing bone mineral deposition (Horton et al., 2008). In pregnant animals, placental clearance of OC can result in falsely decreased concentrations (Rodin et al., 1989). In rabbits, lower serum OC concentrations were associated with infected fractures when compared with rabbits with noninfected fractures. The rabbits with infected fractures also had decreased BALP and

higher DPD concentrations than the noninfected controls (Southwood et al., 2003). Glucocorticoids lower OC concentrations as evidenced by decreased plasma OC concentration in piglets following dexamethasone treatment (Weiler et al., 1995) and in rats given prednisolone (Han et al., 2007). In a mouse model of glucocorticoid-induced osteoporosis, decreases in serum OC concentrations mirrored the reduction in bone formation rate observed microscopically (McLaughlin et al., 2002). In an ovariectomy-induced model of bone loss in cynomolgus monkeys, decreased OC was highly correlated with decreased bone mineral density (Legrand et al., 2003). Serum OC was decreased in streptozotocin-induced diabetic rats, and correlated with decreased ALP activity in femoral bone sections consistent with decreased osteoblast activity/bone formation in this model (Hie et al., 2007). OC is decreased with heart injury, including myocardial infarction and coronary heart disease (Ducy, 2011).

Influencing factors (sources of error, interferences, dietary/fasting, etc.): OC is measured by immunoassays and because it circulates as intact and fragmented forms, results are affected by the specific epitopes identified by the assay. Epitopes in the midfragment are most stable and assays detecting this region tend to be most consistent. Detection may be compromised due to degradation resulting from inadequate storage. Serum should be promptly processed and analyzed. If not assayed within 1 hour, samples should be stored frozen (-20 to -80°C) (Allen, 2003; Herrmann, 2011). Variability in sample quality and/or assay differences may explain the conflicting results sometimes observed with this analyte. For example, Theyse et al. (2006) found that OC concentrations were lowest in dogs with the highest amount of bone formation in a bone distraction study. This is in contrast to a distraction study performed by Lammens et al. (1998) in which OC concentrations were increased dogs with the most bone formation. Serum OC concentrations are higher in smaller strains of mice such as C57BL/6 mice than large-sized mice such as SENCAR mice likely as a reflection of favoring bone growth over remodeling (Murray et al., 1993). Interestingly, C3H/HeJ mice have increased mineral bone density and high bone OC content, but decreased serum OC concentration, relative to other strains (Li et al., 2002). When conducting studies with the OC, it is important to take samples at consistent times, during the day, since serum OC exhibits circadian rhythms in dogs (Ladlow et al., 2002) and mice (Liesegang et al., 1999; Srivastava et al., 2001). Female Gottingen minipigs have significant diurnal variation in OC concentration (Tsutsumi et al., 2004a). Minimal changes in serum OC concentrations were noted in female Sprague-Dawley rats during estrous cycle, pregnancy, and lactation (Sengupta et al., 2005). Serum OC concentrations declined with age in male rhesus macaques, but not females (Black et al., 2001). Cahoon et al. (1996) found that OC declined in both genders in rhesus up to 20 years, then plateaued or increased slightly in animals >25 years. In cynomolgus monkeys, OC is higher in young versus old females (Legrand et al., 2003). OC declined in female minipigs tested for up to 76 months after birth (Tsutsumi et al., 2004a). Calorie restriction in young male rhesus macaques was associated with lower OC at 1 month relative to animals on an unrestricted diet, but concentrations normalized by 6 months (Black et al., 2001).

15.4.9 MOLECULES ASSOCIATED WITH COLLAGEN MATURATION AND DEGRADATION: PROPEPTIDES; CROSS-LINKED C- AND N-TELOPEPTIDES; PYRIDINOLINE, DEOXYPYRIDINOLINE

Physiology, function, and half-life: Collagen type I is the principal organic constituent of the extracellular bone matrix. Proteolytic processing of the precursor, procollagen type I, during bone formation results in the release of free peptides (propeptides) from the amino (N-) and carboxy (C)-termini before incorporation of collagen type I into new bone. These terminal peptides, called procollagen type I N-propeptide and C-propeptide (PINP and PICP), serve as indicators of newly formed collagen type I and active bone formation. They are cleared from the circulation primarily by sinusoidal endothelial cells in the liver (Melkko et al., 1994). The smaller PINP molecule is also

cleared by the kidney (Melkko et al., 1994). Thus, both peptides are measurable in serum, but only PINP can be measured in urine.

Collagen type I has a triple helix structure and in bone, the helices are covalently cross-linked by short peptides (known as telopeptides) at the amino- and carboxy ends. The telopeptides are further linked via pyridinium or pyrrole to neighboring collagen helices (Herrmann and Seibel, 2008). During bone resorption, the degradation of mature type I collagen by CTSK and matrix metalloproteases frees these terminal peptides known as N- and C-Terminal cross-linking telopeptide of type I collagen. In addition, “Crosslaps” is a commercial assay that measures specific CTX-1 degradation products called collagen C-Terminal extension peptides, as well as the related molecule, C-terminal cross-linking telopeptide of type I collagen generated by metalloproteinases (CTX-MMP) (Cremers and Garnero, 2006). CTX-MMP resists further degradation and is released into serum (Eriksen et al., 1993) where it can serve as a sensitive marker of pathological bone resorption in conditions such as metastatic bone disease (Herrmann, 2011). NTX-1 and CTX-1 are sufficiently small to be cleared by renal mechanisms and can therefore be quantified in urine. Results are generally normalized to urine creatinine concentration, for example, urine NTX-1/Cr. However, telopeptides present in many tissues and non-bone-related processes (i.e., cardiac disease, cancer) may influence urine and serum concentrations (Herrmann, 2011).

Unlike CTX-MMP, NTX-1 and CTX-1 are subject to enzymatic digestion resulting in amino acids and free or peptide-bound pyridinoline (PYD) or DPD, the small trivalent linking molecules. Thus, the release of PYD and DPD into serum and urine also signifies degradation of mature (cross-linked) collagen. PYD is found in cartilage, ligaments, and vessels, and DPD is also found in dentin. However, these sources contribute very little to serum or urine concentrations, and PYD and DPD are considered specific markers of bone resorption (Herrmann, 2011). Hydroxylysylpyridinoline and lysylpyridinoline are non-reducible collagen cross-links that stabilize collagen fibrils by increasing tissue resistance to proteolytic resorption, decreasing the tissue’s solubility, and providing proper spacing of bone collagen alpha-chains for normal function (Martinez et al., 2008). Hydroxylysylpyridinoline and lysylpyridinoline serve as markers of mature collagen. Urine concentrations of hydroxylysylpyridinoline and lysylpyridinoline increased in rhesus monkeys exposed to chronic hypergravity (Martinez et al., 2008). Urinary hydroxyproline has been used as a marker of collagen degradation; concentrations increase in humans with reduced weight-bearing conditions such as during spaceflight or during prolonged bedrest (Martinez et al., 2008). It is not specific to bone, however, and can be affected by connective tissue disorders.

Assays for collagen degradation products are frequently antibody-based ([e.g., enzyme-linked immunosorbent assay (ELISA) or radioimmunoassay (RIA)], although HPLC methods may be used (Martinez et al., 2008). PINP and PICP are relatively stable in serum (Herrmann, 2011). Rat and mouse PINP share homology in some regions, but differ considerably from the human peptide. Therefore, specific-assays are important for this endpoint (Han et al., 2007). Serum PINP has been used in rat models of osteoporosis as a marker of bone turnover. In contrast, pyridinolines are highly conserved across species, and there is significant cross-reactivity between human and animal assays (Allen et al., 2000). There is also high cross-reactivity of human and canine assays for urinary DPD, NTX-1, and CTX-1.

Significance of increased concentration/activity: Circulating PICP and PINP increase with bone formation and posttranslational modification of procollagen I. PINP offers a significant advantage in specificity over OC for assessment of bone formation as OC fragments may be released during bone resorption (Ivaska et al., 2004). PINP increases following PTH treatment of in rats, and correlates with increased bone formation/bone mineral density (Han et al., 2007; Hale et al., 2007).

Increased NTX-1, CTX-1, CTX-MMP, urine PYD, and urine DPD are associated with bone resorption and osteoclastic activity. NTX-1 is considered one of the more useful predictors of bone metastasis in people with multiple myeloma and breast cancer (Coleman et al., 2011). Lucas et al. (2008) found that dogs with osteosarcoma have increased serum and urine concentrations of

NTX-1 compared to dogs with osteoarthritis and healthy controls. In contrast, serum CTX-MMP does not discriminate dogs with osteosarcoma from healthy dogs (Hintermeister et al., 2008), although serum CTX-MMP was increased in an experimental canine model of septic osteomyelitis (Philipov et al., 1995). Urinary PYD:Cr was increased following 15 days of dexamethasone treatment of 3 to 5-day-old piglets (Weiler et al., 1995). Urine NTX-1 and DPD were high at birth, but decreased with age in female minipigs. There is a strong negative correlation between bone markers and bone mineral content and mineral bone density measured with DEXA (Tsutsumi et al., 2004b). Serum CTX-1 is higher in older rats compared with younger rats in a model of ageing osteoporosis (Pietschmann et al., 2007). Urinary excretion of DPD and NTX-1 is increased in streptozotocin-induced diabetic rats (Hie et al., 2007). Urinary DPD excretion is markedly increased in rats with cirrhosis-induced osteopenia (Cemborain et al., 1998).

Significance of decreased concentration/activity: Prednisolone administration in rats is associated with decreased serum PINP (Han et al., 2007). Inhibition of CTSK in normal and ovariectomized cynomolgus monkeys results in reduced serum CTX-1 and serum and urine NTX-1 concentrations, consistent with an osteoclast-mediated decrease in bone resorption (Kumar et al., 2007). In a murine model of collagen-induced osteoarthritis, inhibition of CTSK resulted in decreased urinary excretion of DPD (Svelander et al., 2009), which correlated with microscopic evidence of reduced bone erosion. However, serum CTX-1 concentration was increased in this study, which was attributed to augmented matrix metalloprotease activity secondary to inhibition of CTSK. Urinary DPD excretion was not different between control and ovariectomized aged (> 10 years) cynomolgus monkeys (Legrand et al., 2003). Serum NTX-1 and DPD were decreased in cynomolgus monkeys treated with osteoprotegerin, reflecting its ability to inhibit osteoclast differentiation/activity (Smith et al., 2003). Serum CTX-1 and PINP decreased in marmosets given bisphosphonates (Angeliewa et al., 2004).

Influencing factors: CTX-1, NTX-1, CTX-MMP are generally measured by immunoassays, although chromatographic techniques such as HPLC may be used, particularly for urine PYD and DPD. After the age of 50 years, these peptides are elevated in men and women, but more so in women, particularly until late menopause. Immunoassays for these markers may not cross-react across species. Rat PINP shares little homology with the human molecule. Consequently, Han et al. (2007) optimized a mass spectrometry-based assay to measure rat PINP. Pyridinolines in urine samples are subject to photodynamic breakdown and should be protected from light (Allen, 2003). CTX-MMP may lose significant activity if subjected to prolonged storage at room temperature (Kraenzlin and Seibel, 2006). Concentrations may be influenced by age, gender, diurnal variation, and circadian rhythm. Macaques exhibit circadian rhythm in serum PICP (Hotchkiss and Jerome, 1998). Urinary cross-links increase with age in male rhesus macaques, but not females (Black et al., 2001). Cahoon (1996) found that urine PYD, DPD, and hydroxyproline decreased with age in rhesus in both genders up to 20 years, then increased slightly in animals >25 years. Cahoon did not observe gender differences in PYD or DPD in rhesus. Urine NTX-1/Cr and DPD/Cr declined in female minipigs tested for up to 76 months after birth (Tsutsumi et al., 2004a). In a rat ovariectomy model of osteoporosis, serum PINP concentration correlated more closely with histologic parameters of bone formation than either OC or CTX-1 (Rissanen et al., 2008). Diurnal variation can be significant for NTX-1 and CTX-1 concentrations in serum and urine (Hermann, 2011) and collection times should be standardized. Urinary NTX-1 concentrations exhibit diurnal variation in female Gottingen minipigs (Tsutsumi et al., 2004a). CTX-1 exhibits circadian variation in C3H/HeJ mice (Srivastava et al., 2001). Dogs show significant diurnal variation in serum concentrations of CTX-MMP and urinary DPD, but not urine NTX-1 (Ladlow et al., 2002). Circadian rhythms also exist for PYD and DPD in dogs (Liesegang et al., 1999). Despite diurnal changes, Ladlow et al. (2002) found no significant longer-term (up to 12 weeks) variability in these turnover markers in dogs. Diet may influence telopeptide concentrations through alterations in net acid or base intake. Collecting samples from fasted animals is recommended (Hermann, 2011), although diet reportedly has no effect on urine PYD or

DPD concentrations (Cahoon et al., 1996). Age and gender are important preanalytical variables. Growing animals tend to have higher urinary CTX-1 and NTX-1 (Allen et al., 2000). Urinary CTX-1, serum CTX-1, DPD, and PICP were higher in young male cynomolgus macaques versus young females (Legrand et al., 2003); urinary NTX-1 and CTX-MMP were not different between genders. Serum CTX-MMP, urine DPD, and urine PYD decrease with age in dogs (Allen et al., 2000) during the first 7 years of age. Urine PYD and DPD are high in rhesus monkeys less than 3 years of age, and these values decline until late in life (>25 years) when they rise (Cahoon et al., 1996). PINP is higher in young rats versus older animals (Han et al., 2007); these investigators found that assay sensitivity may need to be optimized for lower concentrations in older animals. Impaired renal function may result in increased CTX-1 and NTX-1 due to decreased clearance.

15.4.10 TARTRATE-RESISTANT ACID PHOSPHATASE ISOFORM 5B

Physiology, function, and half-life: TRACPs are produced primarily by macrophages, dendritic cells, and osteoclasts, although detectable concentrations are present in many tissues (Hayman, 2008). Six isoenzymes have been elucidated by electrophoresis. Isozyme 5 is tartrate-resistant and has two isoforms (a and b). TRACP5a is produced by macrophages and dendritic cells, and 5b is secreted by osteoclasts. Functionally, TRACP5b cleaves type I collagen fragments liberated by CTSK and matrix metalloproteases (Cremers and Garnero, 2006) and circulating TRACP5b is considered a marker of osteoclast number and function (Herrmann, 2011). In human serum, TRACP5b circulates complexed with alpha-2-macroglobulin (and likely other molecules), but the biological significance of this is unclear. In rat serum, TRACP5b is found as a free molecule (Ylipahkala et al., 2003). TRACP5b can be measured by enzymatic methods, although these lack specificity for the 5b isoform and immunoassays are preferred to detect 5b alone. Serum TRACP5b activity has been evaluated in healthy dogs by an enzymatic method (Sousa et al., 2011). In beagle dogs with surgically induced osteoarthritis, Lee et al. (2008) found no effect on serum TRACP5b activity, however synovial fluid activity was elevated. In genetically modified rodents, decreased TRACP5b activity results in mild osteopetrosis due to decreased resorption (Hayman et al., 1996), while overexpression leads to osteoporosis due to increased resorption that is partly compensated by increased bone synthesis (Angel et al., 2000).

Significance of increased concentration/activity: increased serum concentrations of TRACP5b indicate increased osteoclast numbers and bone resorption. Pathologic conditions leading to increased serum TRACP5b activity include renal secondary hyperparathyroidism (e.g., chronic renal failure), osteoporosis, metastatic bone disease, hyperparathyroidism, and Paget's disease (Halleen et al., 2006). Because TRACP5b is not eliminated by renal mechanisms, it can be useful in the assessment of metabolic bone disease in animals with kidney failure (Cremers et al., 2008a and b). In a rat model of ovariectomy-induced bone loss, serum TRACP5b activity closely paralleled *in vivo* bone resorption as indicated by increased osteoclasts per bone surface/tissue area, suggesting that serum TRACP5b may be a useful surrogate for histomorphometric analysis of osteoclast numbers in tissue sections (Rissanen et al., 2008). In this model, total osteoclast numbers were decreased due to an overall loss of bone, but their activity was increased, suggesting that an increased CTX-1/TRACP5b ratio may indicate whole-body bone resorption. Mammary and ovarian carcinomas, and malignant melanoma, upregulate TRACP expression, which may play a role in the development of bone metastases (Hayman, 2008). Selective estrogen receptor modulator treatment in a cynomolgus monkey model of osteoporosis is associated with decreased TRACP5b activity, ALP, BALP, urinary CrossLaps, and OC and greater bone mass indicating reduced bone turnover (Hotchkiss et al., 2001; Lee et al., 2002).

Significance of decreased concentration/activity: TRACP5b knockout animals exhibit osteopetrosis caused by reduced osteoclast activity. These mice also have impaired macrophage function and abnormal immunomodulatory cytokine responses (Hayman and Cox, 2003; Bune et al., 2001).

In a rat model of age-related osteoporosis, serum TRACP5b concentration was decreased in older rats compared with younger rats (Pietschmann et al., 2007).

Influencing factors (sources of error, interferences, dietary/fasting, etc.): High concentrations of bilirubin may interfere with colorimetric TRACP assays (Alvarez et al., 1999). Serum TRACP5b is stable for up to 48 hours at room temperature, and up to 3 days if refrigerated. Frozen TRACP5b is stable for years; however, re-freezing samples may result in marked decreases in activity (Halleen et al., 2006). In normal Sprague-Dawley rats, serum TRACP5b concentrations remained relatively unchanged from weaning to 20 weeks of age (Horton et al., 2008). Serum TRACP5b activity does not exhibit diurnal variation, and is not affected by feeding (Rissanen et al., 2008).

15.4.11 CATHEPSIN K

Physiology, function, and half-life: The cysteine protease, CTSK, is secreted by osteoclasts into the resorption lacuna. There it cleaves triple-helical collagens at multiple sites into small peptides and degrades noncollagenous termini releasing end products (and markers), such as NTX, CTX, PYD, and DPD. CTSK also regulates TRAP release from osteoclasts, which further digests collagen remnants (Henriksen et al., 2007). Because of its key role in bone resorption, CTSK is a therapeutic target for the treatment of osteoporosis (Deaton and Tavares, 2005). Protein sequences vary across species: rodent CTSK has low homology with the human peptide, while rabbit and primate CTSK exhibit 96% and 100% homology, respectively (Pennypacker et al., 2009). Indeed, CTSK was first cloned from rabbit osteoclasts (Lecaille et al., 2008). The enzyme is expressed by many types of nonbone cells, for example, synovial fibroblasts, a variety of epithelial cells, cartilage, white adipose tissue, macrophages, etc. (Pietschmann et al., 2007), however circulating concentrations are considered to be indicative of osteoclast activity (Herrmann, 2011).

Significance of increased concentration/activity: Increased serum CTSK denotes increased osteoclastic activity and bone resorption. It has been utilized more frequently as a circulating bone marker in humans than animals: concentrations are elevated in people with chronic rheumatoid arthritis (Skoumal M, Haberhauer G, Kolarz G, Hawa G, Woloszczuk W, Klingler A. Serum cathepsin K levels of patients with longstanding rheumatoid arthritis: correlation with radiological destruction. *Nov 2004; 7:R65-R70*), osteoporosis, and Paget's disease (Meier et al., 2006). Genetically modified mice overexpressing CTSK have decreased trabecular bone due to excessive resorption (Lecaille et al., 2008).

Significance of decreased concentration/activity: Pycnodysostosis is a rare autosomal recessive disorder resulting from CTSK deficiency. Defective osteoclast activity causes osteosclerosis and short stature in affected individuals (Lecaille et al., 2008). CTSK-deficient mice have similar lesions. CTSK concentrations decrease with age in humans and rats. Serum CTSK declines in elderly women during calcium carbonate supplementation (Zhao et al., 2010) and in osteoporotic women administered alendronate (Muñoz-Torres et al., 2009). CTSK was slightly decreased in aged rats used as a model of senile osteoporosis (Pietschmann et al., 2007).

Influencing factors (sources of error, interferences, dietary/fasting, etc.): Serum or plasma CTSK can be measured by immunoassay (Skoumal et al., 2005). Concentrations of CTSK decrease with age in people.

15.4.12 MATRIX METALLOPROTEINASES AND TISSUE INHIBITOR OF METALLOPROTEINASES

Physiology, function, and half-life: Matrix metalloproteinases (MMPs) are a large family of calcium or zinc-dependent proteases that cleave a wide variety of substrates in extracellular matrix, as well as nonstructural proteins throughout the body (Nagase et al., 2006; Shiomi et al., 2010). MMP activity is directly controlled by specific inhibitors called tissue inhibitors of matrix metalloproteinases (TIMPs). MMPs and TIMPs are involved in diverse physiologic and pathophysiologic pathways,

including tissue growth and repair, inflammation, tumor metastasis, and fibrosis in many organ systems (van der Jagt et al., 2010; Shiomi et al., 2010). In the skeletal system, MMPs and TIMPs are expressed by osteoblasts, osteoclasts, osteocytes, chondrocytes, and other cells (Hatori et al., 2004). MMPs and TIMPs are involved in skeletal remodeling, endochondral and intramembranous ossification, and vascular invasion/calcification (Andersen et al., 2004; Aiken and Khokha, 2010). They are highly conserved among species (Aiken and Khokha, 2010). While many MMPs and TIMP-1 are secreted and some can be measured in serum and body fluids by immunoassays, their use as clinical markers of skeletal disorders has been hampered by inferior specificity and sensitivity relative to other markers. Serum and synovial concentrations of MMPs and TIMPs have shown some modest value in assessment of conditions such as REF (Keyszer et al., 1999; Hegemann et al., 2002) and osteoporosis (Luo et al., 2006). For example, Hegemann et al. (2003) found that dogs with chronic REF have an increased ratio of synovial MMP-3 to TIMP-1.

15.5 GENERAL PATTERNS OF THE CHANGES IN LABORATORY TESTS RELATED TO SPECIFIC ETIOLOGIES

Markers of bone formation and/or enhanced osteoblastic activity include BALP, OC, PICP, and PINP and markers of bone resorption and/or enhanced osteoclastic activity include NTX-I, CTX-I, PYD, DPD, TRACP5b, and metalloproteases. Because of the complex interrelationships between osteoblasts and osteoclasts, these classifications are somewhat artificial and the markers are probably more accurately applied as a panel as indicators of bone turnover or remodeling. The outcome of changes in bone turnover (i.e., increased bone mass or decreased bone mass) is the balance between bone synthesis and bone resorption processes. Table 15.2 provides general guidelines for several disorders of bone metabolism and the expected findings in widely-available laboratory tests.

15.5.1 OSTEOPOROSIS MODELS

In people, osteoporosis is characterized by low bone mass and microarchitectural deterioration of bone leading to enhanced bone fragility and increased risk of fracture (Vasikaran et al., 2011a).

TABLE 15.2

Conditional Alterations in Bone Biomarkers

	Calcium	Phosphorus	PTH	Vit D3	Other
Primary hyperparathyroidism	Increased	Normal to decreased	Increased	Normal to increased	Increased urine calcium; BALP and OC may be increased
Secondary hyperparathyroidism	Normal to decreased	Increased	Increased	Decreased	–
Hypoparathyroidism	Decreased	Increased	Decreased	Decreased	–
Vitamin D3 excess	Increased	Increased	Decreased to normal	Increased	Normal to increased urine calcium
Vitamin D3 deficiency	Decreased	–	Increased	Decreased	–
Hypercalcemia of malignancy	Increased	Decreased	Normal to low	Normal to increased (inappropriate for concentration of Ca)	PTHrP increased, hypercalciuria

While some species develop osteopenia with age naturally, most experimental animal models of osteoporosis rely on deprivation of reproductive hormones or administration of glucocorticoids for closely approximating the human disease (Herrmann, 2011). Nonetheless, these models have been very important in the discovery of effective therapies. Ovariectomy in females (e.g., mice, rats, sheep, cynomolgus macaques, and rhesus macaques) and orchidectomy in males (e.g., rodents, non-human primates) cause increases in both bone formation and resorption with progressive resorption predominating (Reinwald and Burr, 2008; Sorensen et al., 2007). Other *in vivo* models include dietary interventions, immobilization, retinoic acid-induced hypercalcemia in thyroparathyroidectomized rats, and genetically modified rodents (i.e., osteoprotegerin knockout mice) (Sorensen et al., 2007; Levolas et al., 2008; Reinwald and Burr, 2008). Female aged (>10 years) cynomolgus monkeys develop osteopenia after ovariectomy and have been frequently used to evaluate new treatments, particularly biopharmaceuticals. Many bone turnover markers can be measured in this species (e.g., BALP, OC, PICP, CTX-MMP, CTX-1, NTX-1, urine DPD, and serum PYD) in concert with densitometry, bone histology/histomorphometry, or dynamic histomorphological endpoints. With progression of osteopenia in monkeys, markers such as serum BALP, serum OC, and urine NTX-1/Cr increase significantly reflecting increased bone turnover (Legrand et al., 2003). Ominsky et al. (2011) showed that administration of a RANKL antibody reduced BALP and CTX-1 indicative of decreased bone turnover. CTSK inhibition results in reduced urinary NTx (Stroup et al., 2009) and selective estrogen receptor modulators (i.e. raloxifene, levormeloxifene) lower BALP, TRACP, OC, and urinary collagen degradation products (CrossLaps) (Lees et al., 2002; Hotchkiss et al., 2001). There is considerable interest in applying bone turnover markers in predicting fracture risk in people, although the field is currently hampered by insufficient quality control, assay differences, and limited correlative data (Vasikaran et al., 2011a). There are no standardized bone turnover markers for osteoporosis animal studies. However, an evaluation of markers by the International Osteoporosis Foundation and the International Federation of Clinical Chemistry and Laboratory Medicine concluded that a marker of bone formation (particularly serum PINP) and a marker of bone resorption (particularly serum CTX-1) should be used as reference bone turnover markers in human clinical practice (Vasikaran et al., 2011a, b).

15.5.2 PRIMARY HYPERPARATHYROIDISM

Primary hyperparathyroidism presents as hypercalcemia in concert with inappropriately normal or high PTH concentrations and usually results from increased secretion of PTH by chief cell adenomas, less common causes are parathyroid carcinoma and parathyroid hyperplasia. Prolonged high PTH concentration leads to excessive calcium resorption in the bone and kidney, which results in elevated circulating free and total calcium concentrations and increased urine calcium excretion. PTH inhibits reabsorption of phosphate by the kidney so serum phosphorus concentrations may be normal to low. Most humans are asymptomatic at the time of diagnosis when it is typically recognized during routine laboratory testing (Gopinath and Mihai, 2011). If not diagnosed early—as is more likely to occur in animals—clinical changes related to skeletal weakening and progressive hypercalcemia develop, including lameness, loose teeth, vertebral compression fractures with motor or sensory dysfunction, anorexia, vomiting, constipation, depression, fatigue, and muscle weakness. Although severe skeletal changes are rare in modern clinical practice, untreated patients do exhibit increased bone turnover, decreased bone mineral density, and increased fracture risk (Gopinath and Mihai, 2011). HPTH patients tend to have higher serum BALP and OC compared with healthy controls (Cortet et al., 2000). Trends in other markers are less consistent, that is, CTX-MMP, PICP, and PINP may be similar or increased, and CTX-1/Cr is not different from controls (Cortet et al., 2000). In a rat model of primary hyperparathyroidism, thyroparathyroidectomized animals administered excess PTH for 6 days develop high serum total calcium and 1,25(OH)₂D, low serum phosphorus, and unchanged serum magnesium. Histologic assessment confirmed the presence of nephrocalcinosis and increased numbers of osteoclasts (Jaeger et al., 1987); bone markers were not evaluated.

15.5.3 SECONDARY HYPERPARATHYROIDISM

Secondary hyperparathyroidism may be of nutritional or renal origin. Nutritional hyperparathyroidism occurs when diets contain insufficient calcium or vitamin D or when phosphorus is excessive and calcium content is normal or low. “Cage paralysis” and “simian bone disease” are terms that have been applied to this disorder in New World monkeys, which is due to inadequate vitamin D due to lack of sufficient sunlight exposure or poor diet. Most modern commercial animal diets adhere to species-specific mineral and vitamin requirements, but improper storage or formulation errors can occur. Renal secondary hyperparathyroidism is a multifactorial disorder resulting from the failing kidney's inability to maintain normal excretion of phosphorus in conjunction with reduced calcitriol concentrations due to decreased activity of renal 1- α -hydroxylase. As serum phosphorus rises, FGF23 is upregulated, which further suppresses 1- α -hydroxylase activity. In early kidney failure, declining serum calcitriol and free calcium enhance synthesis and secretion of PTH, which maintains osteoblast activity and stable bone turnover. With disease progression, the parathyroid gland becomes more resistant to calcitriol and to free calcium due to reduced expression of vitamin D receptor and calcium receptor. PTH concentration may actually exceed that observed in primary hyperparathyroidism due to reduced renal degradation of the PTH peptide. Dogs with drug-induced renal failure show increased PTH concentrations within 12 weeks; serum calcium and phosphorus increase after 24 weeks (García-Rodríguez et al., 2003). High dietary phosphorus also exacerbates chief cell hyperplasia and PTH synthesis; indeed, restriction of phosphorus intake can return PTH concentrations toward normal, despite persisting chief cell hyperplasia (Slatopolsky et al., 2001).

With progression, secondary hyperparathyroidism causes severe disturbances in bone metabolism that can lead to fibrous osteodystrophy or osteomalacia. Affected animals may be inactive, less resistant to handling, and may have difficulty in chewing (“rubber jaw”) due to osteoid deposition and fibrous connective tissue proliferation of the jaw. Bones are susceptible to deformity, bowing, and fracture without mineralized calluses. Microscopic lesions include cortical thinning with severe peritrabecular and marrow fibrosis. Soft-tissue mineralization may be evident in the kidneys, cardiovascular system, and intestinal tract. The calcium–phosphorus product ($\text{Ca} \times \text{P}$) has been traditionally used as a marker portending soft-tissue mineralization, but this has been challenged (O’Neill, 2007). Renal failure can be induced in rats by 5/6th nephrectomy. Moderately affected rats have normal total and free calcium, normal phosphorus, low 1,25(OH) $_2$ D, and increased PTH. With increased severity, hypocalcemia develops, but serum phosphate rises only slightly (D’Amour et al., 2011). This model has been used to study the effects of uremia on bone. Treated rats have increased osteoid and changes in bone turnover markers including increased serum concentrations of OC and TRACP and increased urinary PYD and DPD (Oste et al., 2007).

15.5.4 HYPERCALCEMIA OF MALIGNANCY

Animals with humoral hypercalcemia of malignancy or pseudohyperparathyroidism have high serum total and free calcium that is often accompanied by hypophosphatemia, hypercalciuria, and normal or low PTH. Vitamin D may be normal or increased, which is inappropriate in the presence of hypercalcemia. This disorder is caused by autonomous production of PTHrP by neoplastic cells, although other factors (IL-1, TGF- α and - β , vitamin D, TNF α) may play synergistic roles. In dogs, lymphoma is the most common neoplasm associated with hypercalcemia followed by adenocarcinoma of the apocrine gland of the anal sac. In the skeleton, demineralization with increased osteoclasts, decreased trabecular bone, and increased resorptive surface are evident. Mineralization may be seen in soft tissues such as kidney, stomach, or endocardium. Animals exhibit anorexia, vomiting, and constipation due to diminished smooth muscle contractility, weakness, behavioral changes, lameness, bone pain, polyuria and polydipsia, and renal failure (Capen and O’Brien, 2004). Urine NTX-I, Crosslaps, and DPD concentrations are increased in human patients with this disorder (Vinholes et al., 1997).

15.5.5 FUTURE MARKERS OF BONE TURNOVER

As investigators discover new insights into the pathophysiology of bone disorders, potential novel biomarkers have been identified that may provide greater sensitivity and/or specificity relative to current markers. Examples of proposed markers include posttranslationally modified collagen type I, for example, alpha-alpha CTX, beta-beta-CTX, and advanced glycation end products; novel noncollagenous proteins, such as bone sialoprotein, osteopontin, and periostin; and Wnt signaling molecules, including Dickkopf-1 and sclerostin (Cremers et al., 2008).

16.1 GENERAL CONSIDERATIONS

The immune system is a collection of multiple, interconnected and active, and adaptive mechanisms that together are essential for the body's defense against invasion by microbes and other organisms (a thorough review can be found in Tizard, 2013). Immunoglobulin (Ig) proteins or antibodies are an indispensable component of the immune system in vertebrates, including fish, linking the

innate with the antigen-specific defense against invading pathogens such as viruses, bacteria, and parasites. Antibodies are produced by B-lymphocytes and plasma cells, which exclusively transcribe and translate Ig genes by a complex mechanism of recombination. Clonal selection or deletion depending on the affinity of the naturally occurring antibodies produced by their respective lymphocytes to a particular self or foreign antigen results in increasing antigen specificity and affinity, and enhanced efficacy of antigen neutralization or elimination. Aberrant or uncontrolled antibody production against self-antigens can contribute to or cause autoimmune diseases, such as lupus erythematosus. Finally, overproduction of certain antibody classes such as IgE in response to nonpathogenic antigens or allergens can lead to allergic conditions.

Ig can be quantitated either as a protein group in serum analysis or, more specifically, as antigen specific entities. Antibody concentrations vary according to age and are in general absent or lower in neonates, and increase with adulthood and the exposure to naturally occurring antigens in a normal, non-germ-free, environment.

Importantly, Ig can be partially or totally absent in gene-deficient animals (e.g., nude mice). As a consequence, antibody deficiency leads to increased incidence of infectious diseases and debilitating infections with agents of normally low virulence.

Ig diversity, critical for the development of the antigen specific antibody response, is generated through several processes (e.g., V(D)J recombination) that guide somatic rearrangements and mutations of DNA sequences of antigen receptor genes. The processes of simultaneous affinity increase for a particular antigen, and quantitative upgrading of antibody production by specialized plasma cells are unique. For example, through a complex sequence of somatic hypermutation in the Ig gene transcription and translation process, as well as highly regulated mechanisms of clonal expansion of selected B lymphocytes, over a million different antibody specificities with different functions and of variable classes can be identified in one individual. Likewise, clonal deletion of B-lymphocytes with unwanted specificities (e.g., self-recognition) grants protection from self-directed immune reactions in normal individuals. Finally, aberrant regulation of DNA-based recombination events can result in neoplastic geno- and phenotypes of B lymphocytes. There are two types of B lymphocytes (Table 16.1).

Antibody types and concentrations change and increase, respectively, throughout infancy and childhood unless the individual lives in a germ-free environment. Serum levels depend on synthetic rate and degradation or catabolic rate. Antibody secretion by a specialized plasma cell can reach up to several 1000 antibody molecules per second. The half-life depends on the antibody isotype and is longest in the IgG (up to 3 weeks) and shortest in IgD and IgE isotypes. While memory antibodies

TABLE 16.1
B-Lymphocyte Types Contributing to Protective Antibody Titers

	B1	B2
Antibody location	Membrane bound	Secreted, present in blood and tissues
Effect of antigen binding	B-lymphocyte activation, hypermutation, proliferation, antibody secretion, immunoregulation	Effector function: neutralization, complement binding, antibody-dependent cytotoxicity, mast cell degranulation
Isotypes	Blood, mucosal surfaces	Blood, tissues
Location in lymph node	IgM, IgA, IgG	IgG, IgA, IgE
Affinity to antigen	Marginal zone (naive cells)	Follicle (memory cells)
Antigen secretion rate, titers	Low	High
CD5 expression	Low	High, persistent, immunologic memory
	+	-

can persist in serum for years, IgE will disappear within 2–3 days. It follows that the determination of “normal” Ig levels in different laboratory animal species should be accompanied by detailed documentation of health, respectively, infectious pathogen screening programs.

Ig typing and quantification require specific antibodies. Depending on the significance of a particular species to serve as a model of human disease, the qualitative and quantitative analysis of the different isotypes is more or less well documented to date.

Normal antibody levels from a biologic functional point of view cover a certain range. When below this range, increased incidence and severity of infectious diseases are anticipated and seen, including with organisms in general considered of low or no pathogenic potential. On the other side, persistent antibody levels above a certain range can become harmful by formation of immune complexes, leading for instance to glomerular disease in the kidneys.

For reviews concerning maintenance of antibody levels, see Manz et al. (2005); for specifics concerning mucosal antibody production, see Mage et al. (2006); and for details on V(D)J recombination, class switch recombination, and somatic hypermutation, see Xu et al. (2005), Dudley et al. (2005), and Cannon et al. (2004).

16.2 BASIC BIOCHEMISTRY AND GENETIC REGULATION

Most of the initial structural and genetic studies on Ig were performed in the murine and human species. Therefore, much information provided in this chapter is based on these studies to present a general overview of the structure and function of these proteins. However, it is recognized that there is a great diversity of Ig and Ig genes among the different species, and direct extrapolations from mouse and human immune systems are not always possible when studying other species. Some of the structural differences in the Ig of other species, particularly the rabbit, rat, nonhuman primate, and dog will be addressed, and special studies in swine are reviewed below.

Ig from all species possessing such molecules share some common structural features (for a review, see Tizard, 2013). The basic functional unit consists of four polypeptide chains, two light [L], and two heavy [H] chains, linked by interchain disulfide bridges. Each chain can further be subdivided into structural domains, containing at least one intrachain disulfide bond. The domain containing the amino-terminus of each polypeptide chain is termed the variable-region domain, and the domains adjacent to this are referred to as constant-region domains. The ligand-binding ability of Ig resides within the variable portion of the polypeptide chains. The diversity of amino acid sequences found within this region of the polypeptide chains (both H and L) accounts for the great variability of antigen-binding specificities exhibited by Ig. In contrast, the constant-region domains, so named due to their relatively constant amino acid composition among Ig of different specificities, mediate other effector functions associated with the Ig molecule, such as neutralization, complement fixation, protein A binding, opsonization, placental/intestinal transport, immediate hypersensitivity reactions, and antibody-dependent cellular cytotoxicity.

Ig heavy chains are composed of four to five domains, including the variable-region domain. Heavy chains have been further classified based on different structural determinants located in the constant-region domains. In contrast, Ig light chains are composed of only two structural domains and have been classified as being of the kappa (κ) or lambda (λ) isotype chain, again based on determinants found in the constant region of the polypeptide chain. The distribution among different species is shown in Table 16.2. The molecular weight of the light chains from a variety of species has been calculated to be between 20 and 25 kDa. Cross-reactivities between primate species have been noted using light chain inhibition of radioimmunoprecipitation assays (Spiegelberg, 1972).

Much of the information on the structural aspects of Ig molecules comes from molecular genetic studies of the Ig gene. Most of the work in this area was originally done on either mouse or human lymphocytes. Since the findings in the human system (Honjo et al., 1981; Rabbitts et al., 1981) corroborate principles found in the mouse, the murine system will be discussed here (Adams et al., 1981) as a general example of the structure of Ig genes. More recent molecular genetic and structural

TABLE 16.2
Expression of κ and λ Immunoglobulin Light Chain Isotypes in the Sera of Various Species

Order	Species	Percentage of Light Chains in the Serum	
		κ	λ
Lagomorpha	Rabbit	70–90	10–30
Rodentia	Mouse	95	5
	Rat	95	5
	Guinea pig	70	30
Carnivora	Dog	10	90
	Cat	10	90
Primates	Human	70	30
	Rhesus	50	50
	Baboon	50	50

studies of Ig have been conducted on other species and are discussed later (also reviewed in Eason et al., 2004).

Although Ig are composed of only two different polypeptide chains (heavy and light), the genes encoding these polypeptides are highly segmented at the genetic level (Figure 16.1). One should notice that each domain is coded for by one or more segments of DNA with special purpose areas, such as the hinge region or the hydrophobic tail of Ig (allowing insertion into the cell membrane), also encoded by separate gene segments. The heavy chain variable-region domain is encoded by three separate minigene segments (VH, D, and JH) in the germ-line DNA. The VH and D regions of DNA contain many different minigene segments that can be used to construct the variable-region domain, while the JH region contains only four possible segments. During maturation of the B lymphocyte, a recombinational event occurs at the level of the DNA joining one VH segment with one D segment and one JH segment to form a functional VDJ minigene adjacent to the mu

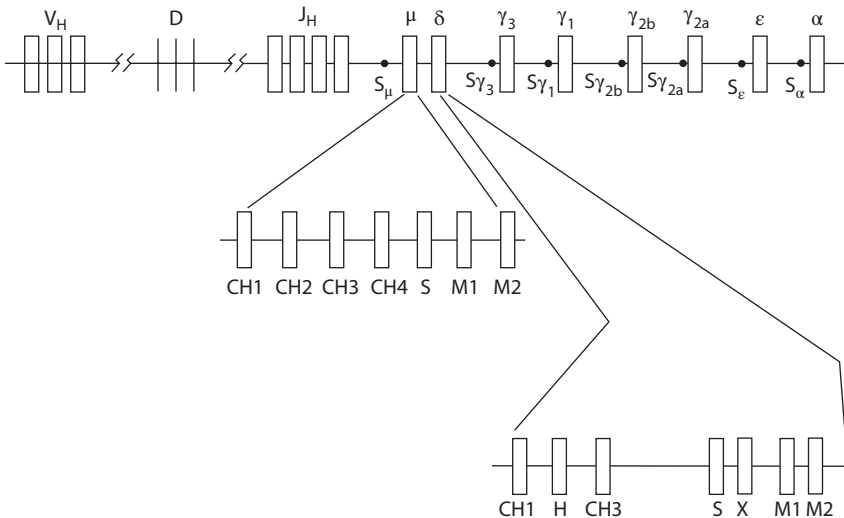

FIGURE 16.1 Diagram of murine Ig heavy chain gene loci. The variable (VH), diversity (D), junction (JH), and constant region genes (μ , δ , γ , ϵ , α) are shown within these loci. The μ and δ constant region portions are expanded to show individual coding segments for the protein domains (CH1–CH3, 4), hinge (H) region and membrane (M1, M2), and secreted (S, γ) tail pieces of the Ig molecule. Also shown are the switch sites (S μ /S γ 3), which allow placement of VDJ gene segments adjacent to the various heavy chain gene regions.

minigene segment (Figure 16.2). Other rearrangements of the genome can also occur to place the VDJ segment in close proximity to other heavy chain constant region minigenes (isotype switching). The VDJ and constant region segments are joined at the level of transcription by RNA splicing to remove the intervening sequences of RNA between individual segments.

The light chain genes have a similar structural basis, with the exception that a D-region segment has not been described, so that only a VJ recombination occurs at the DNA level (Bernard et al., 1978; Sakano et al., 1979; Seidman et al., 1979; Valbuena et al., 1978). Five basic classes, or isotypes, have been defined (IgM, IgG, IgA, IgE, and IgD), and the various aspects of these heavy and light chain isotypes as they pertain to individual species of laboratory animals will be discussed below.

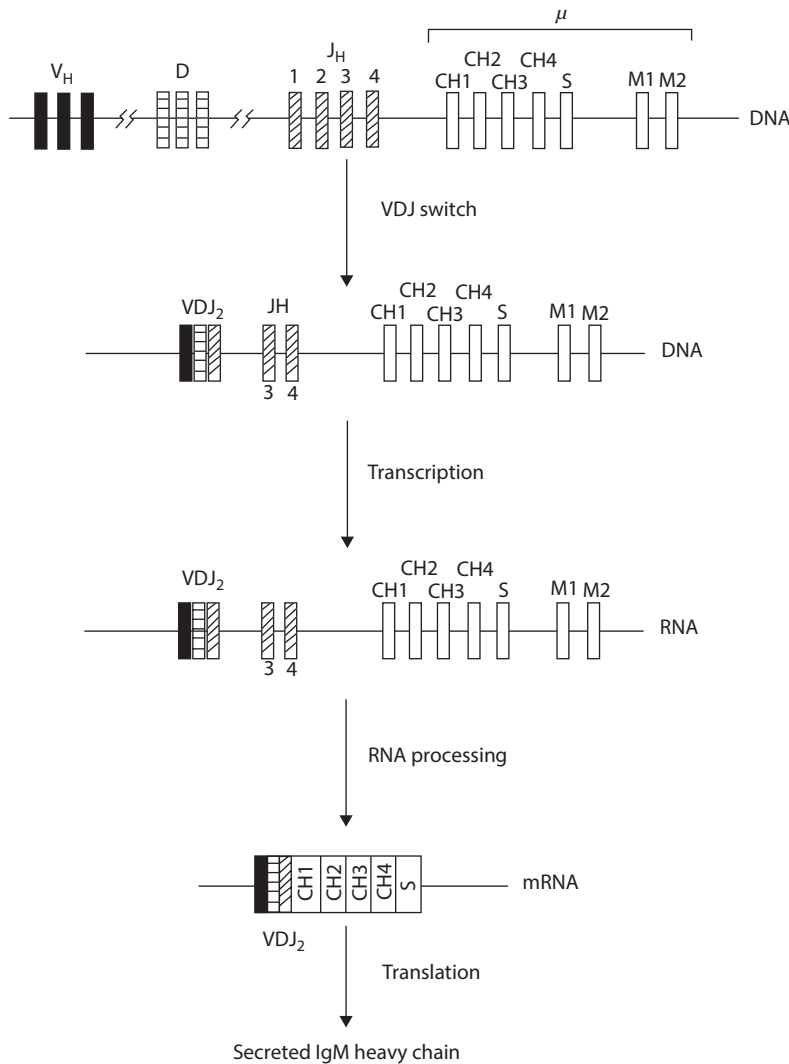

FIGURE 16.2 Diagram of IgM molecule formation (DNA and RNA level). Nascent DNA undergoes a rearrangement early in the development of B cells to yield a VDJ gene combination. The DNA is then transcribed into a precursor RNA molecule, which undergoes further processing and removal of intervening sequences between the VDJ gene segment and the various constant region genes. The mRNA product is then translated into its protein product, in this case a secreted IgM heavy chain molecule.

16.2.1 IMMUNOGLOBULIN ISOTYPES

As mentioned previously, Ig come in different classes known as isotypes. In mammals, there are five antibody isotypes related to the different types of heavy chains the antibody contains, with each heavy chain class named alphabetically: α , γ , δ , ϵ , and μ (known as IgA, IgG, IgD, IgE, and IgM, respectively). Each isotype has different biologic and functional properties (Table 16.3). The classes and subclasses of Ig from a variety of species are shown in Table 16.4, arranged for comparison with their human Ig counterparts. In general, structural and functional correlates of the human Ig subclasses can be found in most other species, although some species appear to lack specific subclasses that can be correlated with their human IgG counterparts.

16.2.1.1 Immunoglobulin G

IgG is the most abundant Ig isotype found in mammalian serum. The central role of IgG is to bind to target antigens and to either activate effector cells (e.g., monocytes) or the complement system to destroy Ig-coated objects (Schroeder and Cavacini, 2010).

All of the IgGs share similar structural and biochemical characteristics. They are composed of two light and two heavy chains and exist in the serum in monomeric form. Interchain disulfide bridges join heavy chains. For example, mouse IgG has three such linkages among the heavy

TABLE 16.3
General Characteristics of Immunoglobulin (Ig) Isotypes in Mammals

Ig Isotype	Heavy Chain	Approximate MW (kDa)	Functional Unit	Description
IgG	γ	150–180	Monomer	Primarily produced by B cells in the spleen and LN, it is the primary circulating Ig responsible for humoral immunity against invading pathogens. The only Ig capable of crossing the placenta.
IgM	μ	900–950	Pentamer	Produced by B cells in the spleen and LN, it is found on B-cell plasma membranes as a monomer, but is secreted into the circulation as a pentamer. Acts as a first responder Ig during the early stages of humoral immunity (prior to IgG secretion).
IgA	α	350–400	Dimer	Produced by B cells; it is found associated with the mucosa of gut, respiratory, and urinary tracts, prevents microbial colonization; also in breast milk, saliva, and tears.
IgE	ϵ	180–200	Monomer	Produced by B cells found in LN draining sites of antigen entry (e.g., the gut and respiratory tracts); least abundant Ig in circulation, it is usually bound to mast cells. Provides protection against parasites and is involved in allergic reactions.
IgD	δ	170–180	Monomer	Produced by B cells, it is found on B-cell plasma membranes often coexpressed with IgM. It is also secreted in low amounts into the circulation. It appears to function as an antigen receptor on B cells that have not been exposed to antigens. It has also been shown to activate basophils and mast cells.

TABLE 16.4
Immunoglobulin Classes and Subclasses in Different Species

Species	Immunoglobulin Class and Subclass				
Human	IgG1, IgG2, IgG3, IgG4	IgA1, IgA2	IgM1, IgM2	IgE	IgD
Ape	IgG ^a	IgA	IgM	IgE	IgD
Monkey	IgG ^b	IgA	IgM ^c	IgE	IgD
Mouse	IgG2a, IgG2b, IgG3, IgG1	IgA1, IgA2	IgM	IgE	IgD
Rat	IgG2a, IgG2b, IgG2c, IgG1	IgA	IgM	IgE	IgD
Rabbit	IgG2, IgG1	IgA1, IgA2	IgM	IgE	IgD
Dog	IgG1, IgG2, IgG3, IgG4	IgA	IgM	IgE	IgD
Swine ^d	IgG1, IgG2, IgG3, IgG4, IgG5, IgG6	IgA	IgM	IgE	IgD

^a Using antisera specific for human subclasses, four corresponding subclasses have been identified in the chimpanzee, gorilla, and orangutan.

^b Four subclasses have been identified in the baboon based on γ -chain differences, though these determinants are not shared with the human subclasses.

^c Two distinct types have been reported in the rhesus monkey after immunization.

^d According to Butler et al. (2009a).

chains, while the rabbit IgG has only a single disulfide link similar to that found in human IgM and IgD. IgG from other species, however, may be more variable in the number of interchain disulfide bridges, as evidenced from the human IgG subclasses, which have 2–15 such linkages among the chains.

The IgG isotype exhibits the greatest degree of diversity with respect to the number of subclasses defined for each species. Four subclasses have been defined for human, dog, mouse, and rat IgG. In nonhuman primates, the cross-reactivity of five different rabbit polyclonal antibodies to human IgG and IgG subclasses (IgG1, IgG2, IgG3, and IgG4) was examined for several apes, including New and Old World monkeys (Asada et al., 2002). The authors demonstrated that, similar to previous reports, the level of reactivity of antihuman IgG antibody with plasma IgG from different primate species was related to the phylogenic distance from humans. Antisera specific for the four human subclasses identified similar molecules in the sera of chimpanzees, gorillas, and orangutans (Alepa, 1968; Alepa and Terry, 1965). Based on antigenic differences in the Fc region of the Ig-heavy chain molecule, baboons demonstrated four IgG subclasses (Damian et al., 1971). More recently, serum protein A- and protein G-purified human IgG consisted of IgG1, IgG2, IgG3, and IgG4, whereas baboon and macaque IgG demonstrated only IgG1, IgG2, and IgG4 (Shearer et al., 1999).

Cleaved by various enzymes, IgG molecules yield specific peptide fragments. For example, treatment with papain cleaves the IgG molecule into three fragments of approximately equal molecular weight (45–50 kDa). Two of the fragments formed contain an intact antigen-binding region (light chain plus two heavy chain domains) and are termed the Fab portion of the molecule. The third fragment, termed the Fc portion, is composed entirely of heavy chain domains from the carboxyl-terminal end of the molecule. The isolated Fc portion of rabbit Ig was found to crystallize from solution, indicating the homogeneity of the isolate (Porter, 1959). However, Fc regions from other species, including the dog, mouse, and rat, do not crystallize easily from solution. In contrast, rabbit IgG is composed almost entirely of a single IgG subclass (IgG1) and therefore would yield a very homogeneous preparation of Fc fragments for crystallization.

Pepsin treatment of IgG from most species, including rabbits (Nisonoff et al., 1960a, b) and people (Nisonoff et al., 1975a), yields a single large fragment termed F(ab')₂ (MW 95 kDa), which includes the hinge region of the original molecule and some smaller fragments of the Fc portion of the molecule that are nonfunctional and not recognized by Fc-specific antisera. However, mouse

IgG has been shown to be sensitive to treatment with pepsin, although not yielding many $F(ab')_2$ fragments; instead, the molecule is digested into smaller fragments. This sensitivity to pepsin digestion is presumed to reflect unfolding or denaturation of the molecule caused by the low pH required for proteolytic activity of the enzyme (Gorini et al., 1969).

The various IgG subclasses have been defined using subclass-specific antisera; however, they differ in their functional (to be discussed later) and some of their biochemical properties. The IgG1 (IgGd) subclass of the dog differs from IgG of other species in that this molecule will not cause precipitation of multideterminant antigens from solution. Structural analysis of both molecules does not show any commonality that could account for this property (Grant et al., 1972).

16.2.1.2 Immunoglobulin M

Immunoglobulin M is the second most abundant and largest Ig isotype found in mammalian serum (Tizard, 2013). Due to its size, IgM is predominantly found in plasma; it does not cross the placenta and is found in tissue fluids in small amounts. Dubbed the “natural antibody,” IgM has been isolated from serum bound to specific antigens without prior immunization (Jayasekera et al., 2007). It is the first antibody to appear in response to initial exposure to an antigen and is superior to IgG at complement activation (i.e., 1000-fold higher binding affinity for C1q than IgG, see Ehrenstein and Notley, 2010). On its own, IgM is not an effective opsonin (Wellek et al., 1976); however, with the activation of complement, it does amplify opsonization by inducing antigen binding by C3b. IgM is also primarily responsible for the erythrocyte agglutination that occurs as result of an incompatible blood transfusion.

IgM has been found in virtually all vertebrates tested and is thought to be the most evolutionarily conserved Ig class. Generally, this class does not show any subclass diversity; however, human IgM is known to exist in two forms (IgM1 and IgM2), and there has been a suggestion that the rhesus monkey may also have two forms of IgM (Lakin et al., 1969).

Secreted IgM from all species exists primarily as a pentamer of the basic 7S subunit characteristic of Ig. This 19S molecule has a molecular weight in the range of 900–1000 kDa (Bours et al., 2005; Tizard, 2013). The 7S chains are linked by a J chain disulfide bonded to the penultimate half-cystine residue of the heavy chains (Mestecky and Schrohenloher, 1974). The J chain is associated with IgM molecules from most species, including people, dogs, rabbits, mice, and rats. The molecular weight of the J chain is between 14 and 16 kDa, depending upon the species from which it was isolated and the procedure used for analysis. The J chain has also been shown to be a highly conserved molecule among the vertebrates. There is a high degree of sequence homology and cross-reactivity of anti-J chain antisera between widely divergent species.

Classically, the IgM pentameric structure can be disintegrated into its components by the reduction of the J chain disulfide links with 2-mercaptoethanol. The 7S unit of IgM is characteristically heavier than its IgG counterpart, having a molecular weight of 190 kDa (Arnason et al., 1964; Fahey et al., 1964a; Lakin et al., 1969). This is due in part to the IgM molecule containing an extra heavy chain domain (four heavy chain domains in IgG, five in IgM) and to the higher proportion of carbohydrate groups associated with the heavy chain (10%–11% carbohydrate for IgM, vs. 2%–3% for IgG). This higher content of carbohydrate allows separation of IgM from IgG by using a lentil-lectin affinity column preferentially binding the IgM molecules. Proteolytic digestion of IgM with papain or pepsin will yield Fab and $F(ab')_2$ fragments, respectively, as found for IgG; however, the Fc portion is usually digested and cannot be isolated as an intact fraction as with IgG (Richerson et al., 1968).

As mentioned above, the polymerization of the IgM molecules results most commonly in secretion of a pentamer. However, though not abundant, a hexameric form of IgM also exists in people and animals (Hughey et al., 1998; Wiersma et al., 1998). While the J chain is found in the pentameric form of IgM, it is not found in the hexameric form (Kownatzki, 1973). Additionally, while its physiologic function/relevance has not been characterized, hexameric IgM has a higher activity of complement fixation than pentameric IgM (Randall et al., 1990). This increased activity can range between 2- and >100-fold depending on species of the complement source (Randall et al., 1990; Collins et al., 2002).

16.2.1.3 Immunoglobulin A

The structure and function of IgA in people and other species have been reviewed (Kerr, 1990; Woof and Russell, 2011; Snoeck et al., 2006; Rogier et al., 2014). This Ig class and the respective B lymphocytes are primarily found in tissues associated with mucosal surfaces, their glands and their secretions, respectively. This includes salivary gland and saliva, liver and bile, mammary gland, colostrum and milk, lacrimal gland and tears, and the intestine. Stability to protease activity is provided by a polymeric structure and the association with the secretory component. While IgA typically will not contribute to agglutination or opsonization, it is an important mediator of antibody-dependent cytotoxicity, and a process called immune exclusion on mucosal surfaces. In terms of immunomodulation, fetal IgA has been found to be able to bind potentially harmful maternal autoreactive antibodies. Typically, activated natural IgA producing B lymphocytes will migrate from the mucosa-associated immune tissue (MALT) through the blood and lymph to high endothelial venules and subepithelial stroma, where potential pathogens will be bound and transported back to the lumen of the gut. An exception to this process was found in rodents and lagomorphs, where polymeric serum IgAs are directly secreted from bile and hepatocytes to the gut.

The secreted form of IgA is typically a dimer (or larger polymer) of the 7S monomer linked by both a J chain and a secretory component (SC, MW 70 kDa). The J chain is structurally the same as that associated with IgM and binds the IgA molecule at the penultimate half-cystine on the heavy chains. The secretory component, which has high carbohydrate content (15%–20%), is also associated with the heavy chains. This association includes both noncovalent and covalent interactions of the secretory component with the IgA heavy chain. The noncovalent interactions occur between the N-terminal SC1 portion of the secretory component and the C α 3 domains of IgA. The covalent associations are the disulfide bonds forming between the SC5 of the secretory component and the cysteine at position 311 of the IgA heavy chain (Mestecky et al., 1991). The secretory component is derived from a transmembrane protein called polymeric Ig receptor expressed on the surface of epithelial cells (Mostov et al., 1980; Mostov and Bloebel, 1982). This protein has structural homologies with the Ig molecule (Mostov et al., 1984) and is used to transport IgA or IgM from the basolateral surface of the cell, across the intracellular matrix (as an endocytotic vesicle), and to the luminal surface, where a proteolytic event cleaves the protein, yielding the soluble secretory piece in association with the polymeric Ig molecules (Mullock et al., 1979; Nagura et al., 1979; Renston et al., 1980; Simionescu, 1979; Sztul et al., 1983).
