FOREWORD

A big part of my role as a physician is educating my patients about their health. I take as much time as each person needs to explain prevention measures, test results, and treatment options. I encourage questions. But in the moment, sitting there in my office, most people do not yet know what to ask me. By the time questions flood their thoughts, they may be back at work or at home.

Numerous events and circumstances can challenge health, and we all need to know what actions we can take to keep ourselves healthy as well as to obtain appropriate treatment for health conditions that do affect us. Knowledge empowers all of us to make informed and appropriate decisions about health care. Certainly there is no shortage of reference material. Yet there is *so* much information available today! Even for physicians, it is challenging to keep up. How can you get to the core of what you want to know, reliably and to the level of detail you need?

The Facts On File Encyclopedia of Health and Medicine is a great resource for up-to-date health information presented in a manner that is both comprehensive and easy to understand no matter what your level of medical knowledge. The encyclopedia organizes entries by body system. The progression of body systems—and entries—throughout the encyclopedia presents topics the way you think about them.

Going beyond this basic structure, however, is another layer of organization that particularly appeals to me, which is a comprehensive structure of cross references that integrates entries across body systems. After all, your body functions in an integrated way; so, too, should a reference series that discusses your body's health. Not very much that happens with your health affects one part of your body in isolation from other body structures and functions. Your body attempts to compensate and adjust, often without your awareness, until it can no longer accommodate the injury or illness. The symptoms you bring to your doctor may reflect this compensation, for example frequent headaches that point not to brain tumor (as many people fear but is very rare) but to eye strain or muscle tension or sometimes to hypertension (high blood pressure).

In my medical practice I emphasize integrative health care, embracing the philosophy that health exists as the intricate intertwining of the body's many systems, structures, and functions. So, too, does the care of health. I received my medical degree from Tufts University School of Medicine in Boston, an institution noted for remaining at the forefront of the medical profession. I also completed clinical programs in Mind-Body Medicine at Harvard University, Integrative Medicine at the University of Arizona School of Medicine, and Medical Acupuncture at the University of California-Los Angeles (UCLA). I am a board-certified obstetrician-gynecologist, a board-certified clinical nutritionist, and a licensed acupuncturist. I see patients in my practice in Cincinnati, Ohio; I teach, I lecture, and I frequently go on television and radio to talk about health topics. In each of these areas, I encourage people to think about their health and health concerns from an integrative perspective. When you understand your health from multiple dimensions, you can better understand what to do to keep yourself as healthy as possible.

I wish you the best of health for all of a long, satisfying life. But when the time comes that you must make decisions about medical care, I want you to have the knowledge to make informed

choices that are right for you. Whether you start here and move on to more specialized resources or locate all the information you need within these four volumes, you will find *The Facts On File Encyclopedia of Health and Medicine* to be a most valuable reference resource.

HOW TO USE
THE FACTS ON FILE ENCYCLOPEDIA OF HEALTH AND MEDICINE

Welcome to *The Facts On File Encyclopedia of Health and Medicine*, a four-volume reference set. This comprehensive resource is an indispensable reference for students, allied health professionals, physicians, caregivers, lay researchers, and people seeking information about health circumstances and conditions for themselves or others. Entries present the latest health concepts and medical knowledge in a clear, concise format. Readers may easily accumulate information and build a complete medical profile on just about any health or medical topic of interest or concern.

A New Paradigm for the Health and Medical Encyclopedia

As the art and science of health and medicine continues to evolve, with complex and elegant discoveries and new techniques, medications, and treatments emerging all the time, the need has arisen for a new paradigm for the encyclopedia of health and medicine—a rethinking of the old, and increasingly outmoded, presentations. Carefully researched and compiled, *The Facts On File Encyclopedia of Health and Medicine* offers many distinguishing features that present readers and researchers with an organization as up-to-date and compelling as the breakthrough information its entries contain.

Recognizing the current emphasis on presenting a truly integrative approach to both health and disease, *The Facts On File Encyclopedia of Health and Medicine* organizes content across volumes within a distinctive format that groups related entries by body system (for example, "The Cardiovascular System") or by general health topic (for example, "Genetics and Molecular Medicine"):

- **Volume 1** presents the sensory and structural body systems that allow the body to engage with its surroundings and the external environment.
- **Volume 2** presents the cell- and fluid-based body systems that transport nutrients, remove molecular wastes, and provide protection from infection.
- **Volume 3** presents the biochemical body systems that support cellular functions.
- **Volume 4** presents topics that apply across body systems (such as "Fitness: Exercise and Health") or that address broad areas within health care (such as "Preventive Medicine").
- The appendixes provide supportive or additional reference information (such as "Appendix X: Immunization and Routine Examination Schedules").

Following Research Pathways

The Facts On File Encyclopedia of Health and Medicine's organization and structure support the reader's and researcher's ease of use. Many encyclopedia users will find all the information they desire within one volume. Others may use several or all four of the encyclopedia's volumes to arrive at a comprehensive, multifaceted, in-depth understanding of related health and medical concepts and information. Researchers efficiently look up information in *The Facts On File Encyclopedia of Health and Medicine* in several ways.

Each section's entries appear in alphabetical order (except the entries in Volume 4's "Emergency and First Aid" section, which are grouped by type of emergency). The researcher finds a desired entry by looking in the relevant volume and section. For example, the entry for **acne** is in Volume 1 in the section "The Integumentary System" and the entry for **stomach** is in Volume 3 in

the section "The Gastrointestinal System." The researcher can also consult the index at the back of the volume to locate the entry, then turn to the appropriate page in the volume.

Terms that appear in SMALL CAPS within the text of an entry are themselves entries elsewhere in *The Facts On File Encyclopedia of Health and Medicine*. Encyclopedia users can look up the entries for those terms as well, for further information of potential interest. Such SMALL CAPS cross references typically provide related content that expands upon the primary topic, sometimes leading the user in new research directions he or she might otherwise not have explored.

For example, the entry **hypertension** is in the section "The Cardiovascular System." The entry presents a comprehensive discussion of the health condition hypertension (high blood pressure), covering symptoms, diagnosis, treatment options, risk factors, and prevention efforts. Among the numerous SMALL CAPS cross references within the hypertension entry are the entries for

- **retinopathy**, an entry in the section "The Eyes" in Volume 1, which discusses damage to the eye that may result from untreated or poorly managed hypertension
- **blood pressure**, an entry in the Volume 2 section "The Cardiovascular System," which discusses the body's mechanisms for maintaining appropriate pressure within the circulatory system
- **stroke** and **heart attack**, entries in Volume 2's "The Cardiovascular System" about significant health conditions that may result from hypertension
- **kidney,** an entry in the section "The Urinary System" in Volume 3, which discusses the kidney's role in regulating the body's electrolyte balances and fluid volume to control blood pressure
- **atherosclerosis, diabetes, hyperlipidemia,** and **obesity**, entries in the sections "The Cardiovascular System" in Volume 2, "The Endocrine System" in Volume 3, and "Lifestyle Variables: Smoking and Obesity" in Volume 4, and all of which are health conditions that contribute to hypertension

Following the path of an encyclopedic entry's internal cross references, as shown above, can illuminate connections between body systems; define and apply medical terminology; reveal a broad matrix of related health conditions, issues, and concerns; and more. The SMALL CAPS cross references indicated within the text of encyclopedic entries lead encyclopedia users on wide-ranging research pathways that branch and blossom.

At the end of the entry for **hypertension** a list of cross references gathered in alphabetical order links together groups of related entries in other sections and volumes, such as **smoking cessation** in Volume 4's "Lifestyle Variables: Smoking and Obesity," to provide specific, highly relevant research strings. These *see also* cross references also appear in SMALL CAPS, identifying them at a glance. Encyclopedia users are encouraged to look here for leads on honing research with precision to a direct pathway of connected entries.

So, extensive cross-references in *The Facts On File Encyclopedia of Health and Medicine* link related topics within and across sections and volumes, in both broad and narrow research pathways. This approach encourages researchers to investigate beyond the conventional level and focus of information, providing logical direction to relevant subjects. Each cross-referenced entry correspondingly has its own set of cross references, ever widening the web of knowledge.

Using the Facts On File Encyclopedia of Health and Medicine

Each section of the encyclopedia begins with an overview that introduces the section and its key concepts, connecting information to present a comprehensive view of the relevant system of the human body or health and medical subject area. For most body systems, this overview begins with a list and drawings of the system's structures and incorporates discussion of historic, current, and future contexts.

Entries present a spectrum of information from lifestyle factors and complementary methods to the most current technologic advances and approaches, as appropriate. Text that is set apart or bold within an entry gives an important health warning, or targets salient points of interest to add layers of meaning and context. Lists and tables

collect concise presentations of related information for easy reference.

Each type of entry (mid-length and longer) incorporates consistent elements, identified by standardized subheadings:

- ***Entries for health conditions and diseases*** begin with a general discussion of the condition and its known or possible causes and then incorporate content under the subheadings "Symptoms and Diagnostic Path," "Treatment Options and Outlook," and "Risk Factors and Preventive Measures."
- ***Entries for surgery operations*** begin with a general discussion of the procedure and then incorporate content under the subheadings "Surgical Procedure," "Risks and Complications," and "Outlook and Lifestyle Modifications."
- ***Entries for medication classifications*** begin with a general discussion of the type of medication and its common uses and then incorporate content under the subheadings "How These Medications Work," "Therapeutic Applications," and "Risks and Side Effects."
- ***Entries for diagnostic procedures*** begin with a general discussion of the test or procedure and then incorporate content under the subheadings "Reasons for Doing This Test," "Preparation, Procedure, and Recovery," and "Risks and Complications."

Entries in Volume 4's section "Emergency and First Aid" are unique within the orientation of *The Facts On File Encyclopedia of Health and Medicine* in that they feature instructional rather than informational content. **These entries do *not* replace appropriate training in emergency response and first aid methods.** Rather, these entries provide brief directives that are appropriate for guiding the actions of a person with little or no first aid training who is first on the scene of an emergency.

Each volume concludes with a complete, full index for the sections and entries within the volume. Volume 4 of *The Facts On File Encyclopedia of Medicine* contains a comprehensive index for all four encyclopedia volumes that researchers can use to quickly and easily determine which volumes contain desired sections or entries.

The Facts On File Encyclopedia of Health and Medicine in Four Volumes

PREFACE TO VOLUME 1

Leading the reader into the four-volume *The Facts On File Encyclopedia of Health and Medicine* through Volume 1 are the structures and functions that lead the body's way in the world. These are the body systems that equip the body to interact with its external environment. Some people refer to these as the "interface" systems, drawing from the concepts and terminology of computers. These systems allow the body to receive and respond to sensory input.

The Ear, Nose, Mouth, and Throat

Volume 1's first section is the "The Ear, Nose, Mouth, and Throat." Through these structures the body receives auditory, olfactory, and gustatory sensory information—sounds, smells, and tastes. The throat does double duty as the conduit to carry both air and nutrition, essential sustenance for the body, and also makes possible the uniquely human form of communication—speech.

The functions of these sensory organs and structures overlap and integrate with each other in ways such that the loss of one sensory system affects others. Speech is difficult without the ability to hear, for example, and the sensory pathways for smell and taste are so intertwined that both networks become impaired when one or the other does not function properly. Olfactory nerve fibers are capable of detecting thousands of odors, enhancing the brain's ability to interpret hundreds of flavors with input from only four basic taste qualities (sweet, sour, salt, and bitter).

The sense of touch resides in specialized nerves that populate the surface of the skin in varying concentrations to provide different levels of tactile response. The lips and fingertips, for example, are exquisitely sensitive, while the surfaces of the arms and legs are less responsive to touch. The structures of the inner ear also regulate the body's balance, integrating with the nervous system as well as the musculoskeletal system (as anyone who has found it challenging to walk after spinning in circles well knows).

The Eyes

Sight is so highly refined in humans that many people consider it the most important of the five senses. The structures of vision function independently from other sensory structures, though the brain combines sensory information to develop complex perspectives about the body's placement and function within its external environment.

The two eyes work independently as well, though synchronously. The brain blends and interprets the information it receives from each eye to form images that have spatial dimension. This provides depth perception, which interplays with proprioception (the body's sense of its placement within its physical environment) and movement. The loss of vision in one eye requires the brain to rely more on other sensory input and on learned responses to help the body navigate in a dimensional world.

The Integumentary System

The structures of the integumentary system—skin, nails, and hair—cover and protect the body from the external environment as well as provide the basis for appearance and identity. Integument is Latin for "cloak," an apt term for the system that envelops the body and literally holds it together.

The integumentary system provides front-line defense against infection as a barrier as well as through immune cells and substances that reside

among the skin cells, helps maintains fluid and body temperature, and contains millions of sensory nerve cells. Most of the body's pain receptors are among these nerve cells. Remarkably resilient and flexible, the skin continually renews itself.

The Nervous System

The nervous system is both command central (the brain) and intercellular highway (the nerves), orchestrating every function within the body—more often than not without conscious awareness of its myriad activities. The nervous system interprets and responds to sensory information, continuously adjusting and accommodating its functions. These functions require chemical messengers—neurotransmitters—as well as electrical activity among cells. Nerves range in size from microscopic to several feet in length.

The Musculoskeletal System

Giving the body the ability to resist the force of gravity to provide shape and mobility is the musculoskeletal system—the bones, connective tissues, and muscles. These structures have density and strength. They use leverage and oppositional function to move the body—walk, run, jump, skip, and even turn cartwheels. These functions require coordination with the nervous system, sensory systems, and balance structures within the inner ear. Health conditions that affect the musculoskeletal system—ranging from injuries such as sprains and fractures to degenerative processes such as osteoarthritis—are among the most common reasons people seek medical care.

Pain and Pain Management

The final section in Volume 1 is "Pain and Pain Management"—not, of course, a body system but rather a discipline (specialty) within the practice of medicine that examines the interactions of the foundational body systems that, when disrupted, result in pain. A complex physiologic experience, pain typically arising from multiple causes that cross these body systems. Consequently, so must its treatment approaches. The entries in "Pain and Pain Management" cover the mechanisms of pain as well as health conditions in which pain is the primary symptom.

THE EAR, NOSE, MOUTH, AND THROAT

The structures of the ear, nose, mouth, and throat carry out the functions of hearing, balance, smell, taste, speech, and swallowing. Practitioners in the medical field of otolaryngology specialize in providing care for these structures. This section, "The Ear, Nose, Mouth, and Throat," presents a discussion of the structures and their functions, an overview of otolaryngologic health and disorders, and entries about the health conditions that can affect them.

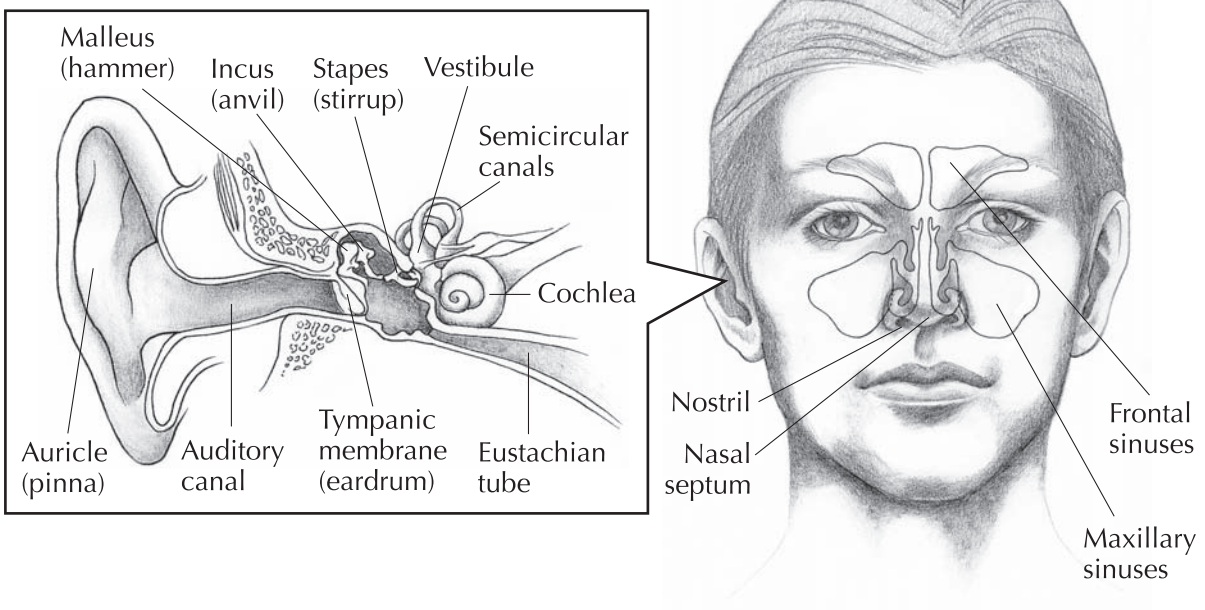
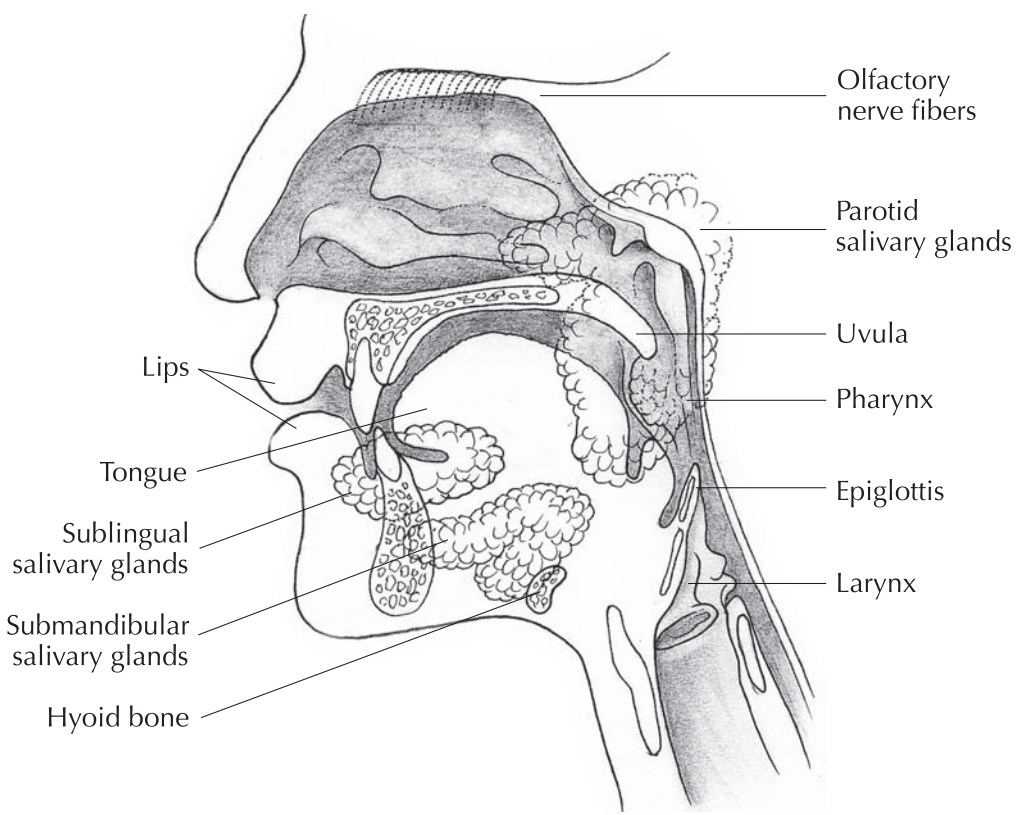
Functions of the Ear, Nose, Mouth, and Throat

The ears, nose, and mouth (along with the eyes) are the primary features of the head and face. They form the hallmarks of recognition and individual identity throughout life. Yet the functions of these features are far more than cosmetic. They are important for survival as well as for refined sensory perception, making it possible to comprehend and interact with the external environment. Taste and smell, the chemosenses, provide the combined sensation of flavor—a blend of the mouth's ability to perceive four distinct tastes and the nose's ability to detect thousands of odors. Hearing allows the BRAIN to register sounds across a broad spectrum of frequency and volume.

The structures responsible for sensory perception begin to take shape as early as the third week of embryonic development and function at a fairly high level by birth. These senses—taste, smell, and hearing—serve as basic survival mechanisms for newborns, helping them identify their mothers, food sources, and hazards until other senses and cognitive abilities adequately develop. Survival also depends on the ability to suck or chew and swallow, requiring coordinated movements of the structures of the mouth and throat. The brain's temporal lobe, which processes hearing, language, and speech as well as smell, takes a developmental leap about three months after a baby's birth, vastly expanding sensory perceptions and communication capabilities. Further cerebral

Structures of the Ear, Nose, Mouth, and Throat





development continues well into ADOLESCENCE, refining the brain's ability to interpret and categorize the signals the senses send to it.

Functions of the ear: hearing and balance Hearing (audition) occurs through air conduction and BONE conduction of sound waves. The structures of the outer and middle ear facilitate air conduction. The outer ear, called the auricle or pinna, is a structure of CARTILAGE and SKIN that extends from the side of the head. Its somewhat dishlike structure serves to "catch" sound waves traveling through the air; its ridges and curves channel those sound waves into the auditory canal. The auditory canal funnels and focuses the sound waves, directing them to the TYMPANIC MEMBRANE or eardrum, which vibrates in response. The tympanic membrane marks the end of the outer ear and the start of the middle ear, creating a sealed chamber. Its vibration activates, in sequence, the three tiny auditory ossicles, or bones, of the middle ear: first the malleus (hammer), then the incus (anvil), and finally the stapes (stirrup). The flat of the stapes rests against the oval window, a small translucent membrane in the wall of the COCHLEA. This point of contact represents the transition from the middle ear to the inner ear and from an environment of air to one of fluid.

The middle ear is pressurized, allowing the tympanic membrane and the auditory ossicles to vibrate freely and without resistance. The EUSTACHIAN TUBE, a short canal of tissue, connects the middle ear with the upper throat at the back of the nose. Somewhat like an elongated valve, it serves to equalize pressure between the middle ear and the external environment. Swallowing and yawning force air into the eustachian tube, causing it to open (sometimes with a perceptible *pop*). Unequal pressure between the middle ear and the atmosphere causes the tympanic membrane to bulge in the direction of the lower pressure, altering its ability to convey the vibrations of sound waves. Circumstances that prevent the eustachian tube from opening to balance air pressure, such as a cold that fills the nasal passages and eustachian tubes with congestion, causes the sensation of muffled hearing and pressure in the ear. When pressure in the middle ear remains lower than the atmospheric pressure for a prolonged time, the body attempts to compensate by drawing fluid into the middle ear. Though the fluid may relieve the sensation of pressure, it further constrains middle ear function. Blocked eustachian tubes establish ideal conditions for middle ear INFECTION (OTITIS media), allowing BACTERIA to move into the middle ear. Until about age 10, the eustachian tubes are nearly horizontal. As the child's facial structure lengthens with maturity the eustachian tubes shift and angle downward from the ears to the throat, improving their ability to drain congestion and remain open.

The vibration of the stapes against the oval window amplifies the energy of the sound waves and sets in motion the fluid (endolymph) within the cochlea on the other side of the oval window. Fluid further focuses and aligns the sound waves into patterns. A second membrane, the round window, dissipates excessive vibration into the fluid of the inner ear (perilymph) on its other side. The moving endolymph within the cochlea in turn stimulates microscopic fibers along a membrane that forms a structure within the cochlea called the organ of Corti. The fibers resonate to specific sound waves, activating NERVE impulses in specialized cells called HAIR cells. The cochlear nerve carries the nerve impulses to the eighth cranial nerve (vestibulocochlear nerve), which in turn transmits them to the brain's temporal lobe. The temporal lobe filters, interprets, and analyzes the nerve impulses, translating them into sound messages including language.

The bony structures of the head and face also conduct sound waves. Bone conduction bypasses the outer and middle ears. Sound waves instead travel as vibrations along the bones to the inner ear, where they pass to the bony part of the cochlea. The vibrations of the bony cochlea pass to the endolymph, and the rest of the hearing process unfolds. Sounds conveyed through bone conduction are significantly restricted in tonal range and volume because they bypass the amplifying structures of the tympanic membrane and auditory ossicles. The sound waves of one's own voice travel primarily through bone conduction along the bones of the face, which explains why it seems so different when heard as a recording in which the sound waves travel by air conduction.

The inner ear also manages the body's balance and motion in relation to gravity. The structures

and functions that do so make up the vestibular system. The bony labyrinth, which also houses the cochlea, supports the membranous labyrinth. Five fluid-filled structures within the membranous labyrinth sense motion and movement: the three semicircular canals, which sense rotational movement, and the saccule and utricle, which sense linear movement. The saccule senses movement that is up-and-down; the utricle senses back-and-forth and left-to-right movement. These structures are all open to one another; however, they form a closed network among themselves that contains endolymph. Movement causes shifts in pressure of the endolymph, which nerve cells register and send as electrical impulses to the vestibular nerve. The vestibular nerve conveys these impulses to the eighth cranial nerve, which in turn carries them to the brain. The brain interprets the vestibular messages along with other input from sensory nerve cells (proprioceptors) located throughout the body, nearly instantaneously responding with neuromuscular signals that initiate movement.

Extremes of movement, such as rapid swinging or spinning, can temporarily disrupt the vestibular system, causing dizziness and NAUSEA. Some people experience such symptoms with less extreme movement, such as riding in a car, boat, or airplane, known commonly as motion sickness. More serious dysfunctions and disorders of the vestibular system, such as MÉNIÈRE'S DISEASE and LABYRINTHITIS, can result in debilitating loss of balance.

Functions of the nose: breathing and smell The nose protrudes from the front of the face. Its placement allows it to draw air into the body in one of life's most basic activities, BREATHING. Most of the nose's external structure is CARTILAGE and SKIN; the nasal bone is less than one half inch long. The ethmoid, vomer, and maxilla bones frame the back of the nose. Ridges in these bones, the nasal conchae, direct the flow of air into the SINUSES. These chambers, along with the nose's mucus lining, moisturize and warm each breath so it does not irritate the airways and lungs. A tissue wall, the nasal septum, divides the nasal cavity into two channels, the nostrils. Tiny hairs line the inner nostrils and are responsible for keeping the nasal passages clear of debris.

The nose is also the body's organ of smell, responsible for the functions of olfaction. The first cranial nerve (olfactory nerve) terminates in the olfactory bulb and a bristlelike patch of olfactory nerve endings along the roof of the nose. These olfactory nerve endings detect the presence of odor molecules in the air that enters the nose. Fibers of the palatine nerves, which detect taste, are also present along the floor of the nose, though not nearly in the abundance with which they infiltrate the mouth. The brain interprets the blend of nerve impulses from the palatine nerve endings and the olfactory nerve endings and integrates them into perceptions of flavor.

Functions of the mouth and throat: taste, swallowing, and speech The mouth and throat make it possible to eat and speak. The powerful masseter muscles open and close the mandible (lower jaw), generating over 500 pounds per square inch of pressure as the TEETH come together to bite and in excess of 3,500 pounds per square inch of force at the back teeth (molars) with chewing. The hyoid bone helps anchor the back of the tongue, another powerful MUSCLE. The SALIVARY GLANDS, present in pairs on each side of the mouth, produce two to three pints of saliva every day. This watery liquid contains enzymes and mixes with food to begin breaking it down, an early stage of digestion, as well as to soften it for swallowing. The cheeks, tongue, and lips help contain food within the mouth and push it to the back of the throat for swallowing; they also shape the flow of air and create the formation of words during speech. These functions require muscular control and coordination.

The sense of taste is called gustation. Though common perception is that the bumps on the tongue are the taste buds, taste buds are microscopic. The bumps are called papillae; they contain clusters of taste buds. Each taste bud contains dozens of taste cells. Though taste buds for the four categories of taste—sweet, sour, salt, and bitter—are present throughout the mouth, the roughly 10,000 of them on the tongue align in patterns of concentration:

- Taste buds on the tip of the tongue are concentrated to detect sweet.

- Taste buds on the sides of the tongue are concentrated to detect sour and salt.
- Taste buds at the back of the tongue are concentrated to detect bitter.

Three CRANIAL NERVES—the 7th (facial), 9th (glossopharyngeal), and 10th (vagus)—carry nerve impulses related to taste to the brain. At its most primitive level, taste helps the brain determine what is safe and what is hazardous to eat. Sweet substances generally contain sugars and carbohydrates, essential nutrients for energy, whereas bitter substances may contain acids or chemicals that are potentially harmful. Recent research indicates that gustation is far more complex than simple delineation among taste buds, however, with some scientists speculating that taste represents learned interpretations as much as response to specific qualities. Further, taste and smell are inextricably intertwined. Though distinct nerve impulses from each reach the brain, the brain analyzes them and creates collective interpretations.

The functions of breathing and swallowing share the structures of the throat. The chamber at the back of the mouth and the top of the throat is the pharynx; it receives both air and food. A flap of cartilage at the base of the pharynx, the epiglottis, closes across the TRACHEA when swallowing and opens to allow the passage of air during inhalation and exhalation. The small flap of tissue that hangs visibly at the back of the throat, the uvula, is an extension of the soft palate. Doctors are uncertain of the uvula's function; it may help keep swallowed food from entering the nasal passages.

The larynx is a sequence of connected cartilage structures that makes speech possible. Air passing through the larynx causes these cartilages and the folds of tissue known as the VOCAL CORDS to vibrate, generating sounds. The muscles of the throat help move the sound vibrations into the mouth, which then forms them into noises and words. Hearing further helps shape speech, providing instant auditory feedback. It is difficult, although not impossible, for someone who has profound HEARING LOSS to speak clearly enough for others to understand. STROKE and neuromuscular disorders such as PARKINSON'S DISEASE are among the common causes of dysfunctions affecting swallowing and speech.

Health and Disorders of the Ears, Nose, Mouth, and Throat

Disorders and dysfunctions of the ears, nose, mouth, and throat range from structural defects present at birth to infections to trauma resulting from ACCIDENTAL INJURIES or diseases such as CANCER. Disturbances of taste, smell, hearing, and balance may accompany numerous health conditions from COLDS to DIABETES, stroke, and Parkinson's disease. Health experts estimate that about 2 million Americans have diminished, altered, or lost functions of taste and smell. More than 28 million have a perceptible loss of hearing ability; 2 million of them are profoundly deaf (unable to hear at a functional level). Disturbances of balance resulting from dysfunctions of the inner ear affect as many as 45 million Americans.

Nearly everyone experiences the most frequent health condition that affects the chemosenses simultaneously: the common cold. Its familiar symptoms include nasal congestion and runny nose (RHINORRHEA), sore throat (PHARYNGITIS), and the sensation of "stuffy" ears and muffled hearing (and sometimes dizziness, when the congestion alters the inner ear's balance mechanisms). This choreography of discomfort results from the intimate integration of both structure and function of these senses.

Limiting or avoiding exposure to loud noise could protect millions of people from hearing loss. Surgical and technological advances hold great promise for restoring some kinds of hearing loss. Though some diminishment occurs naturally with aging, hearing, taste, and smell require minimal effort to maintain healthy function across the spectrum of age.

Traditions in Medical History

Before the advent of ANTIBIOTIC MEDICATIONS and vaccines in the middle of the 20th century, many of today's commonplace ailments involving the ears, nose, mouth, and throat were serious and even life-threatening illnesses. Otitis media (middle ear infection), though less common or perhaps simply less frequently diagnosed 50 years ago than it is

today, accounted for much childhood deafness and frequently led to the complication of MASTOIDITIS, a bacterial infection in the porous mastoid bone behind the ear that in turn often spread to the brain, causing MENINGITIS or ENCEPHALITIS. Even TONSILLITIS frequently resulted in abscesses in children and adults alike; tonsillectomy, in the absence of adequate ANESTHESIA, was not an option.

These infections had grim outlooks, leading to desperate treatments such as lancing (cutting open the ABSCESS or infection) and application of chemical disinfectants (for example, iodine and carbolic acid), which were the standard of treatment for external wounds. The highly toxic nature of these approaches became a calculated risk in the fight for life. Lancing an abscess opened a direct channel into the bloodstream for the BACTERIA, virtually guaranteeing rapid death due to SEPTICEMIA ("blood poisoning" or septic shock). The alternative, however, was suffocation from the swelling that closed off the throat. DIPHTHERIA and PERTUSSIS (whooping COUGH), bacterial infections of the throat, remained the leading causes of childhood death until the 1950s. Today antibiotics, surgery, and routine childhood vaccinations have relegated these diseases, for the most part, to entries in textbooks and encyclopedias.

Breakthrough Research and Treatment Advances

Some the most profound breakthroughs in otolaryngology have been in the area of hearing loss. Digital technology brings the computer to the ear, allowing tiny and fully programmable hearing aids that fit far enough within the auditory canal to be undetectable. Computerized adjustments accommodate individual variations in tonal loss, helping people screen out the kinds of noise interference that have made the traditional HEARING AID a less than ideal solution. The COCHLEAR IMPLANT, which debuted in the 1980s, makes hearing possible for thousands of people with sensorineural hearing loss for whom hearing aids do not work. Hair-thin wires reside within the inner ear, receiving input from outside the ear and conveying it directly to the hair cells within the cochlea in much the same way nerves do. External components collect and, using digital technology, interpret sound signals.

Other advances mark improvements in treatments for ear infections, sinus infections, seasonal allergies, and operations on structures of the orofacial structures. Infants born with cleft deformities today will grow up with little evidence of this once disfiguring CONGENITAL ANOMALY, as advances in anesthesia and surgical techniques now permit surgeons to perform corrective procedures early in childhood and often in a single operation. Endoscopic surgery reduces risk for numerous operations on the nose, middle and inner ear, and throat. New understandings of immune function and allergy response have led to new treatment approaches for chronic SINUSITIS and ALLERGIC RHINITIS. Current research continues to explore age-related changes in hearing, seeking approaches to head off hearing loss.

A

acoustic neuroma A noncancerous tumor of the eighth cranial (vestibulocochlear) NERVE. Acoustic neuromas typically grow over years to decades and in some people cause no symptoms; doctors detect them incidentally. An acoustic neuroma does not invade the surrounding tissues, though it can become life-threatening if it becomes large enough to put pressure on the structures of the brainstem. Most often doctors do not know why acoustic neuromas develop and classify them as idiopathic (of unknown cause). Acoustic neuromas sometimes occur with neurofibromatosis type 2, a rare hereditary disorder in which fibrous growths develop in the CRANIAL NERVES and SPINAL NERVES.

Early symptoms of acoustic neuroma are vague and often perceived as normal consequences of aging because the tumor is so slow growing it typically appears in the later decades of life. Early symptoms include

- gradual loss of hearing, especially difficulty understanding speech, in one EAR
- TINNITUS (rushing or roaring sound) in one ear
- balance disturbances such as dizziness or loss of balance with motion

Advanced symptoms occur when the tumor's size begins to encroach on nearby structures such as the seventh cranial (facial) nerve. Such symptoms might include facial PAIN and disturbances of facial expression. An AUDIOLOGIC ASSESSMENT helps determine the level of HEARING LOSS and whether it affects one or both ears. Hearing loss in both ears suggests causes other than acoustic neuroma; it is very rare that a person would have two tumors, one affecting each vestibulocochlear nerve. MAGNETIC RESONANCE IMAGING (MRI) can usually determine the presence of an acoustic neuroma.

Treatment depends on the extent of symptoms and the person's overall health status. For many people, especially those who have no symptoms, the preferred treatment is watchful waiting (observation and regular tests to monitor the tumor's growth). Surgery to remove the tumor or RADIATION THERAPY to shrink the tumor is an option when symptoms interfere with QUALITY OF LIFE or affect vital brainstem functions such as regulation of BREATHING and HEART RATE or motor control. Each method has risks and benefits; individual health circumstances also influence the decision.

When it exists with no symptoms, acoustic neuroma does not interfere with the regular activities of living or present any threat to health. For most people who experience symptoms and undergo treatment, recovery is complete. Idiopathic acoustic neuromas do not return, though acoustic neuromas associated with neurofibromatosis type 2 often recur. Other than neurofibromatosis type 2, there are no known risk factors or preventive measures for acoustic neuroma.

adenoid hypertrophy Enlargement of the ADENOIDS, structures of LYMPHOID TISSUE at the back of the NOSE. The purpose of the adenoids is to trap and destroy pathogens (disease-causing agents) in children; by ADOLESCENCE the adenoids atrophy (shrink) and in adults are not distinguishable. When the adenoids swell, they can block the nasal passage. This disrupts BREATHING and can affect the speech. The eustachian tubes open near the adenoids;

swollen and infected adenoids can trap BACTERIA in the EUSTACHIAN TUBE and middle EAR. Adenoid hypertrophy is a leading cause of OTITIS media (middle ear INFECTION) in children.

Symptoms of adenoid hypertrophy include

- frequent ear infections
- MOUTH breathing
- snoring, and, when hypertrophy is severe, OBSTRUCTIVE SLEEP APNEA
- POSTNASAL DRIP
- bad breath (HALITOSIS)

Because the adenoids atrophy with physical maturation, doctors prefer to treat occasional infections with appropriate ANTIBIOTIC MEDICATIONS. ALLERGIC RHINITIS can also cause adenoid hypertrophy. When adenoid infections become chronic or when the swelling does not retreat, doctors may recommend adenoidectomy (surgery to remove the adenoids). Once the adenoids are removed, any related health problems go away.

aging, otolaryngologic changes that occur with

The natural changes that take place in the structures and functions of the EAR, NOSE, THROAT, and MOUTH as a person grows older. Age-related changes manifest in late childhood, as facial structures elongate, and again in the sixth decade and beyond, as some diminishment of function, particularly sensory perception, develops.

Otolaryngologic Changes in Late Childhood

Though the senses of hearing, taste, and smell are fully developed by about one month of age, changes in facial structure later in childhood alter some aspects of function. The rounded facial structures of the young child begin to change around age five or six and continue into early ADOLESCENCE. The head elongates, expanding the nasal and oral passages. The eustachian tubes lengthen and angle downward, improving their ability to remain patent (open and clear of congestion). The arch of the palate (roof of the mouth) flattens, and the permanent TEETH come in. Control of the tongue, lips, and other muscular structures of the face and neck improves. These changes facilitate the ability to form words. By late childhood, many difficulties with speech begin to resolve. Continued development of the brain's temporal lobe, which processes hearing and language as well as taste and smell, expands and refines speech capabilities and sensory interpretations. Whereas a child may perceive a flavor as "chocolate," an adult will discern that same flavor in terms of multiple descriptors.

Otolaryngologic Changes in Late Life

In healthy adults, sensory perceptions, balance, and language capacity remain intact well into the sixth or seventh decade. Beyond this point, many people experience alterations in taste and smell, and particularly hearing. Health conditions that become more prevalent with age, such as STROKE and PARKINSON'S DISEASE, also affect sensory functions as well as swallowing and speech.

Taste cells, located within taste buds, are the only sensory cells that regenerate, and they do so regularly throughout life. By midlife the rate of regeneration slows, and a person at age 60 has about half as many taste cells as at age 30. The more significant influence on the perception of taste, however, is the loss of olfactory receptors in the nose. The body does not replenish these specialized sensory cells, which detect thousands of odors in comparison to the four basic qualities the sense of taste detects. By age 70 there are about a third as many olfactory receptors as at age 30. These changes influence a person's interest in food and desire to eat, which commonly becomes a reason for inadequate nutrition and diet in the elderly. As well, the loss of teeth due to DENTAL CARIES (cavities) and gum diseases such as PERIODONTAL DISEASE, and decreased saliva production, diminish the ability to chew, further restricting food choices.

The clinical term for age-related HEARING LOSS is PRESBYCUSIS. The HAIR cells within the COCHLEA, which respond to the frequencies of the vibrations that pass into the inner EAR, are extraordinarily sensitive. By the sixth or seventh decade of life, the fibers of the hair cells, particularly those sensitive to high frequency vibrations, break and experience other damage. This causes loss of the ability to register sounds in those frequencies, which manifests as hearing loss. As these are the fre-

quencies of normal conversation, the loss, though gradual, becomes apparent. Hearing aids that amplify sound waves in these frequencies can help restore the function of hearing. OTOSCLEROSIS (fusion of the auditory ossicles, the tiny bones of the inner ear) and damage to tissues that results from impaired blood circulation (caused by ATHEROSCLEROSIS, for example) also diminish hearing.

audiologic assessment Tests to measure hearing ability and to determine the extent of HEARING LOSS. An audiologic assessment consists of preliminary screening and procedures to test specific dimensions of hearing. A comprehensive audiologic assessment may take up to an hour to complete though requires no preparation and involves no discomfort. Basic screening for hearing ability and loss should begin in infancy (90 percent of newborns born in hospitals in the United States are tested before discharge or at the first newborn well-care visit) and continue through life. Health experts recommend routine screening tests for hearing loss in adults every five years, more frequently when there are risk factors, such as noise exposure.

Preliminary Examination

The first step in an audiologic assessment is a preliminary examination in which the audiologist examines the structures of the outer and middle ears with an otoscope. This examination, called an OTOSCOPY, helps detect structural anomalies as well as mechanical impediments to sound conduction (such as compacted CERUMEN in the auditory canal or an infected or damaged TYMPANIC MEMBRANE). The preliminary examination also includes a health history in which the audiologist asks questions about any existing hearing loss, risk factors for hearing loss (including noise exposure), medications, and illnesses such as MEASLES and RUBELLA (German measles).

Audiometry

An audiologist conducts the procedures of audiometry, a battery of tests that measure the ability to discern sounds at different frequencies (pitch) and intensities (volume). During the audiometric examination the person sits in a soundproof booth and the audiologist sits in a control booth. Common audiometric procedures include

- Pure-tone audiometry, which measures the range of sound a person can hear. For this procedure, the audiologist produces tones at certain frequencies and intensities, and the person indicates whether he or she hears them. The audiologist tests each EAR separately.
- Conditioned-play audiometry and visual-reinforcement audiometry, which adapt conventional audiometry to children. These methods use games and visual rewards to elicit responses to the tones.
- Speech audiometry, which determines the lowest sound frequency and intensity at which a person can hear and repeat two-syllable spoken words (speech-reception threshold), and how well the person can hear and repeat single-syllable words spoken at a consistent intensity (word recognition).
- Pure-tone BONE-conduction audiometry, which delivers tones through a vibrating device placed against the bone near the ear. This bypasses the outer and middle ear when there are conductive obstructions present (such as OTITIS media or compacted cerumen in the auditory canal).

The audiologist reports results in decibel (dB) of threshold (sound intensity) for 500 Hertz (Hz), 1,000 Hz, and 2,000 Hz, the frequencies of everyday speech and activities. An audiogram summarizes and presents this information for each ear in a graphic presentation. Any identified hearing loss may require additional tests.

Other Hearing Tests

Sometimes health-care providers need further information to identify the nature and cause of hearing loss, particularly in infants and young children. Other tests for refined assessment include

- auditory evoked potentials, in which electrodes attached to the head measure NERVE transmissions in response to sound
- auditory brainstem response, an auditory evoked potential that specifically measures the response of the eighth cranial nerve (vestibulocochlear or auditory nerve)

- otoacoustic emissions, which measure the response of the cochlea to sound stimulation
- acoustic immittance measures, which assess the function of the middle ear:
  - † tympanometry, to assess eardrum function
  - † acoustic reflex, to determine whether the ear responds to loud sounds
  - † static acoustic impedance, to measure volume of air within the ear canal
- balance assessment to determine vestibular function/dysfunction

Understanding Results

Audiologic assessment helps determine the appropriate therapeutic course for hearing loss. Doctors often can correct conductive hearing loss through medical or surgical interventions. Sensorineural hearing loss requires hearing aids or other solutions (such as a COCHLEAR IMPLANT) to improve hearing ability. Mild hearing loss (26 to 30 dB) is the point at which a person is likely to benefit from a HEARING AID. At the level of severe hearing loss (71 to 90 dB), a person is unable to understand speech without a hearing aid. Because hearing is essential for development of language and communication skills, it is especially important to provide immediate intervention for hearing loss in children.

B

barotrauma Damage to the structures of the EAR resulting from the ear's inability to equalize pressure with abrupt and extreme changes in atmospheric pressure. Such changes most often occur in situations of sudden altitude change such as air travel or diving, though also may result from a sharp blow to the ear that forces a blast of air into the auditory canal. Any of the three parts of the ear—outer, middle, and inner—can experience injury from barotrauma.

- Outer ear barotrauma typically takes the form of small, painful blisters and hemorrhages along the walls of the auditory canal.
- Middle ear barotrauma commonly includes a ruptured TYMPANIC MEMBRANE (eardrum). The pressure within the middle ear can become intense before the tympanic membrane gives way, causing much PAIN. With rupture the pressure immediately equalizes, though hearing ability temporarily diminishes.
- Inner ear barotrauma causes sudden and usually significant VERTIGO (extreme dizziness and balance disturbances) and HEARING LOSS that can be permanent.

Most outer and middle ear barotrauma heals on its own. Many ruptured eardrums heal naturally, though large or irregular tears require surgical repair (TYMPANOPLASTY). Inner ear barotrauma may require surgery to repair damaged structures and may result in permanent functional loss if the damage is extensive.

Preventive measures to reduce the likelihood of barotrauma include chewing gum, frequent swallowing, and yawning during activities that involve changes in barometric pressure such as descending during air travel. Some people benefit from nasal decongestant sprays that clear the nasal passages and eustachian tubes. Recreational divers are at greatest risk for inner ear barotrauma; pressure changes are most drastic nearer the surface than deep in the water.

benign paroxysmal positional vertigo (BPPV) A disorder of the inner EAR in which certain positions of the head cause sudden and severe, though brief, episodes of VERTIGO (sensations of spinning or motion). Many people experience symptoms upon awakening from sleep, as they roll from one position to another or tilt their heads. Though the vertigo episode typically lasts only a few minutes, it can result in feelings of NAUSEA and dizziness as well as balance disturbances, that continue for several hours.

Doctors believe calcifications called otoconia, small "stones" of calcium carbonate, cause BPPV. Otoconia occur naturally in the utricle and saccule, two of the structures within the inner ear that are part of the vestibular system, the body's balance mechanisms. When otoconia escape from the utricle they can enter the semicircular canals, where they collide with NERVE endings that send positional messages to the BRAIN. These collisions overwhelm the messaging network. The otoconia tend to dissolve in the inner ear fluid over time. About half the people who develop BPPV experience head trauma or serious INFECTION, such as OTITIS (ear infection) or SINUSITIS (sinus infection), before BPPV symptoms begin, leading doctors to believe that such assaults on the integrity of the inner ear jars the otoconia out of the utricle.

Symptoms and Diagnostic Path

The key symptom of BPPV is sudden, severe, and limited episodes of vertigo without TINNITUS (ringing or rushing sound in the ears) or hearing impairment. The presence of either or both of the latter suggests another disorder. Symptoms tend to occur with certain positions, though symptoms can occur even when avoiding trigger positions. Between episodes, there are no symptoms. The pattern of symptoms is fairly conclusive, though doctors typically conduct a comprehensive AUDIOLOGIC ASSESSMENT to determine whether there is any HEARING LOSS with the expectation that results will be normal.

Other diagnostic procedures for BPPV may include

- Dix-Hallpike test, positional test performed during physical examination; positive for BPPV when it causes NYSTAGMUS (rapid and involuntary darting movements of the eyes) or brings on an episode of vertigo
- caloric test, in which the doctor gently instills warm and then cold water into each ear; normal response evokes vertigo and abnormal response, diagnostic of BBPV, evokes little or no vertigo
- electronystagmography, in which tiny electrodes placed around the eyes detect the abnormal darting eye movements characteristic of vertigo
- imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) to rule out other possible causes for the symptoms

The combination of test results and history of symptoms helps the doctor distinguish BPPV from other disorders that affect the vestibular system.

Treatment Options and Outlook

For many people who have BPPV, the symptoms simply go away over time, generally within several months, as the inner ear fluid dissolves the otoconia. Some people benefit from ANTIHISTAMINE MEDICATIONS or scopolamine, drugs that suppress vestibular function, or antinausea medications. There are several positional treatments (among the most commonly used are the Epley maneuver and the Semont maneuver) that some doctors perform to attempt to jolt the otoconia out of the semicircular canals and at least into the vestibule if not back into the utricle. These maneuvers succeed 70 to 90 percent of the time.

Rarely the otolaryngologist may recommend one of two operations for BPPV if it continues for longer than a year without response to other treatment:

- Posterior ampullar neurectomy severs a branch of the nerve that conveys motion signals from the utricle, ending its ability to send messages of motion to the brain.
- Posterior canal plugging seals the involved semicircular canal so the otoconia can no longer float in its fluid.

Surgery nearly always ends BPPV; when it does not, further examination typically reveals complicating factors or conditions that contribute to the symptoms. Nearly everyone who develops BPPV eventually recovers fully from the condition, with balance restored to normal. During the course of the condition and while undergoing treatment with one of the maneuvers, doctors recommend avoiding positions that may trigger symptoms, especially tilting the head back, until BPPV symptoms no longer occur. Once BPPV is resolved, it generally does not recur.

Risk Factors and Preventive Measures

Otoconia seem to naturally occur in many people, causing problems only when they become lodged in vestibular structures such that they interfere with the movement of fluid that is essential for balance. It also appears that the body's natural processes dissolve and absorb the otoconia over time, so most of these calcifications do not become large enough to obstruct the vestibular channels. Because doctors do not know what causes otoconia to form, there are no known methods for preventing them. Prompt treatment for ear and sinus infections to reduce further trauma to the inner ear may help keep otoconia from causing symptoms.

blowing the nose The process of clearing mucus and congestion from the nasal passages. Blowing

the NOSE generates significant pressure that can force congestion into the SINUSES and eustachian tubes. The best method is to blow through both nostrils with a gentle and steady pressure with the head upright, pausing between blows to allow gravity to help move congestion downward toward the nostrils. Short, hard bursts of blowing can activate a REFLEX action, which commonly occurs after a SNEEZE, in which the nasal passages briefly swell and fill with mucus. Doctors believe this reflex congestion occurs as a protective measure to block harmful substances from entering the nose, as sneezing is a mechanism for ejecting foreign matter from the nose. Applying unscented lotion or aloe to the SKIN around the nostrils helps protect against irritation and INFLAMMATION from frequent nose blowing.

Bogart-Bacall syndrome An overuse condition affecting the VOCAL CORDS and larynx. The key characteristic is a low, husky speaking voice (such as immortalized by famed actors Humphrey Bogart and Lauren Bacall, the namesakes of this condition). Speaking in the lower registers of pitch strains the muscles of the larynx and the tissues of the vocal cords, causing symptoms such as voice fatigue (inability to maintain volume when speaking), soreness or PAIN in the THROAT, and hoarseness or raspiness when speaking. Treatment focuses on improving breath control to speak when the lungs contain an adequate volume of air. Efficient BREATHING during speech lessens the tension of the muscles in the throat that control the vocal cords and flow of air. Some people, particularly women, whose voices are naturally in a higher register of pitch than the voices of men, benefit from VOICE THERAPY to learn to speak at a higher pitch.

broken nose A FRACTURE of the nasal BONE, typically resulting from a direct blow. The NOSE is especially vulnerable to impact injuries, and the nasal bones are the most commonly fractured on the face. Injury to the CARTILAGE and other tissues of the nose often accompanies a nasal fracture; these injuries are typically painful and result in significant swelling and bruising. A fracture can displace the bones and the cartilage, altering the flow of air through the nose, and can result in bleeding within the nasal passages. Ice applied to the area as soon as possible after the injury helps contain the swelling.

Most often the doctor will order X-rays of the face to confirm a nasal fracture as well as to determine whether other fractures, such as of the orbital bones around the eyes, also exist. The doctor often can reduce (reposition) a simple nasal fracture by external manipulation done with local ANESTHESIA (closed reduction). Injury more extensive than a simple nasal fracture typically requires surgery to return the bones to their normal positions (open reduction). A protective splint worn over the nose helps safeguard the fracture from further injury while it heals. The bones become set in about a week; the fracture heals fully in four to six weeks. Sometimes after HEALING is complete the structures of the nose remain out of alignment, which can affect BREATHING. Such complications require further medical assessment by an otolaryngologist or facial surgeon and may require further surgery. Most nasal fractures heal uneventfully and have no long-term consequences.

C

canker sore Ulcerous sores, also called aphthous ulcers, that develop inside the MOUTH. The typical canker sore is round, with a slightly white center and a red rim. Sometimes a tingling or burning sensation precedes the eruption of the sore. A canker sore is painful and irritating for three to five days, then begins to heal and generally goes away in about three weeks. Researchers do not know what causes canker sores, though the tendency to develop canker sores appears to run in families. Theories about the causes of canker sores include immune function abnormalities, nutritional deficiencies, and FOOD ALLERGIES. Some women notice canker sores are more common when they are menstruating.

Treatment targets relieving the discomfort and may include

- frequently rinsing the mouth with a weak solution of saltwater, hydrogen peroxide, diphenhydramine liquid, or milk of magnesia (rinse and spit, do not swallow any of these solutions)
- applying milk of magnesia or a topical anesthetic preparation for oral use directly to the canker sore with a cotton swab
- taking acetaminophen or a nonsteroidal anti-inflammatory DRUG (NSAID) for generalized pain relief
- taking a lysine supplement
- avoiding foods and seasonings that irritate the canker sores

Prescription medications containing amlexanox (such as the brand-name product Aphthasol) may reduce INFLAMMATION and expedite HEALING when sores are large or occur frequently. Such medications come in topical and mouthrinse preparations. Researchers have yet to identify any preventive measures to keep canker sores from developing.

cauliflower ear A casual and descriptive term for an auricle (external EAR) damaged and deformed through trauma. Cauliflower ear is commonly associated with repeated injury such as occurs with boxing. However, even a single blow to the ear significant enough to cause bleeding can result in deformity as the cartilaginous structure of the external ear heals. CARTILAGE has no BLOOD supply of its own but instead draws nutrients from the blood supply of the SKIN. Any damage that disrupts blood flow (such as injury that causes bleeding) causes cartilage tissue to die. Where cartilage dies, the structure it supports shrinks as the skin around it heals, forming the characteristic irregularities of cauliflower ear.

Prompt treatment of any injury to the external ear to minimize the interruption of blood flow and control any INFECTION that may develop helps prevent deformity. Ear PIERCINGS into the upper ear that become repeatedly infected or cause scarring also can result in cauliflower ear. OTOPLASTY (surgery to alter the appearance of the auricle) can improve the auricle's appearance though may not be able to restore it to its natural structure. A key preventive measure is wearing appropriate headgear during activities that expose the outer ears to the risk of traumatic injury.

See also ATHLETIC INJURIES; BLEEDING CONTROL; LACERATIONS.

cerumen A soft waxy secretion, commonly called EAR wax, that the glands in the auditory (ear) canal produce to help remove debris from

within the canal. Cerumen is usually yellowish brown in color and its presence is normal, though many people attempt to clean it from the ears for aesthetic reasons. Most health experts recommend against using cotton swabs within the auditory canal for this purpose; it is possible for the swab to compact the cerumen, push foreign objects deeper into the ear, or damage the TYMPANIC MEMBRANE (eardrum). Tightly compacted cerumen can block sound waves from traveling through the auditory canal, interfering with hearing, and create unequal pressure, causing balance disturbances. It also can trap water in the auditory canal, allowing fungal or bacterial INFECTION to develop. Softening drops help loosen compacted cerumen so the ear's natural mechanisms can push it out of the auditory canal. When this does not work, removal may require a health-care provider to perform EAR LAVAGE or other techniques.

For further discussion of cerumen within the context of otolaryngologic structure and function, please see the overview section "The Ear, Nose, Mouth, and Throat."

See also CLEANING THE EAR; FOREIGN OBJECTS IN THE EAR OR NOSE.

cholesteatoma A growth that develops within the middle EAR. Most cholesteatomas develop as a consequence of frequent middle ear infections (OTITIS media) or chronically blocked eustachian tubes, such as by frequent SINUSITIS (sinus infection) or ALLERGIC RHINITIS. A cholesteatoma starts as an outpouching of SKIN on or near the TYMPANIC MEMBRANE (eardrum). SKIN cells accumulate inside the pouch, causing it to enlarge and exert pressure against the tympanic membrane and auditory ossicles (tiny bones of the middle ear). Over time the increased pressure can destroy the auditory ossicles, causing HEARING LOSS. A large cholesteatoma can also exert pressure inward against the inner ear, causing VERTIGO and balance disturbances.

Symptoms of cholesteatoma include the sensation of fullness in the affected ear, diminished hearing, dizziness and vertigo if there is pressure against the inner ear, and aching or dull PAIN behind the ear. Symptoms are often positional and may worsen at night, especially pain. Some people experience a puslike drainage, often apparent on the pillow. The diagnostic path may include X-rays, COMPUTED TOMOGRAPHY (CT) SCAN, and MAGNETIC RESONANCE IMAGING (MRI) of the head. Treatment requires overcoming any INFECTION with ANTIBIOTIC MEDICATIONS and sometimes surgery to remove the cholesteatoma and clean the area.

Treatment often restores hearing, though when the cholesteatoma is large or has been present for a long time the otolaryngologist may be unable to repair the damage to the middle ear. Damage that occurs within the inner ear often is permanent. Prompt treatment of sinusitis or otitis minimizes the risk for cholesteatomas to develop, though these growths are not preventable. Early diagnosis and treatment of cholesteatoma offers the best opportunity to prevent permanent hearing loss and vestibular (inner ear) dysfunction. Untreated cholesteatoma can result in profound hearing loss in the affected ear as well as MASTOIDITIS and MENINGITIS.

cleaning the ear Hygienic measures to keep the ears clear of debris. For the most part, the ears are self-cleaning. Tiny hairs (cilia) line the inside of the auditory canal, moving in wavelike motions to sweep particles of dust and pollen, as well as sloughed SKIN cells, to the outer edge of the EAR. CERUMEN, or ear wax, helps collect these particles for easy removal. Most people need only to wash the outer ear during regular bathing to remove any accumulations of cerumen and debris. However, many people feel the need to wipe the inside of the auditory canal with cotton swabs. Most health-care providers recommend against this. Persistent swabbing of the auditory canal can lead to compacted or impacted cerumen that blocks the canal, interfering with hearing as well as preventing the ear's normal cleansing mechanisms from functioning. It also is possible for pieces of the cotton swabbing to come off inside the canal, creating obstructions, and to perforate the TYMPANIC MEMBRANE with the tip of the swab. A doctor should evaluate any concerns about excess cerumen or foreign objects in the ear. A health-care provider can perform EAR LAVAGE when additional cleaning is necessary. A popular admonition among otolaryngologists is, "Never put anything smaller than an elbow into the ear."

cleft palate/cleft palate and lip Congenital anomalies in which the bones of the face that form the roof of the MOUTH fail to close properly in the early stages of embryonic development. These structures originate as separate entities and, in the course of normal embryonic development, join together by 10 weeks of gestation. Cleft defects, known clinically as congenital craniofacial anomalies, occur in varying degrees and combinations that may include separations of the hard palate, soft palate, upper gum, and upper lip. The most common presentation is isolated cleft palate (the defect involves only the roof of the mouth), or cleft palate and lip (the defect extends from the roof of the mouth to the external lip). These anomalies are the fourth most common type of birth defect in the United States, affecting about 1 in 1,000 infants born each year.

An intact palate is necessary for proper eating, swallowing, and speech. An infant with a cleft palate, and especially cleft palate and lip combination, often cannot suck well enough to obtain adequate nutrition. A complete cleft palate blends the nasal and oral openings into a single chamber, which interferes with BREATHING. Craniofacial anomalies also occur among the deformities of numerous other congenital syndromes. There is a particular correlation between isolated cleft palate and other congenital defects, notably HEART anomalies. Because of these correlations, doctors evaluate newborns with cleft palate defects for other congenital disorders.

Symptoms and Diagnostic Path

Doctors detect most cleft palate defects shortly after birth or in early childhood. Many clefts are visible or palpable (the doctor can feel the defect by running a finger along the roof of the infant's mouth). A missing or bifid (two-part) uvula, the small flap of tissue that hangs from the soft palate at the back of the THROAT, often though not always indicates a cleft palate. Doctors may not detect minor cleft palate disorders until the infant has trouble eating or does not appear to be gaining weight. X-rays, COMPUTED TOMOGRAPHY (CT) SCAN, and MAGNETIC RESONANCE IMAGING (MRI) are among the procedures that can confirm and define the extent of the defect.

Treatment Options and Outlook

Nearly always surgery is the treatment of choice to close the cleft, for functional as well as aesthetic reasons. Surgeons generally prefer to do these operations as early as the infant's health permits, typically between the ages of 3 and 18 months. Mild to moderate defects often require only a single operation. Extensive deformities may require two or three operations done in stages, with follow-up speech therapy. Severe deformities that involve the upper gum and structure of the TEETH may require ongoing orthodontic and dental work, along with speech therapy, extending into ADOLESCENCE. The outlook following surgical repair is exceptional, with few complications for most infants as they grow older. By adulthood there generally is little apparent evidence of the cleft or its repair.

Risk Factors and Preventive Measures

Cleft palate and cleft lip appear to be random occurrences though are common with certain genetic disorders such as DOWN SYNDROME. Some studies suggest that these disorders are more common among infants of mothers who take certain antiseizure medications or ANTIANXIETY MEDICATIONS in the benzodiazepine family. Cleft palate and cleft lip are also more frequent among children of women who drink ALCOHOL and smoke cigarettes before and during pregnancy. Other studies show that taking folic acid and vitamin B supplements during pregnancy, which is a standard practice in PRENATAL CARE in the United States to reduce the likelihood of NEURAL TUBE DEFECTS, helps prevent craniofacial clefts. When a woman gives birth to a child who has a cleft palate, any subsequent children are more likely than normal to have the same kind of disorder.

cochlea The organ of the inner EAR that converts sound waves to NERVE impulses. Contained within the bony labyrinth, the cochlea resembles a snail shell. Thousands of specialized nerves, called HAIR cells because of the fine fibers that project from

them, line the fluid-filled inner chamber of the cochlea. The membrane that contains the hair cells is the organ of Corti. Sound waves activate the hair cells, which convert the stimulation into nerve signals. The nerve signals converge at the cochlear nerve, which carries them to the vestibulocochlear nerve (eighth cranial nerve) for transport to the BRAIN. The hair cells are very sensitive and vulnerable to damage from excessive noise. The longest of the hair cells are those that respond to sounds in the decibel range of normal speech; because of their length, they are the most vulnerable to such damage. Hair cells also break off with aging. Damaged cochlear hair cells do not regenerate.

For further discussion of the cochlea within the context of otolaryngologic structure and function, please see the overview section "The Ear, Nose, Mouth, and Throat."

cochlear implant An inner EAR prosthesis to provide a degree of hearing ability for those who have profound HEARING LOSS—greater than a 90 decibel (dB) loss of hearing—in both ears and receive no benefit from hearing aids. This tiny electronic device receives incoming sound waves and translates them into frequency impulses that stimulate undamaged auditory nerve fibers that remain within the COCHLEA. The NERVE fibers convey the impulses to the BRAIN via the cochlear nerve. Though there are several designs of cochlear implant, all feature external components and internally implanted electrodes.

Because the nerve fibers within the cochlea are limited the impulses those fibers convey to the brain are also limited, leaving "gaps" in speech. Over time, the person learns where these gaps are and learns to interpret many of them into intelligible units of language. It can take adults several years to develop proficient hearing skills. The level of restored hearing generally correlates to the length of time between the onset of profound hearing loss and placement of the cochlear implant. Children who receive cochlear implants typically learn or regain language understanding and speech skills more quickly than adults, though children who have been profoundly deaf since birth (prelingual loss of hearing) typically do not acquire hearing and speaking skills comparable to those of children who have normal hearing.

cold sore An eruption of the HERPES SIMPLEX virus 1 (HSV1) in the form of a sore with a crusty scab, most commonly on the lips. Less commonly HSV2, the variation of the herpes simplex VIRUS that causes GENITAL HERPES, causes sores around the MOUTH. Which variation of the herpes virus that is responsible does not matter. People sometimes refer to cold sores as FEVER blisters because they tend to appear with fever or during viral infections such as COLDS; doctors believe viral infections are among the triggers that activate HSV1. Hormonal shifts during MENSTRUATION and exposure to the sun also appear to activate HSV1.

HSV1 lies dormant in the nerve endings in the SKIN near the sites where cold sores have previously occurred and, when activated, causes new sores to erupt. Many people experience itching or tingling at the site in the 24 to 36 hours before a cold sore erupts. Doctors call this the prodrome stage. When sores are present the herpes virus is highly contagious and easily spread to other body locations as well as to other people through contact or shared items such as drinking glasses, straws, and eating utensils. Rubbing the EYE after finger contact with a cold sore can spread the virus to the eye, where it can infect the CORNEA and cause scarring that can lead to blindness. Frequent HAND WASHING is an effective method for restricting the spread of the virus.

Treatment options are limited. Doctors may prescribe ANTIVIRAL MEDICATIONS for recurrent or severe episodes of cold sores. These medications appear to shorten the course of the INFECTION from the usual 7 to 10 days to 3 to 5 days when taken or applied at the first indication (ideally in the prodrome stage) of activation. Numerous topical products to provide relief and moisturization are available over the counter, though these preparations do not shorten the course of the infection. Some people have fewer cold sores when they take lysine supplements. Cold sores typically heal without scarring or other complications.

cough The forceful expulsion of air through the airway as a REFLEX designed to prevent matter, including mucus, from entering the LUNGS. Cough can be a symptom of many health conditions, from minor and temporary irritations of the pharynx (upper THROAT) and structures of the airways, such as those COLDS and allergens can cause, to serious and potentially life-threatening conditions such as laryngeal CANCER, TUBERCULOSIS, CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD), and LUNG CANCER. Cough also can signal a blockage of the airway, which is a medical emergency. Occasionally cough is an undesired SIDE EFFECT of certain medications, notably the angiotensin-converting enzyme (ACE) inhibitor medications prescribed to treat HYPERTENSION (high BLOOD PRESSURE).

Coughs fall into two major classifications: acute and chronic. Acute cough comes on suddenly and lasts less than three weeks; chronic cough continues for longer than three weeks. Within these classifications, cough may be productive (bring up mucus or sputum) or nonproductive (typically a dry, hacking cough). Treatment depends on the kind of cough and focuses on first eliminating any underlying causes. There are two main classifications of cough medications: antitussive (suppresses the cough) and expectorant (thins the mucus).

When Cough Is an Emergency

A sudden cough, especially one that comes on when eating, may indicate that the person has aspirated (inhaled into the airway) a particle of food or other object. Do not allow someone who starts coughing while eating to leave the table unattended. Instead, ask the person to give a verbal answer to the question, "Are you okay?" If the person cannot speak to answer the question, he or she likely has a blocked airway.

Aspiration is a medical emergency that requires prompt response. Perform a HEIMLICH MANEUVER immediately for a blocked airway. Call 911 for emergency medical aid if the coughing or choking continues.

Acute Cough

An acute cough generally accompanies a health condition of sudden onset such as an upper respiratory INFECTION (colds, flu, BRONCHITIS, PNEUMONIA), SINUSITIS (sinus infection), and PHARYNGITIS. An acute cough can be either productive or nonproductive though is usually productive because the IMMUNE SYSTEM increases mucus production to help rid the body of the PATHOGEN. ANTIBIOTIC MEDICATIONS are necessary to treat infections that are bacterial. Viral infections typically run their course and do not require medications except to relieve symptoms. In infections, coughs are often productive, bringing up dead cells and other debris that the body needs to clear from the airways. POSTNASAL DRIP, which irritates the pharynx, is a key cause of coughs related to upper respiratory infections.

COVERING A COUGH

Coughs can spread infections both through droplets in the air and through hand contact. Health experts recommend coughing into the crook of the arm rather covering the mouth with the hands. Frequent HAND WASHING also helps reduce the spread of pathogens.

Chronic Cough

A chronic cough may signal an underlying health condition or may exist as a response to continued irritation, most commonly cigarette smoking. Other common causes of chronic cough include

- GASTROESOPHAGEAL REFLUX DISORDER (GERD), in which gastric acid from the stomach enters and irritates the throat
- asthma and seasonal allergies
- chronic sinusitis
- pulmonary diseases such as chronic bronchitis, COPD, and BRONCHIECTASIS

Generally, eliminating the underlying cause of chronic cough also eliminates the cough. A significant risk with smoker's cough is that it develops so gradually the smoker may not realize how often he or she coughs. The cough may exist as a response to the irritation of smoking or may signal a serious health condition such as lung disease or

throat or lung cancer. A doctor should evaluate chronic cough in smokers on a regular basis to monitor for more significant health problems. SMOKING CESSATION may end the cough; cough that continues longer than six months beyond smoking cessation may indicate another health condition and requires a doctor's assessment.

Treating Cough

Treatment focuses first on eliminating any underlying reasons for cough. Antibiotic medications are helpful only when there is a bacterial infection. The most effective cough suppressant medications are those which contain DEXTROMETHORPHAN, benzonatate, or NARCOTICS such as codeine and hydrocodone. Products containing benzonatate (a non-narcotic) or narcotics require a doctor's prescription and are not generally appropriate for chronic cough. Products containing dextromethorphan are numerous and available over the counter; extended-release products can provide relief for 10 to 12 hours per DOSE.

Expectorants help thin mucus and secretions so the coughing mechanism can more easily bring them out of the airways. Doctors do not agree on whether expectorants are truly helpful, and there are few clinical research studies that have investigated their effectiveness. The most common expectorant in cough products sold in the United States is guaifenesin. Manufacturers recommend drinking plenty of water when taking products containing guaifenesin; some health experts believe increased water intake alone is adequate to thin mucus.

Most cough products, both prescription and over the counter, combine ingredients, so it is important to read product labels carefully. Products may include a cough suppressant and an expectorant as well as a decongestant, an antihistamine, and other substances. Maintaining adequate moisture in the air (as with a cool humidifier), drinking plenty of liquids, and avoiding substances that irritate the throat and airways are effective nonmedication methods for managing cough, especially chronic cough.

croup A viral INFECTION of the upper respiratory tract that produces a characteristic barking COUGH, most commonly in children under age three. Other symptoms include rapid BREATHING, a high-pitched noise with inhalation (stridor), and FEVER. In many children, the top of the airway at the back of the THROAT becomes swollen and congested, reducing the flow of air. The barking cough results from air being forced through this narrowed passage as the body attempts to clear the congestion of the infection. Croup often follows COLDS and its symptoms tend to worsen at night. The most effective treatment is prompt exposure to moist air. Parents often find that as soon as they get the child buckled into the car seat for the late-night trip to the hospital emergency room, coughing lessens and breathing eases. The cool night air helps open the airways. Often it brings the child relief to sit, wrapped in a blanket for warmth, with a parent in the night air for a few minutes. An alternative method is to turn on a hot shower and close the bathroom door so the bathroom fills with steam, then sit with the child in the steam.

The child needs immediate medical attention when symptoms

- last longer than three days
- include a fever higher than 102°F
- suggest that the child is not getting enough oxygen, such as CYANOSIS (blue lips)
- include excessive drooling

Though frightening for parents, croup is most often self-limiting and has few complications. Because croup is viral, ANTIBIOTIC MEDICATIONS do not bring about any improvement in symptoms. And, being viral, croup is contagious, spread through droplets in the air from coughing as well as by hand contact.

deafness See HEARING LOSS.

dental caries The clinical term for cavities, erosions through the enamel of the TEETH that expose the inner pulp and sometimes the NERVE of the tooth. A dentist is the health-care provider who diagnoses and treats dental caries. Untreated dental caries can lead to INFECTION of the tooth's root structure and potentially an ABSCESS of the nerve canal, health conditions that require treatment with ANTIBIOTIC MEDICATIONS as well as dental care. The accumulation of BACTERIA can contribute to HALITOSIS (bad breath). A cavity that penetrates into the inner tooth often causes TOOTHACHE. Appropriate ORAL HYGIENE and routine dental care can help prevent dental caries.

ear The structures of the ear support the functions of hearing and balance. The ear has three divisions:

- The outer ear consists of the auricle (pinna) and auditory canal, structures that collect, focus, and channel sound waves.
- The middle ear consists of the auditory ossicles, three tiny bones that vibrate in sequence to focus and amplify sound.
- The inner ear contains the COCHLEA, which converts sound waves to NERVE impulses, and the structures of the vestibular system that regulate balance, the bony labyrinth, and the semicircular canals.

The TYMPANIC MEMBRANE, or eardrum, separates the outer ear and the middle ear; the EUSTACHIAN TUBE connects the middle ear with the THROAT to equalize pressure on both sides of the eardrum. Many causes of HEARING LOSS arise as a result of damage to or dysfunction of the structures of the outer and middle ear. The inner ear is entirely sealed from the external environment. Fluid bathes the delicate structures of the inner ear, helping protect them as well as isolate them from external stimuli that could affect their functions. Most disturbances of balance, often called vestibular dysfunction, stem from problems with the inner ear.

COMMON CONDITIONS AFFECTING THE EAR, HEARING, AND BALANCE

ACOUSTIC NEUROMA	BAROTRAUMA
CHOLESTEATOMA	HEARING LOSS
LABYRINTHITIS	MÉNIÈRE'S DISEASE
MYRINGITIS	OTITIS (INFECTION)
OTOSCLEROSIS	OTOTOXICITY
TINNITIS	VERTIGO

earache A generalized term for sensations of pressure, discomfort, and PAIN in the area of the EAR. Pain messages from other structures of the head and neck, such as the NOSE and THROAT, also sometimes appear to come from the ear (referred pain). A common cause of earache in children is OTITIS media (INFECTION of the middle ear).

Congestion in the eustachian tubes can cause fluid to accumulate between the TYMPANIC MEMBRANE (eardrum) and the inner ear, creating increased pressure, which causes pain. A child

who is too young to speak may pull or tug at the ears. INFLAMMATION or infection of the auditory canal, commonly called swimmer's ear, is a frequent cause of earache in older children and adults. Referred pain in adults may indicate health conditions such as temporomandibular JOINT (TMJ) disorder, dental problems, SINUSITIS, TONSILLITIS, and PHARYNGITIS.

Treatment depends on the underlying cause of the earache. ANTIHISTAMINE MEDICATIONS can reduce congestion due to allergic response. ANTIBIOTIC MEDICATIONS are necessary when the infection is bacterial. ANALGESIC MEDICATIONS to relieve pain, such as acetaminophen and NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS), can ease the discomfort while HEALING takes place. Generally, treating the underlying reason for the pain causes the earache to go away.

eardrum See TYMPANIC MEMBRANE.

ear lavage Gentle flushing of the outer EAR to remove accumulated CERUMEN or foreign objects. Typically a health-care provider performs ear lavage in the doctor's office or a clinical setting, using a bulb syringe to instill warm water or other liquid and a basin to collect the solution as it drains from the auditory canal (ear canal). Ear lavage generally does not cause discomfort. People who have middle or inner ear disorders, vestibular disorders, or MYRINGOTOMY tubes in place should not undergo ear lavage.

ear wax See CERUMEN.

electrolarynx A handheld device that makes speech possible for people who have undergone LARYNGECTOMY (surgical removal of the larynx) or whose larynx is otherwise nonfunctional. The normal larynx consists of the VOCAL CORDS, CARTILAGE, MUSCLE, and ligaments. These tissues vibrate to generate the sounds the structures of the MOUTH convert into speech. The electrolarynx uses a rapidly moving diaphragm to generate vibrations that can help restore speaking ability.

There are two kinds of electrolarynx in common use:

- The transcervical electrolarynx rests against the neck or the cheek and sends vibrations through the muscles of the neck. Similar in appearance to a small flashlight, the transcervical electrolarynx requires one hand to hold it in place and has a finger-activated switch.
- The intraoral electrolarynx uses a small tube, somewhat like a straw, that rests along the inside of the cheek and sends vibrations directly to the structures of the mouth. Some models mount components in a denture or orthodontic device. An external amplifier and speaker project the sound.

Nearly all models of either kind operate on batteries and are easy for most people to use. The transcervical electrolarynx requires enough remaining healthy muscle tissue in the neck to transmit vibration. It is not a viable option when there is extensive tissue loss due to injury, such as trauma or BURNS, or surgery, such as for laryngeal CANCER. The vibrating diaphragm of the electrolarynx cannot produce the same intensity or range of tone as the natural structures of the healthy larynx, resulting in speech that tends to be machine-like and difficult to understand.

epiglottitis A severe and rapidly progressing INFECTION of the epiglottis, a broad flap of tissue in the back of the THROAT that closes when swallowing to prevent food from entering the TRACHEA (windpipe). Epiglottitis brings on severe swelling in the throat, obstructing the flow of air through the trachea. Death can occur in minutes if the swelling completely blocks the airway.

Epiglottitis is a medical emergency that requires immediate hospital care.

Although epiglottitis can affect people of any age, it most commonly occurs in children ages two to seven years. The main cause of epiglottitis in children is bacterial infection with *Haemophilus influenzae* type b (Hib). In adults, epiglottis gener-

ally follows bacterial PHARYNGITIS such as "strep" throat.

Symptoms of the infection begin suddenly and worsen rapidly. Key symptoms include

- sore throat
- high FEVER (above 102°F)
- gasping for breath and stridor (high-pitched sounds on inhalation)
- profuse drooling
- desire to sit upright with the neck extended and the head tilted forward

Treatment is immediate hospitalization for administration of intravenous ANTIBIOTIC MEDICATIONS and often insertion of a breathing tube to maintain breathing until the swelling subsides. This course of treatment typically brings the infection under control within 48 to 72 hours, though hospitalization may be necessary for a week or longer. Prompt medical treatment of epiglottitis usually leads to complete recovery. The routine IMMUNIZATION of infants and children with the Hib vaccine has greatly contributed to the steady decrease in instances of this life-threatening infection.

epistaxis The clinical term for a bloody NOSE. The inner nasal passages have a rich and plentiful supply of BLOOD vessels, and there are many causes for epistaxis. During an episode of epistaxis, blood may come from the nostrils or from the back of the nose and into the nasopharynx (back of the THROAT). Most people who have normal clotting do not lose a significant amount of blood during an epistaxis episode, even when bleeding appears profuse. Blood loss often appears greater than it is because the blood mixes with nasal secretions.

To slow or stop epistaxis:

1. Keep the head upright.
2. Apply firm pressure to both nostrils using the thumb and forefinger.
3. Hold the pressure for at least 10 minutes without release.

The most common causes of epistaxis are injuries due to local irritation (notably insertion of fingers, especially in children, and presence of foreign objects in the nasal passages), BREATHING dry and especially cold air, heavy sneezing, nasal polyps, and external trauma such as a blow to the nose or face. Epistaxis may also indicate deviated septum, which alters the flow of air through the nostrils and exposes the nasal lining to chronic irritation.

People who have bleeding disorders, regularly take NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) including aspirin, or who have uncontrolled HYPERTENSION (high BLOOD PRESSURE) are more likely to experience heavy epistaxis, though these circumstances do not usually cause the bleeding. Epistaxis is usually self-limiting (the bleeding stops following initial treatment) and does not require a doctor's attention.

A doctor should evaluate bleeding that persists after taking basic measures to stop the nosebleed. A heavy blood flow may require, with local anesthetic, cauterization to seal the bleeding area or medicated packing (gauze strips, absorbent pledgets, or nasal tampons) placed into the area of the bleeding to hold continuous pressure against the blood vessels. Doctors typically prescribe a course of oral ANTIBIOTIC MEDICATIONS when it is necessary to place nasal packing, to safeguard against SINUSITIS (bacterial INFECTION of the SINUSES) or TOXIC SHOCK SYNDROME (a serious systemic bacterial infection). The doctor must remove any nasal packing, typically three days after its placement.

When extended treatment becomes necessary, the doctor will also request blood tests to assess blood cell counts and CLOTTING FACTORS and may choose to admit the person to the hospital for monitoring of the bleeding as well as the ability to maintain adequate breathing. Severe bleeding may require BLOOD TRANSFUSION or infusions of clotting factors. Rarely surgery is necessary to halt the bleeding, usually when the cause is external trauma or there are underlying health conditions that prevent the body's clotting mechanisms from properly functioning. Most often epistaxis is a minor problem that quickly resolves, though a doctor should evaluate recurring nosebleeds.

esophageal speech A learned method to restore verbal communication for people who have undergone LARYNGECTOMY (surgical removal of the larynx, or voice box). When the THROAT is intact, air coming out of the LUNGS passes through the VOCAL CORDS and other structures of the larynx, generating sound vibrations that travel to the MOUTH. The mouth then forms these vibrations into words. Laryngectomy removes the throat; air instead enters and leaves the TRACHEA through a surgically created opening, or stoma. For esophageal speech, the person takes air into the mouth and swallows it, which sends the air into the ESOPHAGUS (tube that carries food to the STOMACH). When the esophagus expels the air back into the mouth, the force of the moving air generates sound in the form of a burp or belch. The mouth then forms these bursts of air into words. The technique takes considerable practice; however, it is possible produce a fairly natural voice, although certain sounds may be difficult to form and understand.

Tracheoesophageal speech is a variation of esophageal speech in which the surgeon creates an opening between the trachea and the esophagus at the point of the stoma, called a tracheoesophageal puncture, and inserts a small shunt (connecting tube) with a one-way valve. The person then learns to force air from the trachea into the esophagus instead of taking air in through the mouth and forcing it into the esophagus. This is somewhat more natural and many people find it an easier technique to master.

See also ELECTROLARYNX.

eustachian tube An elongated, valvelike channel of tissue that connects the middle EAR and the THROAT. The eustachian tube relaxes or constricts to equalize the pressure between the middle ear and the external environment. The sensation of the ears "popping" indicates air moving through the eustachian tube. Congestion easily blocks the eustachian tube, particularly in children because their small, compact facial structure causes the eustachian tubes to be nearly horizontal. In adults, the eustachian tubes angle downward from the ear to the throat, thwarting progression of fluid from the throat to the middle ear. Blocked eustachian tubes result in a feeling of fullness in the ears and can set the stage for OTITIS media (INFECTION of the middle ear).

For further discussion of the eustachian tubes within the context of otolaryngologic structure and function, please see the overview section "The Ear, Nose, Mouth, and Throat."

F

foreign objects in the ear or nose Material that enters the EAR or NOSE. This is a common occurrence with young children, who tend to put objects into their noses and ears. Typically, the object is visible, though drainage or odor may signal an undetected obstruction that is causing an INFECTION. Attempts to retrieve or clear the object can result in pushing it instead farther into the auditory canal or nasal passages; there is a risk with foreign objects in the nose of inhaling them into the airways or LUNGS. A health-care provider should assess and remove any foreign object that does not come out of the ear or nose with minimal effort, as well as any circumstance in which an infection might exist. Particles of food and objects such as paper wads attract moisture and can swell, lodging more firmly in the ear or nose.

To treat an insect in the ear:

1. Lie on the side with the affected ear up.
2. Use an eyedropper to gently fill the auditory canal with warm mineral oil or olive oil.
3. Wait a few minutes for the oil to suffocate the insect.
4. Often the insect will float to the top of the canal. If it does not, turn the head so the affected ear is down and allow the oil to drain from the auditory canal, bringing the insect with it.

Do NOT put water into the ear canal in an attempt to remove an insect or other foreign object. Water may cause the insect or object to swell, lodging it more firmly into the ear canal.

When there is an object in the nose:

1. Breathe through the mouth to avoid inhaling the object or lodging it farther into the nasal passages.
2. Hold the clear nostril shut and breathe out through the blocked nostril.
3. Do not blow forcefully or insert anything into the nose to attempt to prod or pull the object free.

If these techniques are not effective, a health-care provider will need to remove the object. Removal of the foreign object is nearly always a complete remedy, unless there is a secondary infection that requires further treatment.

G

gag reflex A rapid and intense contraction of the pharyngeal muscles to expel material before it enters the THROAT. Touching the back of the soft palate activates the gag REFLEX in most people, causing a retching action. The gag reflex is more sensitive in some people, interfering with health examinations of the throat or dental examinations and treatment. HYPNOSIS and BIOFEEDBACK are two methods by which people can learn to delay or minimize the gag reflex. Health conditions that can activate the gag reflex include severe PHARYNGITIS, EPIGLOTTITIS, and profuse POSTNASAL DRIP. Sprays to anesthetize the throat, such as to treat relieve sore throat PAIN or for ENDOSCOPY procedures, temporarily numb the nerves in the soft palate to subdue the gag reflex. A reduced or absent gag reflex, which can result in potentially life-threatening ASPIRATION, may occur with STROKE and neurologic disorders such as CEREBRAL PALSY and PARKINSON'S DISEASE.

See also SWALLOWING DISORDERS.

gingivitis INFLAMMATION of the gum tissue around the TEETH. Most gingivitis is an early form of PERIODONTAL DISEASE. Signs of gingivitis include painless bleeding (spontaneous or with brushing) and swollen gums that may be bright red or shiny. Some people develop painless sores or ulcerations on the gums that indicate INFECTION. Though people may seek medical care because of the bleeding, dentists and periodontists provide dental-based care for gingivitis. People who have DIABETES, people who smoke cigarettes, or use smokeless tobacco, and women who are pregnant have increased susceptibility for gingivitis.

glossitis An INFLAMMATION of the tongue that is typically the result of irritation, viral or bacterial INFECTION, vitamin B deficiency, or ANEMIA. Glossitis may also develop as an opportunistic condition in people who have IMMUNE SYSTEM disorders.

A rare though potentially life-threatening complication of glossitis is swelling that causes the tongue to block the airway. This requires emergency medical attention.

In glossitis, the tongue often hurts, has a characteristic "beefy" appearance, and has a surface that is deep red and smooth. Swallowing and speaking may be difficult. Most glossitis responds to corticosteroid mouthrinses to reduce the inflammation. Mouthrinses with diphenhydramine may also bring relief. A bacterial infection requires treatment with ANTIBIOTIC MEDICATIONS; a yeast infection requires treatment with ANTIFUNGAL MEDICATIONS. Dietary changes or nutritional supplements are necessary when vitamin B or iron deficiency is the cause. Appropriate treatment typically resolves the symptoms, and the tongue returns to normal.

H

hairy tongue The common term for the circumstance of overgrown filiform papillae on the tongue, a condition known clinically as lingua villosa. Filiform papillae are long, resemble hairs, and do not contain taste buds. Their purpose is to help move food during chewing and swallowing. Normally the wear and tear of this function breaks them off, a process called desquamation. Various circumstances inhibit desquamation, allowing the filiform papillae to grow up to 10 times longer than normal. The overgrown filiform papillae then trap food debris and other substances that impart color (such as coffee and tea), giving the characteristic "colored hair" appearance of hairy tongue. The causes of hairy tongue are numerous and include eating habits centered around soft foods, which do not scrape the tongue, and inadequate ORAL HYGIENE.

From a medical perspective hairy tongue is harmless, though people in whom it develops tend to find it aesthetically displeasing and in some it tickles or irritates the soft palate during swallowing. Brushing the tongue as a routine aspect of oral hygiene, or using a tongue scraper, nearly always restores the desquamation process and reduces the length of the filiform papillae. Hairy tongue is also slang for a bad hangover, probably stemming from the correlation between chronic ALCOHOL abuse and poor oral hygiene habits.

See also HALITOSIS.

halitosis The clinical term for bad breath. Halitosis can indicate numerous local or systemic health conditions. Local halitosis occurs when an abundance of BACTERIA that release sulfur as a waste byproduct colonize in the mouth. Systemic halitosis occurs as a response to metabolic and chemical changes that the disease process causes in the body.

LOCAL CAUSES OF HALITOSIS	SYSTEMIC CAUSES OF HALITOSIS
poor ORAL HYGIENE	PEPTIC ULCER DISEASE
food stuck between TEETH	GASTROESOPHAGEAL REFLUX DISORDER (GERD)
inadequate saliva production	certain cancers
TONSILLITIS, adenoiditis, SINUSITIS	DIABETES
POSTNASAL DRIP	LIVER disease
	kidney disease

Treatment for underlying conditions often reduces or eliminates halitosis. When the source is ineffective ORAL HYGIENE, improved brushing and flossing techniques can help clean food debris from the MOUTH, which reduces the presence of sulfur-producing bacteria. Medications can cause dry mouth and even leave unpleasant odors in the mouth. Some people are predisposed to mouth conditions that support the presence of bacteria. Typically, a dentist treats halitosis related to oral hygiene, PERIODONTAL DISEASE, DENTAL CARIES, and other dental conditions. A doctor may recommend approaches to minimize halitosis that exists secondary to other health conditions. Thyme, eucalyptus, peppermint, and caraway are among the herbal remedies for halitosis.

hearing aid An external device that amplifies sound to compensate for HEARING LOSS. A hearing aid incorporates a receiver (microphone) to pick up sound waves, an amplifier to magnify the sound waves, and a battery that powers the receiver and amplifier. Sound quality with a hearing aid is different from sound quality the natural EAR perceives, and it takes time to become accustomed to using hearing aids. Hearing aids cannot restore normal hearing though they can increase

the range of frequency and pitch the ear can detect through amplification and modulation. Hearing aids are most effective in sensorineural hearing loss and can improve hearing in one ear or both ears.

Kinds of Hearing Aids

There are five kinds of hearing aids in common use today:

- Completely in the canal (CIC) hearing aids are the smallest available and fit well into the auditory canal. They are barely visible when in place. CIC hearing aids are most effective for mild to moderate hearing loss. People who have small auditory canals or limited manual dexterity may not be able to use CIC hearing aids. CIC hearing aids allow the wearer to use the telephone without adaptive devices.
- In the canal (ITC) hearing aids fit into the start of the auditory canal. A bit larger than CIC hearing aids, ITC hearing aids are somewhat noticeable when in place. They are easier to handle than CIC hearing aids and also are most effective for mild to moderate hearing loss.
- In the ear (ITE) hearing aids fit at the opening of the auditory canal and are visible on the outer ear (auricle). The larger size of ITE hearing aids give them the capacity to contain larger amplifiers, extending the range of hearing loss they can accommodate. ITE hearing aids are effective for mild to moderately severe hearing loss.
- Behind the ear (BTE) hearing aids drape over the external ear (auricle), with the housing for the electronics and battery behind the ear. A thin tube runs from the BTE hearing aid over the front of the auricle and into the auditory canal. BTE hearing aids accommodate the broadest range of hearing loss because they can hold larger amplifiers and the larger batteries necessary to provide power.
- Implantable middle ear devices are surgically implanted in the middle ear. They attach to and directly stimulate the auditory ossicles, the tiny bones in the middle ear that amplify and transmit sound to the inner ear. There are two variations of implantable middle ear devices, one that is completely implanted (with the receiver embedded in a pouch of tissue behind the ear) and one that has internal and external components (the receiver hangs behind the ear). Implantable middle ear devices accommodate moderate to severe hearing loss and typically become an option when conventional external hearing aids are ineffective.

One other style, the body hearing aid, attaches to the belt or fits within a pocket. About the size of a cellular phone, the body hearing aid can contain a very large amplifier and comparable battery to power it. Wires run from the body hearing aid unit to the ears. Though significantly less convenient than other styles of hearing aids, the body hearing aid can make limited HEALING possible for people with profound hearing loss.

BTE hearing aids can be analog or digital; CIC, ITC, and ITE hearing aids and implantable middle ear devices are digital. Analog units receive incoming sound waves and transmit them directly to the amplifier; they make sound only louder. Many people consider analog technology outdated, though it nonetheless provides improved hearing across a broad spectrum of hearing loss. Some analog hearing aids have manual volume controls and others can accept a wider range of adjustment via computer programming. Digital hearing aids convert incoming sound waves to binary signals that are much faster to process electronically. Many digital models use computer microchips to allow a broad range of customized adjustments that can filter out certain sounds (such as background noise) and independently enhance or subdue specific frequencies of sound. Digital hearing aids are programmable and provide sounds closer to natural hearing, though they are significantly more expensive than analog hearing aids. For many people cost is a framing factor in choosing a hearing aid because most health insurance plans do not provide coverage for hearing aids.

Adjusting to Hearing Aids

Hearing aids cannot replace natural hearing or restore the function of hearing to normal. Simplistically, hearing aids overstimulate the remaining sensorineural structures of the inner ear so they can respond to sound signals. People using hear-

ing aids must learn to consciously filter unnecessary noise and sounds. In natural hearing, the structures of the ear and the BRAIN work in close integration to receive, transmit, and interpret sound waves. Hearing aids disrupt that integration. Sound interpretation becomes a conscious activity, though with practice it becomes automatic. It takes concentration and focus to participate in ordinary conversation, and many people find the effort tiring even when they become proficient at it. However, most people find the effort a reasonable trade-off for the return of some hearing ability.

hearing loss The diminishment of hearing ability. Hearing loss can be temporary or permanent, sudden or progressive, unilateral (affect only one EAR) or bilateral (affect both ears), partial or profound (total), congenital or acquired. There are two kinds of hearing loss: sensorineural (NERVE) and conductive. About 28 million Americans have some level of hearing loss; 30 percent of them are over age 65 and 20 percent are under age 18. About 1 in 1,000 infants born in the United States each year has a congenital hearing loss.

Though there are numerous dimensions to hearing, audiologists measure hearing loss in terms of sound intensity. Healthy human hearing perceives tones between frequencies of 500 Hz (very low) and 4,000 Hz (very high). AUDIOLOGIC ASSESSMENT measures the intensity of sound required to hear tones at certain levels within the range of normal hearing and reports deviations in decibels (dB) of loss. Hearing loss begins when the level of loss reaches 16 dB. Health experts classify hearing loss greater than 90 dB as profound; at this level the ability to hear the normal sounds of everyday activities is lost. Though profound hearing loss can occur in only one ear, the term typically refers to lack of hearing in both ears. Most health-care providers use the American Speech-Language-Hearing Association (ASLHA) classification system for assessing the degree of hearing loss.

Hearing loss may result from damage (congenital or acquired) to the nerves and related structures of the inner ear that receive and transmit sound signals to the BRAIN; this is sensorineural hearing loss. It accounts for 90 percent of all hearing loss and is usually permanent. Hearing loss also may result from circumstances that prevent sound waves from traveling through the outer and middle ears; this is conductive hearing loss and is often correctable with medications or surgery. Temporary conductive hearing loss is common, especially in children who have middle ear infections (OTITIS media). Congestion due to COLDS and allergies is a common cause of temporary con-

DEGREE OF HEARING LOSS

Classification	Level of Loss	Loss Threshold
minimal (slight)	16 to 25 dB	ticking of a watch, normal BREATHING
mild	26 to 30 dB	hum of electrical appliances
moderate	31 to 50 dB	falling rain, whispering, residential neighborhood noise, library, typical office, normal voice of a child
moderately severe	51 to 70 dB	normal conversation, washing machine, sewing machine, vacuum cleaner, birds, freeway traffic, normal television volume
severe	71 to 90 dB	telephone ringing, alarm clock, doorbell, city traffic, noisy restaurant, flushing toilet
profound	91 db or greater	hair dryer, small power tools, crying infant, shouting, police/fire/medical aid siren

ductive hearing loss in adults. Compacted CERUMEN (ear wax) in the auditory canal and OTOSCLEROSIS (fusion of the auditory ossicles, the tiny bones of the middle ear) are common causes of treatable conductive hearing loss. Damage to the areas of the brain that process hearing, speech, and language can result in auditory processing disorders in which, though the structures and mechanical functions of hearing may remain intact, the person cannot understand spoken words. Typically other language impairments, such as the abilities to read and write, also exist with auditory processing disorders.

Hearing loss in children, whether congenital or acquired, has significant developmental consequences. It is now the standard of care in the United States to test newborns for hearing in the first few weeks of life, with regular screening for hearing difficulties at well child checks and routine medical examinations through ADOLESCENCE. The ability to hear forms the basis for understanding language. Early intervention to correct or accommodate hearing loss in prelingual children is essential for appropriate development and communication. A teacher's voice in a classroom projects an intensity of about 70 dB; children with hearing loss at this level or greater will be unable to hear in school.

The majority of hearing loss in adults is acquired. Excessive noise exposure and changes related to aging (PRESBYCUSIS) are the most common causes of acquired adult hearing loss. Hearing loss may also result from health conditions, such as ACOUSTIC NEUROMA and MÉNIÈRE'S DISEASE, that interfere with the functions of hearing. Trauma, such as FRACTURE of the bones in the face and head or BURNS that damage the external ear, can cause hearing loss. Various medications, including certain antibiotics, diuretics, antihypertensives, high doses of aspirin, and CHEMOTHERAPY drugs, also can damage or destroy hearing.

Symptoms and Diagnostic Path

Sudden hearing loss in adults is typically obvious. Progressive hearing loss is often subtle and noticed more by others than the person experiencing the loss. Common indicators of diminishing hearing ability include

- perception that "everyone" mumbles when speaking
- unable to hear the telephone or doorbell ring
- volume is past the halfway mark when listening to television or radio
- easier to hear someone talking when looking directly at him or her
- restaurants are "too noisy" for conversation

TINNITUS (sensation of roaring or buzzing sound in one ear or both ears) may be an early sign of sensorineural hearing loss. Children with undetected hearing loss may fail to respond when spoken to or to follow instructions, have difficulty in school, seem to mumble or slur their words, or be developmentally delayed especially in language skills.

Diagnosing hearing loss begins with physical examination of the outer and middle ears to look for obvious problems such as compacted cerumen, inflamed or damaged TYMPANIC MEMBRANE (eardrum), and structural anomalies. An audiologic assessment then measures hearing response to a variety of tests. If questions remain about the cause of the hearing loss, the doctor may request COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI).

Treatment Options and Outlook

Medical or surgical treatments can restore most conductive hearing loss. Sensorineural hearing loss requires interventions such as hearing aids, which amplify sound, or cochlear implants, which directly stimulate nerve cells in the inner ear. Hearing lost as a result of health conditions such as acoustic neuroma often returns when the neuroma is removed. Accommodations for profound hearing loss include training in lip reading and SIGN LANGUAGE.

Hearing loss, however subtle, can significantly affect on a person's ability to function in, and enjoy, everyday life. Even mild to moderate hearing loss removes many common sounds from daily experience. Early intervention and appropriate accommodation can mitigate to the extent possible much hearing loss. Hearing aids, though they cannot restore normal sound quality and hearing, make it possible to participate in conversation and to hear

many of the sounds that provide orientation to one's personal environment. With accommodation, most people with hearing loss are able to fully participate in nearly all activities those who have normal hearing can experience. In the United States, the Americans with Disabilities Act (ADA) requires public facilities and most employers to provide reasonable accommodations for people who have profound hearing loss.

Risk Factors and Preventive Measures

The most significant risk factors for acquired hearing loss are age and noise exposure. Researchers are exploring the processes of aging that cause hearing loss, looking for ways to mitigate or eliminate them. Limiting noise exposure appears to be one way to help reduce sensorineural hearing loss, even as a component of aging. Just 15 minutes of exposure to noise at greater than 115 dB (jet engine, chain saw, rock concert, sporting event in a stadium or arena) damages the HAIR cells within the cochlea. The US Occupational Safety and Health Administration (OSHA) establishes guidelines and regulations for protection from exposure to noise in the workplace. Other mechanisms that contribute to age-related hearing loss are likely genetic; research continues in this area as well.

Because numerous medications can damage the structures of the inner ear, it is important to always ask the doctor or pharmacist whether this is a potential SIDE EFFECT. When it is, ask if there are alternatives that are less risky for hearing. Illnesses such as MEASLES, though now less common because of vaccines, also can cause hearing loss. RUBELLA (German measles) remains a leading cause of congenital hearing loss.

labyrinthitis An INFLAMMATION or INFECTION of the vestibular system, the body's balance mechanism within the inner EAR. The sudden onset of VERTIGO (feeling of spinning) is the characteristic symptom. Many people also experience transitory or temporary hearing problems and TINNITUS (a ringing or roaring sound). When an infection is present, it can be viral or bacterial. Bacterial labyrinthitis typically develops as a consequence of chronic OTITIS media (middle ear infection). Doctors believe viral labyrinthitis develops when the bloodstream carries a VIRUS into the inner ear. Inflammatory labyrinthitis may be an autoimmune condition; doctors are not certain of its etiology (origin and development). It is sometimes difficult to diagnose and distinguish the kind of labyrinthitis because access to the inner ear is so limited. Often in bacterial labyrinthitis there are signs of infection around the TYMPANIC MEMBRANE (eardrum), or might be signs of infection elsewhere including the mastoid (MASTOIDITIS) and less commonly, MENINGITIS.

Bacterial labyrinthitis has potentially serious complications, including destruction of the labyrinth and COCHLEA, which results in permanent and profound HEARING LOSS. It requires treatment with ANTIBIOTIC MEDICATIONS. Untreated bacterial labyrinthitis also can extend into other infections such as mastoiditis and meningitis. Viral labyrinthitis and inflammatory labyrinthitis generally do not leave lasting damage. Because distinguishing the cause of labyrinthitis is sometimes difficult and the consequences of untreated bacterial labyrinthitis can be severe, doctors typically prescribe antibiotics when the diagnosis is unclear, even though antibiotics will not treat viral labyrinthitis. Sometimes medications to suppress vertigo and resulting NAUSEA are also necessary, at least until the inflammation or infection is under control.

laryngectomy Surgical removal of the larynx, which includes the VOCAL CORDS and other structures that produce sound for the function of speech. Surgeons perform the majority of laryngectomies to treat CANCER due to cigarette smoking. Laryngectomy results in the loss of the ability to speak.

In laryngectomy, the surgeon makes an incision in the neck and removes the structures of the larynx, typically including the vocal cords and upper portion of the TRACHEA as well as surrounding MUSCLE tissue to obtain a cancer-free margin. The ESOPHAGUS, which carries food from the MOUTH to the STOMACH, remains intact. In the OPERATION's final stage the surgeon creates a permanent opening through the neck into the trachea, called a stoma, for BREATHING.

The operation takes five to eight hours for the surgeon to perform, and most people stay in the hospital for 10 to 14 days following the surgery. Rehabilitation begins immediately and includes instruction to care for the stoma as well as swallowing exercises. Many people also start to learn ESOPHAGEAL SPEECH, though speech therapy is most extensive during outpatient rehabilitation following discharge from the hospital. The surgical wound heals completely in about six to eight weeks.

Occasionally doctors diagnose the cancer early enough to permit a partial laryngectomy, in which the surgeon removes only the tumor and tissues

in proximity to it. With partial laryngectomy the airway and often part of the vocal structures remain intact, so breathing and speech are normal after recovery, though the quality and volume of the voice may change.

laryngitis Irritation or INFLAMMATION of the larynx (voice box) that results in hoarseness or loss of voice. Most laryngitis is viral, though may accompany or follow a bacterial INFECTION such as STREP THROAT. Laryngitis is also common in people who strain their voices through loud singing, yelling, and extended talking, and in people who smoke or who work or live in environments that are smoky. Resting the voice by speaking softly (though not whispering as it further stresses the tissues of the larynx) and sucking on hard candy or COUGH drops help soothe the irritated tissues. A cool-mist humidifier, especially when sleeping, helps reduce irritation. Most laryngitis goes away within 10 to 14 days and does not need medical treatment. Bacterial laryngitis requires treatment with an appropriate ANTIBIOTIC MEDICATIONS.

A doctor should evaluate laryngitis when:

- hoarseness/discomfort last longer than 14 days
- an accompanying cough produces yellow or green sputum
- FEVER is greater than 101°F

Frequent or extended laryngitis might indicate the presence of VOCAL CORD NODULE, VOCAL CORD POLYP, or laryngeal CANCER.

laryngocele An air-filled bulge (herniation) that develops within the tissues of the larynx (voice box), often among the folds of the VOCAL CORDS. Laryngocele may be present at birth as a CONGENITAL ANOMALY or develop later in life, often as a consequence of persistent pressure against the structures of the THROAT. A congenital laryngocele may not cause symptoms until environmental stressors that create increased laryngeal pressure cause it to enlarge. Musicians who play wind instruments are particularly vulnerable to laryngoceles, as are people with OBSTRUCTIVE SLEEP APNEA. Occasionally a laryngeal tumor causes a laryngocele.

Hoarseness, a feeling that there is something caught in the throat, dry COUGH, and a soft lump visible on the external throat are among the most common symptoms. A large laryngocele can cause stridor (a high-pitched noise with inhalation) and difficulty swallowing. The diagnostic path typically includes COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) of the throat and laryngoscopy (examining the inside of the throat through a lighted, flexible scope). Because a laryngocele presents a prime opportunity to trap BACTERIA that cause INFECTION as well as the potential to interfere with BREATHING and swallowing, the treatment of choice is an OPERATION through an incision in the neck to close or remove the laryngocele.

leukoplakia Precancerous patches, or lesions, inside the MOUTH. The patches are light-colored and most commonly form on the tongue and insides of the cheeks. Irritation to these tissues over time, such as from all forms of tobacco use and poorly fitting dentures or dental bridges, causes leukoplakia to develop. In a type of leukoplakia specific to people with HIV or AIDS, hairy leukoplakia, the patches look like white fuzz. Hairy leukoplakia often is one of the earliest signs of HIV INFECTION. Leukoplakia may also affect the VULVA in women. Biopsy to examine the cells of the patches confirms the diagnosis. In some people, removing the source of the irritation causes the leukoplakia to go away. Often doctors prefer to remove the lesions surgically, which generally is an office procedure with local ANESTHESIA. When the irritation continues, or in the presence of HIV/AIDS, leukoplakia may return.

M

mastoiditis An INFECTION in the mastoid BONE behind the EAR. Mastoiditis typically develops as a consequence of untreated or chronic OTITIS media (middle ear infection) when BACTERIA migrate from the middle ear to the adjacent mastoid bone. The rather porous structure of the mastoid bone, which is more a collection of small cavities than a solid structure, provides an ideal habitat for bacteria. Untreated mastoiditis can spread to the nasal SINUSES as well as the MENINGES (membranes surrounding the BRAIN and SPINAL CORD), causing bacterial MENINGITIS, and to the brain itself, causing ENCEPHALITIS. These infections are potentially fatal and require immediate medical treatment. Though mastoiditis was once a common cause of childhood death, it has become rare since the advent of ANTIBIOTIC MEDICATIONS.

PAIN behind the ear, FEVER, and a recent episode of otitis media are the leading indications of acute mastoiditis. The person may also have swelling and tenderness in the mastoid area, and the auricle (external ear) may appear to stick out from the side of the head. Chronic mastoiditis may be subclinical; that is, the infection causes few overt symptoms until it spreads beyond the mastoid or destroys mastoid bone tissue. Diagnosis includes blood tests and cultures of any fluid in the ear to look for signs of infection, and occasionally COMPUTED TOMOGRAPHY (CT) SCAN. In most cases of acute mastoiditis, antibiotic medications and occasionally MYRINGOTOMY (insertion of a small tube through the TYMPANIC MEMBRANE to allow fluid to drain from the middle ear) successfully eradicate the infection. Chronic mastoiditis sometimes requires surgery to open, drain, and occasionally remove portions of the mastoid structure. Severe mastoiditis may require mastoidectomy, in which the surgeon removes the entire mastoid bone. Most people recover fully following treatment, though should have an AUDIOLOGIC ASSESSMENT to determine whether there is residual HEARING LOSS.

Ménière's disease A disorder of the inner EAR that results in balance and hearing disturbances. Doctors do not know for certain what causes Ménière's disease. There are numerous approaches to treating the condition's symptoms though there is no known cure for the disease. The most significant consequence of Ménière's disease is permanent and progressive HEARING LOSS. About 2.5 million Americans have Ménière's disease.

The disease is also called endolymphatic hydrops, a reference to the dilation of the structure in the inner ear called the membranous labyrinth. Researchers believe the dilation signals an abnormal accumulation of fluid within the membranous labyrinth, though do not know what causes that accumulation. Current research suggests that the dilation results in small tears that allow the fluid within the membranous labyrinth, the endolymph, to mix with fluid outside the membranous labyrinth, the perilymph. The two fluids have different chemical compositions; some researchers believe changes in the electrolyte content that occur when the fluids mix cause vestibular dysfunction that results in the specific constellation of symptoms that define Ménière's disease. Continued or repeated dilation likely results in repeated tears and recurrent symptoms.

Symptoms and Diagnostic Path

Most otolaryngologists look for four cardinal, or defining, symptoms that occur with repeated

episodes (recurrent symptoms) when distinguishing Ménière's disease from other forms of vestibular dysfunction. These are

- VERTIGO (sensation that the person or the environment is spinning or whirling), often with NAUSEA and vomiting, and sometimes debilitating loss of balance
- TINNITUS (rushing or roaring sound) in one ear, often worse during vertigo attacks
- hearing loss in one ear that returns with the conclusion of each episode of symptoms though progressively worsens with multiple episodes
- sensation of fullness or congestion in one ear

Symptoms may last 20 minutes to several hours, and may fluctuate within, as well as vary among, episodes. Doctors disagree on whether all four symptoms must exist to constitute Ménière's disease, and whether symptoms other than vertigo must involve only one ear. Diagnosis is primarily by exclusion, with findings to rule out other vestibular dysfunctions and causes. Diagnostic tests and procedures often include

- OTOSCOPY (visualization of the auditory canal and middle ear with a lighted instrument)
- complete blood count (CBC) to look for signs of infection or immune response
- COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) to rule out tumors and structural problems
- NEUROLOGIC EXAMINATION to rule out ACOUSTIC NEUROMA or disorders affecting the CRANIAL NERVES
- AUDIOLOGIC ASSESSMENT to evaluate hearing loss

Findings that fail to support any other diagnosis, in combination with the four cardinal symptoms, point to a diagnosis of Ménière's disease.

Treatment Options and Outlook

Treatment largely focuses on relieving symptoms and varies depending on the relief various efforts provide. Common treatments may include antinausea medications, anticholinergic medications, ANTIHISTAMINE MEDICATIONS, and scopolamine to reduce the vertigo. When the vertigo is such that it prohibits the activities of living for an extended time, surgically cutting the vestibular NERVE ends the nerve messages the labyrinth sends to the BRAIN yet preserves hearing. When vertigo is severe and hearing loss is complete, labyrinthectomy becomes a treatment option. The otolaryngologist may surgically remove the labyrinth or instill a DRUG, such as the antibiotic gentamicin, into the inner ear that chemically destroys the NERVE endings in the labyrinth.

The outlook for people who have Ménière's disease is variable and unpredictable. About 20 percent have only one attack; typically there are few long-term consequences when this is the case, though some people experience mild permanent hearing loss. About 40 percent have recurrent attacks, sometimes years apart, that medical treatments effectively mitigate. Hearing loss tends to worsen with each episode of symptoms, however, and can become profound (complete) in the affected ear. Another 20 percent have frequent and debilitating attacks that do not respond to medical treatments. For these people, Ménière's disease significantly interferes with QUALITY OF LIFE and often produces moderate to severe hearing loss over a relatively short period of time. The remaining 20 percent of people who have Ménière's disease fall along the continuum.

The most favorable improvement for those who have repeated episodes of symptoms is with vertigo, which seems to go away roughly 10 years after diagnosis in about 70 percent of people. Doctors have no explanation for this; though medical treatments can lessen the severity of vertigo during attacks, they do not appear to influence this 10-year resolution marker.

Risk Factors and Preventive Measures

There are no known measures to prevent Ménière's disease from developing in the first place. Lifestyle factors appear to influence the return and severity of symptoms in many people who have the condition, though researchers have yet to establish definitive connections. These factors include the amount of sodium in the diet, fluid consumption and balance, smoking, stress, and certain food triggers. Many people find that restricting dietary sodium and limiting fluid intake reduce the fre-

quency of episodes because it helps prevent the accumulation of fluid throughout the body, including in the inner ear. The doctor may also prescribe a diuretic medication to further minimize fluid retention. Local and online support groups can provide encouragement and anecdotal information about successful symptom management methods.

mouth The facial structure that provides the sensory function of taste, performs the mechanics of speech, and prepares food for entry into the gastrointestinal system. The base of the skull establishes the roof of the mouth; the mandible, or lower jaw, establishes the floor of the mouth. The muscular cheeks help move food through the mouth during mastication (chewing) as well as shape the mouth for forming the sounds of speech. The tongue contains most of the taste buds, specialized papillae (or bumps) that contain the taste cells, though some taste buds appear on the soft palate and back of the THROAT. The tongue also moves food through the mouth and then pushes it to the top of the throat for swallowing. The tongue's shape and placement within the mouth help direct the flow of air and sound during speech. The TEETH function primarily to tear and pulverize food and also provide a solid structure for the tongue to push against during speech. SALIVARY GLANDS produce saliva, which keeps the inside of the mouth wet and aids in breaking down food to pass down the throat.

myringitis INFLAMMATION and irritation of the TYMPANIC MEMBRANE (eardrum), usually as the result of a viral or bacterial INFECTION. The characteristic symptom is the sudden onset of PAIN, sometimes severe. Many people also experience temporary HEARING LOSS in the affected EAR. In bullous myringitis (also called myringitis bullosa), fluid-filled, blisterlike vesicles form on the tympanic membrane and cause intense pain. Sometimes the doctor lances, or carefully punctures with a MYRINGOTOMY scalpel, the vesicles to release the fluid and relieve the pain. OTITIS media, infection of the middle ear, can extend to involve the tympanic membrane. The pain associated with this form of myringitis often includes the sensation of pressure. Doctors typically prescribe ANTIBIOTIC MEDICATIONS to treat the infection and ANALGESIC MEDICATIONS to relieve the pain. Appropriate treatment resolves most myringitis in 10 to 14 days, and any temporary hearing loss returns. Occasionally myringitis causes the tympanic membrane to perforate, which may require further medical treatment.

See also RUPTURED EARDRUM; TYMPANOPLASTY.

myringotomy A surgical incision in the TYMPANIC MEMBRANE (eardrum) to allow fluid in the middle EAR to drain out. Fluid in the middle ear is a key symptom of OTITIS media (middle ear infection). The buildup of pressure causes considerable PAIN and can cause the tympanic membrane to perforate (tear or rupture). When otitis media is chronic or recurrent, the surgeon places a tympanostomy tube in the incision to retain a pathway for drainage to continue. The tube is very small and generally falls out within several months, then the opening in the tympanic membrane heals closed. The OPERATION is a same-day surgery done under general anesthetic, and usually takes no longer than 20 minutes per ear. Recovery is rapid.

N

nasal polyp A noncancerous, fleshy growth within the interior NOSE. Polyps are outgrowths of the mucous membrane and extend from the membrane on a stemlike projection called a pedicle. Polyps have a rich BLOOD supply and bleed easily. Because of this and because there is a chance for them to become cancerous over time, doctors prefer to surgically remove them. Nasal polyps that form in the air passages and SINUSES can obstruct the flow of air, interfering with BREATHING. Chronic irritation (such as from ALLERGIC RHINITIS) and INFECTION (such as SINUSITIS) seem to encourage the growth of polyps; treating the underlying conditions helps prevent polyps from recurring. Multiple nasal polyps are common in people who have CYSTIC FIBROSIS.

nasal vestibulitis A bacterial INFECTION of the HAIR follicles around the base of the nostrils that results in INFLAMMATION and irritation of the tissues. Symptoms include redness, swelling, and PAIN. Sometimes the tissue becomes raw and bleeds. Nasal vestibulitis typically develops with extended sneezing and nose blowing such as occurs with COLDS and ALLERGIC RHINITIS. Treatment with topical and occasionally oral ANTIBIOTIC MEDICATIONS generally resolves the infection within 10 to 14 days, though symptoms should improve within 2 or 3 days. Most people experience complete recovery with no residual complications, though occasionally an ABSCESS develops that requires further medical care.

noise exposure and hearing Excessive exposure to noise can temporarily or permanently damage hearing. Excessive noise exposure is the most preventable cause of HEARING LOSS and accounts for as much as 60 percent of impaired hearing ability.

Several natural mechanisms attempt to protect the EAR from damage due to loud noises. The tympanic REFLEX serves to stiffen the structures of the middle ear, reducing their ability to amplify sound. In response to a loud noise, two muscles in the middle ear reflexively contract. The tensor tympani MUSCLE pulls on the malleus, and the stapedius muscle pulls on the stapes—the first and third bones, respectively, of the auditory ossicles. The effect of this reflex straightens the ossicular chain (the sequence of the ossicles), restricting the movement of the bones and dampening their ability to amplify and transfer sound waves. The ear also may experience a temporary threshold shift in response to sudden loud noises, such as gunshots and fireworks. The burst of noise appears to stun the HAIR cells, rendering them nonresponsive to sound waves in the relevant frequency range. A temporary threshold shift causes sounds to seem muffled. As long as there is no further exposure to loud noise, the hair cells gradually return to function and hearing returns to normal. However, continued or repeated exposure results in the damage becoming permanent.

Measuring Sound Volume

The unit of measure for sound volume is the decibel (dB). The decibel system is logarithmic; each increase of 10 dB represents a 10-fold increase in sound volume. A noise that measures 60 dB, such as the sound of normal conversation, is 10 times louder than a noise that measures 50 dB, such as the sound of falling rain. A clap of thunder, 120 dB, is 10 times louder than shouting directly into someone's ear, 110 dB. A rock concert (130 dB) is 10 times louder than thunder.

Most hearing experts agree that exposure to sounds louder than 85 dB begins to damage the hair cells in the COCHLEA, which activate the nerves that translate sound waves into NERVE impulses. Sounds at higher frequencies (2,000 Hz and above) do more damage at the same decibel level than sounds at lower frequencies (under 800 Hz). Much of human conversation takes place between 2,000 Hz and 4,000 Hz. Damage to the hair cells responsible for sound translation in this frequency range is particularly devastating.

Noise Exposure

Nearly everyone faces exposure to noise at levels capable of causing damage to the hair cells and ultimately hearing loss. The sounds of city traffic, a noisy restaurant, and a flushing toilet all measure in at about 85 dB. The US Occupational Safety and Health Administration (OSHA) has established regulations limiting noise exposure in the workplace. These regulations stipulate the amount of time an employee may experience noise exposure at certain decibel levels, prohibit exposure without protection to sounds over 115 dB, and prohibit exposure of any kind to sounds over 140 dB. The OSHA Web site (www.osha.gov) publishes current noise regulations and guidelines.

Musicians face the unique conundrum of needing to hear the full range of pitch while protecting their hearing from its intensity, particularly in group settings such as playing in a band or orchestra. Yet musicians playing in a rock concert may experience bursts of exposure at 150 dB, as loud as a jet taking off, which causes permanent damage to the inner ear after only a minute or two. The audience at a symphony concert experiences a sound level of 110 dB, equivalent to a car horn, and peaks near 140 dB. Musicians playing the violin, flute, and trombone face continued exposure to 110 dB or greater at frequencies above 2,000 Hz, among the most damaging of exposures. People who work in construction, steel working, mining, air travel, manufacturing, and public safety also face increased exposure to noise that threatens hearing.

Noise exposure exists in personal environments as well. Appliances such as hair dryers, blenders, coffee grinders, and even coffee makers can generate 90 dB of sound or louder. The decibel level of movies on television or in theaters can exceed 120 dB. Stereos played beyond the halfway point on the volume indicator, especially when using headphones, quickly pass the 100 dB mark. Children's noise-making toys can reach 110 dB to 140 dB.

Ear Protection

The most effective protection against noise exposure is to avoid it. As this is not always practical or possible, health experts recommend (and in the workplace OSHA requires) wearing hearing protection for exposure to sound at 90 dB for longer than eight hours and for any exposure that exceeds 90 dB. There are two kinds of ear protection: ear plugs and ear muffs.

Ear plugs fit snugly into the auditory canal and block sound waves from traveling to the middle and inner ear. They are available in various materials and in different sizes and shapes; finding ear plugs that fit properly and comfortably can take some experimentation. Custom ear plugs are also available, made specifically to fit an individual's ears. A common complaint about ear plugs is that they block so much sound that conversation is difficult. This dampening of the sound is called attenuation. Some designs of ear plugs contain channels that allow sounds at certain frequencies to pass through. This improves the ability to hear and understand speech. Customized ear plugs for musicians can block selected sounds so the musician can hear the tones and pitches necessary to play or sing.

Ear muffs fit over the ears with a strap that holds them in place. They form a seal around the ear, which prevents sound waves from traveling into the auditory canal. As with ear plugs, there are various designs that offer different levels of effectiveness and comfort. Ear muffs tend to muffle all sound, though ear muffs and ear plugs have comparable ability to block noise, about 30 dB. People exposed to noise louder than 100 dB to 110 dB should use both ear plugs and ear muffs, which in combination can block up to about 45 dB.

nose The facial structure that serves as the organ of smell as well as the portal through which air

enters and leaves the pulmonary system. Air enters the nose through the nostrils, passing beneath the olfactory NERVE endings. Odor molecules activate the nerve endings, which convert the stimulation into nerve signals the olfactory nerve (first cranial nerve) transmit to the BRAIN. The air then swirls through the paranasal SINUSES, cavities within the bones that form the face. The sinuses warm and moisturize the air, bringing it closer to the temperature and humidity of the inner airways. Because it extends from the face, the nose is vulnerable to traumatic injury and also to environmental exposure hazards such as FROSTBITE and SUNBURN. Numerous dermatological conditions can affect the outer nose, among them ACNE, ROSACEA, SKIN CANCER, ACTINIC KERATOSIS, and KERATOACANTHOMA. Surgery to alter the appearance of the nose, RHINOPLASTY, is one of the most common cosmetic procedures that plastic surgeons perform.

COMMON CONDITIONS AFFECTING THE STRUCTURES OF THE NOSE

ALLERGIC RHINITIS	BROKEN NOSE
EPISTAXIS	NASAL POLYP
NASAL VESTIBULITIS	RHINORRHEA
SEPTAL DEVIATION	SEPTAL PERFORATION
SINUSITIS

O

obstructive sleep apnea A disorder in which blockage of the airways takes place during sleep when the structures of the neck and THROAT relax, causing BREATHING to stop for periods of time. The characteristic symptoms are a repeated pattern during sleep of loud, heavy snoring followed by a period of silence followed by gasping or snorting and tiredness during waking hours. The snoring indicates the structures of the throat are relaxing and the passage for air is narrowing; the silence indicates relaxation has reached the point at which no air is getting through. The gasping or snorting is a reflexive reaction to the drop in the blood's oxygen level; it serves to restart breathing. The cycle results in continuous interruption of sleep, leaving the person deprived of rest. The repeated episodes of oxygen deprivation can cause or contribute to numerous health problems, including HYPERTENSION (high BLOOD PRESSURE), ARRHYTHMIA (irregular heartbeat), PULMONARY HYPERTENSION, and HEART FAILURE (reduced ability of the HEART to pump BLOOD).

Many people who have obstructive sleep apnea are not aware that they do, though often their partners complain about their snoring. Often the first indication is the uncontrollable urge to fall asleep during the day, which may occur at dangerous times, such as when driving. Frequent headaches, lack of energy, and irritability are other symptoms. The diagnostic path includes a detailed sleep questionnaire and careful physical examination with a focus on the structures of the MOUTH and neck. The doctor may also request a sleep lab assessment, in which the person spends the night under observation and with electronic monitoring to objectively assess the sleep experience.

About 40 percent of people who have obstructive sleep apnea have obesity. When this is the case, WEIGHT LOSS AND WEIGHT MANAGEMENT are key to treatment. Lifestyle modifications, such as avoiding ALCOHOL or medications that cause sleepiness (such as ANTIHISTAMINE MEDICATIONS or sleep aids), can improve the body's ability to retain control over the muscles of the throat. Some people benefit from surgery to remove excess tissue at the back of the throat (uvulopalatopharyngoplasty). A continuous positive airway pressure (CPAP) device to maintain pressure against the airways and to keep them open is often an effective treatment when other approaches are not appropriate or not successful.

See also SLEEP DISORDERS; WEIGHT LOSS AND WEIGHT MANAGEMENT.

oral hygiene Self-care methods for maintaining health of the TEETH, gums, and MOUTH. Oral healthcare providers recommend brushing the teeth at least twice daily and flossing or using an interdental device to clean between the teeth once daily. People who snack throughout the day should brush more frequently to clear away food debris and BACTERIA that accumulate after eating. Appropriate oral hygiene helps maintain the health of the teeth, gums, and other structures of the mouth and also reduces the risk of INFECTION in people who have tongue, lip, or other oral PIERCINGS. Tooth decay and gum disease develop more rapidly in people who have diminished saliva production, have DIABETES, or who smoke. Further preventive care measures include regular visits to the dentist and dental hygienist for cleaning and examination to detect oral health problems such as GINGIVITIS, PERIODONTAL DISEASE, and oral CANCER.

otitis An INFLAMMATION of the EAR, typically the middle ear (otitis media) or the outer ear (otitis externa). Otitis can affect the inner ear (otitis interna), though more often doctors identify inner ear problems as LABYRINTHITIS and related conditions. The most common cause of otitis is INFECTION. Otitis media often follows a cold or other upper respiratory infection. Otitis can be acute (comes on suddenly) or chronic (lingers at a subclinical level or recurs).

Otitis Media

Otitis media is one of the most frequent reasons parents take their children to see the doctor. Young children are particularly susceptible to otitis media because the eustachian tubes are nearly horizontal until the child's facial structure begins to elongate at about age six or seven. The change in facial structure pulls the eustachian tubes into more angled positions. The purpose of the EUSTACHIAN TUBE is to maintain pressure equilibrium between the middle ear and the external environment. Inequities in pressure allow fluid to accumulate in the middle ear, which inflames the tissues and provides fertile ground for bacterial growth. The eustachian tubes in a child are also prone to becoming congested, which can feed fluid and BACTERIA into the middle ear.

Symptoms of otitis media are primarily PAIN and FEVER. Very young children often tug at the affected ear, are fussy and sleep fitfully, and may not want to nurse or bottle-feed. Older children can say that their ears hurt or may complain of HEADACHE. When there is a ruptured eardrum, there is usually pus-filled or blood-tinged drainage from the ear. Pain lessens when the eardrum gives way because this releases the pressure. It is not possible for a parent to determine whether a child has an ear infection; the doctor must examine the ear with an otoscope. The doctor looks for signs of effusion, the collection of fluid behind the TYMPANIC MEMBRANE (eardrum). When effusion is present, the preferred treatment is an oral antibiotic medication.

The American Academy of Pediatrics issued treatment guidelines in 2004 that emphasize selective use of ANTIBIOTIC MEDICATIONS for acute otitis media without effusion. Clinical research studies have failed to conclusively demonstrate a more rapid rate of recovery with antibiotics when there is no effusion. The treatment guidelines reflect the growing concern among health-care providers that inappropriate antibiotic use is responsible for an alarming increase in the strains of bacteria that are resistant to antibiotics. The guidelines suggest

- focusing on pain relief by giving the child appropriate doses of ibuprofen or acetaminophen
- allowing 48 to 72 hours for the child's natural immune response to bring the infection and inflammation under control
- prescribing an antibiotic as the first line of treatment only in children under six months of age or who have a history of recurrent otitis media
- prescribing amoxicillin as the antibiotic of first choice unless there is a clinical reason (such as sensitivity or known resistance) to prescribe a different antibiotic

Acute otitis media generally clears up in 10 to 14 days. Chronic or recurrent otitis media may require a more extended course of antibiotic therapy or MYRINGOTOMY with placement of tympanostomy tubes. Adenoidectomy (surgery to remove the ADENOIDS) may be necessary when other measures fail to eradicate the infection. Many children experience temporary HEARING LOSS with otitis media. Repeated infections may cause permanent hearing damage.

Otitis Externa

A common name for otitis externa is swimmer's ear. Infections of the outer ear are most common in the summer months when water activities, especially outdoors, are prevalent. Otitis externa develops when water and bacteria become trapped in the auditory canal. Sometimes excessive CERUMEN production contributes to the situation. Treatment depends on the cause of the inflammation and irritation. Taking care to thoroughly dry the auditory canals after bathing, showering, or swimming can help prevent otitis externa.

See also ANTIBIOTIC RESISTANCE; OTORRHEA.

otoplasty Surgery to alter the appearance of the auricle (external EAR). Otoplasty can be cosmetic (to improve appearance) or restorative (to treat congenital deformities or those that result from trauma and BURNS). The auricle is primarily CARTILAGE and SKIN; the cartilage gives the external ear its shape and position on the side of the head. Numerous causes account for abnormalities. Otoplasty can remodel the cartilage to alter the size, shape, and placement of the auricle and even reconstruct an auricle that is missing or severely deformed.

See also CAULIFLOWER EAR; PIERCINGS; PLASTIC SURGERY.

otorrhea A discharge from the EAR. Most commonly otorrhea signals the presence of OTITIS, an INFECTION of the outer ear (otitis externa) or the middle ear (otitis media). Otorrhea is normal after MYRINGOTOMY and placement of tympanostomy tubes, as the purpose of these procedures is to drain accumulated fluid from the middle ear. Drainage that is yellowish green typically contains pus. Red-tinged discharge contains BLOOD. Either of these may indicate otitis media with a perforated TYMPANIC MEMBRANE (RUPTURED EARDRUM). Drainage that is yellowish brown and thick may be excessive CERUMEN, often in response to the ear's attempts to clear matter from the auditory canal or to soothe irritated tissues.

Bright bleeding or drainage from the ear that is watery and clear requires emergency medical attention.

Trauma to the head, such as from a blow or a fall, can cause outright bleeding from the ear and may indicate a BONE FRACTURE. Trauma also can cause CEREBROSPINAL FLUID to leak into the middle ear and drain from the outer ear when a perforation allows the fluid to pass from the middle ear to the outer ear or from the NOSE (RHINORRHEA) when the tympanic membrane is intact. Drainage of cerebrospinal fluid also sometimes occurs following surgery to remove an ACOUSTIC NEUROMA; in any other circumstance it may indicate MENINGITIS.

Treatment targets the underlying cause. ANTIBIOTIC MEDICATIONS are necessary when otitis is responsible. Other conditions such as DERMATITIS of the auditory canal may improve with topical CORTICOSTEROID MEDICATIONS. When the drainage is cerumen, gently rinsing the ears with warm water during bathing helps remove the excess.

See also CLEANING THE EAR; FOREIGN OBJECTS IN THE EAR OR NOSE.

otosclerosis Abnormal growth of BONE tissue around the auditory ossicles in the middle EAR, causing one or more of the ossicles to become locked into place or fused against the other ossicles. Most commonly affected is the stapes (stirrup), the final of the three auditory ossicles in the sequence of sound wave amplification and transmittal. Conductive HEARING LOSS, which is the primary symptom of otosclerosis, occurs as movement of the auditory ossicles becomes increasingly limited. Occasionally otosclerosis involves the COCHLEA, causing sensorineural hearing loss and sometimes vestibular dysfunction such as balance disturbances and VERTIGO.

An AUDIOLOGIC ASSESSMENT identifies the hearing loss. The otolaryngologist may request a COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) to visualize the structures of the inner ear and to confirm the diagnosis. Surgical treatments often can restore conductive hearing loss to near normal hearing. An OPERATION to remove the immobilized ossicle and replace it with a prosthetic ossicle can permanently restore hearing in most people. Surgery is less successful in restoring hearing loss due to cochlear otosclerosis, though a HEARING AID often can improve hearing.

See also SURGERY BENEFIT AND RISK ASSESSMENT; TINNITUS.

otoscopy A basic visual examination of the outer and middle EAR using an otoscope, a handheld, lighted device with a magnifying lens. The otoscope has cone-shaped tips in varying sizes that fit into the start of the auditory canal. With an otoscope, the doctor can examine the auditory canal for injury, INFLAMMATION, INFECTION (OTITIS externa) blockages such as foreign objects or compacted CERUMEN, and structural deformities. The doctor also can visualize the outer surface of the TYMPANIC MEMBRANE for inflammation, infection,

OTOTOXIC MEDICATIONS

Medications	Commonly Prescribed to Treat	Ototoxic Effects
ANGIOTENSIN-CONVERTING ENZYME (ACE) inhibitors: enalapril, lisinopril, ramipril, quinapril, trandolapril	HYPERTENSION	TINNITUS, HEARING LOSS usually temporary, reversible when medication stopped
aminoglycoside antibiotics: amikacin, gentamicin, kantamycin, neomycin, streptomycin. tobramycin	in intravenous form: *Acinetobacter, Enterobacter, Pseudomonas,* and *Mycobacter* infections in topical form: ear drops following myringotomy	hearing loss, balance disturbances some degree of loss is often permanent; risk increases when also taking any other medications with ototoxic effects
aspirin (salicylic acid)	PAIN, INFLAMMATION, mild anticoagulant	tinnitus, hearing loss with high doses, balance disturbances usually temporary, reversible when medication stopped
platinum-derived CHEMOTHERAPY agents: carboplatin, cisplatin	certain cancers (BLADDER, LUNG, ovarian STOMACH, testicular)	moderate to severe hearing loss usually permanent
loop diuretics: bumetanide, ethacrynic acid, furosemide, torsemide	hypertension, congestive heart failure, KIDNEY disease	tinnitus, hearing loss usually temporary, reversible when medication stopped
macrolide antibiotics: azythromycin, clarithromycin, erythromycin	*Helicobacter pylori* infection (PEPTIC ULCER DISEASE), *Legionella* PNEUMONIA (LEGIONNAIRES' DISEASE), alternative when when there are allergies to penicillin and cephalosporin antibiotics	hearing loss, sometimes severe usually temporary, reversible when medication stopped
NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS): over the counter (OTC): ibuprofen, naproxen sodium, ketoprofen prescription: oxaprozin, diclofenic, etodolac, meloxicam, celecoxib,	pain, inflammation, arthritis	tinnitus, mild to moderate hearing loss, balance disturbances usually temporary, reversible when medication stopped
bismuth subsalicylate (for example, Pepto-Bismol)	gastrointestinal upset, DIARRHEA	tinnitus, mild to moderate hearing loss, balance disturbances usually temporary, reversible when medication stopped
quinine, chloroquine, quinidine	MALARIA, arrhythmias, leg cramps	tinnitus, mild to moderate hearing loss, balance disturbances, vertigo usually temporary, reversible when medication stopped

perforation, deformities, movement, and signs of increased pressure in the middle ear such as bulging or fluid that suggests otitis media (middle ear infection). Otoscopy is the primary diagnostic procedure for many conditions affecting the outer ear, and the first step of the diagnostic path for conditions affecting the middle ear. Otoscopy cannot determine hearing ability or HEARING LOSS.

ototoxicity A medication SIDE EFFECT that results in damage to the functions and structures of the EAR and hearing. The damage can be temporary, in which case symptoms recede and hearing returns when the person stops taking the medication, or permanent. Numerous medications can be ototoxic at therapeutic doses, making it prudent to weigh this potential consequence against the anticipated benefits of the medication. Often medication options are available that can achieve the desired therapeutic effect without the risk for ototoxicity.

Symptoms of ototoxicity include

- TINNITUS (sensation of ringing or rushing sound)
- indications of HEARING LOSS, such as difficulty understanding conversation or being unable to hear the telephone ring
- balance disturbances and dizziness
- VERTIGO (sensation of spinning)

Report any of these symptoms to the doctor immediately, though do not stop taking any medications until discussing the circumstances with him or her. Most ototoxic medications appear to act on the delicate HAIR cells in the COCHLEA, stunning or destroying their ability to translate sound waves into NERVE signals. Ototoxicity is most devastating when it affects high-frequency hearing, the range of normal conversation.

Numerous industrial chemicals are also ototoxic. They include butyl nitrite, carbon disulfide, hexane, manganese, lead, mercury, styrene, and toluene. Hearing loss resulting from exposure to these chemicals is often permanent.

P

periodontal disease Inflammatory and sometimes infectious damage to the gums. Periodontal disease causes gum tissue to recede from the TEETH, which allows teeth to loosen. It also exposes the less protected area of the tooth to BACTERIA that cause tooth decay, resulting in DENTAL CARIES (cavities) and potential INFECTION such as ABSCESS of the root canal. Periodontal disease is the leading cause of tooth loss in adults. Dental care providers estimate that up to 60 percent of American adults have some degree of periodontal disease.

Symptoms of periodontal disease include

- painless bleeding, especially when brushing the teeth
- swollen, shiny, or red gums
- gaps between the gums and the teeth
- loose teeth
- HALITOSIS (bad breath) that does not improve with brushing or mouthwash

Dentists provide diagnosis and treatment for periodontal disease. Appropriate ORAL HYGIENE can prevent most periodontal disease; identifying periodontal disease early allows opportunity for therapeutic interventions to thwart permanent damage. Some health experts believe there are connections between the body's inflammatory response, periodontal disease, and other health conditions such as ATHEROSCLEROSIS and CORONARY ARTERY DISEASE (CAD).

See also GINGIVITIS; INFLAMMATION.

peritonsillar abscess A serious and painful INFECTION of the tissues around the tonsils in the back of the THROAT. Unlike TONSILLITIS, which is primarily an infection among children, peritonsillar ABSCESS is most common among adults in early midlife. Doctors are uncertain what causes a peritonsillar abscess to develop, though it will often follow another infection such as tonsillitis, PHARYNGITIS or mononucleosis.

Symptoms emerge suddenly. They include

- severe and usually one-sided PAIN in the throat
- pain in the EAR on the opposite side from the abscess with swallowing
- FEVER
- a whispery, hoarse voice
- neck stiffness and sometimes swelling on the front of the neck
- difficulty swallowing
- inability to fully open the mouth (called trismus)

Symptoms and physical examination typically make the diagnosis, though the doctor may perform a laryngoscopy to more closely examine the throat. After swabbing the peritonsillar area for culture, treatment with intravenous ANTIBIOTIC MEDICATIONS begins. The person remains hospitalized until the swelling goes down and the pain abates, at which point antibiotic therapy shifts to oral doses for the remainder of treatment at home. When the abscess is large or has the potential to interfere with BREATHING, the doctor may choose to surgically open and drain it (under anesthesia). This provides dramatic relief. Most people recover fully and without complications in about two weeks.

pharyngitis INFLAMMATION and irritation of the pharynx (the top part of the THROAT), often due to viral or bacterial INFECTION. Seasonal allergies, environmental irritants such as smoke, and uncontrolled GASTROESOPHAGEAL REFLUX DISORDER (GERD) are also common causes of pharyngitis, often called sore throat.

Pharyngitis that interferes with BREATHING or swallowing requires emergency medical care.

Many pathogens can cause infections. Doctors estimate that viruses cause about 60 percent of pharyngitis and BACTERIA cause about 30 percent. Distinguishing the responsible PATHOGEN guides treatment, as bacterial pharyngitis requires treatment with ANTIBIOTIC MEDICATIONS. It is difficult to determine the cause of pharyngitis on the basis of symptoms. The only conclusive diagnostic measure is a throat culture to identify what pathogens are present.

The primary symptom of pharyngitis is a scratchy or sore throat. Other symptoms may occur, depending on the cause, such as FEVER, HEADACHE, COUGH, and SNEEZE. Most viral pharyngitis runs its course in 7 to 10 days. Bacterial pharyngitis greatly improves within 2 days of initiating antibiotic therapy, though it is essential to take the antibiotic medication until it is gone. Reducing or eliminating exposure to irritants such as cigarette smoke and pollen helps with noninfectious pharyngitis. A doctor should evaluate acute pharyngitis (pharyngitis that comes on suddenly) that continues longer than 10 days, and chronic pharyngitis (ongoing or recurrent) on a regular basis. Chronic pharyngitis can signal other health problems, such as laryngeal CANCER.

See also ALLERGIC RHINITIS; LARYNGITIS; POSTNASAL DRIP; SINUSITIS; SMOKING AND HEALTH; STREP THROAT.

postnasal drip Mucus from the NOSE that flows down the back of the THROAT. Postnasal drip is a common complaint and may accompany various health conditions, including COLDS, ALLERGIC RHINITIS, SINUSITIS, and OTITIS media. Postnasal drip is a common cause of PHARYNGITIS because it irritates the tissues at the back of the throat (pharynx) and can cause COUGH, especially when lying down or asleep. Swallowed postnasal drip often causes NAUSEA.

Mucus production is the body's natural mechanism for removing pathogens and debris from the nasal passages, and it is normal for it to increase as a protective measure when there is irritation to the nasal passages. Treatment focuses on identifying the underlying cause of continued excessive production. ANTIBIOTIC MEDICATIONS are helpful only when the cause is bacterial INFECTION. Medications to reduce INFLAMMATION in the nasal passages, such as oral ANTIHISTAMINE MEDICATIONS or nasal sprays, can help reduce mucus production; however, overuse of nasal sprays results in rebound congestion (increased mucus production when not using the spray). Drinking plenty of fluids helps keep mucus thin, making it easier for the body to expel. Humidified air may reduce irritation to the nasal passages to slow mucus production.

presbycusis The natural diminishment of hearing ability that occurs with aging. HEARING LOSS affects both ears, is sensorineural, and progresses in a predictable pattern, beginning with sounds in the high frequency range (2,000 Hz to 4,000 Hz). Researchers do not know the precise mechanisms through which presbycusis takes place, though most believe it occurs through a cumulative loss of cells from the inner EAR, the NERVE pathways to the BRAIN, and within the brain itself. Many factors influence the rate of progression. One third of adults between age 65 and 74 and half of those beyond age 74 have age-related hearing loss. Health conditions that affect blood circulation and nerve function, such as ATHEROSCLEROSIS and DIABETES, intensify the effects of age-related changes. Noise exposure can exacerbate the rate and nature of hearing loss. Older adults also are more likely to take medications that have ototoxic side effects, such as loop diuretics and certain antihypertensive medications.

Early indications of presbycusis, which may become apparent when a person is in his or her late 50s or early 60s, include difficulty hearing

certain sounds and words, because the frequency range that is lost is that of conversation. Turning up the volume on the television and perceptions that other people are mumbling are also signs of hearing loss. There are no known methods for preventing presbycusis. Hearing aids often improve hearing ability, though the progressive loss of hearing may eventually exceed the capability of the HEARING AID.

R

rhinoplasty Plastic surgery to repair or reconstruct the NOSE. Surgeons perform rhinoplasty operations for cosmetic and for reconstructive reasons. Cosmetic rhinoplasty is the most commonly performed PLASTIC SURGERY procedure in the United States, with more than 350,000 operations each year. Reconstructive rhinoplasty helps restore the function and appearance of the nose when there are structural defects such as SEPTAL DEVIATION or following serious trauma (such as a BROKEN NOSE) and conditions such as SKIN CANCER or other cancers affecting the nose.

Rhinoplasty is nearly always an AMBULATORY SURGERY performed under general or local ANESTHESIA. The surgeon may reshape the CARTILAGE and occasionally the BONE. Swelling and discoloration are common following the OPERATION, gradually diminishing over two to three weeks. Bleeding and INFECTION are among the potential risks of rhinoplasty. Because the nose has an abundant blood supply, surgeons typically insert compression packing into the nose for one to three days after surgery, which applies pressure to minimize bleeding and maintain the integrity of the reshaping. The packing carries a risk of TOXIC SHOCK SYNDROME, a serious systemic bacterial infection. The surgeon should promptly evaluate any FEVER or increase in PAIN.

As with any surgery, the results of rhinoplasty can vary. It is important to understand the limitations and consequences of the operation and to have realistic expectations for cosmetic results. Reconstructive rhinoplasty may require several operations to achieve the desired outcome. Most people can return to their regular activities within two weeks.

See also BLEPHAROPLASTY; OTOPLASTY; RHYTIDOPLASTY; SURGERY BENEFIT AND RISK ASSESSMENT.

rhinorrhea The medical term for runny NOSE. Mucus discharge from the nose is the body's mechanism for removing foreign matter. Numerous factors can cause rhinorrhea. Among the most common are exposure to allergens, such as pollen and dust, and INFECTION, such as COLDS, SINUSITIS, OTITIS, and PHARYNGITIS. In young children, foreign objects in the nose also commonly cause rhinorrhea. Discharge that contains pus or blood suggests infection.

Clear, watery nasal drainage following head trauma requires immediate medical attention as this may indicate that CEREBROSPINAL FLUID is leaking.

Rebound rhinorrhea can develop with excessive use of nasal sprays as well as oral decongestants and ANTIHISTAMINE MEDICATIONS. When the doctor can identify the underlying cause, treatment targets that cause. Otherwise, treatment targets relief of symptoms. Topical decongestants (nasal sprays) are the treatment of first choice, applied for a short and defined period of time. The doctor may also recommend oral decongestants or antihistamines.

See also BLOWING THE NOSE; EPISTAXIS; FOREIGN OBJECTS IN THE EAR OR NOSE; SNEEZE/COUGH ETIQUETTE.

ruptured eardrum A tear in the TYMPANIC MEMBRANE, or eardrum, that results from trauma of some kind. The primary symptoms are

- sudden and sharp PAIN from the EAR
- drainage (when the cause is INFECTION)
- TINNITUS (a ringing or roaring sound)

- HEARING LOSS in the affected ear

A tear in the tympanic membrane causes it to lose tension, which affects hearing as the breach affects the eardrum's ability to vibrate. When infection (OTITIS media) causes the rupture, the pain of the tear is followed by relief of pain because the tear releases the fluid that has accumulated in the middle ear behind the tympanic membrane. Other common causes of ruptured eardrum include

- exposure to a sudden, loud noise
- BAROTRAUMA (damage from rapid and extreme changes in pressure)
- puncture from a foreign object inserted into the ear, such as a cotton swab or hair pin (bobby pin) being used to clean CERUMEN (ear wax) from the auditory canal

The doctor's otoscopic examination of the ear, which allows visualization of the tympanic membrane, confirms the diagnosis. Most ruptured eardrums heal without intervention in about six weeks, with hearing gradually improving as the tympanic membrane regains integrity and tension. For a large tear, the otolaryngologist may put a small paper patch over the opening to help protect the inner ear while the tear heals or may perform an OPERATION (TYMPANOPLASTY) to repair the damaged eardrum. Earplugs are necessary during bathing or showering to keep water from entering the auditory canal during the time the tear is HEALING. Hearing typically returns when the tear heals. A potentially significant consequence of ruptured eardrum is formation of a CHOLESTEATOMA, a cystlike growth in the inner ear that can permanently damage hearing.

S

salivary glands Structures within the MOUTH that produce saliva, a watery fluid that mixes with food during chewing and maintains the mouth as a moist environment. The major salivary glands are primarily along the floor of the mouth (the sublingual and submandibular glands) and at the back of the mouth just below the EAR (parotid glands). These glands produce a steady supply of saliva that trickles into the mouth to moisturize mucous membranes. Stimuli related to eating, such as the smell or appearance of food, activate an increased flow of saliva to meet the needs of mastication (chewing). Enzymes in saliva begin to break down foods to prepare them for digestion.

The facial and glossopharyngeal nerves, the seventh and ninth CRANIAL NERVES respectively, regulate the functions of the salivary glands. The glossopharyngeal NERVE also handles nerve impulses for the sense of taste. Small mineral calculi, or stones, can block the salivary ducts that drain saliva from the salivary glands, causing PAIN and swelling (SIALOLITHIASIS). Excessive saliva (SIALORRHEA), or drooling, can a symptom of various neurologic conditions, including CEREBRAL PALSY and PARKINSON'S DISEASE, and often accompanies SWALLOWING DISORDERS. Saliva production temporarily increases in young children who are teething, likely an attempt by the body to soothe the discomfort of the new TEETH erupting through the surface of the gums. The parotid glands swell with the MUMPS.

For further discussion of the salivary glands within the context of otolaryngologic structure and function please see the overview section "The Ear, Nose, Throat, and Mouth."

See also SIALADENITIS.

septal deviation A shift from midline in the nasal septum (wall of tissue that separates the air pathways of the NOSE). Septal deviation can cause various health conditions such as chronic SINUSITIS (INFECTION), EPISTAXIS (nosebleed), and obstructed BREATHING. It can occur as a natural defect or result from trauma such as a blow to the nose. The treatment of choice is surgical correction (septoplasty) to restore the septum to midline. Septal deviation often accompanies structural anomalies of the nose that cause people to seek RHINOPLASTY (surgical reconstruction of the nose).

See also SEPTAL PERFORATION; SURGERY BENEFIT AND RISK ASSESSMENT.

septal perforation An abnormal opening in the nasal septum (wall of tissue within the NOSE that divides the nostrils), that occurs as the result of chronic irritation, trauma, or cancer. Septal perforation may develop with long-term use of nasal oxygen, long-term use of corticosteroid nasal sprays (such as to treat ALLERGIC RHINITIS), inhalation of illicit drugs such as COCAINE or aerosols and glues, foreign objects in the nose, chronic digital trauma (picking the nose), or long-term exposure to chromates such as chromic acid and chromium (used in electroplating and other industrial applications). Septal perforation sometimes occurs as a consequence of RHINOPLASTY, particularly when there have been several operations.

Symptoms of septal perforation may include a whistling sound when BREATHING, nasal discharge, and bleeding (EPISTAXIS). The preferred treatment for most septal perforations is surgical repair (septoplasty), though it is sometimes necessary to first remedy the underlying cause. The doctor may place a nasal septal prosthesis, commonly called a

nasal button, that fits into the perforation to create a temporary closure. Untreated septal perforation results in frequent infections and continued erosion of the nasal lining as well as CARTILAGE.

sialadenitis INFLAMMATION and swelling of a salivary gland, usually a submandibular or parotid gland. Common causes include

- SIALOLITHIASIS, in which a small "stone" or mineral calculus blocks the flow of saliva and irritates the tissues of the involved salivary gland
- bacterial INFECTION, which can develop when the blockage persists because the MOUTH contains an abundance of BACTERIA
- viral infection with various viruses, including MUMPS, coxsackie, INFLUENZA, herpes, and human immunodeficiency virus (HIV)
- AUTOIMMUNE DISORDERS such as SJÖGREN'S SYNDROME and SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)

Diagnosis arises mostly through physical examination and other clinical indicators, though sometimes the doctor will order X-rays or other imaging procedures to help distinguish the cause or to determine whether an ABSCESS (pocket of infection) is present. Treatment focuses on the underlying cause of the inflammation. Bacterial sialadenitis requires treatment with ANTIBIOTIC MEDICATIONS. Antibiotics are not helpful for viral sialadenitis, which typically improves in 10 to 14 days. Regardless of cause, drinking plenty of fluids, frequently rinsing the mouth with warm saltwater or applying warm compresses (moist heat) to the outside of the face over the affected area, and taking a nonsteroidal anti-inflammatory drug (NSAID) such as ibuprofen can help relieve discomfort.

See also BACTERIA; HIV/AIDS; NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS); VIRUS; X-RAY.

sialolithiasis The formation of a crystallized mineral deposit, called a salivary calculus ("stone"), in a salivary gland. Sialolithiasis most commonly involves the submandibular and parotid SALIVARY GLANDS. Its primary symptoms are PAIN and swelling when it blocks the flow of saliva from the gland. Sometimes the calculus remains symptomless and undetected until it shows up on an X-RAY done for other reasons such as a routine dental exam. Doctors sometimes use COMPUTED TOMOGRAPHY (CT) SCAN, ULTRASOUND, or sialography to confirm the diagnosis. A small calculus may pass from the gland on its own. Because the risk of INFECTION is high, however, doctors prefer to surgically remove salivary calculi. The OPERATION involves making a small incision into the salivary gland and extracting the calculus. Recovery is usually complete, though some people have recurrent episodes or experience narrowing (stricture) of the affected salivary duct. Researchers do not know what causes salivary calculi to develop.

sialorrhea Excessive saliva production that may result in drooling or choking if there are impairments to swallowing. Sialorrhea often accompanies neurologic disorders and BRAIN injuries that affect the parasympathetic NERVOUS SYSTEM, which regulates the functions of most of the body's glands. People who have sialorrhea are at risk for ASPIRATION (inhaling excessive saliva into the airways and LUNGS), choking, INFECTION, and irritation of the SKIN around the face and neck. Sialorrhea also presents significant hygienic concerns and often is embarrassing to the person who has it.

Anticholinergic medications, which "dry out" the body, curtail sialorrhea in many people. These medications also affect neurotransmitters in the brain, however, which can have unintended detrimental effects on motor function. Some people benefit from botulinum toxin A injections (BOTULINUM THERAPY) into the tissues surrounding the salivary glands, which temporarily paralyzes the muscles that release saliva. Other treatment approaches include surgery to remove or obstruct portions of the submandibular salivary glands, which produce about 80 percent of the saliva, and therapy to improve muscle control and swallowing ability. Treatment success depends on the underlying causes.

sign language A nonverbal language that serves as a system of communication for people who are hearing impaired. Sign language uses hand signals to represent letters of the alphabet and gestures to represent words, phrases, and concepts. As in spoken languages, sign languages incorporate an extensive vocabulary with rules that govern its presentation (grammar and syntax). The sign languages most used in the United States are

- American Sign Language (ASL) derives its structure from French Sign Language, which was the first formal sign language, and is a unique language separate from spoken English. ASL is the third most common language in the United States.
- Signing Exact English (SEE) evolved in the early 1970s as a method to manually code spoken English for children learning to read and for people without hearing impairment who communicate with those who have hearing impairment.
- Pidgin Signed English (PSE) blends aspects of ASL and SEE for colloquial or casual communication.

Though sign languages may carry a culture's name, such as American Sign Language or Japanese Sign Language, there is no correlation between the sign language and the culture's spoken language. Nor are sign languages necessarily similar to each other.

The BRAIN processes sign languages differently from spoken languages. Because spoken languages form the basis for reading and writing, prelingual children who have profound HEARING LOSS may easily learn a sign language and yet have difficulty learning to read and write.

sinuses Cavities within the facial bones around the NOSE, also called the paranasal sinuses, that warm and moisten inhaled air. Mucous membrane lines the sinuses, providing a continuous supply of moisture. Mucus production increases in response to irritation, for example, from environmental particles (pollen, smoke), viruses, and BACTERIA. The maxillary sinuses, on the face along the ridge of BONE commonly called the cheek bone, and the frontal sinuses, above the inside corners of the eyes near the bridge of the nose, are the sinuses that most commonly become congested as a result of COLDS, allergies, and infections. The sinuses also function as sound chambers that give the voice resonance and amplification. Sinus congestion limits this function, resulting in a characteristic "nasal" voice.

For further discussion of the sinuses within the context of otolaryngologic structure and function please see the overview section "The Ear, Nose, Mouth, and Throat."

See also ALLERGIC RHINITIS; NASAL POLYP; SINUSITIS.

sinusitis INFLAMMATION of the SINUSES. The most common causes of sinusitis are INFECTION and environmental irritation such as seasonal allergies (ALLERGIC RHINITIS). Sinusitis affects an estimated 37 million Americans each year. It can be acute (lasts a few weeks), chronic (lasts months to years), or recurrent (occurs in repeated acute episodes). Doctors further define chronic sinusitis by the extent of permanent damage to the mucous lining of the nasal passages. Long-term chronic sinusitis causes narrowing of the openings through which mucus drains out of the sinuses.

Symptoms and Diagnostic Path

The symptoms of sinusitis include

- PAIN across the cheek bones or between the eyes
- pain in the upper jaw and TEETH
- persistent HEADACHE that is worst on awakening in the morning and improves through the day though does not entirely go away
- nasal congestion
- frequent sneezing
- thick, colored discharge from the nostrils
- POSTNASAL DRIP

Some people with sinusitis also have FEVER, COUGH, and PHARYNGITIS (from the postnasal drip). The diagnostic path includes careful examination of the inside of the NOSE. For acute sinusitis the doctor may make the diagnosis on the basis of what he or she observes. Doctors seldom order

regular X-rays, once the standard of diagnosis, because the results are not reliable. For chronic sinusitis the otolaryngologist conducts an extensive examination that includes a COMPUTED TOMOGRAPHY (CT) SCAN and ENDOSCOPY to directly evaluate the condition of the sinuses. The doctor may also culture a sample of the nasal discharge to identify the BACTERIA that are present.

Treatment Options and Outlook

Acute bacterial sinusitis requires to treatment with an ANTIBIOTIC MEDICATIONS. Decongestant medications help relieve stuffiness and congestion by constricting the blood vessels that supply the mucous tissue within the nose. ANTIHISTAMINE MEDICATIONS mitigate the body's immune response to allergens such as dust and pollen that cause local irritation of the nasal tissues.

Chronic bacterial sinusitis often requires irrigation of the sinuses with a solution of antibiotic and decongestant, which the otolaryngologist does as an office procedure. Home treatment may include an oral antibiotic, humidifier to add moisture to the air, and saline nose drops to keep the nasal passages moist. Moisture helps reduce irritation and swelling. Surgery may be necessary to correct any problems such as septal defect, SEPTAL PERFORATION, and NASAL POLYP, or to widen the nasal ostia (openings in the sinuses).

Risk Factors and Preventive Measures

Sinusitis is more common in people who have seasonal rhinitis (allergies). The presence of allergens causes the nasal passages to swell, establishing ideal conditions for bacteria to grow. Keeping seasonal rhinitis symptoms under control helps reduce congestion. Sinusitis is also more common in people with structural anomalies of the nose such as SEPTAL DEVIATION. Untreated, chronic, or recurrent OTITIS media (ear infection) can funnel bacteria to the base of the nose via the EUSTACHIAN TUBE. Prompt, appropriate treatment for acute sinusitis helps limit recurrent and chronic infections.

smell and taste disturbances Dysfunctions of smell and taste result in the inability to perceive odors and tastes or the BRAIN interpreting smell and taste messages incorrectly. Dysfunctions that affect the perceptions of smell and taste are common side effects of medications, consequences of health conditions such as STROKE, and dimensions of aging. Disturbances of smell and taste affect one's ability to enjoy daily pleasures such as the fragrances of flowers and the flavors of foods. But smell and taste are not only matters of QUALITY OF LIFE. These chemosenses, as researchers refer to them, also provide early warning of potentially hazardous circumstances. Many spoiled foods, for example, smell and taste rancid. In the United States, natural gas distributors add the chemical mercaptan, which smells strongly like rotten eggs, to pipelines and storage tanks to warn of gas leaks.

Because the functions and disturbances of smell and taste are nearly inseparable, disturbances of one affect the other. Most commonly, diminished smell reduces the ability to perceive flavors. Though the taste cells within the taste buds may remain fully functional, the brain requires the detailed NERVE signals the olfactory bulb gathers and sends to interpret flavors. The brain perceives primarily bitterness when taste is the only sense sending messages about chocolate, for example, because cocoa, chocolate's key ingredient, is a bitter substance. The brain interprets the distinctive sweetness and flavor of chocolate only when the olfactory sensors detect and report the hundreds of odor molecules that chewing releases from the chocolate, which then swarm into the NOSE from the back of the THROAT. As much as 80 percent of the perception of flavor derives from smell.

Symptoms and Diagnostic Path

Though about 200,000 Americans seek medical care for disturbances of taste and smell, health experts believe millions live with diminished or altered chemosenses without realizing it. People are most likely to notice disturbances that come on suddenly or involve distinctive changes. Most people report problems with taste, though typically the culprit is more often related to smell. Symptoms can range from isolated to total loss of smell, taste, or both. People may notice they no longer taste the seasonings in foods or smell the flowers in a garden. With some health conditions such as PARKINSON'S DISEASE, perceptions of flavor change. People who have DIABETES or HYPERTENSION

often experience general reductions in chemosensory perceptions.

Physical obstructions The most common cause of taste and smell disturbances is congestion, which blocks contact between odor molecules and odor sensors in the nose. Congestion results from a wide range of circumstances, most of which are temporary or transient (come and go). These include COLDS, ALLERGIC RHINITIS (seasonal allergies), and SINUSITIS. Mechanical obstructions such as nasal polyps or SEPTAL DEVIATION alter the flow of air through the nose so that odor molecules pass by only a small section of the olfactory epithelium, the patch of nerve endings extending from the olfactory bulb. Dental problems that cause irritation in the MOUTH, especially of the tongue, can disrupt the functions of taste cells.

Aging The aging process is the second-leading cause of diminished taste and smell. Researchers estimate that diminished chemosensory perception affects more than half of people over age 65; by age 80 the loss is significant enough to interfere with the desire to eat. The olfactory epithelium in the nose loses about 1 percent of its nerve cells each year. Though the tongue renews taste buds every few weeks throughout most of life, the rate of replacement slows in the later decades. By age 80, the number of taste cells in the mouth has diminished by as much as 40 percent. In combination with the loss of olfactory nerve endings, there often is the perception of complete inability to perceive flavors.

Health conditions and medication side effects

Many health conditions can cause disturbances of smell and taste. Among those most frequently implicated are diabetes, hypertension, SARCOIDOSIS, BELL'S PALSY, Parkinson's disease, ALZHEIMER'S DISEASE, and MULTIPLE SCLEROSIS. Olfactory auras (perceptions of smells) often precede migraine headaches and epileptic seizures. Numerous medications affect taste and smell, notably ANTIBIOTIC MEDICATIONS, levodopa (to treat Parkinson's disease), angiotensin-converting enzyme (ACE) inhibitors (antihypertensive medications), "statin" lipid-lowering medications, and CHEMOTHERAPY agents such as cisplatin and methotrexate. Taste and smell usually return to normal after stopping the medication, though chemotherapy-related changes may persist or become permanent. RADIATION THERAPY to the head or neck also alters chemosensory perception, often permanently.

Nerve damage Smell and taste disturbances can result from damage to the nerves that carry chemosensory messages to the brain, such as might occur with injury or neurologic diseases. The first cranial nerve (olfactory nerve) carries most odor messages to the brain, with the fifth cranial nerve (trigeminal nerve) conveying limited signals. Three CRANIAL NERVES—the seventh (facial nerve), ninth (glossopharyngeal nerve), and tenth (vagus nerve)—convey taste messages to the brain. Trauma such as from a BROKEN NOSE can damage the olfactory nerve endings in the roof of the nose. Chronic exposure to cigarette smoke or inhaled drugs (notably cocaine as well as corticosteroid nasal sprays used to treat ASTHMA and allergic rhinitis) also damages these hairlike structures.

Treatment Options and Outlook

Treatment for smell and taste disorders targets the underlying causes of the disturbances to the extent doctors can identify them. Approaches include

- reducing exposure to environmental irritants such as cigarette smoke and allergens
- treating chronic sinusitis, dental disease, and allergic rhinitis
- removing nasal polyps and correcting septal defects in the nose
- evaluating regular medications being taken to identify any that can interfere with smell and taste
- looking for patterns of chemosensory disturbance

Often, idiopathic taste and smell disturbances (those of undetermined cause) improve on their own over time. Changes due to diseases tend to follow the course of the underlying condition, progressively worsening along with the principal condition, as in Parkinson's disease or multiple sclerosis.

Risk Factors and Preventive Measures

Treating infections promptly and avoiding irritants that interfere with olfactory and gustatory func-

tions are the most effective measures for protecting the chemosenses. Subclinical sinusitis (ongoing sinus infection that does not have symptoms), structural defects of the nose (such as nasal polyps and septal deviation), and allergic rhinitis are the most common causes of disturbances involving these senses. Most are correctable, which nearly always restores smell and taste. Other efforts include reducing exposure to cigarette smoke, industrial pollutants, and inhaled drugs such as cocaine. Unfortunately age-related diminishment is permanent. Most people with smell and taste disturbances can learn methods to accommodate the diminished perception of flavor with seasonings (other than salt and sugar) to enhance foods and beverages.

sneeze A REFLEX that forcefully expels air through the NOSE. A sneeze originates with an irritation to the mucous membranes in the nose, sometimes perceptible as a tickling sensation and other times not noticeable, that activates NERVE impulses. The fifth cranial nerve (trigeminal nerve) carries the impulse to a cluster of specialized neurons (nerve cells) in the brainstem (the part of the BRAIN that regulates the body's basic vital functions including reflexes). Scientists call this area the sneeze center, though they do not know its precise location because it is not physically distinct from other portions of the brainstem. The sneeze center sends nerve signals back to the body through numerous nerve pathways that activate a coordinated response.

A sneeze results when the brainstem signals the VOCAL CORDS to close, allowing air pressure to build in the airway, then signals the DIAPHRAGM and various muscles in the chest, THROAT, and face to contract and the vocal cords to open. This sequence of events expels air through the nose with great force; researchers have measured sneezes leaving the nose at the equivalent of 100 miles per hour. The pressure blows mucus and irritants from the nose.

When the irritation stops, the cycle of the sneeze reflex ends. People who have a health condition such as SINUSITIS or ALLERGIC RHINITIS may sneeze so often that their noses become raw and irritated. Nasal sprays containing decongestants help reduce swelling of the nasal passages; those containing antihistamines help subdue the nose's local reaction to allergens. These approaches are often effective in reducing sneezing episodes. Increasing the moisture content of the nasal mucosa, such as by BREATHING humidified air and drinking plenty of fluids, helps relieve irritation.

Many viruses, such as those that cause COLDS and INFLUENZA, have adapted their structures to take advantage of the sneeze mechanism, using it to disperse themselves to new hosts. To reduce the spread of these infections, health experts recommend sneezing into disposable tissues and discarding them, then washing the hands thoroughly with soap and water.

Some people sneeze when they step into sunlight or look up at a sunlit sky, called photic sneezing. Doctors do not know why photic sneezing occurs, though it is an inherited trait. Some researchers speculate that sunlight (or any very bright light) stimulates brain activity near the brain's sneeze center, which sends the message to the body to sneeze. About one in four people experiences photic sneezing.

speech disorders Conditions that affect the ability of structures of the MOUTH and THROAT to form the sounds necessary for speech. Health-care providers often refer to these conditions as disorders of articulation to distinguish them from LEARNING DISORDERS that may affect speech. Learning disabilities typically involve BRAIN function, whereas speech or articulation disorders involve the mechanics of speech.

Many speech disorders arise from structural anomalies that become apparent during early childhood, such as CLEFT PALATE/CLEFT PALATE AND LIP, incorrect placement of the TEETH as they erupt, or deviations in the size and shape of the oral cavity. Functional difficulties, such as tongue control and lip placement during articulation, may also cause or contribute to speech disorders. HEARING

LOSS, neurologic conditions that affect control of the muscles of the face and throat, and brain injury are additional factors that influence the ability to speak, particularly in adults. STROKE is a leading cause of speech disability in adults.

Symptoms of speech disorders range from the obvious to the subtle and may include

- omitted sounds, in which certain consistent sounds do not appear in speech, for example, leaving the starting or ending consonants off words
- substituted sounds, in which one sound substitutes for another, such as *w* for *r* (*wabbit*)
- distorted sounds, in which extra noises such as whistling or whooshing accompany certain words or letters
- slurred, slow sounds, called dysarthria, which represent an inability to coordinate the neurologic and muscular functions necessary for speech

Speech disorders may indicate disorders of brain function; a comprehensive NEUROLOGIC EXAMINATION helps make this determination. Speech difficulties that suddenly arise suggest a physical basis, such as injury to the brain (stroke) or damage to the NERVE pathways between the brain and the face. Speech disorders may also appear as a component of learning disabilities and other developmental factors. In children, the reasons for speech disorders sometimes remain unclear, though speech therapy often can eliminate the symptoms.

The first goal of treatment is to remedy any apparent physical causes such as cleft palate or misaligned teeth. Other treatment targets strengthening the muscles of the tongue and face in conjunction with learning proper placement of the tongue and lips during speech. This is the venue of speech therapy, which provides instruction to help with forming the mouth positions and movements necessary for articulation. The speech therapist, also called speech-language pathologist, may use video and audio recordings in combination with physical findings to assess the extent and possible causes of speech disorders and to develop methods to overcome the difficulties. With appropriate treatment, most people experience improvement, and many people experience complete restoration, of speech. Children may need ongoing speech therapy as their facial features continue to grow and change.

swallowing disorders Conditions that impair the functions of the muscles and nerves of the THROAT, interfering with the ability to swallow. The clinical term for this impairment is dysphagia. Swallowing disorders often exist with neuromuscular disorders such as AMYOTROPHIC LATERAL SCLEROSIS (ALS) and MUSCULAR DYSTROPHY, and as a consequence of damage to portions of the BRAIN resulting from STROKE or TRAUMATIC BRAIN INJURY (TBI). Dysphagia can affect any aspect of the swallowing process, from chewing to entry of the swallowed material into the STOMACH. Swallowing problems in young infants may indicate structural anomalies. Swallowing disorders are common among the elderly and in people of any age who have significant physical debility.

The symptoms of swallowing disorders may vary in severity and sometimes with circumstances. For example, dysphagia may manifest when the person is very tired or eats certain foods though not be apparent at other times. Symptoms may include

- SIALORRHEA (drooling)
- extended chewing because the food will not move to the back of the throat for swallowing
- difficulty initiating swallowing
- inability to swallow certain kinds of substances such as liquids
- frequent choking
- weight loss (secondary to inability to consume adequate calories)

The diagnostic path includes a careful health history and complete physical examination. Swallowing studies evaluate the coordination and control of muscles involved in moving food from the MOUTH to the stomach. A BARIUM SWALLOW X-ray, in which the person swallows a solution containing barium that coats the ESOPHAGUS, or videofluoroscopy can show irregularities in the passageway to the stomach. COMPUTED TOMOGRAPHY (CT) SCAN or

MAGNETIC RESONANCE IMAGING (MRI) can provide added visualization of the throat and upper gastrointestinal tract. Laryngoscopy allows the doctor to examine the structures of the inside of the throat. The diagnostic path may also include a NEUROLOGIC EXAMINATION to determine the presence of conditions such as PARKINSON'S DISEASE that can affect the ability to swallow.

Treatment depends on the underlying cause. Sometimes medications to relax certain muscles or reduce the flow of saliva improve the functions of chewing and swallowing. Swallowing therapy (provided by a speech-language pathologist) can teach methods to strengthen muscles and improve coordination of the steps of swallowing as well as ways to prepare food and position it in the mouth for most effective swallowing. BIOFEEDBACK is helpful for some people. Surgery may be necessary to correct esophageal strictures that narrow the passageway for food.

Most people experience improvement with treatment, though swallowing disorders resulting from degenerative conditions such as Parkinson's disease are likely to worsen as the disease progresses. In such situations, alternatives such as ENTERAL NUTRITION or PARENTERAL NUTRITION (supplemental or replacement feedings) may become necessary. Family members of those who have swallowing disorders should know how to perform the HEIMLICH MANEUVER to dislodge food that becomes aspirated into the TRACHEA.

T

toothache PAIN in a tooth or in the jaw. Toothache typically suggests DENTAL CARIES (cavities) or other dental problems. Dentists provide care when this is the case. Early intervention minimizes tooth loss, the extent of other damage such as to the gums and jaw, and the extent of treatment.

Persistent jaw pain, particularly when it extends from the shoulder into the neck and jaw, can be an early warning sign of HEART ATTACK. A physician should evaluate such pain without delay.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) such as ibuprofen and naproxen effectively relieve most tooth pain in the short term. Topical anesthetics or products containing clove oil, designated for oral use (use in the mouth), temporarily relieve pain when applied to the tooth surface or surrounding gum tissue. Good ORAL HYGIENE and adequate dietary calcium and vitamin D help maintain tooth health.

A toothache sometimes indicates health conditions such as SINUSITIS (sinus infection), OTITIS (ear infection), migraine HEADACHE, TEMPOROMANDIBULAR DISORDERS, and NEURALGIA (INFLAMMATION and irritation) affecting the nerves that supply the face. Physicians provide care for these conditions.

throat The collective term for the structures at the back of the MOUTH that provide passage to the structures and organs of the trunk. The throat includes the pharynx, which carries food to the ESOPHAGUS and air to the TRACHEA, and the larynx, or voice box, which contains the VOCAL CORDS. The tonsils are at the back and top of the throat; the tongue extends to the front and top of the throat. A "sore throat" typically refers to discomfort involving any of these structures. The muscles of the throat participate in swallowing, BREATHING, and speech. The Adam's apple, a bulge in the CARTILAGE visible on the front of the throat (more visible in men than women though present in both) marks the position of the THYROID GLAND and PARATHYROID GLANDS.

thrush A yeast (FUNGUS) INFECTION of the inner MOUTH. The fungus *Candida albicans* causes thrush, which appears in the mouth as reddened patches with a white discharge. Doctors may use the broader terms CANDIDIASIS or moniliasis. *C. albicans* is a common fungus present in the healthy body, kept in check by the BACTERIA that are also present. It becomes pathogenic (disease causing) only when there are disturbances to the body's natural balance that allows it to flourish.

Thrush is most common in infants between the ages of 1 month and 10 months, though it can

occur at any age. Often, and especially in infants, doctors do not know what disturbs the balance to allow thrush to develop. Known causes include treatment with ANTIBIOTIC MEDICATIONS, as antibiotics reduce the overall level of bacteria in the body. IMMUNE DISORDERS such as HIV/AIDS often prevent the body from adequately controlling its bacterial balance.

Doctors generally diagnose thrush based on appearance of the characteristic lesions (patches) in the mouth. Sometimes the doctor will gently scrape away the white surface of a LESION, which reveals the underlying reddened sore and confirms the diagnosis. Treatment is rinsing the mouth with an antifungal solution such as nystatin oral suspension. For young infants, dabbing the solution onto the lesions is sometimes more effective. Treatment continues for 48 hours after the last lesion disappears. *C. albicans* also can erupt as DIAPER RASH and vaginal infection.

tinnitus The perception of a ringing, humming, roaring, or rushing sound in the EAR when there is no external auditory stimulation. Tinnitus may affect one ear or both ears. There is a growing view among otolaryngologists that tinnitus is an early indication of sensorineural HEARING LOSS, heralding damage (temporary or permanent) to the HAIR cells within the COCHLEA that translate sound waves into NERVE messages. Tinnitus is a common symptom of various vestibular disorders such as ACOUSTIC NEUROMA and MÉNIÈRE'S DISEASE. Numerous medications also can cause tinnitus, notably ANTIBIOTIC MEDICATIONS known as aminoglycosides (such as gentamicin and streptomycin) and loop diuretics (such as furosemide).

Occasionally tinnitus results from health conditions that affect the flow of BLOOD in the head, such as HYPERTENSION (high BLOOD PRESSURE) and ATHEROSCLEROSIS. These conditions may increase the turbulence of the blood, making it possible to hear the blood as it flows through the arteries. When these conditions are severe enough, the doctor can also hear the sounds by listening through a stethoscope placed at various locations on the head.

Tinnitus is common, with some experts asserting that nearly every adult will experience the symptom at some time in his or her life. Many people live with low-grade tinnitus that, though annoying when noticed, generally does not affect daily living. For some people, however, tinnitus is severe enough to interfere with concentration and even hearing to the extent of causing disability. Any health conditions that diminish the movement of sound into the ear from the external environment, such as accumulated CERUMEN or an ear INFECTION (OTITIS media or otitis externa) can intensify the tinnitus.

The diagnostic path begins with an otoscopic examination to look for obvious blockages or other physical causes. The doctor will also request a comprehensive AUDIOLOGIC ASSESSMENT to determine whether any hearing loss exists; this helps narrow the potential reasons for the tinnitus. Treatment targets the underlying cause. There are few effective treatments for idiopathic tinnitus (tinnitus that is present without an apparent cause) or for tinnitus that accompanies PRESBYCUSIS (age-related hearing loss). Many people benefit from using intentional background noise (sound masking) to mitigate the tinnitus and from learning conscious refocusing methods.

tonsillitis An INFECTION of the tonsils (lymph structures at the back of the THROAT). Tonsillitis is common and often recurrent in children. Conventional wisdom holds that the tonsils (and the nearby ADENOIDS) serve to produce antibodies to help the body protect itself against invading pathogens (disease-causing agents such as viruses and BACTERIA). However, in the modern environment there is an overwhelming abundance of pathogenic agents, which many health experts believe accounts for the prevalence of tonsillitis. Some researchers believe that the tonsils are becoming, or have become, vestigial structures akin to the appendix.

The characteristic symptoms of tonsillitis are

- PAIN and swelling at the back of the throat
- difficulty swallowing
- FEVER
- HEADACHE

The tonsils may appear enlarged and reddened, and may ooze pus or be covered in small white

dots. The infectious agent may be viral or bacterial; the doctor is likely to swab the throat to perform a rapid strep test to check for streptococci bacteria. Streptococci tend to migrate to other parts of the body such as the HEART valves, making any strep infection potentially dangerous. A throat culture can determine the presence of other pathogenic bacteria. Bacterial tonsillitis, including STREP THROAT requires treatment with ANTIBIOTIC MEDICATIONS. Viral tonsillitis generally runs its course within two weeks. In either case, ANALGESIC MEDICATIONS such as acetaminophen or ibuprofen can provide pain and fever relief.

Children should not receive aspirin for pain or FEVER because of the potential for REYE'S SYNDROME, a rare but serious complication.

The otolaryngologist may recommend tonsillectomy (an OPERATION to remove the tonsils) when recurrent tonsillitis causes the tonsils to remain enlarged to the extent that they interfere with BREATHING. Indications of this include loud snoring when sleeping and mouth breathing when awake, particularly in children. Enlarged tonsils can cause OBSTRUCTIVE SLEEP APNEA, in which there are episodes during sleep when the person does not breathe. In the normal course of development, the tonsils atrophy (shrink) as ADOLESCENCE approaches, and by early adulthood tonsillitis is uncommon. For this reason many doctors prefer to manage tonsillitis medically rather than surgically unless ANTIBIOTIC RESISTANCE develops.

tympanic membrane A thin piece of tissue that stretches across the base of the auditory canal (EAR canal). The tympanic membrane, commonly called the eardrum, vibrates in response to sound waves that reach it by traveling from the outer ear through the auditory canal. The vibrations amplify the sound waves, which activate the auditory ossicles, tiny bones in the middle ear, to set in motion the cascade of events that results in NERVE signals traveling to the BRAIN.

The tympanic membrane is vulnerable to perforation, commonly called RUPTURED EARDRUM. Perforation may occur as a result of injury, such as penetration of an object or from a sharp blow to the outer ear, or spontaneously. Fluid accumulation in the middle ear behind the tympanic membrane, usually the consequence of INFECTION, is the most common cause of spontaneous perforation. Spontaneous perforation generally heals without intervention. Traumatic perforation may require surgical repair (TYMPANOPLASTY).

In addition to amplifying and transferring sound waves, the tympanic membrane protects the middle and inner ear from bacteria and debris. A perforated eardrum exposes the delicate structures behind it to possible infection and other damage. Repeated spontaneous perforation due to chronic OTITIS media (middle ear infection) can permanently scar the tympanic membrane, restricting its ability to vibrate. The otolaryngologist may insert a small tube through the tympanic membrane to allow collected fluid to drain (MYRINGOTOMY) as a preventive measure in children who have chronic ear infections.

See also CLEANING THE EAR; FOREIGN OBJECTS IN THE EAR OR NOSE; HEARING LOSS; MYRINGITIS.

tympanoplasty Surgical reconstruction of the TYMPANIC MEMBRANE (eardrum). Damage to the tympanic membrane can occur as a result of scarring due to repeated OTITIS media (middle EAR INFECTION), traumatic injury, and acquired defects such as might remain following removal of a CHOLESTEATOMA (pocketlike growth). The otolaryngologist cuts out a small piece of FASCIA (thin connective tissue that covers muscle) from the temporal MUSCLE at the point of incision behind the ear when the OPERATION begins; this becomes the new tympanic membrane. Restoration of hearing varies and may depend on factors not related to the tympanoplasty. Infection, which may be present in the middle ear at the time of the surgery, can cause the new tympanic membrane to fail. About 80 percent of adults who undergo tympanoplasty experience improvement in hearing and reduced otitis.

V

velopharyngeal insufficiency Inadequate closure the velopharyngeal sphincter, a MUSCLE at the back of the soft palate, that directs air flow to the NOSE or to the MOUTH. Velopharyngeal insufficiency often accompanies CLEFT PALATE/CLEFT PALATE AND LIP anomalies and interferes with both speech and swallowing. It also can occur as a complication of tonsillectomy and adenoidectomy, operations to remove the tonsils and ADENOIDS, respectively, and of neurologic damage, such as from STROKE, that restricts neuromuscular function of the pharynx. The hallmark symptoms of velopharyngeal insufficiency are nasal speech and regurgitation food into the back of the nose with swallowing. Sometimes the person has chronic or recurrent SINUSITIS resulting from food particles becoming trapped in the sinuses. The doctor may be able to feel a previously undiagnosed cleft in the hard palate beneath an intact soft palate. ULTRASOUND or COMPUTED TOMOGRAPHY (CT) SCAN can confirm the diagnosis.

Treatment for velopharyngeal insufficiency when the cause is a structural anomaly begins with surgery to restore sphincter function to the extent possible. Operations may include repair of a cleft palate or reconstructive surgery to extend the soft palate (pharyngoplasty) to make the velopharyngeal opening smaller. Most people subsequently need speech therapy to retrain oral-facial structures to form the sounds the velopharyngeal insufficiency kept them from properly making. These therapeutic interventions typically restore complete function, though may not be appropriate or successful when the cause of the velopharyngeal insufficiency is neurologic damage or a neuromuscular disorder.

vertigo The perception of movement, usually spinning, when none is taking place. Vertigo represents the body's inability to accurately interpret its position and movement within its environment. People with vertigo feel either that they are moving or the setting around them is moving. Vertigo occurs when the balance mechanisms of the vestibular system, including the NERVE pathways to the BRAIN, malfunction. The disturbance can range from mild and brief to extended and debilitating. Vertigo is a symptom of numerous health conditions that can be vestibular (affecting the structures of the inner EAR) or neurologic (affecting the brain or nerves). Situations that overstimulate the vestibular system, such as spinning rapidly in circles (as in carnival rides) or experiencing gravitational force (as in taking off in a jet or a space shuttle), also often generate temporary vertigo.

Causes of Vertigo

Vertigo develops when the brain receives conflicting or incomplete information from the vestibular system about the body's orientation in its environment. This can occur because injury or disease damages the structures of the vestibular system or the parts of the NERVOUS SYSTEM that convey balance and movement information to the brain. Brain injury, such as from trauma or STROKE, that affects parts of the brainstem involved in movement also can result in vertigo.

Most commonly vertigo reflects dysfunction of the vestibular system and the structures of the inner ear. The semicircular canals, three fluid-filled loops, detect rotational movements. The saccule and the utricle, also fluid-filled chambers, detect linear (horizontal and vertical) movements.

The nerve cells in these structures send a continuous stream of signals to the movement centers of the brain, which in turn direct the muscles to respond in ways that keep the body upright and stable. This flow of communication takes place immeasurably fast and without conscious awareness, as long as all components of the system are functioning properly.

Situational disruptions of vestibular functions (such as a carnival ride creates) resolve spontaneously when the stimulatory overload stops and the body returns to normal functions, though residual sensations of NAUSEA or queasiness may remain. Pathologic disruptions—changes brought about by damage or disease—often result in persistent balance disturbances, the key symptom of which is vertigo.

Relieving Vertigo

Situational vertigo, such as from spinning in circles, resolves itself when the environmental stimulation stops. When vertigo is pathologic, certain ANTIHISTAMINE MEDICATIONS, commonly marketed for relief of motion sickness, often provide relief. Researchers do not know the mechanisms through which antihistamines intercede with vestibular functions. Most antihistamines that can relieve vertigo also cause substantial drowsiness, making them unsuitable in situations that require alertness and concentration.

Maintaining the focus of the eyes on the direction of movement can help stabilize the vestibular system. This method provides additional information to the brain via sight about the body's position and movement. It also is a diagnostic device in helping distinguish the nature of the dysfunction: vestibular or neurologic. Many people obtain relief from ACUPUNCTURE and acupressure. Pressure bands are available that activate the acupuncture points on the inner wrists; rubbing the earlobes activates the acupuncture points there.

Surgical interventions may become necessary to treat severe, unremitting vertigo that becomes disabling. These are procedures of final resort, as they create permanent disruptions in the vestibular system such as severing the vestibular nerve or removing the labyrinthine structures of the inner ear. Because the function of hearing also uses these structures, surgical interventions are typically viable options only when there is also profound and irreversible HEARING LOSS.

Preventing Vertigo

Situational vertigo is preventable by avoiding the circumstances that cause it. Pathologic vertigo results from underlying disease processes that often are not possible to mitigate. Methods such as focusing the eyes in the direction of movement can sometimes minimize a vertigo episode. Some vertigo is positional, so avoiding the positions prevents the vertigo. Quick movements of the head, particularly upward, are known to bring on vertigo in many conditions in which vertigo occurs (such as Ménière's disease).

Space flight is providing an ideal opportunity for researchers to study the mechanisms of balance and vertigo, as nearly all astronauts experience vertigo under the extreme gravitational and centrifugal forces to which leaving and reentering the earth's gravitational field subjects them as well as the absence of gravity during space flight. The normally functioning vestibular system uses gravity as its point of reference for determining the body's position and movement. Researchers hope that gaining understanding of how the body adapts to the absence of gravity will shed light on how the vestibular system functions as well as dysfunctions, leading to new preventions and treatments for vertigo and the conditions for which it is a symptom.

vestibular neuronitis A dysfunction of the vestibular system that causes sudden and severe VERTIGO (sensation of spinning) with accompanying NAUSEA, VOMITING, and balance disturbances. The prevailing view is that viral infections cause vestibular neuronitis. Because hearing remains unaffected, doctors believe the INFECTION inflames the vestibular NERVE, the branch of the eighth cranial nerve (vestibulocochlear nerve) leading from the vestibular structures to the BRAIN. INFLAMMATION causes the vestibular nerve to transmit confused and erroneous signals to the brain. The brain responds to the incoming signals as though

they were legitimate, instructing the body to react to movement that is not occurring or failing to direct reaction when there is movement. This confusion results in vertigo and a sense of spatial disorientation. Vestibular neuronitis most commonly occurs in adults between the ages of 40 and 60.

Symptoms and Diagnostic Path

The distinguishing symptoms of vestibular neuronitis are severe vertigo and one-sided balance disturbances without TINNITUS or HEARING LOSS. Any hearing-related symptoms suggest a different diagnosis. The vertigo causes nausea and often vomiting. Attempts to move, or to move the head, result in repeated vertigo. The symptoms often are debilitating, with the person falling toward the affected side when attempting to walk and sometimes when attempting to sit upright. Symptoms appear abruptly though often follow a cold or occur among groups of people who are in close contact. An initial episode of symptoms can last 7 to 10 days.

The diagnostic path is fairly straightforward; any pattern of vestibular disturbance that includes additional symptoms is likely to have a different cause. Confirming diagnostic signs the doctor looks for include

- horizontal NYSTAGMUS (rapid movements of the EYE with certain positions or movements)
- diminished or absent response to caloric testing (alternating warm and cool water infused into the auditory canal)

Imaging procedures are not likely to offer diagnostic information unless the doctor is uncertain of the diagnosis, in which case MAGNETIC RESONANCE IMAGING (MRI) or COMPUTED TOMOGRAPHY (CT) SCAN can rule out other conditions such as ACOUSTIC NEUROMA.

Treatment Options and Outlook

The VIRUS causing the vestibular neuronitis must run its course, which typically takes 10 to 14 days. During this time, certain ANTIHISTAMINE MEDICATIONS used to treat motion sickness can provide relief from the vertigo and associated nausea. These antihistamines include the prescription medications hydroxyzine (Atarax, Vistaril) and promethazine (Phenergan) and the over-the-counter products dimenhydrinate (Dramamine), meclizine (Antivert, Bonine) and diphenhydramine (Benadryl). The two prescription medications diazepam (Valium) and clonazepam (Klonopin) appear to act on the vestibular system directly to subdue the vertigo, though cause more sedation than antihistamines and can be addictive when used for an extended period of time. ACUPUNCTURE gives some people relief. Most people recover completely and are free from residual consequences in three to four weeks. A small percentage experiences recurrent episodes over the following months to years, though the severity of symptoms diminishes with each episode.

Risk Factors and Preventive Measures

Because doctors do not know for certain what causes vestibular neuronitis, they cannot identify risk factors or preventive measures. Prompt diagnosis and treatment help relieve symptoms more quickly but do not appear to alter the course of the inflammation or affect the likelihood of RECURRENCE.

vocal cord cyst A saclike growth on the vocal cord that usually develops as a result of persistent irritation such as from smoking or GASTROESOPHAGEAL REFLUX DISORDER (GERD), which may flush the VOCAL CORDS with gastric juices when an individual is lying down and especially when he or she is sleeping. A vocal cord cyst often contains fluid though can contain solid tissue. A cyst can develop deep within the vocal folds, causing significant changes or difficulties with the voice. The primary symptom of vocal cord cyst is hoarseness. Though vocal cord cysts are noncancerous, otolaryngologists generally operate to remove them because they tend to enlarge. Endoscopic surgery allows the otolaryngologist to remove most vocal cord cysts through the THROAT. Recovery from the surgery takes two to four weeks; most people benefit from follow-up VOICE THERAPY to teach methods for preserving vocal cord integrity and voice quality.

See also OPERATION; SMOKING AND HEALTH; VOCAL CORD NODULE; VOCAL CORD POLYP.

vocal cord nodule A noncancerous, fibrous growth on the vocal cord, usually the result of overusing the voice through repeated shouting, singing, or public speaking. Vocal cord nodules typically develop in book-matched pairs on the folds of the VOCAL CORDS at points where the cords vibrate in contact with each other. Nodules arise from the epithelium, or surface layer of tissue, that covers the vocal cords (unlike vocal cord polyps, which arise from the mucous membrane that forms the vocal cords). Vocal cord nodules have the appearance of calluses and cause the voice to take on a "breathy" quality, though some people also experience hoarseness. The otolaryngologist can remove vocal cord nodules through the THROAT using endoscopic surgery. The surgical wound takes about six weeks to heal, after which VOICE THERAPY helps the person learn methods to protect the vocal cords and voice. Because vocal cord nodules develop through overuse, they are likely to recur with continued extensive speaking or singing.

See also VOCAL CORD CYST; VOCAL CORD POLYP.

vocal cord paralysis The inability of the vocal cord, a membranous flap of tissue in the larynx, to open or close properly with the passage of air. PARALYSIS may affect one vocal cord or both VOCAL CORDS. Paralysis that affects both vocal cords is rare and often affects BREATHING, as air cannot move freely through the THROAT. Symptoms include hoarseness, a "breathy" quality to the voice, diminished vocal volume, and occasionally throat PAIN. Vocal cord paralysis often develops without an identifiable cause, though also results from injury to the throat or nerves that supply the throat, BRAIN injury (such as trauma or from STROKE), and neurologic conditions such as MULTIPLE SCLEROSIS and PARKINSON'S DISEASE. People who use their voices extensively, such as singers and teachers, are especially prone to vocal cord paralysis.

The diagnostic path typically includes laryngoscopy to examine the larynx and vocal cords. Because vocal cord paralysis often goes away on its own, doctors often take a watchful waiting approach in combination with VOICE THERAPY to improve voice function and quality. If the paralysis continues, the otolaryngologist can inject a bulking agent such as collagen into the paralyzed cord. This closes the gap between the cords and encourages both sets of cords to vibrate equally. These measures improve, and often restore, vocal cord function.

vocal cord polyp A fleshy growth on the vocal cord. Vocal cord polyps occur singly, rather than paired as do vocal cord nodules, though more than one polyp may be present. A polyp arises from the mucous membrane that forms the VOCAL CORDS; it grows out from the vocal cord on a stem-like appendage, which allows the polyp to move freely as the vocal cord vibrates. The location and size of the polyp determine the ways that it interferes with speech and hence its symptoms, which can include a "breathy" quality to the voice, hoarseness, difficulty "starting" the voice, and sometimes loss of the voice.

Polyps develop as a result of irritation such as from smoking, chronic POSTNASAL DRIP, environmental pollutants, and allergic PHARYNGITIS. Because polyps in other locations of the body, such as the intestines and the SINUSES, occasionally become cancerous, otolaryngologists recommend prompt surgical removal. Most people fully recover within four to six weeks. VOICE THERAPY can teach methods to preserve and protect the voice. Continued exposure to the causative irritants, such as cigarette smoke, is likely to result in recurrent polyps.

vocal cords A paired fold of thick, fibrous tissue in the back of the larynx that vibrate with the passage of air to produce sounds. The vocal cords run lengthwise in the larynx. Muscles that attach the vocal cords to the larynx contract and relax to change the tautness of the vocal cords, producing variations in sound tone and volume. The vocal cords relax during BREATHING to allow free passage of air through the larynx. The "talk test" for AEROBIC EXERCISE is an indirect measure of the volume of air flowing through the THROAT: being unable to speak during exercise means air flow is high enough that the vocal cords cannot contract.

Singing and extended talking can greatly strain the vocal cords, resulting in inflammation (LARYNGITIS) that causes the voice to sound scratchy or hoarse. Environmental irritants such as pollen or smoke can also cause laryngitis. Cigarette smoking is particularly stressful for the vocal cords, causing extended irritation that may result in chronic hoarseness and growths such as a VOCAL CORD CYST or VOCAL CORD POLYP. Cancerous tumors related to smoking can develop on the vocal cords. Loss of the vocal cords, such as due to LARYNGECTOMY (surgical removal of the larynx) for laryngeal CANCER, results in loss of the voice.

For further discussion of the vocal cords within the context of otolaryngologic structure and function please see the overview section "The Ear, Nose, Mouth, and Throat."

voice therapy Methods and techniques for improving the ability of the larynx (voice box) to produce speech. Voice therapy focuses on the mechanical aspects of vocal cord function, MUSCLE control and coordination, and breath control. Voice therapy typically follows operations on the VOCAL CORDS and larynx to restore voice volume and quality. Professionals who use their voices, such as singers and lecturers, may find voice therapy beneficial in overcoming the deleterious effects of overusing the voice. A voice therapist also may work with a person who has had a LARYNGECTOMY (surgical removal of the larynx) to improve the quality of alternate articulation methods such as ESOPHAGEAL SPEECH or ELECTROLARYNX speech.

The techniques of voice therapy vary according to the diagnosed speech disorder or clinical situation, the person's speaking needs, and the desired outcome. Voice therapy may incorporate resting the voice completely, which allows only 15 minutes of total voice use in a 24-hour period of time. Other techniques focus on using the breath to generate voice volume and quality, and learning to adjust the pitch of the voice rather than only volume to add emphasis to speech.

THE EYES

The eyes conduct the function of vision. Practitioners who provide care for the eyes and vision may be ophthalmologists (medical doctors who specialize in ophthalmology, providing medical and surgical treatment for diseases of the EYE) or optometrists (doctors of optometry who specialize in diagnosing and correcting REFRACTIVE ERRORS of vision). This section, "The Eyes," presents a discussion of the structures of the eye and how they function to provide the sense of sight, an overview of VISION HEALTH and disorders, and entries about the health conditions that can affect the eyes and vision.

Functions of the Eye

Ancient philosophers viewed the eyes as the windows to the soul, based on the belief that the PINEAL GLAND, located deep within the BRAIN, held the soul. Their rudimentary understanding of anatomy and physiology led them to conclude that the optic nerves connected the pineal gland and the soul directly to the outside world through the eyes. Though modern knowledge of the body's structure and function clarifies that no such physical pathway exists, ancient scientists were not entirely off track. The pineal gland does appear to receive direct information from the external environment, which influences its production of MELATONIN, a HORMONE related to the body's circadian cycles (cycles of wakefulness and sleep). Researchers do not fully understand the mechanisms of this, and it is possible the OPTIC NERVE plays some role. However, the primary function of the optic NERVE is to provide a direct conduit from the EYE to the brain through which the brain receives about two thirds of the information it processes about the environment outside the body.

The eye resides within the protective enclosure of the orbit, a socket of BONE in the skull. Thin pads of fat cover the orbital bones to cushion the eye. A small opening in the back of the orbit allows passage of the optic nerve and the blood vessels that supply the eye. The eyelids, upper and lower, blink—automatically open and close—15 to 20 times a minute to rinse the eye with tears. Reduced blink rate is a characteristic of neurologic disorders such as PARKINSON'S DISEASE; increased blink rate occurs with eye irritation such as CONJUNCTIVITIS and diseases such as MENINGITIS. The tears then drain from the lacrimal sac at the inner corner of the eye into the upper NOSE. The eyelids also close to protect the eye from hazards such as foreign objects and very bright light, and to cover the eye during sleep to keep it moist. The eyelashes, extending from the eyelids, also help keep foreign objects from striking the eye and the eyebrows channel sweat around the eyes.

Six muscles attach the eye to the orbit, functioning in pairs as well as in coordination with one another to move the eye. These muscles integrate into the sclera, the fibrous outer layer of the eye, and extend to the back of the orbit where they anchor to the bone. When one MUSCLE in a pair contracts, the other relaxes. Typically both eyes move in tandem, which allows the eyes to simultaneously focus on the same object. This

provides depth perception and accommodates each eye's "blind spot." Some people have the ability to intentionally move their eyes independent of each other, though unintentional disparate movement generally indicates a pathologic condition. Discordant movement may characterize neurologic disorders such as progressive supranuclear palsy (PSP) and TRAUMATIC BRAIN INJURY (TBI). Abnormal eye movements also accompany vestibular disorders (disturbances of the balance mechanisms of the inner EAR).

MUSCLES THAT MOVE THE EYE

- ***Superior oblique*** and ***inferior oblique*** rotate the eye primarily in a circular motion.
- ***Superior rectus*** and ***inferior rectus*** move the eye primarily up and down.
- ***Lateral rectus*** and ***medial rectus*** move the eye primarily side to side.

How the eye "sees" The sclera gives the eye its shape and rigidity. The front part of the sclera forms the "white" of the eye, the coloration coming from the white pigmentation of the fiber cells. In its center, the sclera becomes transparent, forming the CORNEA. The middle layer of the eye's wall is the choroid, a thin, dark membrane rich in BLOOD vessels. The choroid loosely attaches to and nourishes the sclera and the eye's innermost layer, the RETINA, where sight becomes vision.

Specialized cells infuse the retina, which lines the back of the inner eye. These cells, rods and cones, convert lightwaves into electrical impulses. Rods are the most plentiful, numbering about 120 million on each retina, and detect light in perceptions of shades of gray. Cones detect color and detail; there are about 6 million of them on each retina. Cones are sensitive to red, green, or blue. Rods and cones contain photosensitive chemicals that react to different wavelengths of light. The reactions alter the electrical charges of the rods and cones, creating nerve signals. Each minute of wakefulness thousands of these impulses traverse the optic nerves, carrying messages the brain then interprets and assembles as visual images.

The optic nerve, which contains more than a million nerve fibers, carries these signals to the brain. The pigmented cells of the retina are rich in melanin, the same chemical that causes the SKIN to darken in response to sun exposure. In the retina, these cells form a "blackout screen" that eliminates reflection, allowing lightwaves to reach and activate the rods and cones without interference. The macula, a small circular area in the center of the retina, contains the most dense distribution of cones and handles fine detail vision. The "blind spot," the point at which the optic nerve enters the retina, is the optic disk; it contains no rods or cones. RETINITIS PIGMENTOSA (hereditary degeneration of the retina) and RETINAL DETACHMENT (separation of the retina from the choroid) are among the conditions that can affect the retina, resulting in impaired vision and blindness.

The physics of vision Lightwaves pass through the cornea and the LENS to enter the eye through the pupil, the opening in the circular muscle that rings the lens, the iris. The iris is the colored part of the eye; the pupil in its center appears black because it reveals the dark interior of the eye. The iris dilates (increases the size of) the pupil to allow more light to enter the eye and constricts (decreases the size of) the pupil to reduce the light that enters the eye. The cornea and the lens each refract, or bend, the entering lightwaves. The ciliary muscles contract and relax to move the lens, which thickens or flattens, respectively, to improve focus. After about age 40 the lens gradually loses its FLEXIBILITY, accounting for age-related difficulty with near vision (PRESBYOPIA).

Refracted light forms a final focal point that, in the healthy eye, aligns in a pattern on the retina at the back of the eye. The mechanics of this refractory process are such that the image resulting on the retina is upside down. When interpreting and assembling nerve signals from the eye, the brain automatically reverses the image to perceive it right-side up. Refractive ASTIGMATISM, HYPEROPIA, and MYOPIA when the final focal point falls short of or extends beyond the retina, resulting in images that are out of focus or distorted.

Helping keep the lightwaves from fragmenting during refraction are two chambers of fluid, the aqueous humor, which fills the space between the cornea and the lens (the anterior chamber), and the vitreous humor, which fills the interior of the eye. The ciliary processes, specialized folds of the eye's choroid layer that extend into the posterior chamber at the corners of the lens behind the iris,

produce aqueous humor. This watery fluid is about the consistency of saliva and serves also to lubricate and nourish the cornea. Aqueous humor circulates through the anterior chamber between the cornea and the lens, then drains from the eye via the drainage angle, a channel between the iris and the cornea. Dysfunction of the drainage angle is a hallmark characteristic of GLAUCOMA.

Vitreous humor forms when the eye completes its development during the final trimester of gestation. A substance similar to water in chemical composition and to gelatin in consistency, vitreous humor maintains the eye's shape and helps keep the retina smooth and even against the back of the eye. The volume of vitreous humor increases as the eye grows though otherwise remains constant (unlike the aqueous humor, which the eye continuously produces). Around age 40 years the vitreous humor begins to liquefy as a normal process of aging, causing VITREOUS DETACHMENT, which usually has little effect on vision though can produce FLOATERS (fragments of tissue that become suspended in the vitreous humor).

VISION IMPAIRMENT

- ***Refractive errors*** occur when the focal point of light-waves entering the eye fails to align properly on the RETINA (ASTIGMATISM, nearsightedness, farsightedness).
- ***Functional limitations*** result when corrected vision remains insufficient to allow participation in activities or occupations that require sight.
- ***Legal blindness*** exists when corrective measures cannot restore VISUAL ACUITY to 20/200 or VISUAL FIELD to greater than 20 degrees.

Health and Disorders of the Eyes

More than 150 million Americans have a VISION IMPAIRMENT that requires CORRECTIVE LENSES (eyeglasses or contact lenses)—30 percent of men and 40 percent of women. About 12 million Americans have uncorrectable vision impairments that result in functional limitations; 10 percent of them meet the criteria for legal blindness. Among those who have uncorrectable vision impairments, 50 percent are age 65 or older. Though the eyes arise directly from the evolving brain very early in fetal development, their formation becomes complete during the final 12 weeks of PREGNANCY. Infants born before 32 weeks of gestation are at risk for RETINOPATHY of prematurity, a leading cause among children of vision impairments ranging from STRABISMUS (inability to focus both eyes on the same object) to legal blindness.

Traditions in Medical History

As refractive errors are very common, practitioners throughout history have tried various and sometimes hazardous methods for improving or restoring vision. The earliest documentation of corrective lenses for this purpose dates to 16th China. European traders who traveled to China noted the elderly holding quartz crystal lenses to see objects close to them. Eyeglasses set in frames and worn on the face began to appear in Europe in the 17th and 18th centuries. By the late 19th century inventors were experimenting with glass lenses placed directly on the eye. These attempts produced large, heavy, and ultimately unfeasible lenses that covered the entire surface of the eye. The contact lens finally became a reality in the 1950s with the advent of high-tech plastics that were lightweight, optically clear, and inert (did not react with body fluids). Subsequent advances over the next 30 years brought about lenses made of surgical plastics that allow oxygen to reach the cornea, much improving comfort and safety. By the 1990s, daily wear disposable contact lenses became the standard of contact lens correction.

CATARACT, the clouding and discoloration of the eye's lens that develops with aging, has for centuries been the leading cause of blindness in adults. It also is one of the earliest documented vision problems for which practitioners used surgical treatments to remedy, perhaps because the cause of the problem, the cloudiness, was so apparent. CATARACT EXTRACTION AND LENS REPLACEMENT has become so commonplace in contemporary ophthalmology that the procedure is no less an expectation for restoring vision than are eyeglasses for correcting refractive errors. In about 20 minutes, the ophthalmologist removes the clouded lens and replaces it with a synthetic one. Ancient physicians, lacking the benefits of the anesthetics that make the surgery painless for today's patients, became skilled at "couching" a cataract in only seconds. The procedure required the doctor to distract the patient long enough to puncture the cornea and push the lens out of the

line of vision. The lens remained within the eye as though resting, hence the term "couching." The result was less than perfect because the person lost the refractive ability of the lens, but the procedure restored enough vision to allow one to function in daily life. In the 1950s ophthalmologists began removing the cataract from the eye, but not until the 1970s did technology and technique converge in procedures that incorporated a replacement lens.

Breakthrough Research and Treatment Advances

The evolution of knowledge and advances in laser technology are converging to present treatment options that were science fiction a decade ago. New procedures are greatly expanding the potential for permanent correction of disorders and defects of the eye, including refractive disorders, that reduces and may eventually even eliminate the need for corrective lenses. Refined laser techniques such as LASIK allow ophthalmologists to reshape the cornea in precise, microscopic increments. Implantable rings inserted around the edge of the cornea can help flatten and reshape it to alter its refractive ability. Permanent contact lenses attached over the lens can have similar effect. Implantable replacement lenses are expanding beyond their initial application in cataract extraction and replacement to offer nearly ideal vision for people with severe astigmatism or myopia (nearsightedness).

Cataract extraction and lens replacement now routinely restores sight for more than 90 percent of people who otherwise would lose vision to cataracts. Other surgical procedures offer hope for altering the course of glaucoma. New treatments may stem the loss of vision due to AGE-RELATED MACULAR DEGENERATION (ARMD). These conditions are the leading causes of vision impairments that lead to functional limitations or legal blindness among adults. And research continues to explore a "bionic" PROSTHETIC EYE that can convert lightwaves to nerve impulses and transmit them to the brain. Such a prosthesis would function similarly to the COCHLEAR IMPLANT used to restore some types of neurosensory HEARING LOSS. Because many of the conditions that result in vision impairment are not preventable, technological innovations such as these appear to be the future of ophthalmologic treatment.

A

age-related macular degeneration (ARMD) A progressive condition that results in the gradual deterioration of the macula, the portion of the RETINA that provides the ability to see fine detail, and loss of vision from the center of the field of vision. ARMD is the leading cause of VISION IMPAIRMENT, resulting in functional limitations and legal blindness in people over the age of 50. ARMD develops when the retina's BLOOD supply diminishes. The macula's high concentration of cones, the cells responsible for color and fine detail vision, makes it especially vulnerable to damage and its cells begin to die. The death of the cells result in diminished vision. ARMD may affect one eye at first, though nearly always affects both eyes as it progresses.

There are two forms of ARMD, atrophic (commonly known as dry) and neovascular (commonly known as wet). All ARMD begins as the atrophic form, in which the nourishing outer layer of the retina withers, or atrophies. Approximately 90 percent of ARMD remains in this form and progresses slowly. In the remaining 10 percent, new blood vessels begin to grow erratically within the choroid, the blood-rich membrane that nourishes the retina. These blood vessels are thin and fragile, and bleed easily. The resulting hemorrhages cause the retina to swell, distorting the macula and accelerating the loss of cells.

Symptoms and Diagnostic Path

ARMD begins insidiously and people tend to attribute early symptoms to the normal changes of aging. Early symptoms include

- blurring of words when reading
- "missing pieces" in the field of vision, such as parts of words or gaps in the appearance of lines or objects
- the need for increased light to perform tasks that require close vision
- faded colors
- tendency to look slightly to the side of objects to see them clearly
- distorted or wavy lines on linear objects such as signs, doorways, and railings (suggests wet ARMD)

As the macular degeneration progresses, a blind spot in the center of vision becomes apparent and enlarges. Wet ARMD progresses far more rapidly than dry ARMD. A simple screening test called the AMSLER GRID can show the gaps in vision that occur with either form of ARMD. The ophthalmologist uses further procedures, such as OPHTHALMOSCOPY and SLIT LAMP EXAMINATION, to visualize the retina and macula and determine which form of ARMD is present and how extensive the damage. The ophthalmologist looks for signs of exudation (swelling of the tissue that oozes fluid) that suggests wet ARMD, and for drusen (spots of depigmentation on the macula that signal the loss of retinal cells). For wet ARMD, the ophthalmologist may perform a diagnostic procedure called fluorescein angiography, in which the ophthalmologist injects fluorescein dye into a VEIN and then takes photographs of the retina as the dye flows through its blood vessels.

Treatment Options

Treatment options for ARMD are limited, and at this time there really are no treatments for dry

ARMD. Some research studies demonstrate the rate of degeneration slows with increased consumption of the antioxidants lutein and zeaxanthin, and vitamins A, C, and E. For wet ARMD the laser treatments photocoagulation and photodynamic therapy are sometimes effective in sealing bleeding blood vessels and thwarting their growth, though they cannot permanently halt the neovascularization or restore vision already lost. Photocoagulation uses a hot laser to cauterize the blood vessels but also destroys cells in the vicinity of the targeted blood vessels. With photodynamic therapy, the ophthalmologist injects a photosensitive DRUG into the person's veins, then uses a cool laser to target blood vessels in the retina when the drug reaches them. The light of the laser is not intense enough to burn the tissue though activates the drug, which then destroys the blood vessels.

Outlook and Lifestyle Modifications

For most people who have ARMD vision declines slowly and may affect only one eye for a long time before affecting the other eye as well. Because the loss affects the center of the field of vision, vision loss is not complete though affects activities that require detailed focus, such as reading and driving, and typically reaches the level of legal blindness. Numerous community and health-care resources can assist with adaptive methods to accommodate diminishing vision. Even with wet ARMD, which progresses more rapidly and more severely than dry ARMD, some vision remains.

Causes and Preventive Measures

Researchers do not know what causes ARMD, though it appears to have a hereditary component in that it runs in families. There are few treatments, and there is no cure, though there is evidence that antioxidants slow the rate of deterioration and the loss of vision. Vision loss is permanent. As yet there are no known measures to prevent ARMD. It appears that ARMD is more common in people who:

- smoke cigarettes
- have blue or green eyes
- experience extensive exposure to ultraviolet rays, as in sunlight exposure
- have CARDIOVASCULAR DISEASE (CVD) such as HYPERTENSION (high blood pressure), ATHEROSCLEROSIS, or CORONARY ARTERY DISEASE (CAD)

People who have more than one risk factor, especially when one of the risk factors is family history, should frequently and regularly monitor their vision using the Amsler grid. Early diagnosis is particularly important with wet ARMD, for which limited treatment options exist. ARMD develops in people over age 50. An ophthalmologist should evaluate changes that alter the field of vision, especially those that take the form of distortions or "missing pieces." Regular ophthalmic examinations are important to detect ARMD as well as other conditions that affect the eye and vision with advancing age.

aging, vision and eye changes that occur with

The structures of the EYE and the processes of vision begin to undergo changes in the late fourth or early fifth decade of life. By age 65, 50 percent of people have vision impairments. By age 80, more than 90 percent of people have vision impairments. Treatment can mitigate some of these changes, such as PRESBYOPIA and CATARACT. Some conditions that affect the eye and vision develop secondary to other health conditions that are more prevalent in older people, such as DIABETES, HYPERTENSION, and KIDNEY disease, all of which can cause RETINOPATHY. Much loss of vision related to aging is progressive and permanent, interfering with activities such as driving, reading and other close work, and seeing at night. However, most people retain the ability to see well enough to function in everyday activities.

Adaptations to accommodate the changes of the eye and vision with aging are numerous and can help maintain a desirable QUALITY OF LIFE for many people. CORRECTIVE LENSES or reading glasses are effective for presbyopia. Surgery can improve vision impairments such as cataract (CATARACT EXTRACTION AND LENS REPLACEMENT), corneal damage (corneal reshaping or CORNEAL TRANSPLANTATION), and PTOSIS and ECTROPION (BLEPHAROPLASTY). death of cones in the macula	AGE-RELATED MACULAR DEGENERATION (ARMD)	diminished VISUAL ACUITY in the center of vision
white rim around the CORNEA	arcus senilis	none
LENS cloudiness and discoloration	CATARACT	blurred or hazy vision; faded colors; progressive loss of vision
"STROKE" of the OPTIC NERVE that interrupts the flow of blood	ISCHEMIC OPTIC NEUROPATHY	diminished visual acuity; decreased VISUAL FIELD; progressive loss of vision
slowed chemical reactions in the rods	NIGHT BLINDNESS	diminished visual acuity in low-light circumstances
liquefaction of the vitreous humor	VITREOUS DETACHMENT	FLOATERS
loss of lens FLEXIBILITY	PRESBYOPIA	diminished ability to focus on near objects
atrophy (weakening) of the eyelid muscles and tissues, shifting of the orbital fat pads	PTOSIS; ECTROPION	partial occlusion of visual field; can cause CONJUNCTIVITIS, KERATITIS, CORNEAL INJURY

fiers for reading and close work, adjustments on televisions and computers to enlarge screen images, voice-activated telephone dialers, high-intensity light sources, and screen readers with voice output are among the devices available to accommodate low vision.

amblyopia A VISION IMPAIRMENT, commonly called "lazy eye," in which the pathways between the EYE and the BRAIN do not properly handle the processes of sight. Amblyopia is most common in children. The impairment often develops when there are circumstances that allow one eye to become dominant in sending NERVE impulses to the brain, such as STRABISMUS (the inability of the eyes to focus on the same object) or congenital cataracts (opacity of the lens). Amblyopia can also develop when there is significant disparity in the refractive capabilities of the eyes, such as when one eye is hyperopic (farsighted) or myopic (nearsighted) and the other eye has normal vision. The brain becomes accustomed to messages the dominant eye and "ignores" nerve signals from the nondominant, or "lazy," eye. Untreated amblyopia can result in permanent vision impairment or legal blindness.

The diagnostic path includes close examination of the eyes to determine whether other disease processes are present that might account for the vision deficit. Treatment targets those processes, such as cataracts or REFRACTIVE ERRORS, when they exist. When the eye is otherwise healthy and normal, treatment consists of forcing the brain to rely on the amblyopic eye, usually by patching the dominant eye for structured periods of time. Sometimes the ophthalmologist will substitute atropine drops in the eye, which dilate the pupil and distort the eye's ability to focus, when a child refuses to wear an eye patch or an eye patch is otherwise not the most appropriate therapeutic choice. The dilation interferes with the eye's ability to focus, forcing the brain to interpret nerve messages from the untreated eye.

When detected and treated in children who are under age 9, most amblyopia responds to treatment and vision returns. Delayed or inadequate

treatment may result in permanent dysfunction of the eye–brain pathways, as these become entrenched by age 9 or 10. After this time the vision pathways are well established and amblyopia can no longer develop.

Amsler grid A basic test to detect or monitor the progression of AGE-RELATED MACULAR DEGENERATION (ARMD), a condition in which the macula, the area on the RETINA responsible for fine detail vision, deteriorates. The Amsler grid is a square with evenly spaced horizontal and vertical lines, and a dot in the center of the grid. The grid's four corners and lines should appear visible, straight, and intact. Wavy lines, gaps in the lines, or missing segments suggest damage to the macula. Such a result requires further examination from an ophthalmologist who specializes in retinal disorders.

See also VISUAL ACUITY.

astigmatism A common refractive error of vision that results from an irregularly shaped CORNEA. Astigmatism may affect one EYE or both eyes. Typically the irregularity results in two focal points of light that reach the RETINA instead of a single focal point, resulting in blurred or distorted images. Astigmatism often coexists with HYPEROPIA (farsightedness) or MYOPIA (nearsightedness) and tends to run in families. Corrective measures include eyeglasses, contact lenses, and REFRACTIVE SURGERY. Mild astigmatism may not produce noticeable vision disturbances, in which case it does not require correction. The success of corrective measures depends on the extent and nature of the corneal irregularities. Astigmatism often accompanies age-related changes in the eyes and vision, and is a common SIDE EFFECT of CORNEAL TRANSPLANTATION.

Less commonly astigmatism results from irregularities in the surface of LENS, called lenticular astigmatism. Options to correct for lenticular astigmatism are CORRECTIVE LENSES or lens-replacement surgery to implant an intraocular lens.

black eye Bleeding into the tissues around the EYE resulting from trauma to the area, such as a blow or surgical OPERATION. As with any other bruise, the bleeding causes swelling and discoloration. The most significant concerns with a black eye are damage to the eye or fractures of the orbital bones, which require immediate medical attention.

Seek immediate medical attention if these symptoms accompany a black eye:

- **seeing dark spots (FLOATERS) or flashes of light**
- **any cuts on the insides of the eyelids or on the eye**
- **blurry, distorted, or double vision**
- **numbness on same side of the face**
- **trouble moving the eye to look up, down, or to either side**

Treatment for a simple black eye is cold to the area as quickly as possible after the injury occurs and at frequent intervals during the first 24 hours or until the PAIN subsides and the swelling stabilizes. A black eye may take two weeks to fully heal, and undergoes a number of color changes as HEALING progresses. People who participate in sports such as softball, baseball, basketball, tennis, racquetball, soccer, and similar events should wear appropriate eye protection.

blepharitis INFLAMMATION of the eyelids. The most common causes of blepharitis are INFECTION and irritation. Anterior blepharitis is INFLAMMATION of the outer surface of the eyelid, typically along the rim at the base of the eyelashes. Posterior blepharitis affects the inner surface of the eyelid, typically resulting from blocked oil glands (meibomian glands) along the eyelid. Symptoms of either form of blepharitis may include

- itching or burning sensation
- crusting along the eyelids, especially upon awakening
- swelling and redness
- PHOTOPHOBIA (excessive light sensitivity)
- excessive tearing
- blurry vision

Blepharitis may develop as a result of other conditions such as DERMATITIS or ROSACEA (disorders that cause SKIN inflammation). When this is the case, treatment targets the underlying condition. When the cause of the inflammation is bacterial, treatment is topical and sometimes oral ANTIBIOTIC MEDICATIONS. Occasionally the viruses HERPES SIMPLEX I (which causes cold sores) and HERPES ZOSTER (which causes shingles) can infect the eyes. Viral infections such as these cause symptoms until they run their course, typically in 7 to 10 days. Whatever the cause of the inflammation, moist, warm compresses help loosen crusted secretions and keep the eyelids clean. EYE care professionals recommend gently washing the eyelids with a mixture of water and baby (tear-free) shampoo. Blepharitis tends to be chronic so good eyelid hygiene helps minimize recurrences as well as discomfort during episodes.

blepharoplasty A surgical OPERATION to remove excess tissue from the eyelids to correct drooping upper eyelids and "baggy" lower eyelids. Such conditions most commonly develop as a consequence of aging or extensive weight loss or when there is damage to the nerves that control the eyelid muscles (such as with PARKINSON'S DISEASE). An ophthalmologist or a plastic surgeon performs blepharoplasty, usually as an AMBULATORY SURGERY (also called outpatient or same-day surgery). Recovery takes two to four weeks; there can be significant swelling, bruising, and discoloration especially during the first two weeks after the operation. Cold compresses help reduce these symptoms. The risks of blepharoplasty include excessive bleeding and INFECTION.

blepharospasm Involuntary closure of the eyelid that results from dysfunction of or damage to the nerves that control the muscles of the eyelids. Episodes of closure may range from brief (a minute) to extended (several hours). Extended closure interferes with vision. Doctors do not know what causes blepharospasm, though it is a symptom of numerous neurologic and neuromuscular disorders that affect MUSCLE control such as PARKINSON'S DISEASE and DYSTONIA. Blepharospasm that develops without an apparent underlying disorder is benign essential blepharospasm. Blepharospasm often begins with minor twitches and tics or squinting, progressing over time to forceful and prolonged contraction of the eyelid muscles. PHOTOPHOBIA (sensitivity to light) is common. Fatigue and CAFFEINE may initiate episodes of spasms.

The diagnostic path may include a NEUROLOGIC EXAMINATION to determine whether underlying neurologic disorders exist. Blepharospasm requires treatment when it begins to interfere with the activities of everyday life. Moderate blepharospasm often responds to MUSCLE RELAXANT MEDICATIONS such as clonazepam (Klonopin) or Lioresal (Baclofen), or to medications used to treat Parkinson's disease such as levodopa. Many people obtain long-term relief from injections of botulinum toxin, which temporarily paralyzes the eyelid muscles. Surgery to remove muscle tissue (myectomy) or to cut the nerves supplying the eyelid muscles (neurectomy) may provide relief. Though therapeutic measures can control symptoms, as yet there is no cure for blepharospasm.

braille A tactile (touch-based) system of written language that features patterns of raised dots to represent letters of the alphabet, common words and contractions, mathematical symbols, and punctuation. Named after its developer, Louis Braille (1809–1852), braille allows people who are blind to read and, with adaptive typewriters and computer technology, to write. Six dots, in two columns of three dots each, form the foundation for braille; the presence or absence of dots in specific patterns identifies the letter, number, symbol, or concept. There are a number of braille variations, or codes, in common use in the United States. The major ones are these:

- American literary braille code uses about 250 patterns to create book-length materials using short-form words, contractions, single-cell words, and symbols; patterns may have multiple meanings interpreted by context.
- Grade 2 braille code is an abbreviated variation of American literary braille code used primarily for recreational reading materials such as novels and nonacademic nonfiction.
- Grade 1 braille code is the basic alphabet and numerals 0 through 9.
- Nemeth braille code contains about 600 unique, specialized patterns that are distinct from American literary braille code for use in mathematics and science.
- Computer braille code provides a mix of American literary braille code, Nemeth braille code, and unique symbols for computer programming and instruction documentation.
- Music braille code is specialized for transcribing musical scores.

Learning each variation of braille code is like learning a different language. Most people learn the one or two variations they are most likely to use. People whose vision is intact also can learn braille, and should if they have regular interactions with people who are blind. Many communities have schools and consultants who teach braille as well as libraries that provide braille publications. Most public signage in the United States includes braille translations.

bullous keratopathy Swelling (edema) and blistering of the CORNEA. Bullous keratopathy most commonly develops as a complication following CATARACT EXTRACTION AND LENS REPLACEMENT or other surgery on the EYE, though it also may develop as a consequence of chronic irritation such as might occur with DRY EYE SYNDROME.

The healthy cornea is about 75 percent water. One function of the cells that surround the cornea is to maintain this fluid balance. Irritation and trauma that damage these cells diminishes their ability to function, and the cornea retains more water. The swelling stretches the surface of the cornea, pushing the cornea into closer contact with the eyelid and resulting in further irritation. Bullae, or blisters, develop as the cornea's attempt to relieve the discomfort, much as blisters develop on the feet or hands in reaction to friction.

Early symptoms of bullous keratopathy are a sensation of grittiness in the eye, blurred vision, excessive tearing, and PHOTOPHOBIA (sensitivity to light). When bullae form, and especially when they rupture, the PAIN often is severe. The ophthalmologist can diagnose bullous keratopathy using SLIT LAMP EXAMINATION of the cornea, a painless procedure that combines an intense light focused in a slit with magnification through a ophthalmologic microscope. Eye drops or ointment with a higher saline concentration than tears helps draw fluid out of the cornea, reducing the swelling. Soft contact lenses, which absorb fluid from the eye and shield the cornea from contact with the eyelid, relieve discomfort for many people. Bullous keratopathy tends to be chronic, and over time may result in damage to the cornea that requires the cornea's surgical removal (keratotomy) or CORNEAL TRANSPLANTATION.

cataract Cloudiness and discoloration of the LENS. Cataracts become increasingly common with advancing age, affecting half of all people age 80 and older. Cataracts were once a leading cause of age-related blindness. Today ophthalmologists surgically remove cataracts and replace the lens with a prosthetic intraocular lens (IOL) that restores vision.

Cataracts result from protein deposits that accumulate within the lens. These deposits disperse light in much the same way cracks in a window might splinter sunlight shining through. The fragmented light creates areas of accentuated brightness, causing the halos and sensitivity to lights at night. The opacity of the cataract interferes with the refractive function of the lens, causing blurry or hazy vision. The yellow or gray discoloration of the lens common with mature or "ripe" cataracts filters the lightwaves that enter the EYE, particularly affecting those in the spectrum of blue. The location of the cataract on the lens determines the nature and extent of VISION IMPAIRMENT.

Age-related cataracts Most cataracts develop as a function of aging. Protein structures within the body, including the lens of the eye, begin to change. The lens becomes less resilient. Such changes make it easier for proteins to clump together, forming areas of opacity that eventually form cataracts. Nuclear cataracts form in the nucleus (gelatinous center) of the lens and are the most common type of age-related cataract. Cortical cataracts form in the cortex, or outer layer, of the lens and often do not affect vision.

Congenital cataracts Infants may be born with cataracts. A congenital cataract affecting only one eye typically is idiopathic (without identifiable cause); congenital cataracts affecting both eyes often suggest genetic disorders such as DOWN SYNDROME. A congenital cataract that is in the line of vision (on the visual axis) can cause significant vision impairment or blindness because the pathways for vision develop in the infant's first few months of life. Ophthalmologists usually remove such cataracts as soon as possible. Other congenital cataracts may be small and located so they are inconsequential to vision; ophthalmologists generally take an approach of watchful waiting with these.

Cataracts of diabetes GLUCOSE, which can be present in high blood levels with DIABETES, interacts with the protein structure of the lens, causing protein clumping. People who have type 1 (INSULIN-dependent) diabetes are at greatest risk for cataracts of diabetes, which often develop at a young age. People who have type 2 diabetes or insulin resistance also are at increased risk. Developing cataracts account in part for the vision disturbances that are among the symptoms of diabetes. Treatment for cataracts of diabetes is the same as for age-related cataracts.

Symptoms and Diagnostic Path

Because cataracts develop slowly, symptoms become gradually noticeable. Symptoms usually affect only one eye (though cataracts may develop concurrently in both eyes) and may include

- blurry or hazy vision
- double vision
- halos around lights at night
- difficulty seeing at night
- colors appearing faded or dull, or difficulty perceiving shades of blue and purple

Gradual loss of vision at middle age and beyond may be a symptom of AGE-RELATED MACULAR DEGENERATION (ARMD) or GLAUCOMA. Untreated, these conditions result in significant and permanent vision impairments. Any decrease in vision requires an ophthalmologist's or optometrist's prompt evaluation.

The ophthalmologist can see cataracts during OPHTHALMOSCOPY, a painless procedure for examining the interior of the eye.

Treatment Options and Outlook

CATARACT EXTRACTION AND LENS REPLACEMENT is the treatment of choice for nearly all cataracts. There is no element of time-sensitivity for the surgery. Though VISUAL ACUITY will progressively deteriorate as the cataract enlarges, there is no permanent harm to vision by waiting to extract the cataract. Following cataract surgery, more than 90 percent of people experience vastly improved vision. Some people who are unable to receive an IOL because of other eye conditions will need to wear a special contact lens or eyeglasses to carry out the refractive functions of the extracted lens. Nearly everyone will still need reading glasses to accommodate PRESBYOPIA.

Risk Factors and Preventive Measures

Cataracts are primarily a consequence of aging. Cataracts also can develop as a SIDE EFFECT of long-term STEROID use (therapeutic or performance enhancing). Cigarette smoking, excessive ALCOHOL consumption, and extended exposure to sunlight (ultraviolet rays) are among the lifestyle factors associated with early or accelerated cataract development. There are no known methods for preventing cataracts.

cataract extraction and lens replacement An OPERATION to remove the LENS from the EYE after a CATARACT (cloudy occlusion in the lens) forms and replace it with a prosthetic intraocular lens (IOL). Ophthalmologists can extract a cataract at any stage of its development. The vast majority of people who undergo cataract extraction fully recover without complications and experience VISUAL ACUITY correctable to 20/40 or better.

Surgical Procedure

Cataract extraction is nearly always an outpatient surgery performed under local anesthetic and a mild general sedative for comfort. There are three surgical procedures for cataract extraction. Each takes 20 to 30 minutes for the ophthalmologist to complete. Many variables influence the ophthalmologist's choice for which to use.

Phacoemulsification The most commonly performed cataract extraction procedure is phacoemulsification, which requires a tiny incision into the capsule containing the lens. The ophthalmologist first uses ULTRASOUND to liquefy the central nucleus (inner, gelatinous portion of the lens) and then uses aspiration to remove it. Last the ophthalmologist removes the cortex (outer layer of the lens) from the capsule in multiple segments.

Extracapsular cataract extraction The extracapsular cataract extraction procedure requires a slightly larger incision in the capsule, through which the ophthalmologist removes the central nucleus of the lens intact, then removes the cortex in multiple segments.

Lens replacement After extracting the cataract, the ophthalmologist inserts either a monofocal or multifocal IOL to give the eye the ability to focus. Contemporary lens designs allow the ophthalmologist to fold the lens, insert it into the lens capsule through the tiny incision used to extract the cataract, and unfold the IOL to place it in position.

BENEFITS AND RISKS OF CATARACT EXTRACTION

Benefits	Risks
restores vision	postoperative PAIN and swelling (uncommon)
improves QUALITY OF LIFE	postoperative INFECTION (uncommon)
	RETINAL DETACHMENT (rare)

Risks and Complications

Most ophthalmologists prescribe antibiotic and anti-inflammatory eye drops applied to the eye for four to six weeks following surgery, and recom-

mend wearing dark glasses in bright light to help protect the eye from light sensitivity. Swelling and irritation of the tissues around the operated eye is normal in the first few weeks following surgery. Clear vision may take four to six weeks, though many people experience dramatic improvement immediately. Though the short-term risks of cataract extraction and lens replacement are minor, RETINAL DETACHMENT can occur months to years following surgery.

Cataract extraction is a permanent solution for cataracts. Once removed, cataracts cannot grow back. Some people do develop a complication called posterior capsule opacity, in which the membrane behind the IOL becomes cloudy (opaque). This is a complication that results when residual cells that remain after removal of the lens begin to grow across the membrane, causing the membrane to thicken. A follow-up procedure, either yttrium-aluminum-garnet (YAG) laser capsulotomy or conventional surgery, is necessary to remove the membrane.

Outlook and Lifestyle Modifications

About 90 percent of people experience vastly improved vision after cataract extraction. However, other eye problems or underlying conditions (such as RETINOPATHY of diabetes) can affect the quality of vision. Many people do need eyeglasses after cataract extraction, as the IOL does not adjust for focus as does a natural lens. It is important to see the ophthalmologist for follow-up and routine eye care as recommended.

chalazion A painless, hard nodule that arises from a gland (meibomian or sebaceous) along the edge of the eyelid, the result of glandular secretions that granulate. A chalazion may extend deep into the structure of the eyelid. A chalazion sometimes forms at the site of a recurrent HORDEOLUM (an infected eyelid SEBACEOUS GLAND, also called a stye). Often a small chalazion will go away on its own, without treatment. Moist heat applied to the eyelid helps dissolve the granulated material and draw it from the gland. Because of the risk of scarring and pain, the ophthalmologist may recommend excising (surgically removing) a chalazion that does not go away or that recurs. The procedure, with local anesthetic to numb the eyelid, takes only a few minutes in the doctor's office. The wound typically heals within two weeks and leaves no scarring. Inflammatory skin conditions such as DERMATITIS or ROSACEA can block the eyelid's glands, causing a chalazion to develop. Careful eyelid hygiene helps keep secretions from accumulating.

cicatricial pemphigoid An autoimmune disorder in which painful blisters form on the inner surfaces of the eyelids (and may form on other mucus membranes, such as in the MOUTH and NOSE). SCAR tissue that forms after the blisters heal continues to irritate the inner eyelids as well as the outer surface of the EYE (sclera and CORNEA). The blisters commonly involve the lacrimal (tear) glands and ducts, reducing tear production and causing DRY EYE SYNDROME. Cicatricial pemphigoid occurs when the body's IMMUNE SYSTEM produces antibodies that attack the cells that form the mucus membranes. Trauma appears to activate the eruptions of blisters and may be as inconsequential as rubbing the eye or the irritation such as occurs with exposure to environmental particulates such as pollen and dust. Some people first experience outbreaks of cicatricial pemphigoid following eye operations such as CATARACT EXTRACTION AND LENS REPLACEMENT or BLEPHAROPLASTY.

The diagnostic path includes laboratory tests to assess the levels of antibodies in the blood, particularly IMMUNOGLOBULIN G (IGG) and IMMUNOGLOBIN A (IGA), the antibodies most closely associated with cicatricial pemphigoid. Treatment focuses on reducing BLISTER formation and minimizing scarring, typically by taking oral CORTICOSTEROID MEDICATIONS or IMMUNOSUPPRESSIVE MEDICATIONS. As with other AUTOIMMUNE DISORDERS, cicatricial pemphigoid tends to be chronic and recurrent. The persistent irritation can result in damage to the cornea that causes VISUAL IMPAIRMENT and, when severe, results in blindness.

color deficiency A VISION IMPAIRMENT in which the ability to distinguish certain, and rarely all, colors is impaired. Color deficiency represents a shortage of normal cones, the specialized cells on the RETINA that detect color. Cones contain photosensitive chemicals that react to red, green, or blue. The most common presentation of color deficiency, accounting for about 98 percent of color deficiency, is red/green deficiency, in which the person cannot distinguish red and green. A small percentage of people cannot distinguish blue and yellow. Rarely, a person sees only in shades of gray.

Color perceptions occur when lightwaves of certain frequencies (lengths) activate the photochemicals in cones that are sensitive to the frequency. The BRAIN interprets the varying intensities and blends of the photochemical responses. Color deficiency occurs when the cones that perceive one of the three primary colors (red, green, blue) do not function properly.

The most common test for color vision and color deficiency is a series of disks that contain dots of color in random patterns with a structured pattern of differing color within the field. The structured pattern may be a number (most commonly) or an object. There is no treatment to compensate for color deficiency. People who are color-deficient learn to accommodate the deficiency through mechanisms such as memorizing the locations of colored objects (such as the sequence of lights in a traffic signal) and by making adaptations in their personal environments. A person may have friends or family members sort clothing by color, for example, and label the color groups. Some people who have mild color deficiency experience benefit from devices such as colored glasses and colored contact lenses that filter the lightwaves that enter the EYE. A yellow tint may improve blue-deficient color vision, for example.

Most color deficiency is an X-linked genetic MUTATION, affecting about 8 percent of men and ½ percent of women. Color deficiency may also develop with AGE-RELATED MACULAR DEGENERATION (ARMD), RETINOPATHY, neurologic disorders such as MULTIPLE SCLEROSIS, and HEAVY-METAL POISONING such as lead or mercury. Antimalarial drugs can cause permanent changes in the RETINA that affect color vision; the ERECTILE DYSFUNCTION medication sildenafil (Viagra) can temporarily intensify the perception of blue.

conjunctivitis An INFLAMMATION of the conjunctiva, or mucous tissue that lines the inside of the eyelids. There are many causes for conjunctivitis, commonly called pink EYE, including INFECTION (bacterial, viral, or fungal) and contact contamination such as due to pollen or substances in the air or on the fingers that irritate the tissues. Infectious conjunctivitis is highly contagious and very common, especially in children. Symptoms include

- red, swollen conjunctiva and sclera (inner eyelids and the "white" of the eye)
- itchy or scratchy sensation
- thick, yellowish discharge that crusts
- PHOTOPHOBIA (sensitivity to light)

The doctor can usually diagnose conjunctivitis from its appearance. Typical treatment is application of an antibiotic medication in ophthalmic preparation (drops or ointment). Most conjunctivitis dramatically improves with 48 hours of initiating treatment, though symptoms may resolve gradually over 10 to 14 days, and does not require further medical attention. The doctor may culture the discharge when there is reason to suspect CHLAMYDIA or GONNORHEA is the cause, or when symptoms do not improve with treatment. Warm, moist compresses help relieve discomfort and clear away the discharge. Frequent HAND WASHING helps prevent spreading the infection. Untreated conjunctivitis, particularly when chlamydia or gonorrhea is the infectious agent, can cause permanent damage to the CORNEA, which results in VISUAL IMPAIRMENT or blindness.

cornea The transparent portion of the sclera, the EYE's outer layer. The cornea functions as a window to allow light to enter the eye and is the first point of refraction (bending lightwaves to focus them on the RETINA). Irregularities in the surface of the cornea can distort refraction, resulting in

ASTIGMATISM. Though the cornea has no BLOOD vessels it has numerous NERVE endings that make it highly sensitive. Because it is the outermost portion of the eye, the cornea is also highly vulnerable to injury.

For further discussion of the cornea within the context of ophthalmologic structure and function please see the overview section "The Eyes."

See also CORNEAL INJURY; CORNEAL TRANSPLANTATION; LENS; REFRACTIVE ERRORS.

corneal injury Lacerations, punctures, and blunt trauma to the CORNEA. Because of its position, somewhat protruding at the front of the EYE, the cornea is at risk for damage that can jeopardize vision.

Corneal injuries require immediate medical attention. Any puncture or penetrating wound to the eye is a medical emergency. Loosely patch *both* eyes to minimize eye movement.

Dust, dirt, pollen, and other particulates in the air can scratch the surface of the cornea. Particles that adhere to the inside of the upper eyelid or objects that slash across the cornea before the eyelid reflexively closes may cause lacerations (cuts) to the cornea. Though the cornea has no blood vessels and thus cannot bleed, it has numerous nerve endings that unmistakably sound the alert when injury occurs. Injury to the cornea also can diminish VISUAL ACUITY. Puncture or penetrating injuries can destroy the cornea and expose the inner eye to traumatic damage as well as INFECTION. Even minor ABRASIONS and lacerations can cause temporary vision impairment as well as present the risk for infection. Loss of the eye is possible when a significant penetrating wound allows the inner contents of the eye to escape.

Symptoms of corneal injury include

- discomfort ranging from a scratchy sensation to frank PAIN
- PHOTOPHOBIA (sensitivity to light)
- excessive tearing
- inability to keep the eye open
- blurred or distorted vision

The ophthalmologist can identify a corneal injury with FLUORESCEIN STAINING, a simple and painless procedure. Any areas of injury on the cornea absorb the fluorescein dye, causing them to glow green under blue light. Serious injuries to the cornea, or embedded foreign objects, may require immediate surgery to minimize loss of vision. Treatment for injuries that affect only the surface of the cornea may include ophthalmic ANTIBIOTIC MEDICATIONS (drops or ointment) and patching of the affected eye. Protective eyewear, worn whenever there is the potential for particles or objects to strike the eye, helps prevent corneal injuries.

See also CORNEAL TRANSPLANTATION; TRAUMA TO THE EYE.

corneal transplantation The replacement of a diseased CORNEA with a healthy donor cornea. In the United States, ophthalmologists perform more than 45,000 corneal transplantations each year; up to 90 percent of people who receive transplanted corneas experience restored vision; success depends on the reason for the transplant. Ophthalmologists may recommend corneal transplantation to treat:

- BULLOUS KERATOPATHY
- KERATOCONUS
- KERATITIS
- significant CORNEAL INJURY

Donor corneas are harvested within a few hours of death and can be preserved for up to 14 days. Current practice does not employ blood type or tissue type matching for corneal transplantation, though some studies suggest matching the blood type of donor and recipient reduces the risk for rejection.

CORNEA DONATION

Nearly anyone can donate his or her corneas after death. There is no cost to the donor. An eye bank coordinates the harvesting, testing, storage, and dispensing of donated corneas. Many states incorporate organ donor authorization with driver's licenses. People should tell family members that they wish to donate their corneas.

Corneal transplantation surgery takes place with a local anesthetic to numb the eye and an intravenous sedative medication for relaxation and comfort. The operation takes 45 to 60 minutes. From the donor cornea, the ophthalmologist uses a trephine, a device that cleanly punches out a buttonlike segment of the cornea's center. Using a surgical microscope, the ophthalmologist then removes a similarly shaped segment from the diseased cornea and places the donor button in its place. Very fine suture, sometimes thinner than a human hair, secures the donor corneal button in position and remains in the eye for three months to one year. The ophthalmologist often removes the sutures a few at a time as HEALING progresses, using an ophthalmic anesthetic to numb the affected eye, depending on the rate of vision improvement. Some sutures may remain in place indefinitely.

Full recovery typically takes about a year. Some people will have ASTIGMATISM and require CORRECTIVE LENSES following corneal transplantation, resulting from irregularities in the shape of the cornea that develop during healing. Corneal transplantation may correct another VISION IMPAIRMENT such as HYPEROPIA (farsightedness) or MYOPIA (nearsightedness) because the OPERATION changes the shape of the cornea.

The most common complication of corneal transplantation is rejection of the transplanted cornea, which occurs overall in about 15 percent of corneal transplantations. Rejection is most likely to take place in the first two years after the operation. Early detection and prompt treatment with ophthalmic CORTICOSTEROID MEDICATIONS can reverse the rejection process. Signs of rejection include

- diminished VISUAL ACUITY
- PAIN
- redness of the eye
- PHOTOPHOBIA (sensitivity to light)

Other complications that can occur include INFECTION and bleeding within the eye.

See also ORGAN TRANSPLANTATION; PHOTOTHERAPEUTIC KERATECTOMY (PTK).

corrective lenses Eyeglasses or contact lenses that alter the focal point of the lightwaves entering the EYE to correct REFRACTIVE ERRORS of vision, including HYPEROPIA (farsightedness), MYOPIA (nearsightedness), ASTIGMATISM (blurred or distorted vision), and PRESBYOPIA (age-related hyperopia). The eye's natural focusing structures, the CORNEA and the LENS, gather lightwaves and refract (bend) them toward their centers. The cornea refracts the lightwaves first. The lens, which can thicken or flatten to refine its focal efforts, refracts the somewhat focused lightwaves that come to it from the cornea. In normal vision, this sequence results in the focal point of the lightwaves striking the RETINA.

When refractive errors exist the focal point falls in front of or behind the retina, resulting in blurred images. Corrective lenses add a third level of refraction to compensate for the error, bending the lightwaves before they enter the cornea to realign their focal point. The direction of refraction depends on the refractive error:

- In myopia, the focal point falls short of the retina. A lens that corrects for myopia bends the lightwaves inward, narrowing the span of light as it enters the cornea to lengthen the focal point. Such a lens is thicker at the edges than in the middle (concave); it is a minus spherical correction.
- In hyperopia, the focal point extends beyond the retina. A lens that corrects for hyperopia bends the lightwaves outward, broadening the span of light as it enters the cornea to shorten the focal point. Such a lens is thicker in the center than at the edges (convex); it is a plus spherical correction.
- In astigmatism, irregularities in the surface of the lens cause a second focal point. A lens that corrects for astigmatism refracts along a specific axis, realigning the lightwaves. This is a cylinder correction.

Corrective lenses can, and often do, combine spherical and cylindrical corrections. A multifocal lens further incorporates a correction for presbyopia in the form of a bifocal, trifocal, or progressive lens. The bottom of the lens is a plus section,

added to the corrective prescription, that accommodates the limited ability of the lens to focus on near objects (such as when reading).

Eyeglasses

Eyeglasses are plastic resin or polycarbon, and less commonly glass, lenses ground to the thicknesses and shapes necessary to achieve the desired refractive specifications. Because eyeglasses are external to the eye, they can correct for a broad range of refractive errors and are the most common means of refractive correction. Eyeglasses also can contain tints and dyes that change their color; some have additives that provide protection from ultraviolet light. About 85 percent of people who have refractive errors of vision wear eyeglasses to correct them.

Bifocal and trifocal eyeglasses have a clear shift (sometimes visible as a line on the lens) to the presbyopic correction; a progressive lens transitions to the presbyopic correction. Reading glasses such as those available without an eye care practitioner's prescription, are magnifying lenses that enlarge close objects, requiring the lens to make less of an adjustment to bring them into focus. How well reading glasses work depends on whether there are refractive errors that remain uncorrected. With aging, most people develop at least a small degree of astigmatism, which can result in blurred or distorted images not related to presbyopia.

The primary risk of wearing eyeglasses is traumatic injury due to a blow that strikes the glasses. The energy of such a blow concentrates initially at the contact points on the NOSE. The frame may break, causing lacerations to the face. Of more significant consequence is a blow that breaks the lens, which can result in vision-threatening injury to the eye. Polycarbonate lenses have the highest inherent shatter resistance; plastic resin and glass lenses should have shatter-resistant coatings or additives. People who engage in physical activities such as ball sports should wear polycarbonate eyeglasses or custom protective eyewear.

Contact Lenses

Contact lenses fit directly onto the eye, covering the cornea. There are two basic kinds of contact lenses in use today: gas permeable (hard) and hydrophilic (soft). Gas-permeable contact lenses float on a layer of tears over the center of the cornea and often are the contact lens of choice to correct for moderate to significant astigmatism as well as KERATOCONUS, a condition in which the cornea's center bulges outward. Gas-permeable lenses also can correct for mild to moderate myopic and hyperopic refractive errors. Made of rigid polymers of fluorocarbon and polymethyl methacrylate, gas-permeable lenses allow oxygen molecules to pass through but do not absorb moisture from the eye. Hydrophilic contact lenses cover the entire cornea and can correct for mild to moderate myopia and hyperopia. Soft and flexible, hydrophilic lenses contain a high percentage of water and draw additional moisture from the tears to remain hydrated. A special kind of hydrophilic lens, the toric lens, is necessary to correct for astigmatism. A toric lens has varying thicknesses that compensate for corneal irregularities to correct refraction.

Contact lenses can incorporate correction for moderate presbyopia, though this tends to be a less satisfactory approach than eyeglasses. There are two methods for accommodating presbyopia with contact lenses: progressive or bifocal lenses and monovision. Progressive or bifocal contacts function much the same as progressive or bifocal eyeglasses, with the lower portion of the lens containing the presbyopic correction. Because contact lenses shift position on the eye with blinking and when the wearer alters the angle of the head (such as when lying down), the presbyopic correction may not remain in an effective position. Monovision takes the approach of modifying the BRAIN's interpretation of visual signals. One eye, usually the dominant eye, wears a contact lens with the refractive correction. The other eye wears a contact lens with the presbyopic correction. The brain learns to distinguish which signals to interpret, accepting those from the dominant eye during normal visual activities and those from the other eye when reading or doing close-focus work.

The primary risks of wearing contact lenses are damage to the cornea and INFECTION. Even hydrophilic lenses can irritate the cornea and

cause corneal ABRASIONS, particularly in dusty, windy, or dry environmental conditions. Contact lenses tend to accumulate protein deposits that cause irritation. Most hydrophilic lenses are disposable, so frequent replacement helps minimize this as a problem. The optician may need to clean or gently grind the surface of gas-permeable lenses to clear away deposits. Contact lens hygiene, including diligent HAND WASHING before handling lenses and storing lenses in the appropriate disinfectant solution, is essential.

Reading a Corrective Lens Prescription

Optometrists and ophthalmologists measure refractive errors in diopters, a representational scale of the distance in front of or behind the eye's lens the focal point of lightwaves entering the eye must shift to allow the light waves to clearly focus on the retina. The larger the diopter number, the more the lens refracts, or bends, the light. A corrective lens prescription represents the diopter as minus or plus, according to the direction the correction shifts the focal point. For example, the following prescription corrects for myopia and astigmatism:

OD	– 5.75	+ 0.50	164
OS	– 6.00	+1.75	115

This prescription denotes different refractive corrections for the right eye (OD) and left eye (OS). The minus diopter is the spherical correction for the myopia; the plus diopter is the cylindrical correction for the astigmatism, and the last number is the axis position for the cylindrical correction. A lens with a strong correction may also include an adjustment that tilts the lens to alter its optical center, the prism, allowing a thinner lens to deliver the same corrective power or to accommodate a significant difference in the refractive correction for each eye (anisometropia).

D

dacryocystitis INFLAMMATION of the lacrimal (tear) ducts, typically the nasolacrimal ducts in the corners of the EYE near the NOSE. Dacryocystitis develops when there is a blockage of the lacrimal duct, which may result from DACRYOSTENOSIS (narrowing of the lacrimal duct), INFECTION, or chronic irritation such as might occur with ALLERGIC RHINITIS or ALLERGIC CONJUNCTIVITIS. Dacryocystitis can be acute (of sudden onset) or chronic (recurrent or long-standing). It also can be congenital (the result of defects of the lacrimal gland and duct structures) or acquired. Most people who have acquired dacryocystitis are over age 65.

Common symptoms include

- redness and swelling between the eye and the bridge of the nose
- rhinitis (runny nose)
- PAIN
- overflowing tears
- FEVER when an infection is present

The doctor can typically diagnose dacryocystitis based on its presentation. Dye tests, in which the doctor places a special dye in the eye and watches to see whether the dye discolors nasal discharge, help identify the extent of blockage causing the inflammation. Treatment includes ANTIBIOTIC MEDICATIONS when there is an infection, or procedures to dilate the lacrimal duct when there is no infection. Sometimes surgery is necessary to correct dacryostenosis or other structural defects. Appropriate treatment resolves the dacryocystitis.

See also BLEPHARITIS; EYE PAIN; OPERATION; ORBITAL CELLULITIS.

dacryostenosis Narrowing of the lacrimal (tear) duct, usually congenital, that blocks the flow of tears. An infant does not produce a great volume of tears during the first few weeks to months after birth, so the doctor may not suspect or diagnose dacryostenosis until the infant is three to four months of age. The most common symptom is tears that overflow the eye and run down the face (epiphora). Most infants outgrow dacryostenosis by age six months, so doctors tend to take an approach of watchful waiting. When dacryostenosis persists, the doctor may dilate the lacrimal duct (under anesthetic) to gently stretch and enlarge the opening for tears to pass unimpeded. Untreated dacryostenosis can result in frequent episodes of DACRYOCYSTITIS (infected lacrimal ducts) in adulthood. Appropriate treatment can completely resolve dacryostenosis.

dark adaptation test A test that assesses the ability to see in a dimly lighted environment. There are several ways to perform a dark adaptation test. One of the most common is to have the person sit in a dimly lit room. The examiner shines a light into the EYE, gradually increasing the light's intensity until the person reports seeing the light. The examiner notes the light's intensity and the length of time it takes for the light to become noticeable. Depending on the reason for the test, the examiner may direct the light to different parts of the RETINA to test the responsiveness of the rods (the cells responsible for low-light vision). A decrease in dark adaptation response is normal with aging as the photochemical reactions in the eye slow.

diplopia The medical term for double vision, a circumstance in which a person perceives a single object as a two distinct images. Diplopia can be vertical (images one above the other) or horizontal (images beside each other). Diplopia that is present when using both eyes and goes away when covering one EYE is binocular; diplopia that persists even when one eye is covered is monocular. Each has different clinical implications. Numerous health conditions can cause diplopia or have diplopia among their symptoms.

Causes of Monocular Diplopia	Causes of Binocular Diplopia
ASTIGMATISM	BRAIN injury (traumatic or STROKE)
CATARACT	BRAIN TUMOR
DRY EYE SYNDROME	DIABETES
KERATOCONUS	cranial NERVE disorders
PTERYGIUM	GRAVES'S OPHTHALMOPATHY
RETINOPATHY	MULTIPLE SCLEROSIS
STRABISMUS	MYASTHENIA GRAVIS

The diagnostic path begins with basic OPHTHALMIC EXAMINATION and NEUROLOGIC EXAMINATION. The findings of these exams determine the direction and nature of further testing. As diplopia is a symptom rather than a condition, treatment targets the underlying cause. In degenerative disorders such as MULTIPLE SCLEROSIS and MYASTHENIA GRAVIS, diplopia may persist or worsen as the condition progresses. For monocular diplopia, patching the affected eye may alleviate the double image.

dry eye syndrome A condition in which the lacrimal (tear) glands do not produce enough tears or the tears evaporate too quickly, causing the EYE to become dry and irritated. Dry eye syndrome has numerous causes, the most common of which are aging, medication side effects, and extended exposure to a dry or dusty environment. People who work in occupations that require close focus, such as with computers or assembly-line tasks, also may develop dry eyes as a result of insufficient blinking. Dry eyes also may accompany autoimmune conditions such as SYSTEMIC LUPUS ERYTHEMATOSUS (SLE), RHEUMATOID ARTHRITIS, and SJÖGREN'S SYNDROME. Cigarette smoking exacerbates dry eye syndrome.

The symptoms of dry eye syndrome include redness, itching, and the sensation of grit in the eyes. The diagnostic path targets identifying the underlying cause when possible. ANTIHISTAMINE MEDICATIONS, antihypertensive medications, ANTIDEPRESSANT MEDICATIONS, and medications to treat PARKINSON'S DISEASE commonly cause dry eyes as a SIDE EFFECT; sometimes switching to a different medication reduces eye dryness and irritation.

Treatment is frequent use of artificial tears or restasis drops and remedying any identifiable cause when possible. The ophthalmologist may treat persistent dry eye syndrome with lacrimal plugs (also called punctal plugs), tiny segments of acrylic that become soft and gelatinous when inserted into the lacrimal ducts. These plugs slow the drainage of tears from the eye. Some recent studies suggest that increasing dietary intake of essential fatty acids, notably linoleic and gamma-linolenic acids, improves the eye's ability to produce tears.

E

ectropion Loss of elasticity or control of the eyelid, usually the lower eyelid, that causes it to sag away from the EYE. Ectropion allows tears to overflow the lid rather than remaining in the eye. It also fails to protect the eye, and especially the CORNEA, permitting dryness and exposure to environmental particles that create irritation and possibly injury to the cornea and sclera ("white" of the eye). Common causes of ectropion include

- aging
- damage to the nerves that control the eyelids
- CICATRICIAL PEMPHIGOID

Ectropion is a common symptom of BELL'S PALSY, a temporary paralysis of one side of the face that results from INFLAMMATION of the seventh cranial NERVE (facial nerve), and also may accompany neurologic disorders such as PARKINSON'S DISEASE and MULTIPLE SCLEROSIS.

With ectropion the eye feels irritated and scratchy. Tear production becomes excessive as the eye attempts to lubricate and protect itself, and tears typically run over the lip of the lid and onto the cheeks. The doctor can diagnose ectropion based on its appearance. Treatment is typically surgery to tighten the lid structure to permit the lid to stay against the eye. Whether the ectropion recurs depends on the underlying cause. Untreated ectropion may result in extensive damage to the surface of the eye and cornea, including INFECTION, that interferes with vision and the health of the eye.

electroretinography A test that measures the electrical activity of the RETINA's rods and cones in response to light stimulation. The ophthalmologist places anesthetic drops in the EYE to numb it, then attaches an electrode to the surface of the CORNEA. The electrode detects electrical impulses on the retina when the ophthalmologist flashes a beam of light onto the retina, and sends signals to the electroretinograph machine. An electroretinogram is the recording the machine makes of the retina's responses. Electroretinography helps diagnose disorders of the retina such as RETINAL DETACHMENT and RETINITIS PIGMENTOSA.

See also DARK ADAPTATION TEST; RETINOPATHY; SLIT LAMP EXAMINATION.

entropion Deformity of the eyelid in which the lip of the lid, including the eyelashes, curls inward toward the EYE. Scarring that results from CICATRICIAL PEMPHIGOID (an AUTOIMMUNE DISORDER in which painful blisters repeatedly form on the insides of the eyelids) or recurrent CONJUNCTIVITIS (INFLAMMATION or INFECTION of the inner lining of the eyelids) is a common cause of entropion. Entropion may also develop for unknown reasons (idiopathic). The ophthalmologist can diagnose entropion by its presentation. The irritation of the lid and lashes against the surface of the eye is painful and can cause significant damage to the CORNEA, resulting in VISION IMPAIRMENT and perhaps the need for CORNEAL TRANSPLANTATION. Treatment seeks to relieve the irritation. In mild entropion, lubricating eye drops may be sufficient to protect the eye. Moderate to severe entropion requires surgery to restore the eyelid to its appropriate structure. Once corrected, entropion usually does not recur.

See also CORNEAL INJURY; ECTROPION; KERATITIS.

enucleation Surgical removal of a cancerous EYE or a severely diseased or damaged eye. The OPERATION, performed under general ANESTHESIA, takes about an hour. After removing the eye, the surgeon places an implant to fill the shape of the socket and provide a means of attaching a PROSTHETIC EYE. A pressure dressing stays in place over the eye orbit for one to two days to minimize swelling and allow the implant to become firmly rooted in the conjunctival tissue. During this time it is common as well as frightening for people to have difficulty opening the other eye, as the eyes are accustomed to functioning together. Once the bandage comes off and the eyelid of the operated eye is free to move, the eyelid for the unoperated eye resumes normal functioning. Complete HEALING takes about six weeks, during which time it is necessary to place anti-inflammatory and antibiotic drops in the operated eye socket to keep swelling and the risk for INFECTION to a minimum.

Though the operation is uncomplicated and the body quickly heals following the surgery, enucleation can be a difficult procedure for people to accommodate emotionally. Even when the eye has been visionless for a long time, the prospect of losing the eye troubles many people. The modern prosthetic eye is typically such a close match for the remaining eye that it is unapparent to other people. Once the operative site heals, the eye orbit (socket) and implant require little care or attention beyond cleaning the external eyelid area for hygienic purposes.

episcleritis INFLAMMATION of the episclera, the membrane that covers the sclera (fibrous outer layer, the "white," of the EYE). Most episcleritis is idiopathic (occurs for unknown reasons), though the condition sometimes accompanies AUTOIMMUNE DISORDERS such as RHEUMATOID ARTHRITIS and REITER'S SYNDROME. Episodes are self-limiting though may recur over time, with each episode of inflammation generally lasting 7 to 10 days. Symptoms may include mild irritation and redness, and occasionally a nodule (bump) on the surface of the sclera. The doctor can diagnose episcleritis by its appearance. Lubricating eye drops help relieve the irritation until the inflammation subsides. This is usually the only treatment necessary. Some studies suggest a correlation between episcleritis and hormonal shifts such as occur with the MENSTRUAL CYCLE or MENOPAUSE. Episcleritis is three times more common in women than men. Episcleritis does not affect vision or result in any long-term effects on the health of the eye.

exophthalmos Bulging outward of the EYE, sometimes called poptosis. Most exophthalmos results from Graves's disease and is a classic symptom of this form of HYPERTHYROIDISM. Thyroid-related exophthalmos results from swelling of the tissues around the eye and within the orbit that develops in reaction to the high levels of thyroid HORMONE present in the circulation. Other causes of exophthalmos include ORBITAL CELLULITIS, the autoimmune disorder Wegener's granulomatosis, and FRACTURE of the facial or orbital bones that push the eye out of place. Less common causes of exophthalmos include tumors of the eye, OPTIC NERVE, or BRAIN that protrude into the orbital socket and ANEURYSM (ballooning of the arterial wall) of the internal carotid ARTERY, a branch of which runs behind the eye. Exophthalmos can affect one eye (unilateral) or both eyes (bilateral), and when bilateral can affect one eye more prominently than the other.

Exophthalmos can cause significant and permanent vision impairment, and requires prompt treatment.

The diagnostic path begins with an OPHTHALMOLOGIC EXAMINATION and blood tests to assess thyroid function. When Graves's disease or hyperthyroidism is the cause, treatment to restore appropriate levels of thyroid hormones often though not always returns the eye to its normal position. Persistent exophthalmos may prevent the eyelids from closing over the eye, exposing the CORNEA to excessive dryness and potential trauma. Untreated exophthalmos results in VISION IMPAIRMENT that can progress to blindness.

eye The organ of vision. The paired eyes work in coordination to present NERVE impulses the BRAIN interprets as dimensional (stereovisual) images. The function of sight requires close integration among the structures of the eye, the neurologic system, and the muscular system. Each eye is a fluid-filled, elongated globe of fibrous tissue, about ¼ inch from front to back and 1 inch from top to bottom and side to side, contained within the protective cavity of the orbital socket in the skull. The OPTIC NERVE, the second cranial nerve, provides a direct pathway from the back of the eye to the brain. Six muscles move each eye up and down, from side to side, and in rotation. These muscles direct the eye toward objects within the VISUAL FIELD and hold the eyes steady.

The process of vision begins when lightwaves enter the eye through the CORNEA, a transparent portion of the eye's tough outer layer, the sclera. The cornea's convex front surface initially refracts the lightwaves for preliminary focusing. The cornea is soft and flexible but fixed; it does not adjust or move. The LENS, a transparent and flexible convex disk behind the cornea, further refracts the lightwaves. Tiny muscles at the edge of the lens, the ciliary muscles, cause the lens to thicken or flatten to adjust the degree of refraction for optimal focus. The resulting light pattern strikes the RETINA, activating the specialized cells that detect color (cones) and brightness (rods). These cells convert the light to nerve impulses that converge at the back of the retina at the optic disk, their portal to the optic nerve. The optic nerve conveys the signals to the brain, which interprets them as images.

eye pain Sensations discomfort involving the EYE and its supporting structures. Eye PAIN may vary

COMMON CAUSES OF EYE PAIN

Quality of Pain	Possible Causes	Medical Attention Required
itchy or scratchy sensation	DRY EYE SYNDROME, ALLERGIC CONJUNCTIVITIS, dirty contact lenses, EYE STRAIN	self-care such as artificial tears or ANTIHISTAMINE MEDICATIONS; timely doctor's assessment if symptoms persist after self-care efforts to relieve them
burning and PHOTOPHOBIA, may include discharge	CONJUNCTIVITIS, HORDEOLUM, CHALAZION, BLEPHARITIS, KERATITIS, DACRYCYSTITIS, ENTROPION	prompt doctor's assessment; infections require antibiotic medications
burning, photophobia, excessive tearing, visible blisters on surface of the eye	BULBOUS KERATOPATHY, CICATRICIAL PEMPHIGOID, corneal abrasion	immediate medical attention
sharp, deep, or intense pain that may increase with, or prevent, eye movement	ORBITAL CELLULITIS, trauma to eye, GLAUCOMA, optic neuritis, chemical or flash BURNS	medical emergency

from scratchy irritation to intense and debilitating pain. Much eye pain in the form of burning and itching arises from minor and treatable causes that affect the structures around the eye rather than the eye itself. Eye pain that is throbbing, stabbing, deep, or accompanies visual disturbances may suggest conditions such as GLAUCOMA.

Eye pain that is sudden and severe, accompanies partial or complete loss of vision, prevents movement of the eye, or follows TRAUMA TO THE EYE or face requires emergency medical attention. When there is the possibility of penetrating eye injury, loosely patch both eyes to minimize movement.

The diagnostic path begins with careful examination of both eyes, which may include OPHTHALMOSCOPY, FLUORESCEIN STAINING when the doctor suspects CORNEAL INJURY, TONOMETRY to measure the pressure inside the eye, and SLIT LAMP EXAMINATION for further assessment of the RETINA and other structures of the inner eye. The doctor may place an anesthetic medication (numbing eye drops) in the eye to determine whether the pain is coming from the surface of the eye, in which case the pain will go away, or from within the eye, in which case the pain will persist. Often the doctor will also conduct basic tests of VISUAL ACUITY such as a SNELLEN CHART reading.

People who wear contact lenses should remove them at the first sign of discomfort. Treatment for eye pain targets the underlying cause. Most minor causes resolve without complications or permanent VISION IMPAIRMENT. Causes such as severe corneal injury (BURNS, lacerations), glaucoma, and ORBITAL CELLULITIS seriously threaten vision and can result in permanent and complete vision loss without urgent and appropriate treatment.

eye strain The sensation of tiredness and irritation of the eyes, often accompanying long periods of time involved in performing the same task such as reading, computer work, watching television, playing video games, and assembly work. EYE strain generally results from overuse of the muscles that move the eyes. The overuse tires the muscles, which become less responsive to the focusing needs of the eyes. The difficulty generates temporary vision disturbances such as blurring, and may also cause muscle tension headaches. Insufficient blinking, which causes the eyes to become dry and irritated, often accompanies the overuse.

These measures can help relieve eye strain:

- Blink frequently.
- Use artificial tears to improve the moisture content of the eyes.
- Make sure lighting is of the appropriate intensity and placement.
- Reduce glare and reflection.
- Look away from close tasks every 10 to 15 minutes to focus on objects in the distance.
- Wear reading glasses or CORRECTIVE LENSES to accommodate PRESBYOPIA.
- Wear eye protection when in environments that are dusty or windy, and when in the sun.

Contrary to popular belief, eye strain (such as reading in dim light) does not cause permanent VISION IMPAIRMENT. However, eye strain may result from undetected vision impairment, such as ASTIGMATISM and HYPEROPIA, that affect the eye's ability to focus on near objects. An ophthalmologist or optometrist should evaluate eye strain that persists despite efforts to improve the visual environment.

F

farsightedness See HYPEROPIA.

flashes Visual phantoms that appear as spots of light. An ophthalmologist should evaluate occurrences of flashes, as they can be symptoms of RETINAL DETACHMENT or other conditions affecting the RETINA. Flashes represent stimulation of the rods and cones, the cells of vision carpeting the retina, that occurs when the gelatinous fluid holding the retina in place (vitreous humor) moves across them. Because the NERVE signals these cells send to the BRAIN encode patterns of light, the brain interprets messages from them as light. A blow to the head that causes a person to "see stars" has similar effect when it is forceful enough to jostle the vitreous humor against the retina. Flashes may appear as multiple spots of light, "light showers," or lightning-like streaks.

The ophthalmologist typically performs a full OPHTHALMIC EXAMINATION to assess the integrity of the retina. Prompt treatment is necessary to intervene with a retinal tear or retinal detachment, to preserve vision. Isolated flashes of light generally are harmless and may occur for various reasons. Lines or waves of light that last 20 to 60 minutes are common with migraine headaches and have no significance for vision or the health of the eye.

See also FLOATERS; HEADACHE; VISION IMPAIRMENT; VITREOUS DETACHMENT.

floaters Fragments of inner EYE material that float through the vitreous humor, casting shadows against the RETINA as entering light strikes them. Floaters may take various shapes and sizes, and typically move around the VISUAL FIELD, changing position with blinking or eye movement. Most floaters are harmless, though large floaters may interfere with vision. Holding the eye still may allow the floater to settle to the bottom of the eye, out of the visual field. A sudden increase in the number of floaters, or floaters that occur in combination with FLASHES, can signal a retinal tear or RETINAL DETACHMENT. Prompt intervention is necessary to prevent further retinal damage and preserve vision. Floaters may also indicate UVEITIS. Large floaters may remain indefinitely; small floaters may eventually break apart and become absorbed into the vitreous humor. There is no treatment for floaters.

See also VISION IMPAIRMENT; VITREOUS DETACHMENT.

fluorescein staining A simple procedure for diagnosing CORNEAL INJURY or foreign objects in the EYE. The ophthalmologist places a strip of paper containing fluorescein at the edge of the eye. The dye rapidly leaches into the tears. Some people experience a slight burning sensation when the dye washes across the eye for the first time. Blinking disperses the tears across the CORNEA. With the regular room lights turned off, the ophthalmologist shines a cobalt blue light on the eye. Any breach in the eye's surface shows as bright green. The tears wash the fluorescein from the eye within a few minutes.

See also OPHTHALMIC EXAMINATION; SLIT LAMP EXAMINATION; TRAUMA TO THE EYE.

G

glaucoma A serious and progressive EYE condition in which the cells at the front of the OPTIC NERVE where it intersects with the RETINA, the retinal ganglia, die, resulting in vision loss. Early diagnosis and treatment can minimize vision loss. Health experts estimate that 5 million Americans have glaucoma, though only about 2 million of them know it. Glaucoma is the third-leading cause of blindness in the United States, primarily because it remains undetected until damage to the optic NERVE becomes significant. Glaucoma becomes more common after age 65, though there is a congenital form that manifests in early childhood (congenital glaucoma).

Until the late 1990s ophthalmologists perceived glaucoma to be the exclusive consequence of increased pressure within the eye (INTRAOCULAR PRESSURE) that caused the death of retinal ganglia cells. Current understanding of the disease process of glaucoma affirms the death of retinal ganglia cells as the cause of damage to the optic nerve, though recognizes that numerous factors, intraocular pressure being only one among them, contribute to this damage. About 30 percent of people who have glaucoma have normal intraocular pressure, and only about 10 percent of people who have elevated intraocular pressure have glaucoma.

There are two general forms of glaucoma: open angle and closed angle (also called angle-closure). The designations refer to whether the channel through which aqueous humor drains from the eye, called the angle, is open but dysfunctional (open-angle glaucoma) or becomes blocked by the iris (closed-angle glaucoma). In glaucoma, the drainage angle either malfunctions (open-angle glaucoma) or a segment of the iris seals over it (closed-angle glaucoma). When the aqueous humor cannot properly drain, it causes the pressure to increase in the anterior chamber. Increased pressure in the chambers puts increased pressure on the inner eye, causing intraocular pressure to rise. Extreme or extended elevations in intraocular pressure compress the optic disk, causing nerve cells to die.

Acute closed-angle glaucoma requires emergency medical attention. Without immediate treatment, severe to complete vision loss can occur within hours of the onset of symptoms.

Open-angle glaucoma is chronic, progressing over years, and is the most common form of glaucoma, accounting for about 85 percent. Closed-angle glaucoma can be acute, with the sudden onset of severe symptoms, or chronic with symptoms similar to those of open-angle glaucoma. The function and dysfunction of aqueous humor drainage is the dimension of glaucoma doctors and researchers understand most clearly, and most treatment approaches target reducing aqueous humor production or improving its drainage from the eye. Less clear are the other factors that contribute to death of the retinal ganglia cells and corresponding destruction of the optic disk. These factors are especially significant for the 30 percent of people who have glaucoma with normal intraocular pressure. Researchers are investigating the roles of genetics, autoimmune processes, and correlations with conditions such as DIABETES and HYPERTENSION (high BLOOD PRESSURE).

Symptoms and Diagnostic Path

The key symptom of chronic glaucoma, open-angle or closed-angle, is the gradual and painless loss of VISUAL ACUITY and VISUAL FIELD. Often the

pattern of progression begins with loss of peripheral (outside) vision. Over time the field of vision becomes increasingly narrow, which people often describe as "tunnel vision." Other symptoms include excessive tearing (especially with close focus tasks such as reading), halos around lights at night, aching eyes, and headaches. Sudden throbbing PAIN in the eye, loss of vision, severe HEADACHE, halos around lights, and a dilated pupil in the affected eye are symptoms of acute closed-angle glaucoma.

GLAUCOMA SYMPTOMS

Chronic (Open-Angle or Closed-Angle)	Acute Closed-Angle
slow loss of peripheral vision	sudden, throbbing PAIN in the EYE
"blind spots" in the field of vision	sudden, severe HEADACHE
halos around lights at night	sudden restriction or loss of vision
teary eyes with close focus tasks	dilated pupil in affected eye
achiness in the affected eye	NAUSEA and vomiting

Though eye care practitioners routinely use TONOMETRY to screen for increased intraocular pressure, this test alone is not sufficient to detect glaucoma. Detecting glaucoma requires a full OPHTHALMIC EXAMINATION including fundus examination to assess the condition of the optic disk. The ophthalmologist will also conduct a visual acuity test and a peripheral vision test. Other procedures that can help diagnose glaucoma in its early stages or quantify the extent of damage in moderate to advanced glaucoma are ULTRASOUND of the eye and OPTICAL COHERENCE TOMOGRAPHY (OCT).

Treatment Options and Outlook

Acute closed-angle requires emergency measures to relieve intraocular fluid and the accumulation of aqueous humor. Such measures typically include a combination of procedures to open the drainage angle, ophthalmic medications to lower intraocular pressure, and systemic medications to draw fluid from cells (osmotics). The ophthalmologist is also likely to administer medications for pain and to minimize NAUSEA and vomiting. Ongoing treatment with glaucoma medications or glaucoma surgery is then necessary. Ophthalmic medications (drops, inserts, and ointments) to open the drainage angle and lower intraocular pressure are the standards of treatment for chronic glaucoma of either form, and typically can control glaucoma for many years.

Surgery becomes an option to treat glaucoma that becomes advanced or does not respond to

COMMON GLAUCOMA MEDICATIONS

Type of Drug	Actions
alpha-blockers (apraclonidine, brimonidine)—topical ophthalmic preparations	reduce aqueous humor production by slowing function of ciliary processes; increase drainage of aqueous humor
beta-blockers (betaxolol, carteolol, levobunolol, metipranolol, timolol)—topical ophthalmic preparations; oral products sometimes used	reduce aqueous humor production by slowing function of the ciliary processes
carbonic anhydrase inhibitors (brinzolamide, dorzolamide)—topical ophthalmic preparations	reduce aqueous humor production by blocking the action of the enzyme necessary for its production, carbonic anhydrase
miotics (pilocarpine, carbachol)—topical ophthalmic preparations	increase drainage of aqueous humor
prostaglandin analogs (latanoprost, travoprost, bimatoprost, unoprostone)—topical ophthalmic preparations	increase drainage of aqueous humor via secondary routes

medication therapy. Surgical treatments for glaucoma include the following:

- For iridotomy, the ophthalmologist uses an ophthalmologic laser to place a small opening in the iris. The opening provides another route of drainage for the aqueous humor and helps keep the iris from blocking the drainage angle in open-angle glaucoma.
- For trabeculoplasty, the ophthalmologist uses an ophthalmologic laser to make numerous "dots" in the trabecular meshwork—the fanlike network of tiny channels at the end of the angle that disperse the draining aqueous humor—to expand its the draining capacity.
- For trabeculotomy, the ophthalmologist places an aqueous shunt, a tiny opening from the anterior chamber through the sclera, to allow aqueous humor to drain to the outside of the eye.
- For cytophotocoagulation, the ophthalmologist uses an ophthalmologic laser to destroy portions of the ciliary processes to reduce aqueous humor production.

Early diagnosis and treatment offer the best opportunity for minimizing vision loss. It is important to diligently follow the directions for using glaucoma medications, as glaucoma requires consistent control. Appropriate treatment can slow the progression of vision loss in most people who have glaucoma.

Risk Factors and Preventive Measures

Age is the most significant risk factor for glaucoma; glaucoma is uncommon in people under age 40 and about two thirds of people who develop glaucoma are over age 65. Glaucoma is more common in people of African American and Asian ethnicity and tends to run in families. Glaucoma also is more likely to develop in people who have hypertension, ATHEROSCLEROSIS, diabetes, and severe MYOPIA (nearsightedness) and in people who take CORTICOSTEROID MEDICATIONS. Prevention focuses on regular ophthalmic examinations to detect glaucoma early in its course.

Graves's ophthalmopathy Changes in the EYE that occur as a result of Graves's disease, a form of HYPERTHYROIDISM, and occasionally as a result of other forms of thyroid disease. The most prominent feature of Graves's ophthalmopathy is EXOPHTHALMOS, an outward bulging or protrusion of the eyes that often is the first indication of Graves's disease. The exophthalmos results from enlarged extraocular muscles (the muscles that move the eye) and edema (swelling due to retained fluid) in the tissues around the eye and within the ocular orbit (eye socket). This circumstance restricts the ability to move the eyes, particularly upward and side to side, as well as to close the eyelids. Graves's ophthalmopathy can involve only one eye (unilateral) though most often involves both eyes (bilateral). Symptoms and consequences range from mild to severe, with about 5 percent of people experiencing substantial loss of vision that may include loss of the eye. Graves's ophthalmopathy can appear before there are any indications of Graves's disease, at the onset of hyperthyroid symptoms, or months to years after the diagnosis of Graves's disease.

Graves's ophthalmopathy presents a significant threat to vision. The swelling in and around the orbit pressures the structures of the eye and can compress the OPTIC NERVE, which can result in OPTIC NERVE ATROPHY (the death of cells in the optic NERVE) and permanent VISION IMPAIRMENT. The external pressure against the eye also raises the pressure inside the eye (INTRAOCULAR PRESSURE), which can result in GLAUCOMA. The combination of exophthalmos and restricted lid movement prevents the eyelids from closing completely, which allows the CORNEA to become dry. The resulting irritation and INFLAMMATION (KERATITIS) reduces VISUAL ACUITY and also exposes the inner eye to INFECTION. Though the symptoms that threaten vision eventually subside, many of the changes that result, including exophthalmos and vision impairment, are permanent.

Symptoms and Diagnostic Path

The symptoms of Graves's ophthalmopathy include

- exophthalmos (sometimes called poptosis)
- DIPLOPIA (double vision)

- CONJUNCTIVITIS (inflammation of the inner eyelids)
- diminished visual acuity (blurry or distorted vision)
- PHOTOPHOBIA (sensitivity to light)
- excessive tearing

As these symptoms are distinctive for Graves's ophthalmopathy, the doctor often can make the diagnosis based on their presentation. Tests of thyroid HORMONE levels in the BLOOD confirm Graves's disease, if not already diagnosed. Conventional OPHTHALMIC EXAMINATION and SLIT LAMP EXAMINATION allow the ophthalmologist to assess the status of vision and health of the structures of the eye. A COMPUTED TOMOGRAPHY (CT) SCAN helps assess the extent of orbital swelling and compression of the optic nerve.

Treatment Options and Outlook

The course of Graves's ophthalmopathy seems to unfold in two stages, regardless of treatment for or status of the underlying hyperthyroidism. The first stage is the acute or active phase, during which symptoms emerge. During this stage, which extends over 18 to 30 months, ophthalmologic treatment focuses on reducing pressure on the eye and stabilizing vision, and may include

- ophthalmic lubricating drops or ointment to keep the cornea hydrated
- patching the eyes at night to protect the corneas during sleep
- NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) to reduce inflammation and relieve discomfort
- CORTICOSTEROID MEDICATIONS to suppress the body's immune response
- ANTIBIOTIC MEDICATIONS to treat bacterial infection of the eyelids (BLEPHARITIS), conjunctiva (conjunctivitis), and cornea (keratitis)

In the second stage of Graves's ophthalmopathy, the progression of symptoms ends. However, the changes that have occurred are permanent. Fibrous deposits replace lymphocytes in the eye muscles, maintaining their enlargement and continuing the exophthalmos. Treatment in this stage targets minimizing these permanent consequences through surgeries to relieve the pressure within the orbit (orbital decompression), reduce the size of the extraocular muscles (myectomy), and reconstruct the eyelids so they close completely over the eye (BLEPHAROPLASTY). Corneal reshaping (keratoplasty) or CORNEAL TRANSPLANTATION may be necessary to restore vision when damage to the cornea is extensive. If infection resulted in loss of the eye, the ophthalmologist will place a PROSTHETIC EYE.

Risk Factors and Preventive Measures

Graves's ophthalmopathy occurs only in conjunction with thyroid disorders, nearly always hyperthyroidism. It may appear months to several years before other clinical indications of hyperthyroidism, or a comparable time after beginning treatment for hyperthyroidism. Prompt diagnosis and treatment are essential to preserve vision, as the changes that occur with Graves's ophthalmopathy are generally permanent. An ophthalmologist should evaluate any changes in the appearance of the eyes. Regular eye examinations help screen for Graves's ophthalmopathy as well as other eye health problems.

H

hordeolum A bacterial INFECTION of a gland or an eyelash follicle along the edge of the eyelid, commonly known as a stye. A hordeolum causes swelling, redness, PAIN, and a discharge that leaves a crusty layer on the eyelids during sleep. The doctor can usually diagnose hordeolum by its presentation. BLEPHARITIS (infection of the inside surface of the eyelid) and CONJUNCTIVITIS (infection of the conjunctiva, the membrane lining the eyelids) may instigate, accompany, or follow hordeolum. The doctor often chooses to anesthetize the area and lance (make tiny punctures or incisions under sterile conditions) the hordeolum to drain its contents and relieve the pressure. Further treatment is ophthalmic ANTIBIOTIC MEDICATIONS, typically in ointment form, applied to the area. Sometimes oral antibiotic medications are also necessary. Warm, moist compresses soothe the irritated tissues and help draw out any remaining pus.

Most hordeola clear up in 7 to 10 days with treatment and heal without residual consequences. A hordeolum does not itself cause VISION IMPAIRMENT, though untreated hordeola can lead to significant EYE problems if the infection spreads to other structures of the eye. Some people experience recurring hordeola, while others experience only a single episode. A hordeolum may also form the basis for a CHALAZION (painless nodule) to develop in its place.

hyperopia A refractive error, commonly called farsightedness, in which the EYE has difficulty focusing on near objects. Hyperopia results when the focal point of lightwaves entering the eye extends past the RETINA, causing the images the retina registers to be blurred. The refractive error occurs because the distance from the front to the back of the eye is shorter than normal. Symptoms of hyperopia include

- squinting when reading or doing close work
- HEADACHE
- fatigued eye muscles (aching around the eyes)
- blurred vision when looking at near objects yet clear vision when looking at distant objects

CORRECTIVE LENSES (eyeglasses or contact lenses) can compensate for hyperopia by altering the focal point of lightwaves so it falls directly on the retina. They do so by refracting (bending) the lightwaves outward. REFRACTIVE SURGERY, which permanently alters the shape of the CORNEA, can provide refractive correction for people with mild to moderate hyperopia. Hyperopia sometimes occurs following refractive surgery for MYOPIA (nearsightedness) as a consequence of overcorrection. Eye professionals denote refractive corrections in units of measure called diopters. For hyperopia, the expression of diopter is a positive number. Corrective lenses for hyperopia have a magnifying appearance that make the eyes look bigger than they are.

Hyperopia is less common than myopia, affecting about 20 to 25 percent of adults. Few people who have hyperopia have greater than +6 diopters of refractive error, so nearly always corrective measures result in normal VISUAL ACUITY.

I

intraocular pressure The pressure within the EYE that maintains the eye's form and structure. Normal intraocular pressure in an adult is 12 to 22 millimeters of mercury (mm Hg). A device called a tonometer measures intraocular pressure, either through light contact against the anesthetized eye or via the force of resistance to a puff of air blown against the eye's surface (a noncontact method that does not require anesthetic drops). Elevated intraocular pressure is called ocular hypertension. Lower than normal intraocular pressure is called ocular hypotension.

Ocular hypertension (greater than 21 mm Hg) is a hallmark sign of GLAUCOMA, an eye condition that, if untreated, results in complete loss of vision. Other health conditions that can increase intraocular pressure include tumors that press against the eye, ORBITAL CELLULITIS, and GRAVES'S OPHTHALMOPATHY. Increased intraocular pressure damages the cells on the front of the OPTIC NERVE (the retinal ganglia), leading to permanent VISION IMPAIRMENT. Ophthalmic medications that reduce intraocular pressure work through various mechanisms, depending on the cause of the increased pressure.

Ocular hypotension, in which the intraocular pressure is lower than normal (less than 12 mm Hg), characterizes chronic UVEITIS (INFLAMMATION of the structures of the eye) and of certain tumors of the eye. Ocular hypotension also sometimes accompanies systemic HYPOTENSION (low BLOOD PRESSURE) and as a SIDE EFFECT of medications, notably general anesthesia agents.

iritis INFLAMMATION of the iris, the MUSCLE surrounding the pupil of the EYE. Iritis may develop as a result of INFECTION, such as CONJUNCTIVITIS that spreads to involve other structures of the eye. Iritis also occurs as part of the inflammatory process in AUTOIMMUNE DISORDERS such as RHEUMATOID ARTHRITIS. The symptoms of iritis include

- irritation and a "gritty" sensation in the eye
- redness of the eye
- PHOTOPHOBIA (sensitivity to bright light)
- blurry vision
- excessive tearing

The ophthalmologist can diagnose iritis based on the appearance of the iris and the eye, though will additionally perform a SLIT LAMP EXAMINATION to look for involvement of other structures of the eye. Treatment is ophthalmic ANTIBIOTIC MEDICATIONS (eye drops or ointment) when the ophthalmologist suspects bacterial infection and ophthalmic CORTICOSTEROID MEDICATIONS to reduce the inflammation. When the cause of the inflammation is systemic, the ophthalmologist may prescribe anti-inflammatory medications such as corticosteroids or NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS). Treatment usually resolves the symptoms without residual VISION IMPAIRMENT. Untreated or recurrent iritis can have long-lasting effects on vision, including increased INTRAOCULAR PRESSURE.

ischemic optic neuropathy Damage to the OPTIC NERVE resulting from insufficient blood supply, sometimes called "STROKE" of the optic nerve. Ischemic optic neuropathy is occurs most commonly in people over age 55 and causes mild to

complete VISION IMPAIRMENT. There are two forms: arteritic, associated with giant-cell arteritis (an inflammatory disorder of the arteries that typically affects the temporal arteries) and nonarteritic, which correlates with CARDIOVASCULAR DISEASE (CVD) such as HYPERTENSION (high BLOOD PRESSURE) and ATHEROSCLEROSIS. Other conditions associated with the nonarteritic form include DIABETES, HYPOTENSION (low blood pressure), and RHEUMATOID ARTHRITIS.

Vision impairment due to ischemic optic neuropathy comes on suddenly. In a characteristic pattern, a person wakes up in the morning with noticeable loss of VISUAL ACUITY and VISUAL FIELD. This may continue for several days, improving as the day goes on, though in short order becomes permanent. The diagnostic path begins with OPHTHALMOSCOPY and SLIT LAMP EXAMINATION to visualize the optic disk (portion of the optic nerve that attaches to the RETINA), which appears pale and swollen. Diagnosis of giant cell arteritis by temporal ARTERY biopsy confirms the diagnosis of the arteritic form of ischemic optic neuropathy. Doctors arrive at the diagnosis of the nonarteritic form on the basis of symptoms and ruling out other causes.

Treatment for arteritic ischemic optic neuropathy is CORTICOSTEROID MEDICATIONS to reduce the INFLAMMATION. Vision loss, however, is irreversible. There are no effective treatments for the nonarteritic form, which does not appear to improve with corticosteroids. Lifestyle modifications such as SMOKING CESSATION improve circulation in general with the presumption that such improvement also affects optic structures. ASPIRIN THERAPY, such as prescribed as a prophylactic measure for HEART ATTACK and stroke, may have a preventive effect with the arteritic form. It is especially important to manage underlying health conditions that affect circulation, such as hypertension and diabetes.

When the ischemic optic neuropathy affects only one EYE, the person can make adaptations and adjustments to accommodate the vision impairment that do not necessarily require substantial changes in lifestyle. Most people can still read, work, and perform other functions of daily living with visual acuity in only one eye. Ischemic optic neuropathy that involves both eyes can significantly affect lifestyle.

K

keratitis INFLAMMATION of the CORNEA, usually the result of an INFECTION. The cause of the infection is more commonly viral, such as HERPES SIMPLEX or HERPES ZOSTER, than bacterial. Symptoms of infectious keratitis include

- redness and irritation of the EYE and conjunctiva (inner eyelids)
- discomfort or PAIN
- excessive tearing
- difficulty keeping the eye open
- diminished VISUAL ACUITY (usually blurred vision)
- eye discharge or crusting

Viral keratitis usually runs its course without complication, though occasionally a secondary bacterial infection may develop. ANTIVIRAL MEDICATIONS sometimes shorten the course of chronic herpes infections. Bacterial keratitis typically follows a CORNEAL INJURY, such as an abrasion or laceration, and requires treatment with ophthalmic ANTIBIOTIC MEDICATIONS. Chronic or recurrent keratitis can cause permanent scarring of the cornea, resulting in diminished visual acuity such as ASTIGMATISM. Extensive corneal damage may require CORNEAL TRANSPLANTATION.

SUNBURN is the most common cause of noninfectious keratitis. Extended exposure to the sun, especially on or around water, exposes the surface of the eye to the same ultraviolet rays that cause sunburn of the SKIN. Ultraviolet burns to the cornea are painful; treatment with ophthalmic CORTICOSTEROID MEDICATIONS helps reduce the inflammation.

keratoconus A degenerative disorder in which the CORNEA thins, allowing it to protrude from the surface of the EYE in somewhat of a cone shape. Keratoconus affects both eyes though often progresses at different rates in each eye. Ophthalmologists do not know what causes keratoconus, though it appears to run in families. Keratoconus is painless though results in progressive VISION IMPAIRMENT, typically in the forms of MYOPIA (nearsightedness) and ASTIGMATISM (distortions of vision resulting from the irregular surface of the cornea). As these REFRACTIVE ERRORS are the primary symptoms, the keratoconus may not become apparent until the coning becomes obvious.

Treatment for mild to moderate keratoconus is rigid gas-permeable contact lenses, which correct the refractive errors of vision as well as help contain the shape of the cornea. As the keratoconus progresses, however, contact lenses become less effective, and the thinned cornea may not be able to tolerate them. Keratoconus ultimately destroys the cornea and is a leading reason for CORNEAL TRANSPLANTATION, which replaces the diseased cornea with a donor cornea. Corneal transplantation successfully restores vision in about 90 percent of people who have keratoconus and undergo the procedure.

In 2004 the US Food and Drug Administration (FDA) approved a new treatment for keratoconus, corneal inserts, which are tiny plastic rings the ophthalmologist implants along the edge of the cornea. The corneal inserts flatten the cornea, reducing the coning. Corneal inserts come in different thicknesses to allow less or more flattening and are replaceable.

L–M

lens The primary focusing structure of the EYE, located in the center at the front of the eye. The lens is transparent, convex (rounded outward on each side), round, and flexible. A thin membrane encloses the lens. Tiny muscles at the front edges of its sides, the ciliary muscles, contract to flatten the lens and relax to thicken the lens. These adjustments alter light refraction (the angle at which the lens bends lightwaves entering the eye) to accommodate near and distant vision. The most common health conditions that affect the lens are PRESBYOPIA, in which the FLEXIBILITY of the lens diminishes with aging, and CATARACT, in which protein deposits cloud the lens and obscure vision. The lens is also vulnerable to accidental injury, particularly from blunt force (such as a baseball) or puncture.

For further discussion of the lens within the context of ophthalmologic structure and function please see the overview section "The Eyes."

mydriasis Excessive or persistent dilation of the pupil that is a symptom of ophthalmic or systemic conditions. The ophthalmologist may induce mydriasis, using topical atropine, to examine the inner EYE. Therapeutic mydriasis using atropine-based ophthalmic drops is an alternate treatment for AMBLYOPIA. Two eye conditions can cause mydriasis: GLAUCOMA and damage to the iris. In the healthy eye the iris, a muscular membrane, controls the opening of the pupil. INFLAMMATION of or tears in the iris affect its ability to function, which also can result in mydriasis.

Other causes of mydriasis are systemic, involving damage to NERVOUS SYSTEM structures and functions, and may include TRAUMATIC BRAIN INJURY (TBI), STROKE, and medication response such as with narcotic use, which causes the muscles to relax. Eye disorders often affect only one eye (unilateral mydriasis), whereas systemic conditions typically affect both eyes (bilateral mydriasis). PHOTOPHOBIA (sensitivity to bright light) often accompanies mydriasis as the dilated pupil cannot limit light from entering the eye. VISION IMPAIRMENT depends on the extend of the dilation; a fully dilated pupil prevents focus on near objects.

The diagnostic path begins with a basic OPHTHALMIC EXAMINATION including SLIT LAMP EXAMINATION and OPHTHALMOSCOPY, unless there is clear evidence that the mydriasis results from systemic causes. TONOMETRY, which measures the pressure within the eye (INTRAOCULAR PRESSURE), determines whether glaucoma is present. Tears of the iris are typically apparent when looking at the eye as they distort the iris (the colored portion of the eye). Inflammation of the iris (IRITIS) often reddens the eye and is apparent with ophthalmoscopy. Further diagnostic measures turn to NEUROLOGIC EXAMINATION. Treatment targets the causative condition.

See also EYE PAIN; NARCOTICS; TRAUMA TO THE EYE.

myopia A refractive error commonly called nearsightedness, in which the EYE has difficulty focusing on distant objects. Myopia results when the focal point of lightwaves entering the eye falls short of the RETINA, causing the images the retina registers to be blurred. The refractive error occurs because the distance from the front to the back of the eye is longer than normal. Symptoms of myopia include

- squinting when looking at distant objects
- straining to see when driving

- difficulty seeing the ball when playing baseball, tennis, and similar sports
- frequent headaches at the end of the day

CORRECTIVE LENSES (eyeglasses or contact lenses) can compensate for myopia by altering the focal point of lightwaves so it falls directly on the retina. They do so by refracting, or bending, the lightwaves inward. Eye professionals denote refractive corrections in units of measure called diopters. For myopia, the expression of diopter is a negative number. REFRACTIVE SURGERY, which permanently alters the shape of the CORNEA, provides refractive correction for mild to moderate myopia (–1 to –15 diopters). In 2004 the US Food and Drug Administration (FDA) approved an implantable contact lens to improve severe myopia (–15 to –30 diopters). Severe myopia sometimes cannot be fully corrected, resulting in VISION IMPAIRMENT with functional limitations or legal blindness. Myopia is the most common refractive error, affecting about 35 percent of adults.

N

nearsightedness See MYOPIA.

night blindness Impaired dark adaptation resulting from slowed photochemical reactions in the rods, the specialized cells of the RETINA that perceive contrast and detect visual images in low light. Night blindness becomes increasingly common after middle age. The person with night blindness may be unable to see at all in dim light or may experience delayed adjustment when going from a lighted environment to a dim or dark environment. A diminished VISUAL FIELD with restricted peripheral vision also contributes to night blindness, as the outer edge of the retina where peripheral vision takes place contains mostly rods.

There are not many treatment options for night blindness. Nutritional supplementation of vitamin A and the antioxidants LUTEIN and ZEAXANTHIN, which some studies show help maintain the health of the eye and improve the functioning of the rods, seem to aid some people. Adequate lighting when reading and especially when watching television or movies reduces the need for the eye to make accommodations for changing light. Increased lighting can compensate for diminished dark adaptation in static settings such as rooms and offices, though it is not possible to make similar accommodations for functions such as driving.

nystagmus Involuntary movements of the eyes, usually rapid and repetitive. Nystagmus can be congenital or acquired; in either circumstance it is a symptom of underlying disorders rather than itself a condition. Nystagmus nearly always indicates VISION IMPAIRMENT; if congenital, the impairment may improve or completely resolve with age. Vision impairment in adults depends on the underlying cause of the nystagmus. Temporary induced nystagmus, such as may occur with caloric testing (warm or cool water infused into the auditory canal) to assess disorders of the vestibular system, does not affect vision, although vestibular disorders can cause nystagmus.

Causes of Congenital Nystagmus	Causes of Acquired Nystagmus
ALBINISM (absence of retinal pigmentation)	vestibular disorders
congenital macular defects	brainstem or cerebellum damage or tumor
congenital CATARACT	MULTIPLE SCLEROSIS
absence of iris	TRAUMATIC BRAIN INJURY(TBI)
anomalies of the OPTIC NERVE	TRAUMATIC BRAIN INJURY(TBI)
	chronic ALCOHOL abuse

The diagnostic path includes a comprehensive OPHTHALMIC EXAMINATION and NEUROLOGIC EXAMINATION. Treatment targets the underlying cause. Some adults who have acquired nystagmus receive relief from the muscle relaxant medication baclofen (Lioresal), which interrupts NERVE signals from the BRAIN to the muscles that control the eyes. The long-term consequences for vision depend on the cause and duration of the nystagmus. Occasionally nystagmus occurs as an undesired SIDE EFFECT of antiseizure medications, and typically goes away with switching to another medication.

ocular herpes simplex An INFECTION of the eyes with HERPES SIMPLEX VIRUS 1 (HSV-1), which causes cold sores, or herpes simplex virus 2 (HSV-2), which causes GENITAL HERPES. The virus spreads to the eye to cause the initial infection via contamination from contact with an existing herpes sore elsewhere on the body. Ocular herpes simplex features similar eruptions of sores on the surface of the EYE and inside the eyelids. The sores are very painful and can cause permanent scarring of the CORNEA.

About half of people who have one outbreak of ocular herpes simplex will experience a second; about 20 percent have persistently recurring infections, ranking ocular herpes simplex as the leading infectious cause of corneal destruction. A serious complication of ocular herpes simplex is stromal KERATITIS, in which the IMMUNE SYSTEM begins to attack the stromal cells that make up the cornea. This leads to scarring deep within the cornea, resulting in distortions of vision and diminished VISUAL ACUITY.

The sores of ocular herpes simplex are characteristic of the infection. The antiviral medication acyclovir may reduce the severity of outbreaks of the infection when taken at the first sign of symptoms. Some studies show that taking acyclovir for 12 months significantly reduces recurrent ocular herpes simplex. However, there is no cure for herpes infection. Damage that occurs as a consequence of infection is permanent. Infection-control methods, such as frequent HAND WASHING and keeping the fingers away from the eyes, can help prevent initial infection.

ocular herpes zoster INFECTION of the eyes with the varicella zoster VIRUS, a member of the HERPES SIMPLEX family of viruses that causes CHICKENPOX and shingles. After the infectious stage of chickenpox subsides, the virus submerges itself in NERVE roots. It may reemerge years to decades later, erupting in a rash of painful blisters along a nerve tract that hosts the virus. Ocular herpes zoster occurs when an outbreak that affects the face, usually along the tract of the trigeminal nerve, spreads to the EYE. Usually the outbreak affects only the eye on the same side of the face as the shingles eruption, though sometimes the shingles eruption affects both sides of the face. When this is the case, ocular herpes zoster can affect both eyes as well. As in other locations, the shingles blisters in the eye cause intense PAIN.

The blisters and pain are characteristic of ocular herpes zoster, making it possible for the doctor to make the diagnosis based on their presentation. Treatment typically includes ANTIVIRAL MEDICATIONS (such as acyclovir), ophthalmic CORTICOSTEROID MEDICATIONS to reduce INFLAMMATION, tricyclic ANTIDEPRESSANT MEDICATIONS to prevent postherpetic NEURALGIA, and ANALGESIC MEDICATIONS to relieve pain. Symptoms may take several weeks to several months to resolve. Numerous complications are possible that can have long-term consequences for vision, including GLAUCOMA and CATARACT. Ocular herpes zoster very seldom recurs, though this is a risk for those who are immunocompromised such as with HIV/AIDS or receiving IMMUNOSUPPRESSIVE THERAPY such as following ORGAN TRANSPLANTATION.

ophthalmic examination The basic diagnostic procedures an ophthalmologist uses to assess the

health of the EYE and vision, and detect problems with the structures and functions of the eye. The standard ophthalmic examination includes several components. For certain parts of the examination the ophthalmologist may place drops in the eyes that anesthetize the eye and dilate the pupils, to facilitate examining the structures of the back of the eye such as the RETINA and optic disk. Some people experience mild stinging when the drops first enter the eye. There is otherwise no discomfort with an ophthalmic examination. The complete exam takes about 10 minutes.

Physical Examination

The ophthalmologist begins with an examination of the orbital tissues, outer eyelids, inner eyelids, and conjunctiva (membrane lining the inner eyelids) of first one eye and then the other, checking to see that the eyelids open and close properly and looking for any growths or irritation. The ophthalmologist then checks the movement of the eyes, typically by asking the person to follow the track of an object such as a pen. Using a small light, the ophthalmologist checks the reaction of the pupils. These procedures help the ophthalmologist to assess the basic neurologic aspects of the eye's functions.

Visual Acuity and Visual Field

The familiar SNELLEN CHART test for VISUAL ACUITY features lines of letters in differing sizes and order of presentation. Covering first one eye and then the other, the person reads the line with the smallest letters that appear clear. The ophthalmologist records the result as a ratio that represents actual visual acuity compared to a standard of 20/20, with a score of 20/20 being what the normal eye sees at a distance of 20 feet. Diminished visual acuity may result from REFRACTIVE ERRORS such as MYOPIA (nearsightedness) or HYPEROPIA (farsightedness), or signal conditions of the eye such as CATARACT or GLAUCOMA.

The ophthalmologist tests for basic VISUAL FIELD by having the person focus on an object in the distance and signal when he or she can see an object (such as a pen the ophthalmologist holds) that moves into the field of normal vision. This test assesses peripheral vision and helps detect scotomas (small blind spots in the field of vision), which are both symptoms of glaucoma and RETINITIS PIGMENTOSA.

Slit Lamp Examination

The SLIT LAMP EXAMINATION, also called a biomicroscopic examination, uses light focused as an elongated slit in combination with magnification. Slit lamp examination allows the ophthalmologist to closely examine the front structures of the eye including the sclera, CORNEA, iris, and LENS. It is a common procedure for diagnosing cataract. The ophthalmologist may also use FLUORESCEIN STAINING to check for CORNEAL INJURY such as ABRASIONS or lacerations.

Ophthalmoscopy

The ophthalmoscope is a hand-held device that resembles a flashlight. It has narrowly focused beam of light and a magnifying lens. The ophthalmologist uses it to examine the inner structures of the back of the eye known collectively as the fundus: the retina, optic disk, and macula. The ophthalmologist usually dilates the pupil for OPHTHALMOSCOPY. This test helps detect numerous problems of the eye including RETINAL DETACHMENT, RETINOPATHY, OPTIC NERVE ATROPHY, and PAPILLITIS. Conditions such as glaucoma cause characteristic changes to the fundus.

Tonometry

The tonometer is a device that measures INTRAOCULAR PRESSURE (the pressure within the eye). The most simple variation involves measuring the force it takes for a puff of air to indent the cornea, a noncontact test. For more accurate results the ophthalmologist numbs the eye with anesthetic drops and touches a TONOMETRY probe against the surface of the eye to measure the pressure. Tonometry is a basic screening test for glaucoma, for which increased intraocular pressure is a key symptom.

ophthalmoscopy Examination of the EYE using an ophthalmoscope, a hand-held, lighted magnifying lens. The ophthalmoscope projects a narrowly

focused beam of light that illuminates the structures of the eye. Ophthalmoscopy is the essential introductory examination of the eye and can determine what, if any, further diagnostic procedures are necessary. Ophthalmoscopy allows the doctor to examine the inner surfaces of the eyelids, general surface of the eye (sclera and CORNEA), pupil response, and iris. It also allows the doctor to visualize the inner structures at the back of the eye, notably the RETINA, optic disk, and macula.

See also OPHTHALMIC EXAMINATION; OTOSCOPY; SLIT LAMP EXAMINATION; TONOMETRY.

optical coherence tomography (OCT) An imaging procedure that noninvasively and painlessly permits the ophthalmologist to visualize the layers of the RETINA. OCT can provide a "virtual biopsy" of retinal tissue, helping diagnose or monitor AGE-RELATED MACULAR DEGENERATION (ARMD), macular holes, retinal tears, and OPTIC NERVE inflammation or damage such as can result from GLAUCOMA. The ophthalmologist can perform OCT in the office; no preparation or recovery is necessary.

optic nerve The second cranial NERVE, which conveys nerve impulses from the EYE to the BRAIN. There are two optic nerves, one from each eye. The fibers that become the optic nerve originate in the occipital lobes of the cerebrum, in an area called the visual cortex. Each extends along structures called the optic tracts that pass through the temporal lobes and the center of the brain, converging in the optic chiasm. At this point the optic tracts cross, such that the one originating in the left visual cortex goes to the right eye and the one originating in the right visual cortex goes to the left eye. Each optic nerve enters the back of the eye, terminating in the RETINA.

The ophthalmologist can see through the ophthalmoscope the end of the optic nerve, called the optic disk. It appears as a pale circle, about the size of a pencil eraser, against the dark background of the retina. The retina's network of nerves extends from the optic nerve, gathering nerve impulses from the rods, cones, and other nerve cells in the retina.

CONDITIONS THAT CAN AFFECT THE OPTIC NERVE

optic nerve atrophy Death of NERVE cells within the OPTIC NERVE, affecting the optic nerve's ability to convey nerve signals from the EYE to the BRAIN. Optic nerve atrophy can be partial or complete; when complete there is total loss of vision. Conditions of the eye or systemic neurologic disorders can cause optic nerve atrophy. Symptoms include diminished VISUAL ACUITY and VISUAL FIELD.

CAUSES OF OPTIC NERVE ATROPHY

Eye Conditions	Neurologic or Systemic Conditions
congenital OPTIC NERVE HYPOPLASIA	MULTIPLE SCLEROSIS
ISCHEMIC OPTIC NEUROPATHY	TRAUMATIC BRAIN INJURY (TBI)
congenital CATARACT	STROKE
RETINITIS PIGMENTOSA	methanol poisoning
GLAUCOMA	untreated SYPHILIS

The diagnostic path begins with OPHTHALMOSCOPY, which allows the ophthalmologist to see the visual changes in the optic disk (end point of the optic nerve where it joins the RETINA) that denote its atrophy. Further assessment to determine the cause may include diagnostic imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) and a comprehensive NEUROLOGIC EXAMINATION. Treatment targets the underlying cause, though it cannot recover vision already lost. Treatment that can halt the causative condition can prevent further loss of vision, though when the cause is a degenerative disorder such as MULTIPLE SCLEROSIS vision loss is likely to continue.

People who smoke cigarettes or consume high quantities of ALCOHOL, particularly in combination, have a higher risk for developing idiopathic optic nerve atrophy (in which the cause remains undetermined. NUTRITIONAL SUPPLEMENTS containing vitamin A and the antioxidants LUTEIN and ZEAXANTHIN may improve visual acuity.

See also OPTIC NERVE HYPOPLASIA; RETROBULBAR OPTIC NEURITIS; TOXIC OPTIC NEUROPATHY.

optic nerve hypoplasia A congenital condition in which the OPTIC NERVE fails to develop completely in the unborn child. Optic NERVE hypoplasia is the third leading cause of congenital vision loss in the United States. The defect is random and may affect one EYE or, more commonly, both eyes. Children who have optic nerve hypoplasia may have barely noticeable to complete VISION IMPAIRMENT depending on the extent to which the optic nerve develops. Diminished peripheral vision and depth perception are common. Typically the pediatrician detects an abnormality of the optic nerve shortly after birth, though mild optic nerve hypoplasia may escape notice until the child begins having vision difficulties. Optic nerve hypoplasia does not progress, so VISUAL ACUITY typically remains stable. CORRECTIVE LENSES may accommodate for vision impairments. Other treatment focuses on teaching the child adaptive methods. There are no known preventive measures.

optic neuritis See PAPILLITIS.

orbital cellulitis INFLAMMATION and swelling of the tissues surrounding the EYE, including the eyelids.

Orbital cellulitis requires emergency medical attention. Delayed treatment can result in permanent vision loss.

The most common causes are infections that affect the eyelids such as HORDEOLUM and BLEPHARITIS, DACRYOCYSTITIS (infected tear duct), and infections of adjacent structures such as SINUSITIS (sinus infection), PHARYNGITIS (throat infection), tooth ABSCESS, and occasionally OTITIS media (middle ear infection). Insect bites that become infected also can cause orbital cellulitis. Orbital cellulitis may affect one eye or both eyes, depending on the underlying cause. The eyelids typically swell closed and may appear bruised, with considerable PAIN as well as inability to see. Often there is a moderate FEVER (above 102°F) and EXOPHTHALMOS (bulging of the eye).

The diagnostic path includes assessment of VISUAL ACUITY and VISUAL FIELD, to the extent possible, as well as COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) to visualize the extent of the infection and determine its site of origin. Treatment is immediate intravenous ANTIBIOTIC MEDICATIONS with hospitalization until fever and swelling subside. Prompt and appropriate treatment improves the likelihood for full recovery and restored vision. Complications can include increased INTRAOCULAR PRESSURE, which is damaging to the RETINA and OPTIC NERVE. Because the optic NERVE presents a direct channel to the BRAIN, INFECTION also may spread to cause MENINGITIS or ENCEPHALITIS.

See also CONJUNCTIVITIS; TRAUMA TO THE EYE.

P

papilledema Swelling of the optic disk, the point at which the OPTIC NERVE enters the RETINA, that results from increased pressure within the skull. Papilledema typically signals serious neurologic damage such as STROKE or TRAUMATIC BRAIN INJURY (TBI) that causes bleeding (HEMORRHAGE), brain tumor, extreme HYPERTENSION, or inflammatory INFECTION such as ENCEPHALITIS and MENINGITIS. Though papilledema is not a disorder of the EYE, untreated it will result in complete loss of vision because the swelling interrupts the flow of blood to the optic NERVE.

Doctors check for any signs of papilledema during a routine OPHTHALMIC EXAMINATION, as often papilledema is an early sign of a neurologic problem. The need for intervention to relieve the intracranial pressure is urgent, not only to preserve vision but also often as a lifesaving measure. The nature of the intervention depends on the underlying cause. Extremely elevated blood pressure points to hypertension as the cause; other causes require NEUROLOGIC EXAMINATION for further evaluation and diagnosis. With prompt treatment to reduce the intracranial pressure, papilledema typically resolves in about six to eight weeks and vision, if affected, returns to its previous level.

Swelling around the optic disk may occur for various reasons that are not the result of increased intracranial pressure. These are usually ophthalmologic in nature, such as GLAUCOMA and ISCHEMIC OPTIC NEUROPATHY. The conditions threaten vision, but they are not life-threatening.

See also OPTIC NERVE ATROPHY; RETROBULBAR OPTIC NEURITIS; TOXIC OPTIC NEUROPATHY.

papillitis INFLAMMATION of the optic disk, the portion of the OPTIC NERVE that enters the RETINA (also called the "blind spot"). Papillitis typically results from, and may be an early diagnostic indicator of, systemic inflammatory conditions such as MULTIPLE SCLEROSIS and temporal arteritis. The inflammation also may follow viral or bacterial INFECTION such as SINUSITIS, especially in children, and occurs rarely as a complication following stings from wasps and bees. Papillitis often affects only one EYE though can involve both eyes. Within hours of its onset the inflammation can cause complete loss of vision in the affected eye. Rapid treatment to reduce the inflammation, or to treat the underlying condition causing the inflammation, can salvage vision. However, loss of vision is often the reason people seek medical attention, by which time there may already be permanent damage to the optic disk. Occasionally the inflammation develops over the course of several weeks, producing progressive loss of vision as well as loss of color perception.

photophobia Heightened sensitivity to bright light, usually the result of INFLAMMATION or irritation to structures of the EYE or with MYDRIASIS (extended dilation of the pupil). Photophobia causes discomfort in the eye ranging from a burning sensation to outright PAIN. Often there is excessive tearing and the eye becomes reddened in response to the irritation. In severe photophobia it may be impossible to keep the eye open. Photophobia is common in the HEALING period following CATARACT EXTRACTION AND LENS REPLACEMENT and CORNEAL TRANSPLANTATION. Photophobia may be a symptom of numerous conditions affecting the eye, including

- CORNEAL INJURY, such as ABRASIONS and burns

- INFECTION, such as BLEPHARITIS, CONJUNCTIVITIS, IRITIS, HORDEOLUM, KERATITIS, UVEITIS
- CHALAZION
- ENTROPION
- Dirty contact lenses or contact lenses worn too long

Photophobia that occurs with FEVER may indicate MENINGITIS and requires emergency medical attention.

The diagnostic path typically includes SLIT LAMP EXAMINATION with FLUORESCEIN STAINING to determine whether there is corneal injury and OPHTHALMOSCOPY to evaluate the structures of the inner eye. These examinations often require anesthetizing drops in the eye to numb the discomfort the lighted instruments cause. Treatment targets the underlying cause, which, when resolved, generally ends the photophobia. ANTIBIOTIC MEDICATIONS, usually ophthalmic solutions or ointment placed in the affected eye, are necessary to treat bacterial infections. Wearing sunglasses to restrict the amount of light that can enter the eye helps reduce the sensitivity response. Some people are naturally photophobic without underlying eye conditions and should wear sunglasses for improved comfort in bright-light settings.

See also BACTERIA; TRAUMA TO THE EYE.

phototherapeutic keratectomy (PTK) Treatment with an excimer (cool) laser to smooth irregularities and dissipate cloudiness in the CORNEA. PTK is an AMBULATORY SURGERY procedure, with local anesthetic to numb the surface of the EYE and a mild sedative for comfort. The procedure takes 20 to 45 minutes, depending on the extent of corneal sculpting needed. The ophthalmologist may prescribe ophthalmic ANTIBIOTIC MEDICATIONS and anti-inflammatory medications after the procedure. Changes in VISUAL ACUITY are generally complete in one to two months.

CONDITIONS PTK CAN TREAT

ASTIGMATISM	corneal clouding
corneal degeneration	corneal dystrophy
corneal scarring	recurrent corneal erosion
recurrent KERATITIS	REFRACTIVE ERRORS

The risks and potential complications of PTK include

- INFECTION
- worsened visual acuity
- RECURRENCE of the original problem

Most people experience improved visual acuity or relief from corneal PAIN following PTK.

pinguecula A thickened area of the conjunctival tissue on the EYE, usually forming on the inner (NOSE) side of the eye. A pinguecula may be clear, yellow, or gray in color, and develops slowly. It presents no threat to vision or the eye, and is more common in people over age 50. Many people do not notice that they have pingueculae or consider them normal features of their eyes, though some people experience irritation and a sensation of grittiness in the affected eye. People who spend a lot of time in the sun or have other long-term ultraviolet light exposure are more likely to develop a pinguecula. Ophthalmologists recommend wearing sunglasses or protective eyewear that filters ultraviolet light. There is no reason to treat a pinguecula unless it puts pressure on the CORNEA or otherwise interferes with vision.

presbyopia A progressive change in the eyes that occurs with aging, in which it becomes increasingly difficult to focus on near objects. Presbyopia occurs because the LENS loses FLEXIBILITY, limiting its ability to adjust between near and far focus. The lens becomes unable to contract to thicken in the center as near focus requires, resulting in the inability to see objects that are close, such as when reading. Most people begin to notice presbyopia when they reach their mid-40s in age. People who have MYOPIA (nearsightedness) may also find that their distant vision improves as presbyopia advances. The EYE changes responsible for presbyopia reach their end point by about the mid-50s, after which the stiffening of the lens stabilizes. Eyeglasses, contact lenses, and surgery offer options for correcting presbyopia.

Eyeglasses

The conventional treatment for presbyopia is reading glasses, which are magnifying lenses that enlarge near objects to allow the eyes to focus on them. Many retail and optical stores sell standard reading glasses that come in common magnifications typically ranging from +1.00 to +3.00 in gradations of 0.25 power. This is often the least expensive and most convenient option. An optometrist also can prescribe custom-strength lenses.

People whose eyes otherwise do not require refractive correction wear reading glasses as needed for close vision. People who have other REFRACTIVE ERRORS, such as myopia or ASTIGMATISM, and wear eyeglasses require bifocal or trifocal CORRECTIVE LENSES that provide multiple levels of correction to accommodate both the refractive correction and the magnification for close vision. Eyeglass lenses may be progressive, in which there are no discernible lines on the lens to mark the transition from one level to another. People who wear contact lenses to correct refractive errors often choose to wear reading glasses as needed with the contacts for close vision, or may choose to switch to eyeglasses.

Contact Lenses

Contact lenses may also have multiple levels of refractive correction (multifocal contact lenses). Another approach using contact lenses is monovision, in which one eye, typically the dominant eye, wears a lens that fully corrects for refractive error and the other eye wears a lens that undercorrects. The BRAIN learns to distinguish which eye to use for close and for distant focusing, automatically shifting as necessary. It may take a week or two for the brain to make the adjustment and for monovision to feel comfortable. However, some people do not adjust to monovision at all. Monovision results in some loss of depth perception, which some people find barely noticeable and other people find intolerable.

Surgery

In the United States, the two most commonly used surgical methods to correct presbyopia are conductive keratoplasty and LASIK (an acronym for laser-assisted in situ keratomileusis), both done as ambulatory procedures that require no overnight hospital stay. In conductive keratoplasty, the ophthalmologist uses radiofrequency energy applied in a concentric pattern around the base of the CORNEA to shrink corneal collagen. This constricts the cornea's base, causing the center of the cornea to thicken and rise, which improves close focus. It may take several weeks to experience the full effect. In LASIK, the ophthalmologist uses an excimer laser to reshape the cornea. There is little recovery time with LASIK, and effects are apparent almost immediately.

Each surgical method establishes a permanent degree of monovision. Depending on the age of the person and the anticipated progression of the presbyopia, the ophthalmologist may leave a margin of correction to allow for future changes. Many ophthalmologists recommend a trial of monovision with contact lenses before surgery to determine whether the approach produces acceptable results. The risks of surgical correction for presbyopia include INFECTION, vision that still requires corrective lenses even after surgery, and, rarely, worsened vision. Some people may have other eye conditions, vision problems, or general health conditions that exclude them from surgery as an option to correct presbyopia.

prosthetic eye A cosmetic replacement, also called an ocular prosthesis or artificial EYE, for a surgically removed (enucleated) eye. A specialist called an ocularist designs the prosthetic eye to be as close a match in appearance as possible for the remaining natural eye.

The most common type of prosthetic eye attaches to a spherical implant the same size and shape of the eye that the surgeon places in the orbit (eye socket) after removing the eye. As the HEALING process takes place, other tissues and blood vessels grow into and around the implant, anchoring it firmly within the orbit. Once healing is complete, the surgeon drills into the front of the implant to attach a small post. The post then holds the prosthetic eye, a "facing" that fits over the front of the implant. The muscles of the orbit move the implant in coordination with the movements of the healthy eye, providing a natural appearance to the prosthetic eye.

Another type of ocular prosthesis is a scleral shell, which covers a dysfunctional and disfigured eye that remains in place. The scleral shell is somewhat like an oversize contact lens, fitted to rest on the eye as does a contact lens. The ocularist designs the front of the shell to match the appearance of the other eye. Because the scleral shell rests on the surface of the eye, it moves in synchronization with the other eye for a natural appearance.

Over time the orbital structures change and the materials of the prosthetic eye experience some natural deterioration. Most people need to replace the prosthetic eye every two years, though the implant is permanent. Children may need more frequent replacements to keep pace with their growth. The prosthesis requires regular care and cleaning.

pterygium A growth arising from the conjunctival tissue around the perimeter of the EYE, usually on the side near the NOSE. A pterygium characteristically grows in a triangular shape, and has its own BLOOD supply to support its growth. Growth generally is slow. Often a pterygium remains innocuous, though some people experience irritation and a sensation of grittiness in the affected eye. Occasionally the growth encroaches on the CORNEA, applying pressure or growing into the corneal region. When this occurs, surgery to remove the pterygium is necessary to preserve vision. Pterygia tend to recur following surgery, though it may take a number of years to reach a size that interferes with vision.

ptosis Drooping of the upper eyelid. Ptosis often is a consequence of MUSCLE weakness or neurologic damage, and is sometimes a symptom of a neurologic condition such as MYASTHENIA GRAVIS or MUSCULAR DYSTROPHY. Ptosis may be congenital (present at birth), the result of underdevelopment or absence of the levator muscle that raises the eyelid. Ptosis also may develop with advanced age, reflecting weakening of the muscles that control the eyelid.

When the drooping obscures vision, surgery to raise the eyelid is necessary to prevent AMBLYOPIA. Surgery may result in a slight asymmetry in the movements of the upper eyelids, particularly in congenital ptosis, when the levator muscle is missing and the surgeon must configure eyelid movement to make use of other muscles. Generally no treatment is necessary when the ptosis does not interfere with vision, except as desired for cosmetic purposes.

R

refraction test A diagnostic procedure to measure REFRACTIVE ERRORS of the EYE, such as MYOPIA, HYPEROPIA, and ASTIGMATISM. An optometrist or ophthalmologist conducts the test using a device called a refractor. The refractor fits against the face somewhat like a flattened pair of binoculars, with a chin rest and forehead pad to support the head in proper position. After covering one eye, the eye professional applies combinations of lenses to the eye piece. The person looks through the eye piece and lens at a rendition of the SNELLEN CHART. The eye professional examines first one eye with the other eye covered, switches eyes, and finally examines both eyes together to confirm the appropriate refractive correction.

See also CORRECTIVE LENSES; OPHTHALMIC EXAMINATION.

refractive errors Vision disorders in which a defect of the EYE does not allow proper refraction of light. When the eye is longer than normal from front to rear, the lightwaves entering the eye focus short of the RETINA, resulting in MYOPIA (nearsightedness). When the eye is shorter, the lightwaves that enter the eye focus behind the retina, resulting in HYPEROPIA (farsightedness). An irregular surface or shape to the cornea may produce distortions of refraction, resulting in ASTIGMATISM. The optometrist or ophthalmologist measures refractive errors using a refraction test. Treatment is CORRECTIVE LENSES (eyeglasses or contact lenses) or REFRACTIVE SURGERY. Refractive errors may change frequently during childhood, though usually stabilize by early adulthood. Severe refractive errors may be uncorrectable, notably myopia, resulting in functional or legal blindness.

See also PRESBYOPIA; VISION IMPAIRMENT.

refractive surgery Operations to correct REFRACTIVE ERRORS of vision such as MYOPIA (nearsightedness), HYPEROPIA (farsightedness), and ASTIGMATISM (irregularity of the CORNEA). Refractive surgery became an option for permanent refractive correction in the United States in the 1980s, following its introduction and rapid growth in popularity in Europe. Now, about 1.5 million Americans undergo refractive surgery operations each year.

Surgical Procedure

There are numerous refractive surgery techniques in use today. They fall into the general categories of those that use lasers, those that use microkeratomes (specialized blades), and those that use implants to alter the eye's natural structure. There are five commonly performed refractive correction operations:

- LASIK (laser-assisted in situ keratomileusis) has become the standard procedure for most refractive corrections. The EYE surgeon makes a small flap to expose the inner portion of the cornea, uses an excimer (cool) laser to remove microscopically thin layers of corneal tissue, and replaces the corneal flap. Because the surface of the cornea, which contains NERVE endings, remains intact, there is almost no postoperative discomfort and results are immediately apparent. LASIK is most effective for hyperopia, astigmatism, and moderate myopia.
- Photorefractive keratectomy (PRK) was the original refractive LASER SURGERY. The eye surgeon uses an excimer laser to reshape the surface of the cornea. Results are not apparent until the cornea heals, which takes several weeks. There is some discomfort during the

HEALING phase. PRK is particularly effective for people who have large pupils or thin corneas, because it does not create a corneal flap, which reduces the likelihood of postoperative glare and halos at night.

- Automated lamellar keratoplasty (ALK) is similar in concept to LASIK, though the surgeon uses a microkeratome, a specialized surgical blade. The eye surgeon makes a flap in the cornea and removes minute segments of corneal tissue, then replaces the flap. As with LASIK, there is little discomfort during healing and results are apparent immediately. ALK is particularly successful for severe myopia.
- LENS replacement uses techniques perfected through 60 years of CATARACT EXTRACTION AND LENS REPLACEMENT surgery. The eye surgeon removes the natural lens and replaces it with one curved to accommodate for severe hyperopia or myopia. Multifocal lens implants allow the eye to adjust between close and distant vision.
- Phakic intraocular contact lens implantation places a permanent contact lens in front of or behind the natural lens to supplement its focusing ability. This approach preserves the focusing ability of the natural lens.

The eye surgeon may choose other methods, depending on an individual's refractive situation, age, and general health status. Not everyone with refractive errors is a good candidate for refractive surgery. It is important to consult with a qualified and experienced eye surgeon and to understand the potential risks and benefits of the different operations. Refractive surgery permanently alters the eye's structure, although subsequent operations can often refine the effects when they are not as expected. Severe refractive errors may require multiple procedures.

Risks and Complications

As with any surgery, a potential complication of refractive surgery is postoperative INFECTION that can range from mild discomfort to significant damage to the eye with resulting VISION IMPAIRMENT. Prompt treatment prevents further complications. Most eye surgeons have stringent follow-up procedures intended to detect operative complications before they cause eye problems; it is important to maintain the recommended follow-up procedures. Other common complications include dry eyes and seeing halos around lights at night. Procedures involving lens replacement carry the additional risks of excessive bleeding and RETINAL DETACHMENT, which can compromise vision. Complications particular to LASIK include irregularity in the corneal surface after the corneal flap heals and overgrowth of corneal tissue that requires subsequent surgery to remove.

Occasionally the outcome is not as desired or expected, perhaps as a consequence of complications during the operation or during the healing process. It is important for the eye surgeon to appropriately match the person with the procedure, which takes into consideration the nature and severity of the refractive error, the person's age and general health status, and the person's expectations. Despite the precision of computer-guided procedures, there remains an element of unpredictability that influences outcome. Some people may find their vision undercorrected and others overcorrected as a consequence of individual variation in eye structure, refractive error, and healing process.

Though the changes of refractive surgery are permanent, the effects on vision are not. Everyone eventually acquires PRESBYOPIA, a decrease in the ability to focus on near objects that is a function of change that occurs with aging. People who have had refractive surgery to correct astigmatism, hyperopia, or myopia will still need corrective measures for close vision as presbyopia develops. Nonsurgical solutions for presbyopia include contact lenses or reading glasses. Surgical solutions for presbyopia currently employ an approach called monovision, in which the eye surgeon undercorrects the vision in one eye for near focus. The refractive correction for the other eye is full, allowing for distant focus. The BRAIN does the work of switching between the eyes according to the vision needs.

Outlook and Lifestyle Modifications

Refractive surgery dramatically improves visual acuity for nearly everyone who has a successful surgical experience—that is, was properly

matched to the correct procedure, had the operation performed by a competent and experienced eye surgeon, and had an uncomplicated course of recovery. Some people are able to completely eliminate the need for corrective lenses. Many people do still require corrective lenses, though at much improved refractive correction and perhaps only for specific applications such as near or midrange vision.

Doctors do not know what, if any, long-term consequences may result from refractive surgery, as most of the laser techniques predominantly in use today have been available only since the 1990s. Routine eye care and ophthalmic examinations are especially important for people who have had surgery on their eyes, to detect complications from the surgery as well as eye conditions such as GLAUCOMA, AGE-RELATED MACULAR DEGENERATION (ARMD), and CATARACT.

retina The innermost layer of the EYE. The retina receives light images and converts them to NERVE impulses the OPTIC NERVE conveys to the BRAIN. The retina is two tissue-thin layers that together are less than ½ millimeter in thickness. The outer pigment layer provides a completely light-absorbing, nonreflective lining. The inner sensory layer contains the photoreceptors (rods and cones) responsible for vision. Rods detect only shades of gray though can register images of very low intensity. Cones detect color and detail.

Laid out flat, like a disk, the retina measures just under 2 inches in diameter. The primary work of vision takes place in an area about the size of a postage stamp called the macula. Most of the retina's 120 million rods and 6 million cones reside in the macula. A section of the central retina no larger than a pencil eraser, the macula, contains almost no rods and an abundance of cones and handles detail vision. A pencil-point depression within the macula, the fovea, has the highest concentration of cones.

The optic nerve enters the retina somewhat to the NOSE-side at the back of the eye, along with the ARTERY and VEIN that manage the retina's BLOOD supply. Vitreous humor, a gelatinous substance, fills the inner eye and holds pressure against the retina, keeping it smoothly and tightly adhered to the choroid.

The ophthalmologist can examine the surface of the retina using OPHTHALMOSCOPY. Under illumination the retina appears reddish orange. The optic nerve disk appears as a pale, pinkish circle. The macula, of similar size, appears as a darker and less distinct circular area with a depression, the fovea, in its center.

CONDITIONS THAT CAN AFFECT THE RETINA

AGE-RELATED MACULAR DEGENERATION (ARMD)	COLOR DEFICIENCY
NIGHT BLINDNESS	COLOR DEFICIENCY
RETINITIS PIGMENTOSA	RETINAL DETACHMENT
RETINOPATHY	RETINOBLASTOMA
	traumatic injury

For further discussion of the retina within the context of eye structure and function please see the overview section "The Eyes."

See also ELECTRORETINOGRAPHY; FLASHES; LENS; VISION IMPAIRMENT; VITREOUS DETACHMENT.

retinal detachment A separation of the RETINA from the choroid, the layer of the EYE's structure that nourishes and attaches the retina. Retinal detachment may occur as a result of TRAUMA TO THE EYE, AGE-RELATED MACULAR DEGENERATION (ARMD), VITREOUS DETACHMENT, RETINOPATHY of DIABETES, or surgery on the eye. Retinal detachment may also occur spontaneously, a circumstance more common in people with moderate to severe MYOPIA (nearsightedness).

Prompt treatment to reattach the retina is necessary to save vision.

Symptoms and Diagnostic Path

Retinal detachment does not cause PAIN or discomfort. Detachment may be gradual, in which case symptoms are progressive, or sudden, in which case loss of vision may be the only symptom. Symptoms of retinal detachment include

- seeing flashing lights or multiple FLOATERS
- the perception of a curtain or shadow dropping across the VISUAL FIELD, often from top to bottom though sometimes from the side

- blurred vision
- loss of VISUAL ACUITY

OPHTHALMOSCOPY to examine the interior of the eye provides the diagnosis.

Treatment Options and Outlook

Most often, the preferred treatment for reattaching the retina is surgery. The surgeon may use laser, photocoagulation (heat), or cryotherapy (freezing) techniques. Other approaches include injecting sterile silicone oil into the inner eye or injecting a sterile gas bubble (pneumotherapy) into the vitreous humor to hold the retina in place with pressure. A rapidly reattached retina often fully recovers without measurable loss of vision. Delay in reattaching the retina, or when the retina suddenly and completely detaches, often results in less successful vision preservation. An untreated retinal detachment results in permanent, complete loss of vision in the eye.

Risk Factors and Preventive Measures

People who have moderate to severe myopia (greater than – 8 diopters) are at increased risk for retinal detachment because of the eye's shortened length. Retinal detachment is also a complication of LASIK surgery, CATARACT EXTRACTION AND LENS REPLACEMENT surgery, and serious inflammatory conditions of the eye such as SCLERITIS. Retinopathy, in which extra blood vessels grow into the retina, also increases the risk for retinal detachment. Protective eyewear to reduce the risk of trauma to the eye can prevent trauma-related retinal detachment. In other circumstances, early detection and reattachment are the most effective measures to preserve vision.

retinitis pigmentosa The collective term for a group of hereditary disorders that result in progressive loss of vision. Retinitis pigmentosa generally begins with diminished night vision, as the degeneration affects primarily the rods (photoreceptors responsible for vision in dim light and for peripheral vision). Eventually the condition progresses to rods, and then cones, throughout the RETINA. In most people symptoms begin between the ages of 10 and 30, with complete loss of vision by around age 40.

When viewed through the ophthalmoscope, the areas of degeneration appear darker than the surrounding areas of retina. The diagnostic path may also include a DARK ADAPTATION TEST and ELECTRORETINOGRAPHY. There is no known treatment for retinitis pigmentosa. Several INHERITANCE PATTERNS are responsible for retinitis pigmentosa; doctors recommend GENETIC TESTING and GENETIC COUNSELING for family members when there is a diagnosis of this condition. Retinitis pigmentosa also may accompany a number of other hereditary syndromes.

retinoblastoma A cancerous tumor of the RETINA that most often occurs in children. Most retinoblastomas are hereditary and develop in early childhood, usually by age four. Some retinoblastomas are the result of new germline mutations though are not hereditary. About 70 percent of retinoblastomas involve only one EYE. Treatment in such cases is surgery to remove the EYE (ENUCLEATION), with placement of a PROSTHETIC EYE for cosmetic reasons. When retinoblastoma is bilateral (involves both eyes), treatment attempts to save vision while eradicating the CANCER. Treatment for bilateral retinoblastoma may include enucleation of one eye and cryotherapy or photocoagulation to reduce as much as possible the tumor in the other eye, with follow-up CHEMOTHERAPY or RADIATION THERAPY. Treatment is successful in about 90 percent of children when doctors detect the tumor before it metastasized beyond the eye. However, about 70 percent will experience second retinoblastomas by adulthood.

See also ADULT SURVIVORS OF CHILDHOOD CANCER; CANCER TREATMENT OPTIONS AND DECISIONS; GENE TESTING; GENETIC COUNSELING.

retinopathy A dysfunction of the RETINA in which new BLOOD vessels grow across the retina's surface. This growth causes the death of photoreceptors, the specialized cells (rods and cones) in the retina that receive lightwaves and convert them to NERVE impulses for transmission to the BRAIN. The blood vessels are also delicate and

prone to bleeding, which further damages the surface of the retina. The most common forms of retinopathy are the following:

- Retinopathy of DIABETES results from chronically elevated blood GLUCOSE levels. Retinopathy of diabetes takes one of two forms: proliferative, in which the new blood vessels that grow across the retina are unstable and bleed, or nonproliferative, in which existing blood vessels deteriorate and form aneurysms that rupture and bleed. Retinopathy of diabetes typically develops over decades, is more common in people who require INSULIN THERAPY, and is the most common cause of blindness in people under age 60.
- Retinopathy of prematurity occurs in some infants born earlier than 32 weeks of gestational age in whom the retinal blood vessels, which develop late in gestation, have not yet formed. In most infants, the blood vessels resume growth and establish normal retinal vasculature with no damage to vision. In some premature infants who have retinopathy, inadequate blood supply to the retina or abnormal vessel development can cause RETINAL DETACHMENT with resulting VISION IMPAIRMENT.
- Hypertensive retinopathy develops as a consequence of untreated or poorly managed HYPERTENSION (high BLOOD PRESSURE). Blood vessels in the retina, like blood vessels throughout the body, become stiff and inflexible as a result of the continuous pressure. This brittleness makes them susceptible to rupture, which floods the retina with blood.
- Central serous retinopathy, in which fluid accumulates between the retina and the choroid, causes the retina to swell and lift up from the choroid.

Symptoms and Diagnostic Path

Most often, retinopathy does not cause symptoms until eye damage becomes significant. When symptoms are present, they may include

- blurred or distorted vision
- diminished near vision for reading and other close focus
- FLASHES and FLOATERS
- sudden loss of vision

OPHTHALMOSCOPY typically reveals discolored areas of the retina that indicate diminished blood supply (pale) or bleeding (dark). The ophthalmologist may also be able to see frank bleeding or irregularities in the surface of the retina that indicate accumulated fluid. When the cause of the retinopathy is hypertension, there may also be PAPILLEDEMA (swelling of the OPTIC NERVE). Ophthalmoscopy in combination with health history generally provides the information the ophthalmologist needs to make the diagnosis.

Treatment Options and Outlook

Often retinopathy improves on its own, especially retinopathy of prematurity and central serous retinopathy. Retinopathy of diabetes or hypertension typically improves with tighter control of the underlying condition. When retinopathy improves, vision may return to its previous state or damage to vision may be minimal. Retinopathy that progresses leads to vision impairment, including total loss of vision. Central serous retinopathy tends to recur. Proliferative and nonproliferative retinopathy often require laser treatment.

Risk Factors and Preventive Measures

The key risk factors for most retinopathy are the underlying health conditions associated with the retinopathy. Preventive measures emphasize control of the underlying condition—maintaining stable blood glucose levels in retinopathy of diabetes, and healthy blood pressure in retinopathy of hypertension. Consistent PRENATAL CARE and attention to maternal health (notably SMOKING CESSATION) help reduce the risk for PREMATURE BIRTH. Regular ophthalmic examinations can detect retinopathy in its early stages, allowing therapeutic interventions to minimize damage to the eye.

retrobulbar optic neuritis INFLAMMATION of the OPTIC NERVE outside the globe of the EYE, between the eye and the BRAIN. Retrobulbar optic neuritis can result from INFECTION such as MENINGITIS or ENCEPHALITIS, as a consequence of toxic exposure,

and as a manifestation of MULTIPLE SCLEROSIS. Symptoms may include

- PAIN with eye movement
- diminished VISUAL ACUITY (blurred or dim vision)
- eye is tender to touch or pressure
- blind spots (scotomas)
- dulled colors

The diagnostic path includes visual acuity and VISUAL FIELD testing, OPHTHALMOSCOPY to examine the optic NERVE disk (which often becomes more pale), and MAGNETIC RESONANCE IMAGING (MRI) or COMPUTED TOMOGRAPHY (CT) SCAN of the brain when the doctor suspects multiple sclerosis or another neurologic cause. Most retrobulbar optic neuritis eventually goes away without treatment. The doctor may prescribe CORTICOSTEROID MEDICATIONS when the inflammation persists. Because retrobulbar optic neuritis is so often associated with multiple sclerosis, the doctor may recommend more extensive NEUROLOGIC EXAMINATION to determine whether this condition is the underlying cause. Recurrent or severe retrobulbar optic neuritis may result in permanent VISION IMPAIRMENT.

S

scleritis An INFLAMMATION of the sclera, the white fibrous outer layer of the EYE. The inflammation develops gradually, involving the connective tissue structure of the sclera. The scleritis may involve a small portion of the sclera (sectoral scleritis) or the entire globe of the eye (diffuse scleritis). Some people develop nodules that may become necrotic (cause tissue death). Necrotizing scleritis, with or without nodules, results in severe damage to the eye (including perforation) and often loss of vision. More than half of the people who develop scleritis also have connective tissue disorders, the most common associations being with RHEUMATOID ARTHRITIS and VASCULITIS.

CONDITIONS OFTEN ASSOCIATED WITH SCLERITIS

ANKYLOSING SPONDYLITIS	RHEUMATOID ARTHRITIS
SARCOIDOSIS	SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)
VASCULITIS	Wegener's granulomatosis

Deep, aching PAIN characterizes scleritis, often severe enough to disrupt sleep. Referred pain sometimes affects the jaw or cranial bones around the eye. The affected area of the sclera is erythematous ("bloodshot"), and the eye typically tears in response to light (PHOTOPHOBIA). The eye may protrude from the front of the orbit when scleritis involves the back of the eye. The diagnostic path typically includes SLIT LAMP EXAMINATION and OPHTHALMOSCOPY, and possibly ULTRASOUND to determine whether the inflammation involves the back of the eye.

Treatment is topical CORTICOSTEROID MEDICATIONS and oral NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS), which suppress inflammation as well as relieve pain. Eye drops to constrict the blood vessels in the eye reduce swelling and redness. Diffuse or severe inflammation may require a therapeutic course of systemic corticosteroid medication such as prednisone. Prompt diagnosis and treatment can preserve the eye and vision. However, permanent structural damage to the eye with resulting loss of vision is a significant risk even with treatment. Scleritis may recur when it is a manifestation of an underlying connective tissue or AUTOIMMUNE DISORDER.

scotoma An area of the RETINA in which there are few or no cones or rods, the specialized NERVE cells that convert light signals to nerve impulses, creating a blind spot in the VISUAL FIELD. Scotomas may represent healed injuries to the retina such as retinal tears or degeneration of the retina such as may occur with AGE-RELATED MACULAR DEGENERATION (ARMD) or GLAUCOMA. A simple test called the AMSLER GRID, a grid of equally spaced vertical and horizontal lines, detects scotomas.

slit lamp examination The examination of the outer EYE using a bright light focused into an elongated slit in combination with a biomicroscope. The examination takes place in a darkened room, with the person sitting on one side of the slit lamp and the ophthalmologist on the other side. The ophthalmologist moves the light across the surface of the eye to examine the inner eyelids, sclera, CORNEA, iris, and LENS. The ophthalmologist may also put drops in the eyes to dilate the pupils, then use the slit lamp to examine the structures at the back of the eye, such as the RETINA and OPTIC NERVE, as well. The bright light of the slit lamp is sometimes uncomfortable as it passes across the eye, especially with dilated pupils that allow the full

intensity of the light to enter the inner eye. The examination takes only a few minutes.

Snellen chart The familiar eye chart, featuring lines of letters and numbers that progressively decrease in size, to assess VISUAL ACUITY. Dutch ophthalmologist Herman Snellen (1834–1908) developed the chart in the 1860s. The top letter is typically E. A person with normal vision can read a one-inch letter from 20 feet away, designated as 20/20 vision. Each line on the chart represents a ratio of normal vision. A person who can see at 20 feet what someone who has normal vision could see at 60 feet has 20/60 vision. A REFRACTION TEST then determines the precise correction necessary to bring visual acuity as close to 20/20 as possible. To take a Snellen test, a person reads the smallest line possible with each eye separately (one eye covered) and both eyes together.

strabismus A condition, also called tropia, in which the eyes do not focus simultaneously on the same object. One EYE may turn inward ("cross-eye" or esotropia), or one eye may turn outward ("walleye" or exotropia). Congenital strabismus may occur with RETINOBLASTOMA or RETINOPATHY of prematurity and becomes apparent in the first few months after birth. Most strabismus develops in children between the ages of one and five. About half of the time the cause of strabismus in children is unknown (idiopathic) and not associated with any underlying condition.

In adults, strabismus may develop as a consequence of TRAUMA TO THE EYE, TRAUMATIC BRAIN INJURY (TBI), or STROKE. Adults may experience double vision (DIPLOPIA) or uncoordinated movements of the eyes. Adults also may acquire strabismus as a consequence of vision loss in one eye, which results in lack of visual signals that cue the BRAIN for MUSCLE movements of the eye. Common causes of acquired strabismus in adults include stroke, trauma, GRAVES'S DISEASE, and other surgery.

The diagnostic path includes comprehensive ophthalmic and NEUROLOGIC EXAMINATIONS. Timely treatment in children is essential to prevent AMBLYOPIA, in which the brain learns to perceive images from only one eye. This learning establishes the brain's vision pathways, and if untreated becomes a form of permanent vision loss. Strabismus treatment may include exercises or surgery to strengthen the eye muscles of the weak eye.

T

tonometry A test that measures INTRAOCULAR PRESSURE (the pressure within the EYE). The primary reason for tonometry is to screen for GLAUCOMA, a condition for which elevated intraocular pressure is a characteristic symptom. Increased intraocular pressure is also common with ORBITAL CELLULITIS and GRAVES'S OPHTHALMOPATHY. Tonometry is a standard component of the OPHTHALMIC EXAMINATION.

There are several methods of tonometry. The most commonly used are

- applanation, in which the ophthalmologist puts anesthetic drops in the eyes and then touches a device called a tonometer to the surface of the CORNEA to measure how much pressure it takes to depress the cornea
- noncontact, or air puff, in which the person stares at a focused light while a device blows a quick puff of air at the cornea, then measures the change in reflected light from the cornea

Elevated intraocular pressure, or intraocular HYPERTENSION, requires further evaluation to detect and correct the cause. Intraocular pressure that remains elevated damages or destroys the OPTIC NERVE, resulting in total vision loss in the affected eye.

See also OPHTHALMOSCOPY; SLIT LAMP EXAMINATION.

toxic optic neuropathy Damage to the OPTIC NERVE, RETINA, and other structures of the EYE as a SIDE EFFECT of medications or exposure to environmental or systemic toxins. Many substances can harm vision, and any substance that is a neurotoxin (damaging to the NERVOUS SYSTEM) has the potential to damage the optic nerve. Long-term cigarette smoking or ALCOHOL abuse, and especially a combination of these practices, causes various disturbances of vision and ocular function. Severe or chronic MALNUTRITION, notably vitamin B_{12} deficiency, also results in toxic optic neuropathy. As well, numerous medications cause temporary visual disturbances, among them sildenafil (color shifts) and antidepressants (distorted perception and VISUAL ACUITY).

POSSIBLE SOURCES OF TOXIC OPTIC NEUROPATHY

amiodarone	carbon monoxide
chloroquine	digoxin
ethambutol	ethanol (drinking ALCOHOL)
ethylene glycol (antifreeze)	industrial chemicals
isoniazid	lead
mercury	methanol (wood ALCOHOL)
methotrexate	NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS)
pyridoxine	quinine
radiation exposure	sulfonamide
tamoxifen	tobacco use
ultraviolet light	

Symptoms and Diagnostic Path

Most often toxic optic neuropathy develops slowly as the consequence of cumulative exposure. Symptoms may include

- dimness and diminished clarity
- altered color perceptions (dyschromatopsia)
- blind spots in the visual field (SCOTOMA)
- PHOTOPHOBIA (extreme sensitivity to light)
- DIPLOPIA (double vision)

Symptoms progressively worsen with continued exposure to the toxic substance. Symptoms may begin in one eye though nearly always

involve both eyes as the effects of the toxic exposure continue to develop.

Treatment Options and Outlook

Treatment is immediate cessation of exposure to the causative agent, though it is unwise and potentially harmful for individuals to stop taking prescribed medications without consulting their physicians. In many circumstances the damage is reversible and normal vision returns after exposure to the toxin ends, though it may take several weeks to several months for the damage to heal.

Risk Factors and Preventive Measures

The primary risk for toxic optic neuropathy is exposure to ocular toxins. Because these are numerous and may be prescription or over-the-counter medications, it is important to know the possible side effects of all medications individually as well as in combination. Avoiding ocular toxins or stopping medications that cause vision disturbances helps prevent permanent damage to the eyes.

tropia See STRABISMUS.

uveitis INFLAMMATION of the uveal structures of the EYE, which include the iris, ciliary body, and choroid. Uveitis most commonly affects the front of the eye (anterior uveitis) though may involve specific segments of the eye or the uveal tract throughout the eye (diffuse uveitis). Symptoms can vary from mild to severe and may include blurred vision, PHOTOPHOBIA (extreme sensitivity to light), burning sensation, prominent blood vessels ("bloodshot" appearance) radiating from the iris into the sclera, excessive tearing, and PAIN. GLAUCOMA is a serious potential complication of uveitis that can lead to VISION IMPAIRMENT.

The diagnostic path includes SLIT LAMP EXAMINATION and OPHTHALMOSCOPY. Treatment includes cycloplegic drops to immobilize the iris, which helps subdue the inflammation, and corticosteroid drops. Some people need to use corticosteroid drops up to several months. With prompt treatment, most people recover fully and without damage to the eye or to vision. Chronic uveitis may occur with certain AUTOIMMUNE DISORDERS such as INFLAMMATORY BOWEL DISEASE (IBD), RHEUMATOID ARTHRITIS, and REITER'S SYNDROME.

V–X

visual acuity The ability to see objects clearly and sharply. Visual acuity assesses central vision and represents the function of the CORNEA, iris (pupil size), LENS, and RETINA. The SNELLEN CHART, which presents lines of letters of diminishing size, is the standard measure of visual acuity. Environmental factors that influence visual acuity include lighting and contrast. The most common disturbances of visual acuity are REFRACTIVE ERRORS such as MYOPIA (nearsightedness), HYPEROPIA (farsightedness), and ASTIGMATISM (blurred vision). PRESBYOPIA, age-related changes in the cornea's FLEXIBILITY, affects near-vision visual acuity.

See also NIGHT BLINDNESS; VISION IMPAIRMENT.

visual field The total area or scope of vision. EYE care specialists map the visual field by measuring the boundaries of peripheral vision in degrees from the point of central vision. A normal field of vision is 135 degrees vertically (60 degrees up and 75 degrees down) and 160 degrees horizontally (100 degrees outward and 60 degrees inward). Everyone has a blind spot of about 10 degrees in the direct center of vision, the point at which the OPTIC NERVE enters the RETINA (the optic disk). The optic disk contains no rods or cones. Binocular vision (the ability to see with both eyes) compensates for each eye's blind spot with overlapping visual fields for each eye. People who have monocular vision (the ability to see only through one eye) learn to accommodate for the blind spot by frequently moving the eye to scan the field of vision.

There are several methods for measuring visual field. The simplest though least precise is for the eye care specialist to sit across from the person and, with the person looking at a fixed point the eye care specialist slowly moves a hand or an object such as a pen. The person tells the point at which he or she can see the object. The eye care specialist may repeat this procedure several times for each eye, measuring peripheral vision from each side, above, and below. Other methods may use computerized flashing lights with the person looking at a fixed point (target) within a contained dome. The person presses a button for each light he or she sees, and the eye care specialist creates a map of each eye's visual field that allows calculation of visual field percentages.

CONDITIONS THAT CAN AFFECT THE VISUAL FIELD

AGE-RELATED MACULAR DEGENERATION (ARMD)	DIABETES
GLAUCOMA	GRAVES'S OPHTHALMOPATHY
HYPERTENSION	MULTIPLE SCLEROSIS
RETINAL DETACHMENT	RETINITIS PIGMENTOSA
RETINOPATHY	SCLERITIS
STROKE	TRAUMA TO THE EYE
	tumors of the eye or BRAIN

vision health Personal care for the eyes to protect the eyes and preserve vision. The two most important elements of vision health are EYE protection and regular ophthalmic examinations.

Protective Eyewear

Most injuries to the eyes are preventable by wearing appropriate protective eyewear, which ranges from sunglasses to protect the eyes from sunburn to specialized eyewear for specific needs. Such needs might include

- ultraviolet exposure (sunlight, welding)
- sports (protection from contact; protection when swimming or diving)

- eyeglasses (polycarbon lenses for optimal protection against shattering)
- working with power tools
- exposure to environment with high airborne pollutants (such as sawdust)

Though regular eyeglasses and sunglasses provide some protection against injury, they do not provide adequate protection when working with power tools, during recreational and athletic activities, and for specialized needs (such as welding).

Regular Ophthalmic Examinations

In the United States, basic screening for eye problems takes place shortly following birth (for infants born in hospitals and birthing centers), at regular well-child check-ups, through public school vision screening programs, and as part of the ROUTINE MEDICAL EXAMINATION. People who have normal vision require only ophthalmic examinations, the need for which becomes more frequent with advancing age as the likelihood of health conditions that affect vision increases with age. People who have eye conditions, REFRACTIVE ERRORS, HYPERTENSION, DIABETES, and other chronic health conditions need regular ophthalmic examinations as their physicians or eye care providers recommend.

See also CORRECTIVE LENSES; OPHTHALMIC EXAMINATION; VISION IMPAIRMENT.

vision impairment The uncorrectable loss of vision. About 12 million Americans have vision impairments that prevent them from participating in occupations and activities that have requirements or legal standards for VISUAL ACUITY (the ability to see clearly) and VISUAL FIELD (the scope of peripheral vision). People who have functional vision, also called low vision, generally have visual acuity correctable to between 20/40 and 20/400. More than a million Americans are legally blind. Vision impairment may be temporary or permanent.

LEGAL BLINDNESS

VISUAL ACUITY uncorrectable to 20/200 in the better eye, or
VISUAL FIELD uncorrectable to greater than 20 degrees

Symptoms and Diagnostic Path

In children, the symptoms of vision impairment may be difficult to detect. Those that are obvious include

- STRABISMUS, which indicates AMBLYOPIA
- squinting
- holding objects very close to the face
- sitting very close to the television
- frequent headaches

Routine screening for EYE and VISION HEALTH takes place at birth (for infants born in hospitals and birthing centers), during routine well-child visits, and through school vision screening programs. The diagnostic path for children in whom screenings detect potential vision problems includes a complete OPHTHALMIC EXAMINATION with testing for visual acuity, REFRACTIVE ERRORS, and visual field as the child's needs require. Eye care specialists use assessment methods appropriate for

RECOMMENDED ROUTINE EYE EXAMS

Age	Eye Exam Frequency
Birth to 2 years	screening at well-child visits
3 to 5 years	screening every one to two years at well-child visits
6 to 19 years	screening at routine medical exam; ophthalmic exam as needed
20 to 29 years	ophthalmic exam once during this time
30 to 39 years	ophthalmic exam every five years
40 to 65 years	ophthalmic exam every two years
65 years and older	ophthalmic exam every year

the child's age, comprehension, and communication abilities.

Sudden loss of vision in one eye or both eyes is an emergency that requires immediate medical care.

Adults are generally able to perceive symptoms of vision impairment, though when onset is gradual the symptoms are less obvious (though may be more apparent to co-workers, friends, and family members). Sometimes the first indication of a serious vision impairment comes with a misfortune such as a motor vehicle accident, especially among older adults who do not notice or do not acknowledge diminishing vision. Symptoms of vision impairment include

- dimness or changes in color perception
- need to hold objects closer or farther away from eyes
- frequent headaches or squinting
- loss of sharpness or clarity of vision
- difficulty reading
- difficulty seeing at night or in low light
- the need for bright lighting

The diagnostic path includes a comprehensive ophthalmic examination to assess visual acuity, visual field, and refractive error as symptoms indicate. Further diagnostic procedures may be necessary when the underlying cause of vision impairment appears to be a health condition other than a problem with the eyes, such as MULTIPLE SCLEROSIS or DIABETES.

COMMON CAUSES OF VISION IMPAIRMENT

AGE-RELATED MACULAR DEGENERATION (ARMD)	ALBINISM
AMBLYOPIA	CATARACT
central serous RETINOPATHY	congenital CYTOMEGALOVIRUS (CMV)
congenital disorders	corneal deterioration
GENETIC DISORDERS	GLAUCOMA
INFECTION	MULTIPLE SCLEROSIS
RETINAL DETACHMENT	RETINOBLASTOMA
retinopathy of DIABETES	retinopathy of HYPERTENSION
retinopathy of prematurity	STROKE
TRAUMA TO THE EYE	uncorrectable MYOPIA

Treatment Options and Outlook

Treatment depends on the cause of the VISION IMPAIRMENT. CORRECTIVE LENSES or REFRACTIVE SURGERY typically improve vision in conditions such as severe MYOPIA or ASTIGMATISM, even if these measures cannot fully restore normal vision. Surgery is often the solution for vision impairment due to CATARACT, CORNEAL INJURY or deterioration, RETINAL DETACHMENT, and some forms of GLAUCOMA. Medications can control other forms of glaucoma.

Vision impairment has a significant effect on QUALITY OF LIFE. There are numerous assistive devices for people who have functional limitations as a result of vision impairment. Most people who have vision impairments are able to participate, with reasonable accommodations and sometimes creative effort, in work and recreational activities they enjoy. Continued advances in technology generate new treatment approaches that may offer improved vision.

Risk Factors and Preventive Measures

Many health conditions can contribute to or cause vision impairment. The most significant are diabetes, HYPERTENSION, and glaucoma. Early diagnosis and appropriate treatment can limit or prevent damage to the eyes and to vision. Eye protection, such as sunglasses and safety eyewear for activities with risk for impact or debris, is a key preventive measure. More than 40,000 preventable eye injuries occur every year. Routine ophthalmic examinations detect eye problems early, allowing for the most appropriate and effective interventions to preserve vision.

vitrectomy An OPERATION to remove the vitreous humor from within the EYE as treatment for RETINAL DETACHMENT, vitreous HEMORRHAGE (bleeding into the vitreous humor), RETINOPATHY, and foreign body penetration. In vitrectomy, the ophthalmologist makes three tiny incisions in the sclera (white portion) of the eye for the insertion of a cutting instrument, a light, and an infusion tube. The cutting instrument rotates to gently pull the vitreous humor out of the eye, and the ophthalmologist replaces it with a saline-based solution at the same rate to maintain pressure and stability within the

eye. Recovery from uncomplicated vitrectomy takes about two to three weeks. Complex vitrectomy, such as when there is retinal detachment or a macular tear, may require additional methods to help the eye heal. Recovery from complex vitrectomy may take several months, though usually preserves vision and the eye.

See also AGE-RELATED MACULAR DEGENERATION; CATARACT EXTRACTION AND LENS REPLACEMENT; CORNEA TRANSPLANTATION; SURGERY BENEFIT AND RISK ASSESSMENT.

vitreous detachment The separation of the vitreous humor, the gelatinous substance within the EYE, from the RETINA. Vitreous detachment commonly occurs with advancing age as the vitreous humor thins and takes on more of a liquid consistency. By itself vitreous detachment is harmless and has no effect on vision, though it typically produces FLOATERS (fragments of tissue that float through the vitreous humor). Vitreous detachment with accompanying flashes of light or large numbers of floaters may indicate RETINAL DETACHMENT, an ophthalmologic emergency that requires immediate treatment.

See also VITRECTOMY.

xanthelasma Deposits of fatty plaque that form blisterlike lesions on the eyelids, usually the upper eyelids near the corner of the NOSE. The lesions are yellowish in color and often indicate HYPERLIPIDEMIA (elevated BLOOD levels of cholesterol and triglycerides). Though harmless, the lesions can cause the eyelid to droop, obscuring vision when an upper lid and interfering with lid closure when a lower lid. A plastic surgeon can remove the lesions in a simple outpatient OPERATION, though the lesions tend to recur, particularly when blood lipid levels remain high.

THE INTEGUMENTARY SYSTEM

The integumentary system encloses the body, protecting it from, as well as allowing its interactions with, the external environment. Physician specialists who treat conditions of the SKIN, HAIR, and NAILS are dermatologists. This section, "The Integumentary System," presents an overview of the structures and functions of the integumentary system, a discussion of dermatological health and disorders, and entries about the health conditions that can affect the skin, hair, and nails.

Structures of the Integumentary System

SKIN
- epidermis
- dermis
- subcutaneous layer

SWEAT GLANDS
- eccrine sweat glands
- apocrine sweat glands

HAIR
- follicle
- shaft

SEBACEOUS GLANDS
- sebaceous
- ducts

NAILS
- cuticle
- nail
- nail bed
- matrix
- (nail root)

Functions of the Integumentary System

The integument, from the Latin word for "cloak," covers the body. Its structures—the SKIN, HAIR, and NAILS—form the image the body presents to the outside world. Its functions—protective barrier, tactile perception, temperature regulation, IMMUNE RESPONSE—enable the body to survive in that outside world.

The foundation of the integumentary system is the skin, which, as the body's largest organ, accounts for 15 percent of the body's weight. It sheaths the body in protective insulation from scalp to sole, coating every stretch and fold between. The skin's three layers—epidermis, dermis, and subcutaneous layer—form the interface between the body's internal and external environments. The endless exchange of information is so wearing that the skin completely replaces its outermost layer, the epidermis (about 36,000 square inches of surface area), every three to four weeks. What looks remarkably the same from day to day is, in reality, always changing.

In the beginning Attesting to the skin's importance for survival and function, the skin and the BRAIN are the first two distinctive organs to emerge during embryonic development. The cells of each arise from the primitive neural crest, also called the neuroectoderm. By three weeks of gestational age the neural crest differentiates. The cells that migrate inward become NERVE cells, forming the brain and SPINAL CORD. The cells that migrate outward become the two major cell types of cells that form the skin: keratinocytes and melanocytes.

By seven weeks gestational age the skin develops hair follicles that, six weeks later, begin to cover the head with hair. At 20 weeks gestational age that hair coat, called lanugo, has spread to cover the entire body. Some babies, especially those born prematurely, still sport this coat at birth, which is often disconcerting to anxious parents but quickly falls away. The formation and function of the sebaceous glands parallels that of the hair follicles. As hair begins to sprout, the sebaceous glands secrete a thick, ointmentlike precursor to sebum, called vernix, that covers the skin's surface. Vernix establishes a waterproof barrier that protects the skin as the FETUS floats in AMNIOTIC FLUID. Also by 20 weeks the skin contains SWEAT GLANDS, eyelashes and eyebrows, fingernails and toenails, and the unique surface ridges on the fingertips that will become fingerprints.

Renewal and protection: the epidermis The primary cells of the skin's surface layer, the epidermis, are melanocytes, which produce the pigment melanin, and keratinocytes, which produce the fibrous protein keratin. Both types of cells arise from the base level of the epidermis, the stratum germinativum ("birth"), also called the basal level or the Malpighian level. As the Latin name implies, this level germinates, or originates, cells. Melanocytes remain in the stratum germinativum for all of their existence. Keratinocytes migrate upward to the stratum corneum ("horny"), the cornified or hardened surface level of the epidermis.

Melanocytes produce melanin, the pigment that gives color to the skin, hair, and eyes (iris). This color has a purpose: melanin is the skin's primary protection against the sun's ultraviolet rays. It absorbs ultraviolet lightwaves, preventing them from causing damage to cell structure and function. Melanocytes store the enzyme tyrosinase, which other cells in the body produce, and acquire the amino acid tyrosine from the circulating blood. The tyrosinase catalyzes a series of chemical actions that convert tyrosine to two tones of pigment: eumelanin (black-brown pigment) and pheomelanin (yellow-brown pigment). The melanocytes package these pigments into granules collectively called melanin.

Melanocytes also pigment cells in other organs. When the neural crest differentiates early in embryonic development, some melanocytes migrate with the cells that form the structures of the brain. A dense population of melanocytes settles in a structure in the midbrain, the substantia nigra (a name that means "black substance"). The melanocytes pigment specialized cells in the substantia nigra that produce DOPAMINE, a brain NEUROTRANSMITTER essential to neuromuscular function. When melanocytes in the skin slow melanin production, the result may be depigmentation disorders such as VITILIGO or white hair. Though often distressing, these consequences are not serious threats to health and life. When melanocytes in the substantia nigra stop producing melanin, however, the substantia nigra stops producing dopamine, and the body stops moving, a degenerative condition called PARKINSON'S DISEASE.

Keratinocytes produce two proteins: keratin, a fibrous substance, and cytokine, an IMMUNE RESPONSE mediator. After they mature in the stratum germinativum, keratinocytes pick up melanin granules and begin their migration to the surface. The three and a half week journey to the stratus corneum is a final rite of passage that literally squeezes the life from the keratinocytes. During this passage, the keratinocytes undergo denuclearization, a process of nucleus deterioration that gradually diminishes cell function. The upswell of continuous movement that carries the keratinocytes along compresses their remaining cell structure. By the time the keratinocytes break through to the surface, they are flat, brittle, and lifeless husks of keratin. They layer tightly against one another, forming the tough covering the skin presents to the outside world. The friction of interacting with the external environment brushes them loose and they fall away, a process called exfoliation. Keratinocytes that funnel through the hair follicles become hair shafts.

WHY A WOUND THAT FAILS TO HEAL MAY SUGGEST SKIN CANCER

The epidermis completes a total turnover of cells every 24 to 28 days, meaning that this outer layer of the SKIN is fresh and new about once a month. Any skin wound that takes longer than three or four weeks to heal represents an area of cells that is growing at its own pace, distinct from the other skin cells—in short, a CANCER.

Structure, sustenance, and sense: the dermis The skin's middle layer, the dermis, nurtures and supports the skin. Primarily fibrinogens create a collagen matrix that supports an abundant and effusive network of blood vessels, nerves, and glands (sweat and sebaceous). These structures are elemental to the body's heat regulation mechanisms. The dermis also contains the Langerhans cells, the gatekeepers of the SKIN-ASSOCIATED LYMPHOID TISSUE (SALT) that are the front line of the body's immune response.

The tiny blood vessels—arterioles and venules—that web through the dermis cause the skin to flush when the body is too warm. This function of heat regulation uses the BLOOD vessels for conduction heat dispersal, dilating them to bring a flood of blood to the cooler temperatures near the surface. The vessels contract when body temperature returns to an acceptable range, send-

ing the blood back within the body's core. This same mechanism also responds to strong emotions such as fear or embarrassment, similarly sending blood rushing to the skin. The blood supply of the dermis also nourishes the epidermis, supporting the perpetual production of new cells in the stratum germinativum.

About 5 million sweat glands aid both temperature and fluid regulation, dripping out about 500 milliliters of somewhat salty water every hour. Most of this moisture evaporates without conscious awareness of its presence. Sweating becomes an obvious event only when it becomes profuse, as with intense exercise or heat, or in conditions such as HYPERHIDROSIS. The eccrine sweat glands secrete their fluid directly to the surface of the skin through sweat pores. The apocrine sweat glands, found primarily in the axillae (underarms) and groin areas, secrete their fluids into the hair follicles. Sweat from the eccrine glands is water and electrolytes (salts), while that from the apocrine glands contains lipids and proteins to help it mix with the sebum in the hair follicles. These extra substances account for the familiar odor of sweat as well as the yellowish stains sweating leaves in the underarm areas of clothing.

THE SUNLIGHT VITAMIN

Though the negative consequences of ultraviolet light get the most press, sunlight is a valuable resource for strong bones and TEETH. The dermis contains ergosterol, a chemical that ultraviolet light converts into vitamin D, which the body needs to use calcium to build BONE and tooth enamel.

Millions of specialized nerve endings reside within the dermis, gathering data about temperature, humidity, motion, and contact, which they transmit to the NERVOUS SYSTEM. The skin is the organ of tactile perception, the sense of touch. The highest concentrations of tactile receptors are in the fingertips, the lowest on the soles of the feet. The key structures that detect touch are the discs of Merckel (light touch) and the corpuscles of Meissner (moderate touch), specialized nerve endings that transmit impulses to specially dedicated regions of the cerebral cortex that interpret the nerve messages and initiate the appropriate responses. The structures that detect heavier pressure, the corpuscles of Ruffini and the Pacinian corpuscles, reside deeper in the dermis, near or extending beyond the subcutaneous border.

Cushion and connection: the subcutaneous layer The subcutaneous layer, also called the hypodermis, contains mostly adipose tissue (body fat) and some connective tissue. The adipose tissue warehouses the excess calories the body converts to fat, varying in thickness to accommodate this stored energy source. A rich network of blood vessels and nerves permeates the subcutaneous layer, supplying nourishment to all layers of the skin and conducting nerve impulses from sensory receptors and other nerve structures. The subcutaneous layer gives shape and context to the skin, softening the protrusions and angles of the underlying musculoskeletal structures. It also cushions those underlying structures from the multitude of minor traumas the body's surface experiences every day.

The connective tissue of this deepest layer of the skin binds the upper skin layers to the internal structures of the body, overlaying the muscles. Fibers of connective tissue lace from the subcutaneous layer upward into the epidermis and downward to the musculoskeletal structures, holding the skin in place. These connections allow the skin to respond to the movement of muscles beneath it. In locations such as the knuckles, the connections are loose (appearing deeply creased) to accommodate substantial motion. In the face, by contrast, the skin tethers tightly to the underlying structures. When the facial muscles move the skin on the face moves, too, forming facial expressions.

The hair Hair has different characteristics and functions, depending on its location on the body. Though in many other mammals hair may serve for protection and heat regulation, in humans hair has mostly lost these purposes. The exceptions are the hair on the head and a man's unshaven beard, which help preserve heat and shelter the skin from sunburn. Hair in other locations has specific functions. Hair in the auditory canal and in the nasal passages helps move debris to the outside of the EAR and NOSE, respectively. The eyebrows keep sweat from running into the eyes, and the eyelashes help prevent environmental debris such as dust or pollen particles from entering the eyes.

Deep at the base of the hair follicle within the dermis (middle layer of the skin) is the hair root, which forms the cells that will become the hair fiber. At their formation, hair cells are pliable, living, and colorless. The new cells that emerge from the root divide, pushing the cells that preceded them upward into the hair follicle. As the cells rise, they move beyond the range of the blood vessels that bring nourishment to the hair root and so die.

By the time hair cells rise above the surface of the skin, they are hard and compressed into an elongated, two-layer fiber. The inner layer, the cortex, is about three or four cells thick, composed of melanocytes and keratinocytes. Melanocytes form the melanin (pigment) that gives hair its color and. Large, numerous melanocytes result in black or brown hair; small, scattered melanocytes result in red or blond hair. A reduction in the number of melanocytes results in gray or white hair. The keratinocytes produce the keratin that gives hair its structure. A single layer of cells, the cuticle, encases the cortex. The rounder the hair fiber, the straighter the hair. Curly or kinky hair fibers are flat.

A hair follicle on the scalp typically grows hair for three to five years, then enters a period of dormancy that lasts a few months after which time it drops the hair and the growth cycle begins anew. Some people can grow hair for longer, up to seven or eight years, while others have a shorter growth period. The amount of time hair grows influences though does not regulate the hair's length; a person with a short growth period can have hair that grows rapidly.

Between 10 and 20 percent of the body's hair follicles are dormant at any one time. Hair follicles elsewhere on the body have shorter growth cycles than those on the head. The hairs of the eyebrows regenerate every 100 days or so, for example. An individual's genetic composition determines the shape, color, and length of hair fibers. The cells of the hair fibers within most of the hair follicle and visible above the skin's surface are dead and do not require nourishment or have sensory capability. Their keratin content and cuticle layer keeps them attached to the body.

Fingernails and toenails Keratin also gives the fingernails and toenails their shape and hardness. The nails cover the top portion of the fingers and toes. Though they may appear to have little more function than to serve as decorative platforms, the nails give the fingers (and to more limited extent, the toes) the ability to grip, pry, and scratch. The nails also give firmness and STRENGTH to the ends of the fingers, and help protect the sensitive fingertips.

Health and Disorders of the Integumentary System

The skin performs its myriad functions with remarkable consistency. Because it replaces its outer layer every three to four weeks, the skin remains relatively healthy for most of the lifespan. However, well over a thousand disorders, diseases, and conditions can affect the skin, hair, and nails. While a few can cause permanent tissue damage or even death, most are fairly benign.

Traditions in Medical History

For millennia the internal structures of the body mystified and confounded healers and physicians. The skin, however, was right there on the outside of the body for all to see and touch. The skin's accessibility gave it a perceived, and erroneous, simplicity as nothing more than the body's covering. Not until the electron microscope made it possible to explore the molecular structures of the body did scientists begin to understand the true complexity and intricate functions of the skin.

Today doctors recognize that the skin is a complex and multifunctional organ. Its appearance reveals much about the body's internal functions and a person's health status. Numerous systemic health conditions reveal or manifest themselves through changes in the skin, hair, and nails. Discoloration of the skin, for example, may suggest SUNBURN (red), JAUNDICE and LIVER disease (yellow), or cardiovascular or pulmonary disease (cyanotic blue). Variations on discoloration accompany numerous rashes. The characteristics of skin eruptions are often unique to specific diseases, such as the pustules of CHICKENPOX and the papules of MEASLES. Disturbances of the fingernails and toenails may similarly portend underlying health conditions such as iron-deficiency ANEMIA (koilonychia or spooning) or EMPHYSEMA (yellow nail syndrome). And hair loss, always emotionally distressing, may be a harbinger of undiagnosed thyroid disease or toxic exposure.

Breakthrough Research and Treatment Advances

Among the most exciting advances in dermatology are new techniques in SKIN REPLACEMENT and new laser technologies, which vastly extend treatment options for a wide spectrum of health conditions involving the skin. Skin replacement techniques such as synthetic skin and tissue expansion promise new hope for reconstruction following severe BURNS, trauma, and CANCER surgery. Refinements in laser technology allow dermatologists and surgeons to finely pinpoint potentially damaging or deadly cancer cells to eradicate them without destroying adjacent tissues. Lasers also offer potential relief from severe, disfiguring dermatologic conditions such as PSORIASIS and ACNE. As well, knowledge emerging from HUMAN GENOME mapping is helping researchers identify the causes of persistent or debilitating conditions such as vitiligo and PEMPHIGUS.

Among the greatest successes in modern medicine is the virtual elimination of skin cancer as a threat to life. Basal cell carcinoma and squamous cell carcinoma, the most common skin cancers, are nearly 100 percent curable with early detection and treatment. Dermatologists diagnose these cancers in 1 million Americans each year. Health experts attribute the success in reducing serious consequences and death from these cancers to nearly nil to the combination of effective sunscreens to prevent the sun damage that causes these skin cancers and improved techniques for detecting and removing cancerous and precancerous lesions.

The rapid and continual regeneration of the epidermis intrigues researchers, who continue to explore the molecular foundations of this function. Some scientists believe that there are correlations between KERATINOCYTE replication and stem cells that could hold important clues to understanding what determines how a cell becomes specialized for certain functions. Stem cells have the unique ability to differentiate, or become various kinds of particular cells, depending on the stimulation they receive. Researchers involved in this line of investigation are hoping to find ways to redirect keratinocytes to form other kinds of cells, which has exciting implications for guiding the body to heal itself by growing healthy tissues to repair or replace diseased organs and structures.

A

acne INFLAMMATION of the SKIN's sebaceous structures, also called acne vulgaris, that results in eruptions on the skin surface commonly called pimples, whiteheads, and blackheads. Acne occurs when excessive sebum traps BACTERIA and skin cells, clogging the follicles. The clogged follicles provide an ideal incubator for the bacteria *Propionibacterium acne,* which is normally present on the surface of the skin where continuous exposure to the air keeps it in check. Within the airless environment of a clogged hair follicle, however, these anaerobic bacteria, which do not require oxygen, thrive.

Acne is most common in PUBERTY and is a consequence, most doctors believe, of the natural surge in sex HORMONE production, notably TESTOSTERONE, that heralds the onset of puberty. Testosterone stimulates the sebaceous glands surrounding the HAIR follicles, increasing their production of sebum, a thick, oily substance that helps lubricate the skin. Women experience hormonal changes during MENSTRUATION, PREGNANCY, and MENOPAUSE that may cause acne outbreaks, because estrogen suppresses sebum production. Newborn infants may develop acne during the first few weeks of life, a reaction to the surge of hormones the infant receives from his or her mother in the few days before birth. Contrary to popular belief, foods high in fats or sugars, such as french fries or donuts, have little if any influence on acne. However, cosmetics and oily products applied to the skin that block the sebaceous structures can contribute to or aggravate acne outbreaks.

Acne commonly erupts on the face, upper back, and chest as these areas contain large numbers of hair follicles. Acne seldom affects scalp follicles. An outbreak begins as small, reddened bumps, called comedones or papules, that may hurt or itch. As the sebaceous structures become more inflamed, the bumps enlarge into closed (whiteheads) or open (blackheads) lesions. Lesions that form near the surface of the follicles are pimples; those that expand below the surface of the skin are nodules or cysts. The most serious form of acne is nodulocystic acne, in which numerous nodules and cysts form deep within the follicles though inflammation that extends above the skin's surface. Nodulocystic acne typically leaves scars or pits after the lesions heal, and may extensively damage the skin.

Symptoms and Diagnostic Path

The symptoms of acne are its characteristic bumps and lesions, making diagnosis fairly straightforward. Doctors diagnose acne on the basis of its appearance and the hormonal stages the individual may be going through. Acne that does not fit the characteristic presentation may be a symptom of an endocrine disorder that allows elevated testosterone levels, such as POLYCYSTIC OVARY SYNDROME (PCOS) or CUSHING'S SYNDROME. Laboratory tests to measure hormone levels can assess this possibility. Rarely, the doctor may choose to BIOPSY several lesions to confirm the diagnosis.

Treatment Options and Outlook

Treatment for acne targets reducing inflammation, sebum production and accumulation, and the presence of infective agents such as *P. acne*. Products may be topical (applied to the affected areas of the skin for localized effect) or systemic (medications taken by mouth for generalized effect). *P. acne* tends to develop resistance to antimicrobial products over time, making it necessary to switch among medications for optimal effectiveness. Acne is self-limiting and will improve over time without treatment, though severe acne may leave

scars. Products to treat mild to moderate acne are available without a doctor's prescription. Prescription-only medications, such as topical and oral antibiotics, are necessary for moderate to severe acne. Most people use several kinds of products concurrently.

Over-the-counter products and self-care Products available without a doctor's prescription to treat acne generally contain astringents, exfoliants, and antimicrobials, sometimes in combination with one another. The common product Clearasil, for example, combines resorcinol, which slows the production of keratocytes, and sulfur, an antimicrobial. Such products cleanse excess oils, debris, and dead cells from the skin. Antiseptic or antimicrobial substances help suppress *P. acne* and other bacteria normally present on the skin, reducing the potential for INFECTION and inflammation.

COMMON INGREDIENTS IN OVER-THE-COUNTER ACNE PRODUCTS

Product	Actions
acetone	astringent
ALCOHOL	antimicrobial
benzoyl peroxide	antimicrobial, exfoliant
lactic acid	exfoliant, mild antimicrobial
resorcinol	exfoliant
salicylic acid	exfoliant, astringent
sulfur	antimicrobial

Prescription medications The two general categories of medications doctors prescribe for acne are antibiotics and retinoids, in topical and oral forms. ANTIBIOTIC MEDICATIONS target bacteria such as *P. acne*. Oral antibiotic therapy may extend over six months or longer, at doses lower than those typically prescribed to treat acute infections.

Isotretinoin causes BIRTH DEFECTS. Current practice standards require two negative PREGNANCY tests and use of reliable CONTRACEPTION (such as oral contraceptives) before dermatologists may prescribe isotretinoin therapy for women of childbearing age.

In people who have severe or pitting acne, treatment with oral isotretinoin nearly always ends further acne outbreaks because the isotretinoin permanently alters the structure and function of the sebaceous structures. However, oral isotretinoin has numerous, and potentially serious, side effects that make it a treatment option when other methods have failed to control the acne. All of the retinoids can cause BIRTH DEFECTS; women who are or could become pregnant should not use these medications. Oral contraceptives (birth control pills) often improve acne that follows the MENSTRUAL CYCLE.

COMMONLY PRESCRIBED MEDICATIONS FOR ACNE

Antibiotics	
erythromycin (topical and oral)	minocycline (oral)
tetracycline (topical and oral)	doxycycline (oral)
sulfacetamide (topical)	
Retinoids	
isotretinoin (topical and oral)	tretinoin (topical)
adapalene (topical)	tazarotene (topical)

Outlook Acne is self-limiting. Most acne ceases when the body's hormone levels stabilize. For adolescents, this occurs at the culmination of puberty, generally by the late teens (females) or early twenties (males). In women, acne outbreaks may occur regularly with the menstrual cycle. Acne related to the hormonal changes of pregnancy generally goes away within three months of childbirth. Acne is uncommon in postmenopausal women.

Risk Factors and Preventive Measures

Because acne results from a convergence of factors, key among them hormonal shifts in the body, there are no known measures for preventing its occurrence. Many myths have prevailed through the years about the relationship between foods and acne. Though nutritious eating habits are important for overall health and development as well as the skin's general health, foods do not influence the course or severity of acne. Similarly, though poor hygiene contributes to numerous problems with the skin and may exacerbate acne by encouraging the growth of bacteria, it does not in itself cause acne.

Diligent daily hygiene, such as gentle cleansing with an antibacterial soap, helps prevent acne lesions from becoming infected. Zealous washing

and scrubbing can aggravate acne, causing increased inflammation and irritation. Harsh soaps that dry the skin may temporarily reduce surface oils but can cause flaking and other problems. Using an astringent according to the doctor's instructions can draw excess oils from the sebaceous structures without so much irritation to the surrounding skin. Dermatologists often recommend lubricating lotions and creams that do not block the pores to help maintain the skin's moisture.

acrochordon A polyp that commonly grows externally from SKIN folds, such as those around the eyelids and on the neck, underarms, and groin. Also called a skin tag or fibroepithelial polyp, an acrochordon is noncancerous and harmless (benign). Doctors do not know what causes acrochordons to develop. Some acrochordons contain one of the HUMAN PAPILLOMAVIRUS (HPV) strains, though others do not. Acrochordons become more common with advanced age, and are most likely to appear in people who are between the ages of 50 and 75. Unlike intestinal polyps, acrochordons do not become cancerous. The dermatologist may remove an acrochordon that is in a location of frequent irritation or cosmetically unacceptable.

actinic keratosis Precancerous growths (lesions) on the SKIN, also called solar keratosis, that develop as a consequence of damage from overexposure to the sun. Actinic keratosis becomes more common with advancing age. Lesions are most common on the face, scalp, chest, hands, and arms though can develop anywhere on the body that receive extensive sun exposure. In their early stages, the lesions appear scaly and rough, and bleed easily. In later stages, the lesions acquire a wartlike appearance. Most squamous cell SKIN CANCER arises from actinic keratosis. Removing the lesions prevents them from developing into CANCER. Between 10 and 20 percent of untreated actinic keratosis develops into squamous cell skin cancer, though it is not possible to determine which lesions will remain benign and which will turn cancerous.

Symptoms and Diagnostic Path

The lesions of actinic keratosis follow a typical and consistent progression of symptoms. Actinic keratosis begins with a small, scaly patch of skin that may itch. It often appears to heal or peel off, then recurs. The LESION may be grayish, may reddened (erythematous), or may be the same color as the skin. Most people first feel rather than see the lesion. As changes to the skin cells at the site continue, the lesion becomes more defined and apparent. The lesion may resemble a wart, or may become hardened and overgrown, developing a tough, thick texture (hyperkeratosis).

Because the progression of actinic keratosis is so characteristic, the dermatologist generally makes the diagnosis on the basis of appearance and history of sun exposure. The dermatologist may choose to biopsy larger or suspicious lesions to determine whether they have progressed to squamous cell skin cancer. Unless such suspicion exists, there is no need for biopsy because the standard treatment is to remove the lesion, which consequently eliminates the lesion's risk for evolving into a cancer.

Treatment Options and Outlook

Treatment for actinic keratosis is removal of existing lesions coupled with regular (every 6 to 12 months) examinations of the skin to detect new lesions. Methods for removing the lesions include

- cryotherapy, such as liquid nitrogen, which freezes the lesion, causing the cells to die and slough away
- electrocautery, which burns away the lesion
- curettage, in which the dermatologist scrapes off the lesion using a sharp surgical blade
- topical application of a chemotherapy agent, which causes the cells in the lesion to die and slough away
- photodynamic therapy, in which the dermatologist applies a photosensitive chemical that accumulates in the affected cells and then administers certain frequencies of light exposure that cause the cells containing the photosensitive chemical to die

Treatment may cause discomfort. Small lesions typically heal in two to three weeks with minimal or no scarring. Larger or numerous lesions may result in pitting and scarring that will require subsequent cosmetic treatment. Though removal ends the threat of squamous cell skin cancer from existing lesions, the likelihood is high that new lesions will develop. Dermatologists recommend annual or semiannual skin examinations for people who have had actinic keratosis lesions removed.

Risk Factors and Preventive Measures

Actinic keratosis develops only in people who have repeated or severe exposure to the sun or other sources of ultraviolet radiation such as tanning booths. It reflects longstanding damage, typically that occurred in childhood or over decades of sun exposure in adulthood. The lesions emerge and progress over years and are most common in people age 50 and older.

People who are likely to develop actinic keratosis are those who:

- experienced severe SUNBURN as children (blistering and peeling)
- are fair skinned and do not tan easily
- work outdoors
- engage in outdoor activities such as gardening and sailing that result in prolonged sun exposure
- live in areas where sun intensity is high, such as the southern United States

Preventive measures include avoiding outdoor activities during the highest intensity of sunlight (typically 10 a.m. to 3 p.m. daily) whenever possible, and diligent SUN PROTECTION when outdoors during daylight hours. Dermatologists recommend wearing a full-brimmed hat and long sleeves when extended sun exposure is unavoidable and applying sunscreen to the face, backs of the hands, and other skin surfaces that remain exposed. Sunscreen should have a sun protection factor (SPF) rating of 15 or higher and protect against both ultraviolet A (UVA) and ultraviolet B (UVB).

aging, integumentary changes that occur with Though the premise of aging tends to conjure images of WRINKLES and gray HAIR or baldness, the SKIN, hair, and NAILS undergo numerous changes across the lifespan.

Integumentary Changes in Youth

During infancy and early childhood, the integumentary structures are soft and the hair may be fine. By about age 10 or 11 years, the hormonal shifts of PUBERTY are under way. Isolated pimples may break out on the face, chest, and back. Hair patterns begin to change as the sex hormones stimulate SECONDARY SEXUAL CHARACTERISTICS such as axillary (underarm) and pubic hair growth. Within a few years the hair on the legs thickens and darkens, and boys begin to sprout facial hair. The sebaceous structures kick up sebum production, and the dermis accelerates cell production to accommodate new skin to cover what can amount to several inches of new height each year. ACNE, an inflammatory process involving the sebaceous structures, is the most common skin condition that occurs between the ages of 14 and 22.

The skin, hair, and nails outwardly remain relatively stable during young adulthood, the third and fourth decades of life, though are collecting the cumulative effects of factors such as sun exposure, scarring, and other evidence of life experience. People who work outdoors or participate in outdoor activities begin to show these effects earlier than their counterparts who limit their exposure the natural elements. Repeated sun exposure may result in tanning, a look that may be fashionably desirable though also causes LENTIGINES (freckles and "age" spots), roughness, and wrinkles. The hands may develop calluses and the feet CORNS.

Integumentary Changes in Midlife

At about age 40 the connective tissues throughout the body begin to gradually lose elasticity, allowing the skin to sag and form more wrinkles. Dermatologists call this loss elastosis. As well, the epidermis (outer layer of the skin) and the adipose tissue (fat) beneath the skin both thin. The epidermis becomes more fragile and susceptible to punctures and tears. Though losing a little fat under the skin might sound like a benefit when other areas of the body are demonstrating an age-related propen-

sity to accumulate fat, the diminished integumentary adipose tissue reduces the skin's ability to regulate heat loss and retention. The older people get, the greater their tendency to feel cold even when the external environment is warm. The risk for heat and cold injuries affecting the skin, such as sunburn and frostbite, also increases.

By midlife even the skin of those who are not the outdoors types usually has weathered significant exposure to sun, wind, and chemicals that can cause trauma and damage. ACTINIC KERATOSIS, a condition of precancerous growths on sun-exposed skin, and SKIN CANCER such as basal cell carcinoma or squamous cell carcinoma, may manifest, arising from skin damage that occurred decades earlier. Sunscreen, the mainstay of SUN PROTECTION for children today, had not yet been developed during the childhoods of those who are today over age 30.

Age-related changes begin to affect the hair in midlife, too. Melanocytes, skin cells that produce melanin, thin from the hair follicles, diminishing the amount of pigment that appears in new hair fibers. Reduced pigment produces hair that appears gray; complete absence of pigment produces white hair. These changes occur regardless of the hair's natural hair color. Men and women both experience patterned ALOPECIA (hair loss), though in men the loss of hair is generally more pronounced.

Integumentary Changes in Late Life

By the seventh, eighth, and ninth decades of life, the epidermis becomes so thin as to reveal the coloration of the tissues that lie beneath the skin. The skin drapes loosely over the body, tearing and bruising easily. Blood vessels ridge beneath the skin like pipe cleaners under wet tissue paper, trailing along the backs of the hands and arms and on the lower legs and feet. Threadlike networks of capillaries etch across the cheeks. Late in life, the skin continues to do a remarkable job protecting the body, yet is especially vulnerable to damage.

Maintaining Healthy Skin Across the Lifespan

Anti-aging remedies abound, and some—such as those that add moisture and vitamins to the skin—help the skin remain supple and smooth longer in life than without their use. But the most effective anti-aging approach is to take good care of the skin all through life, beginning in childhood. Appropriate nutrition, protection from the sun and other elements of weather, and good hygiene are simple, yet effective, measures to keep the skin healthy throughout life.

albinism A genetic disorder in which the melanocytes do not produce, or produce reduced amounts of, melanin, the chemical that deposits pigment in cells of the SKIN, HAIR, and structures of the EYE. Without melanin, the skin, eyes, and hair have little or no pigment and consequently lack color. People who have albinism typically have light to white skin and hair, and light or no color to the irises of the eyes (the pigmented rings around the center of the eyes). Albinism reduces or eliminates the skin's ability to protect itself from exposure to ultraviolet light, greatly increasing the risk for damage such as SUNBURN and SKIN CANCER.

The lack of pigmentation characteristic of albinism extends to the interior of the eye as well, resulting in VISION IMPAIRMENT. In the normal eye the RETINA, the inner lining of the back of the eye that receives light images and encodes them as NERVE signals for the OPTIC NERVE to carry to the BRAIN, is highly pigmented such that it appears black. The pigment suppresses extraneous light and supports the functions of rods and cones, the specialized cells of vision that line the retina. Without the protection of pigment, unfocused lightwaves bombard the retina. The brain cannot sort the resulting nerve signals into images and consequently fails to properly establish the neurologic pathways that make vision (the interpretation of patterns of light as images) possible.

There are a number of INHERITANCE PATTERNS for albinism, nearly all of which are recessive (require a defective pigmentation GENE from each parent). Researchers have identified several types of gene mutations that cause most forms of albinism.

Oculocutaneous albinism (OCA) The three types of OCA involve the skin, hair, and eyes to varying degrees.

- OCA type 1 results from a MUTATION of the gene that encodes tyrosinase, an enzyme necessary

to convert the essential amino acid tyrosine to melanin. OCA type 1 features nearly complete absence of pigmentation and usually legal blindness (refractive correction can achieve vision no better than 20/200).

- OCA type 2 results from a mutation of the *P* gene, which encodes proteins that participate in pigmentation. OCA type 2 features moderate pigmentation and moderate vision impairment (usually correctable to 20/60).
- OCA type 3 results from a mutation of the *TRP-1* gene, which encodes proteins that have incompletely understood roles in the formation of pigment.

Ocular albinism (OA) Ocular albinism results from an X-linked mutation of an as-yet unidentified gene. People who have OA have normal or minimally affected skin and hair pigmentation but lack pigment in the structures of the eye, resulting in vision impairment.

Other forms of albinism Other forms of albinism are less common or may be part of a larger complex of symptoms. Among them are

- Chédiak-Higashi syndrome (CHS), a variation of OCA in which there are also immune and neurologic dysfunctions
- Hermansky-Pudlak syndrome (HPS), a multisystem disorder that involves PLATELET dysfunction resulting in excessive bleeding, vision impairment, and inappropriate fat storage in tissues throughout the body as well as absence of pigmentation in the skin and hair
- Waardenburg's syndrome, a complex of symptoms involving HEARING LOSS and partial albinism (often a lock of white hair in the front of the head with the rest of the hair normal color); people with this disorder may also have pale blue eyes or different color in each eye

Symptoms and Diagnostic Path

The most obvious symptom of albinism, pale coloration of the skin and hair, is apparent at birth. Light-colored eyes and vision problems such as STRABISMUS (inability of the eyes to focus in unison), NYSTAGMUS (involuntary rapid eye movements), and PHOTOPHOBIA (extreme sensitivity to light) are common and also manifest early in infancy.

The characteristic absence of pigmentation is fairly conclusive for diagnosis of albinism. A thorough OPHTHALMIC EXAMINATION with OPHTHALMOSCOPY reveals the retina's hypopigmentation. A VISUAL ACUITY test demonstrates the degree of vision impairment. GENETIC TESTING can identify the causative gene mutation, which helps define the inheritance pattern.

Treatment Options and Outlook

There are no treatments for albinism itself. CORRECTIVE LENSES and methods to correct strabismus or nystagmus, if present, can improve vision to the extent possible. Many people who have albinism have functional vision, even if they have legal blindness, and can participate in most activities that require basic vision though may not be able to drive.

Albinism, particularly OCA type 1, may limit outdoor activities in areas that receive intense sunlight. The sun presents a risk for sunburn and related damage as well as harm to the eyes. Photophobia nearly always accompanies albinism and can make it difficult to remain in bright light, even wearing sunglasses, for any substantial length of time. People who have albinism should wear protective clothing, sunglasses, hats, and high-SPF sunscreen whenever they are outdoors.

Risk Factors and Preventive Measures

The sole risk factor for albinism is genetic mutation. Doctors recommend genetic testing and counseling for families in which members have albinism. Though there is no treatment for albinism, early diagnosis helps minimize the extent of vision impairment that may result from nystagmus or strabismus. People who have albinism also should undergo frequent screening for skin cancer, beginning in childhood.

alopecia The clinical term for HAIR loss. There are numerous forms and causes of alopecia, which may be localized or widespread, temporary or permanent. Though alopecia is emotionally traumatic for many people, it does not affect health in any way though may reflect underlying health condi-

tions. Common forms of alopecia include the following:

- Androgenic alopecia, or male pattern hair loss, in which a man's hairline recedes from the temples and forehead and thins on the crown in a characteristic pattern that may culminate with a fringe of hair remaining along the sides and back of the head. Hair loss is permanent. Androgenic alopecia is hereditary and commonly begins in midlife, though may begin as early as a man's mid-20s. Researchers believe androgenic alopecia results from a combination of genetic predisposition and naturally declining TESTOSTERONE levels.
- Female pattern alopecia, in which a woman's hair gradually thins on the top and sometimes back of her head. Hair loss is permanent. Researchers believe female pattern alopecia results from hormonal changes (loss of ESTROGENS and testosterone) that occur following MENOPAUSE.
- ALOPECIA AREATA, an autoimmune disorder in which the body's IMMUNE RESPONSE attacks clusters of hair follicles, temporarily impairing their ability to produce new cells. Alopecia areata may affect any part of the body and occasionally the entire body. Hair loss is temporary, though may be long term.
- Toxic alopecia, which results from exposure to substances that impair the ability of the hair follicles to generate new cells. The most common sources of such exposure are radiation therapy and chemotherapy treatments for cancer. Other causes include vitamin A toxicity and medication side effects, such as from retinoid preparations to treat acne. The extent of hair loss depends on the toxic agent, ranging from localized (such as with radiation therapy to the head) to nearly complete (such as with chemotherapy). Hair growth returns when the toxic exposure ceases.

Scarring, such as occurs as a result of BURNS, wounds, and certain AUTOIMMUNE DISORDERS, destroys the hair follicles so hair loss in such areas is permanent. Conditions and circumstances that damage but do not destroy the follicles often allow hair growth to resume. Medical treatments that stimulate follicle activity can accelerate the return of hair in many such situations.

CONDITIONS ASSOCIATED WITH ALOPECIA

radiation exposure	CHEMOTHERAPY
TRICHOTILLOMANIA	tinea capitis
PREGNANCY	MENOPAUSE
HYPOTHYROIDISM	high FEVER
INFECTION or serious illness	scars from wounds or BURNS
excessive hair care and styling	SUNBURN and sun exposure
AUTOIMMUNE DISORDERS	DISCOID LUPUS ERYTHEMATOSUS (DLE)
hormonal changes	MALNUTRITION
SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)	hair coloring and styling products
stress	
FOLLICULITIS	

Symptoms and Diagnostic Path

Hair loss is the primary symptom of alopecia. The pattern and rate of hair loss help determine the nature of the underlying cause. When alopecia is male pattern or female pattern hair loss, the doctor can make the diagnosis on the basis of appearance. When the cause of hair loss is uncertain, the doctor may biopsy several sites on the scalp, both with and without hair, for microscopic examination. A comprehensive health history and medical examination are important to identify any potential systemic or general health causes for hair loss. Preliminary findings determine what, if any, further testing is necessary.

Treatment Options and Outlook

Treatment first targets any underlying condition that may be responsible for hair loss. In many situations of alopecia related to other health conditions, hair growth will resume without medical intervention. People who are sensitive about their appearance during the period of temporary alopecia may choose to wear hairpieces, hair weaves, wigs, scarves, or hats until their hair returns. Topical products to stimulate hair growth, such as minoxidil (Rogaine) and finasteride (Propecia), sometimes hasten the return of hair follicle function. Such products are often the first choice of treatment for male or female pattern hair loss as well as many forms of nonscarring alopecia. However, hair growth typically continues only for as long as treatment continues.

Minoxidil and finasteride can cause serious BIRTH DEFECTS when they enter the system of a woman who is pregnant. Women of childbearing age generally should not use or handle these products.

Hair replacement methods surgically relocate scalp SKIN with abundant, productive hair follicles to areas of the scalp where there is hair loss. Though these methods cannot restore hair growth to its previous patterns and thickness, they can provide satisfactory results for many people. The color and consistency of the hair influences the success of hair replacement. As well, the scalp must contain adequate areas of productive hair follicles to serve as donor sites.

Risk Factors and Preventive Measures

Risk factors for alopecia include AUTOIMMUNE DISORDERS, toxic exposures, stress, heredity, and aging. Efforts to maintain healthy skin help support productive hair growth though cannot prevent most forms of alopecia. Treating any underlying condition that causes alopecia often results in the return of hair.

alopecia areata A form of HAIR loss (ALOPECIA) that results from an autoimmune disorder in which the IMMUNE SYSTEM attacks clusters of hair follicles, halting hair growth. The clusters typically appear as circular patches of hairless SKIN, which are most noticeable when they occur on the scalp though can occur anywhere on the body. Hair growth within the affected follicles may remain interrupted for months to years; the timing and pattern of attacks seem to be random. Hair growth will eventually resume without treatment, though sometimes years after symptoms first begin. The extent of hair loss varies widely among individuals, ranging from a few isolated patches to the entire scalp or total body. Some people also experience small pits, called stippling, in their fingernails and toenails. Alopecia areata can affect people of any age and is more common in people who have other AUTOIMMUNE DISORDERS.

Researchers suspect an interaction between genetic and environmental factors is responsible for alopecia areata, though they do not yet understand the precise mechanisms. Alopecia areata does not affect health in any way other than hair growth; however, the cosmetic result (particularly scalp involvement) often distresses people who have the condition. Treatments to stimulate follicle activity sometimes can restore normal hair patterns when hair loss is mild to moderate. Cosmetic solutions such as wigs or hairpieces may produce more satisfactory results than medical interventions when the affected areas are extensive.

angioma A noncancerous tumor formed of BLOOD vessels (hemangioma) or LYMPH VESSELS (lymphangioma). Angiomas visible on the SKIN are common and may appear as circular, red growths (cherry angiomas) or weblike networks of blood vessels just beneath the surface of the skin (spider angiomas). Angiomas generally remain small and seldom present health complications. Because it contains such a rich blood supply an angioma may bleed profusely when cut or in a location that receives frequent irritation such as from clothing that rubs or constricts it. The dermatologist may remove an angioma that often bleeds or that the person finds cosmetically unacceptable. Common methods of removal include electrical desiccation (applying a slight electrical current to the angioma) and liquid nitrogen (which freezes the angioma). Angiomas occur more frequently in older adults (beyond age 50), though can develop at any age.

birthmark A discoloration on a newborn's SKIN present at, or that emerges within a few weeks of, birth. Birthmarks are either vascular (composed of BLOOD vessels and red in color) or pigment (patches of skin that differ in color from the surrounding skin). Though some birthmarks, especially large ones, may be permanent, many fade to become faint or unnoticeable by about age 10 years. Most birthmarks do not present any health problems, though large or obvious birthmarks often arouse concern for cosmetic reasons. Occasionally vascular birthmarks arise in sites where they can interfere with vision (when near the EYE or on the eyelid), BREATHING (when near the entrance to the NOSE), or feeding (when on the lips).

Symptoms and Diagnostic Path

Most birthmarks are present at, or appear shortly following, birth. Some vascular birthmarks may not appear for several months after birth. When this is the case, the birthmark appears suddenly and grows rapidly, then remains at a steady size. Many vascular birthmarks then disappear as the child grows older. The doctor can identify most birthmarks based on physical appearance. The doctor may choose to conduct MAGNETIC RESONANCE IMAGING (MRI) or COMPUTED TOMOGRAPHY (CT) SCAN when there is a cavernous hemangioma because this kind of blood vessel tumor (noncancerous) can occur within internal organs such as the LIVER or BRAIN and creates a risk for HEMORRHAGE (uncontrolled bleeding), or the doctor may perform a biopsy (take a tissue sample to examine under a microscope) of lesions of questionable composition. Multiple café au lait spots (six or more) can suggest NEUROFIBROMATOSIS, a genetic disorder, and require further evaluation. Congenital dermal melanocytosis (Mongolian spot) often has the appearance of a large bruise (ECCHYMOSIS), sometimes raising concerns about CHILD ABUSE among those who are not familiar with this birthmark. A health-care provider can quickly distinguish the mark and determine that it is not a bruise.

Any change in the size, color, or characteristics of a birthmark, especially a NEVUS (mole), requires prompt medical evaluation to check for malignant melanoma or other SKIN CANCER.

Treatment Options and Outlook

Most birthmarks fade by ADOLESCENCE, making treatment unnecessary. The doctor may choose to surgically remove nevi (moles) that are large or in locations where they are subject to irritation from clothing or movement, to prevent them from evolving to SKIN CANCER. Port wine stains (flat hemangiomas) are often emotionally distressing when they occur on the face. The dermatologist may use laser therapy to shrink and seal off the blood vessels causing the port wine stain, diminishing its prominence. Cover-up cosmetics are also an option. Children are particularly sensitive about having obvious birthmarks and may need emotional support. Birthmarks are very common, with some experts estimating that about a third of infants are born with them.

Risk Factors and Preventive Measures

Birthmarks appear to be random and common, with as many as a third of newborns having at least one. Because researchers do not know what

BIRTHMARKS

Clinical Name	Type	Common Names	Characteristics
capillary hemangioma	vascular	strawberry hemangioma	red discolorations that resemble strawberries most common on the face, back, chest, and back of the neck may be nonexistent at birth, then within a few weeks appear and rapidly grow generally fade by age 9
cavernous hemangioma	vascular	none	purple or reddish blue cluster of blood vessels beneath, rather than on the surface of, the SKIN may be quite large, with a spongy consistency may exist within internal organs such as the LIVER, BRAIN, and BONE present at birth or appears within a few days of birth susceptible to possibly profuse bleeding with trauma may require surgical removal
congenital dermal melanocytosis	pigment	Mongolian spot, Mongolian blue spot	common among infants with dark skin dusky blue coloration, can cover a large area most often appears on the lower back or buttocks present at birth or appears within a few days of birth generally fades by age 12
congenital NEVUS; giant congenital nevus	pigment	mole	cluster of pigmented cells may be flat or raised may have HAIR growing from it (called hairy nevus) increased risk for malignant melanoma when > 20 centimeters (giant congenital nevus)
nevus flammeus	vascular	stork bite, salmon patch	small, pink, irregular discolorations of the skin most common on the face and back of the neck may be nonexistent at birth, then within a few weeks appear and rapidly grow generally fade by age 4
nevus flammeus	vascular	port wine stain	most often appears on the face persists into adulthood
hyperpigmented MACULE	pigment	café au lait spot	coloration similar to coffee with milk faint appearance at birth, becomes more prominent by age 3 More than five or six spots may suggest neurofibromatosis

causes them to occur, there are no known measures for preventing them. Any changes in a birthmark that has been stable in size and appearance warrant a doctor's evaluation to determine whether the changes signal skin CANCER. Early detection and treatment are especially crucial for malignant melanoma, in which a NEVUS becomes cancerous, as this cancer can be aggressive and lethal when untreated. Birthmarks themselves do not present any risk to overall health.

blister A fluid-filled pocket that develops between the layers of SKIN in response to friction or pressure. Blisters are most common on the feet and hands though can develop nearly anywhere on the body. Blisters often hurt. Their outer layer of skin is vulnerable to tearing, which allows the fluid to leak out. Though the blister may then feel better because there is less pressure, the break in the skin's surface gives BACTERIA access to the inner layers of tissue and establishes a risk of INFECTION.

An intact blister usually will heal within three to five days as the body reabsorbs the fluid and repairs the damaged skin. A ruptured blister is an open wound that requires appropriate WOUND CARE, such as cleansing with mild soap and water and possibly antibiotic ointment and a bandage. The most effective treatment for blisters is prevention such as wearing gloves or thick socks and properly fitting shoes or boots. An area of the skin that repeatedly forms a blister often develops a CALLUS, an accumulations of keratocytes, which increases the skin's thickness and improves its ability to withstand friction or pressure.

botulinum therapy Injections of botulinum neurotoxin to selectively paralyze MUSCLE fibers. The bacterial strain *Clostridium botulinum* produces several forms of paralytic toxin, some of which can cause serious or fatal poisoning (BOTULISM) when ingested. The toxin works by blocking the release of acetylcholine, a NEUROTRANSMITTER that facilitates NERVE signals between muscle cells and the BRAIN. The blockade prevents the muscle cells from contracting. Botulinum therapy products currently available in the United States contain a weakened and purified solution of botulinum neurotoxin A (Botox) or botulinum neurotoxin B (Myobloc).

Botulinum therapy became therapeutically acceptable in the United States in 1990 when the US National Institutes of Health (NIH) issued a consensus statement outlining the clinical applications for its use (*Clinical Use of Botulinum Toxin* [NIH Consensus Statement]. 1990. November 12–14; 8[8]:1–20). These uses include treatment for neuromuscular disorders such as DYSTONIA, BLEPHAROSPASM, CEREBRAL PALSY, STRABISMUS, TORTICOLLIS, MULTIPLE SCLEROSIS, and PARKINSON'S DISEASE, as well as spasms that result from TRAUMATIC BRAIN INJURY (TBI) OR SPINAL CORD INJURY.

An outgrowth of these applications was the discovery that botulinum therapy causes SKIN WRINKLES to lessen or disappear. In 2002 the US Food and Drug Administration (FDA) approved botulinum therapy as a cosmetic treatment for forehead wrinkles (frown lines). Cosmetic applications are becoming increasingly common, with many dermatologists using botulinum therapy to reduce wrinkles around the eyes and other areas of the face and body. In 2004 the FDA approved botulinum therapy for HYPERHIDROSIS, a disorder of the SWEAT GLANDS that results in profuse sweating. The effects of botulinum therapy last about four to six months. Risks are slight and may include localized INFECTION and temporary weakness of the injected muscles.

bulla A large (5 millimeters or greater) blister-like formation, raised and fluid filled, that may hurt or itch. INFECTION, contact irritants, IMMUNE RESPONSE, and systemic health conditions may cause bullae. Bullous DERMATITIS may result from contact with plants such as poison ivy, oak, or sumac. To determine the cause of bullous eruptions, the doctor may biopsy a bulla (remove a small section for examination under the microscope) or perform tests to look for immune proteins. Tense bullae form in the deeper layers and are less likely to rupture. Flaccid or loose bullae form in the superficial layers of the skin and are fragile, making them more likely to tear.

Treatment generally is twofold, targeting the underlying cause as well as aiming to relieve symptoms such as itching and the bullous swellings. Topical CORTICOSTEROID MEDICATIONS often help the symptoms and sometimes the underlying cause when it is an immune response or autoimmune disorder. ANTIBIOTIC MEDICATIONS, often both topical and oral, are necessary to treat bullae that arise from bacterial infection or that become infected. Healed bullae may leave indentations or scars, especially if they were infected.

bullous pemphigoid An autoimmune disorder in which itchy bullae (blisterlike formations) develop on the SKIN. Bullous pemphigoid is more common in people age 50 and older, and typically occurs in those who are 70 or older. The bullae tend to concentrate in areas where there are skin folds, such as the groin and the creases of the elbows and knees. The skin around the bullae may be red and tender. The condition is self-limiting, which means it will improve on its own. However, the bullae are very uncomfortable; medical intervention targets relieving their discomfort and hastening the condition's regression and resolution. The doctor will likely biopsy several of the bullae to obtain a definitive diagnosis. Treatment with topical and oral CORTICOSTEROID MEDICATIONS reduces the IMMUNE RESPONSE and improves symptoms. The B vitamin niacinamide also provides additional relief for some people. The bullae usually heal without scarring. In most people the bullae heal within a few months, though occasionally the course of disease may run several years.

C

callus An accumulation of keratocytes that form a thickened area of SKIN in response to repeated friction or pressure, typically at the site of repeated blistering. A callus may be a different color than the surrounding skin, often grayish or yellowish. Calluses are most likely to develop on the palms, fingers, fingertips, heels, and balls of the feet. Most calluses are not painful and help protect the skin from blisters and other friction-related injuries. Calluses do not require medical intervention unless they cause PAIN. Applying aloe or a moisturizing skin lotion and gently rubbing the callus with a pumice stone while in the shower or bath are measures that can contain the size and thickness of calluses. Wearing gloves to protect the hands and well-fitting socks to protect the feet can help prevent a BLISTER and resulting callus from forming.

carbuncle Clusters of infected HAIR follicles (furuncles) that often form an ABSCESS. Carbuncles are most common on the back of the neck and shoulders, though may form at other locations where furuncles tend to occur. Carbuncles are painful and often result in FEVER and general malaise (not feeling well). The INFECTION is deep within the layers of SKIN and generally requires treatment with an oral ANTIBIOTIC MEDICATION. The doctor may choose to lance (open with a sterile incision) the carbuncle to allow the collected pus to drain. Applying warm, moist compresses four to six times a day helps open the follicles and allow continued drainage as HEALING takes place.

Though poor PERSONAL HYGIENE can contribute to the development of furuncles and carbuncles, the primary cause of these painful sores is BACTERIA, typically *Staphylococcus*, that normally resides on the skin. Carbuncles tend to recur. People who have DIABETES are more likely to develop carbuncles because the diabetes damages the delicate blood vessels responsible for peripheral circulation, preventing the bloodstream from carrying bacteria-fighting blood cells to the site of the infection. People who have impaired immune function are also at increased risk. Untreated carbuncles can result in scars after healing or can progress to systemic infection (SEPTICEMIA).

See also CELLULITIS; FURUNCLE; SCAR.

cellulitis INFLAMMATION of the inner layers of the SKIN and the underlying connective tissues, usually the result of a bacterial INFECTION. People who have PERIPHERAL VASCULAR DISEASE (PVD), DIABETES, or other health conditions that impair BLOOD circulation have increased risk for cellulitis. Cellulitis develops when a break in the skin, such as a cut or an insect bite or sting, allows BACTERIA normally present on the surface of the skin to enter and establish infection. The offending breach often comes from something so small as to appear insignificant until infection sets in. *Staphylococcus* is the most common type of bacteria responsible for cellulitis; *Streptococcus* is sometimes responsible. Bacteria also may enter via contamination of a penetrating object such as a splinter. Cellulitis requires prompt treatment with ANTIBIOTIC MEDICATIONS to minimize tissue damage and prevent the spread of infection.

Symptoms and Diagnostic Path

Swelling, redness, and PAIN or itching are the key symptoms of cellulitis. The edges of the infection are diffuse, often making it difficult to establish a border between healthy and infected tissue. The doctor diagnoses cellulitis primarily on its appear-

ance and symptoms. Usually no blood or other laboratory tests are necessary, unless the doctor suspects systemic infection (SEPTICEMIA) or questions the causative strain of bacteria.

Treatment Options and Outlook

For moderate, localized cellulitis the typical treatment is a course of oral antibiotics with close follow-up to make sure the selected antibiotic is effective against the infection and the cellulitis is improving. Warm, moist compresses over the infected area help draw blood the area, improving the body's ability to fight the infection. When cellulitis affects a large area or multiple areas or worsens after antibiotic therapy begins, the doctor may place the person in the hospital for intravenous (IV) antibiotic therapy and continuous observation. Cellulitis in a person who is IMMUNOCOMPROMISED or otherwise debilitated requires especially aggressive treatment. Untreated or undertreated cellulitis can have serious consequences such as septicemia or GANGRENE (death of the tissue). Cellulitis also presents particular risk to people who have impaired circulation for any reason. With timely and appropriate treatment, most people recover fully.

Risk Factors and Preventive Measures

Wounds that break the skin breach the body's first line of defense against infection. Prompt cleansing of the entry site with antibacterial soap and warm water, followed with topical antibiotic ointment and a bandage, helps reduce the amount of bacteria that enter the skin and limit their ability to cause infection. Early signs of infection, such as swelling, redness, or drainage, require prompt medical intervention that may include oral antibiotic medications. People who have diabetes, PVD, and other conditions that restrict peripheral circulation should develop the practice of regularly examining the feet, lower legs, fingers, hands, and lower arms for minor wounds that could become problematic as a measure for early identification and intervention to prevent cellulitis.

chemical peel A cosmetic procedure to smooth and tighten the surface of the SKIN, typically on the face, to improve the appearance of WRINKLES, scars, ACNE, widespread ACTINIC KERATOSIS, LENTIGINES (brown spots or liver spots), dyschromia (pigmentary irregularities), and other blemishes. The dermatologist applies a chemical solution, either an acid or phenol, to the selected areas of skin. The solution BURNS the skin, causing one layer or more of skin to slough off as HEALING takes place. The new skin that replaces the old skin is smoother, tighter, and lighter in color.

Light Peel: AHA Solutions

The lightest chemical peel is an alphahydroxyl acid (AHA) solution such as lactic acid or glycolic acid. It removes the top layer of skin (epidermis) and is appropriate for treating minor skin irregularities. The dermatologist puts the mild acid on selected skin sites in a series of applications or may mix the solution into a cream or wash for weekly home use until the peel produces the desired results. An AHA chemical peel causes mild irritation and discomfort that resolves as the skin heals. It generally takes six to eight weeks to see results with an AHA peel. An AHA peel requires frequent retreatment to maintain the effect.

Moderate Peel: TCA Solution

A moderate chemical peel uses a stronger acid solution, trichloroacetic acid (TCA), to remove the top and underlying layers of skin (epidermis and upper dermis). The dermatologist applies the TCA solution in one to three sessions spread over several months. A TCA chemical peel is appropriate for treating fine facial wrinkles and pigmentary irregularities. The treated area first forms a frothy coating and then scabs or crusts. The treated area also becomes swollen and may be uncomfortable enough to require mild PAIN relief medication for several days. Full healing takes about two weeks. The effects of a TCA peel generally last a year or longer, though many people need more than one treatment to achieve the desired results.

Deep Peel: Phenol Solution

A deep chemical peel extends through the dermis, the middle layer of the skin, to the hypodermis (innermost layer of the skin). It produces somewhat of a burn effect that causes complete loss and replacement of the skin. The dermatologist

uses a phenol solution to achieve this result, which is appropriate for treating moderate facial blemishes, acne scars, sun damage, actinic keratosis, and most wrinkles. The application procedure takes about an hour, before which the dermatologist generally administers a sedating medication. Following the phenol application the dermatologist coats the treated area with petroleum jelly or other protective covering to reduce discomfort. The treated area is immediately raw and exposed, with scab formation in about 48 hours.

Swelling and discomfort are significant for a week or two after a phenol peel, and most people cannot participate in any regular activities during this time and may require assistance if the swelling causes their eyes to close. Proper care during healing is essential, and typically requires a regimen of ANTIBIOTIC MEDICATIONS and ointments to help keep the healing tissue moist and supple. The treated skin remains red and shiny for up to three months. Full healing takes four to six months, though most people can return to most normal activities in about three weeks.

The effects of a phenol peel typically last several years. The skin commonly loses its ability to produce melanin, however, making sunscreen and protective clothing such as a broad-brimmed hat essential to prevent sun damage and SUNBURN when outdoors. Most dermatologists recommend applying sunscreen daily, after healing, as a routine preventive measure. The loss of melanin also results in a permanently lighter pigmentation of the treated area. Because of this, people who have dark skin should not undergo phenol peels.

Risks and Complications

Though chemical peels can produce smoother, more youthful looking skin, they do so by first damaging the skin so it must repair itself. The risks of chemical peels include infection, scarring, and irregularities in pigmentation after healing. Some people have adverse reactions to the chemical solutions. People who are prone to cold sores or FEVER blisters are likely to develop them during the healing phase; many dermatologists prescribe ANTIVIRAL MEDICATIONS to prevent these viral outbreaks from occurring. Phenol may exacerbate ARRHYTHMIA (irregularity of the heartbeat) in people who have arrhythmia disorders.

chloasma A pattern of hyperpigmentation, often temporary, that typically affects the face. Chloasma, also called melasma, develops with elevated blood levels of ESTROGENS, such as occurs during PREGNANCY, with some oral contraceptive (birth control pill) formulations, and in chronic LIVER disease. When the cause is hormonal, the hyperpigmentation fades when HORMONE levels return to normal. Chloasma may also develop in men or women who have liver conditions such as CIRRHOSIS or HEPATITIS. The melanocytes (melanin-producing cells) in the affected areas of skin overproduce melanin, the pigment that gives SKIN its color. The hyperpigmented areas have clearly defined borders and often appear in symmetry, resulting in a masklike appearance.

The doctor diagnoses chloasma on the basis of its appearance and correlation with factors such as pregnancy or liver disease. Topical solutions such as hydroquinone and tretinoin (Retin-A) help fade the chloasma in some people, though pregnant women should not use these treatments. Both medications have potentially serious side effects and are for short-term use only (eight weeks or less). As sun exposure intensifies melanin production, dermatologists recommend wearing sunscreen (sun protection factor [SPF] 30 or greater) and shading exposed areas of skin from the sun as much as possible. Chloasma is primarily cosmetic and does not present a threat to health other than that of any underlying condition. Most chloasma resolves on its own when the underlying cause health condition changes.

corns Growths of thickened SKIN on the tops and sides of the toes. Corns result from accumulations of keratocytes that develop in response to repeated pressure, typically from shoes that are too tight, and are the body's effort to protect the skin and underlying tissues. A corn has a hard inner core with a surrounding ring of thickened though soft skin. Corns often hurt because they

compress and irritate the nerves in the underlying tissues, and continue to grow as long as the pressure against the toes continues.

The most effective treatment for corns is prevention by wearing low-heeled shoes that fit properly. A shoe with a heel more than half an inch higher than the rest of the shoe's sole causes the foot to slide forward in the shoe, squeezing the toes and subjecting them to pressure from the sides and top. Once a corn develops, treatment focuses on softening the skin and relieving pressure against the area. Self-care measures include

- wearing flat-soled, wide-toe-box shoes
- using corn pads, donut-shaped felt or foam rings, to relieve pressure against the sensitive inner core of the corn while wearing shoes
- gently rubbing the corn with a pumice stone while in the bath or shower
- applying aloe vera gel or moisturizing lotion to the area

Large corns or corns that fail to respond to self-care measures require evaluation and possible treatment from a podiatrist (foot care specialist), who may anesthetize the corn and use a scalpel to shave away some of the overgrown skin.

cradle cap A form of DERMATITIS, also called infantile seborrheic dermatitis, in which the sebaceous structures of the SKIN oversecrete oils. The excessive sebaceous secretions trap loose, dead skin cells, forming crusts or scales. Cradle cap, as the name implies, affects young infants. Doctors believe the condition results from the surge of maternal hormones that infuse the infant's bloodstream shortly before birth, stimulating the sebaceous glands. Because the primary location of body hair on the infant is on the head, the crusts are most common on the scalp. They also may form around the eyebrows. Gentle shampooing helps keep the scalp clean. The caregiver can rub baby oil into crusted areas to soften crusts before shampooing to help remove them. Cradle cap generally clears up within a few months and does not occur after about age 12 months.

D

dandruff A common symptom in which the sebaceous glands on the scalp increase their activity, accelerating the SKIN's normal, continuous process of replacing itself. Consequently the skin on the scalp sheds cells at an accelerated rate, causing visible patches of collected cells that accumulate on the scalp's surface (most commonly on the top of the head) or flaking that may appear in the HAIR and on the clothing. BACTERIA and yeast (FUNGUS) normally present on the skin can irritate and inflame the sebaceous structures of the scalp, a condition doctors call seborrheic DERMATITIS. Dermatologists often diagnose seborrheic dermatitis as the underlying cause of dandruff. PSORIASIS and tinea capitis are also common causes.

Flaky, patchy SKIN on the eyebrows, around the eyelashes, and other sites on the body beyond the scalp may signal a dermatologic condition other than dandruff and requires a doctor's evaluation.

Though numerous factors may contribute to dandruff, dermatologists believe a convergence of genetics, age, hormones, and environmental conditions accounts for most cases, as these are the factors that generally influence sebaceous activity. Dandruff flare-ups are common during PUBERTY, PREGNANCY, and MENOPAUSE, periods of life characterized by hormonal surges. Dandruff also becomes more common during times of physical or emotional stress, and when external environmental conditions are cold and dry such as is typical in the winter.

Symptoms and Diagnostic Path

Light-colored patches on the scalp that flake when scratched or flakes in the hair and on the clothing are the key symptoms of dandruff. The scalp sometimes itches. The diagnostic path includes examination of the skin over all of the body to distinguish simple dry skin, which can cause flaking, from dandruff, as well as to rule out other dermatologic conditions. The dermatologist may conduct further testing, such as skin scraping or biopsy, when there is reason to suspect a condition other than one that commonly causes dandruff.

Treatment Options and Outlook

Mild dandruff—light, barely noticeable flaking that remains along the scalp or in the hair—often clears with daily shampooing and thorough rinsing. Moderate dandruff—obvious flakes in the hair and on the shoulders—may require shampooing with products that contain ingredients to curtail the growth of keratinocytes, the cells that make up most of the skin's outer layer (epidermis). Such shampoos typically contain selenium sulfide, zinc pyrithione, or coal-tar extracts. Which products are more effective seems a matter of personal preference.

Severe dandruff—flakes are always present in the hair and on the clothing—may require prescription shampoos or lotions that often contain stronger concentrations of the active ingredients that over-the-counter products contain. For very severe dandruff with INFLAMMATION of the skin and sebaceous structures, the doctor may prescribe corticosteroid drops or lotion in combination with other remedies. Stubborn dandruff may require a regimen of products to bring it under control, though most people can then keep dandruff in check with a few core products.

Recent research suggests that many people who have seborrheic dermatitis, the most common cause of persistent dandruff, may have a skin

environment that encourages a normally present fungus, *Malassezia* (also called *Pityrosporum*), to flourish in abundance. *Malassezia* subsists on sebum, an oil substance the sebaceous glands secrete. An overgrowth of *Malassezia* depletes the sebum supply, causing the sebaceous glands to increase sebum production. This in turn accelerates cell growth, generating dandruff. Shampoos and lotions containing an antifungal medication such as ketoconazole reduces the scalp's *Malassezia* population, returning cell turnover to normal.

PRODUCTS TO CONTROL DANDRUFF

coal-tar extracts	glycolic acid
ketoconazole and other antifungal shampoos	salicylic acid
selenium sulfide	tea tree oil
zinc pyrithione	topical corticosteroids

Risk Factors and Preventive Measures

Frequent or heavy use of hair products such as hairsprays and styling gels can further clog the sebaceous structures. Stress, hormones, and the environment can precipitate or exacerbate dandruff. Dandruff, or the skin conditions that establish dandruff such as seborrheic dermatitis, are more common in people who have PARKINSON'S DISEASE, though the reason for this remains unknown. People who are prone to dandruff that worsens seasonally often can minimize the severity of their symptoms by beginning therapeutic efforts before flaking becomes a problem.

decubitus ulcer An erosion in the SKIN that results from the pressure of remaining in one position for an extended period of time, commonly called a bedsore or pressure sore. The extended pressure deprives the tissue of blood circulation, allowing cells to die and the tissue to break down. Tissues over areas where the bones are near the skin are most vulnerable, such as the hips, ankles, heels, elbows, shoulders, base of the spine, and back of the head. Decubitus ulcers are a specific risk for people who have debilitating conditions or injuries that limit their mobility, particularly elderly individuals in extended-care facilities. MALNUTRITION and age-related changes to the skin result in fragility that makes the skin more susceptible to damage.

Often, measures such as frequent changes of position and soft surfaces to shelter the skin at contact points can prevent decubitus ulcers. Within contemporary quality of care standards and guidelines in health care, decubitus ulcers raise questions as to whether providers and facilities are delivering appropriate care. Undetected or untreated decubitus ulcers can result in significant tissue loss and threaten overall health. Once established, a decubitus ulcer requires aggressive medical intervention to limit permanent tissue damage and restore healthy skin.

CLINICAL STAGING OF DECUBITUS ULCERS

Clinical Stage	Presentation	Tissue Penetration
stage 1	nonblanching red area	superficial layers of skin (epidermis, first layer of dermis)
stage 2	BLISTER or open sore	full skin (epidermis and full thickness of dermis) to the underlying FASCIA
stage 3	craterlike sore that oozes or bleeds; damaged or necrotic (dead) SKIN; damage to underlying tissues	through the skin and fascia, into the supportive connective and fatty tissue
stage 4	deep ulcer that bleeds; extensive skin and tissue destruction and necrosis	through the skin, fascia, and underlying structures into adjacent MUSCLE, TENDON, and LIGAMENT, and JOINT

Symptoms and Diagnostic Path

The symptoms of decubitus ulcer depend on its stage of development. Health-care providers classify decubitus ulcers on a scale of 1 to 4, with stage 1 being the slightest level of damage and stage 4, the most significant. PAIN is not an effective measure of a decubitus ulcer's severity as the damage to the skin and underlying tissues may destroy NERVE endings. Doctors diagnose a decubitus ulcer on the basis of its appearance.

Treatment Options and Outlook

The first and most urgent action in treating decubitus ulcers is to relieve all pressure on the area. This may include using pillows, cushions, pads, and other items to support the body in positions that do not put pressure on or near the ulcer. Additional treatment may include regularly cleansing the ulcer to prevent INFECTION, or ANTIBIOTIC MEDICATIONS to treat infection that already exists. Deep ulcers (stage 3 and especially stage 4) often require surgical débridement (removing dead and damaged tissue under anesthetic).

Recovery depends on the stage of the ulcer and the general health condition of the person. With early and aggressive intervention, recovery can be complete with minimal permanent tissue damage. Stage 2 and stage 3 ulcers generally heal with some loss of tissue and scarring. Stage 4 ulcers are extensive wounds that may require multiple débridements and long-term treatment by a WOUND CARE specialist. When debilitation is long-term or permanent, the risk for recurring decubitus ulcers is high.

Risk Factors and Preventive Measures

People whose health conditions limit their ability to move parts of their bodies or confine them to wheelchairs or bed have very high risk for decubitus ulcers. Preventive measures include

- position changes every two hours when in bed and every 15 minutes when sitting in a chair or wheelchair
- air mattress with alternating compartments or air flotation mattress
- eggshell mattress or seat cushion
- sheepskin pads over bony protuberances such as the heels and elbows
- active movement at least four times a day when possible and passive range of motion exercises when active movement is not possible
- frequent (at least daily) inspection of areas vulnerable to pressure
- diligent skin hygiene, including daily cleansing and complete drying

Prompt intervention at the earliest signs of a decubitus ulcer can prevent extensive or permanent tissue damage.

dermabrasion A mechanical method for smoothing roughened or scarred SKIN. The dermabrader is a motorized burrlike device that "sands" away the layers of skin to achieve the desired result. Dermabrasion is appropriate for treating skin blemishes such as ACNE scarring or sun damage. The dermatologist administers a sedative and a local anesthetic before the procedure. After the procedure the skin is raw and tender. There is usually significant swelling and moderate discomfort that requires PAIN relief medication. The skin scabs in about 24 to 36 hours. As HEALING progresses, the scabs fall off, with the new skin pink and shiny beneath. Total healing is complete in five to six months, though most people can return to their regular activities in about three weeks. Risks and complications of dermabrasion include bleeding, INFECTION, scarring, and occasionally KELOID (overgrown SCAR) formation. Proper postprocedure care is important to encourage appropriate healing.

dermatitis INFLAMMATION, redness (erythema), and itching of the SKIN. Dermatitis has many causes and manifests in numerous and varied presentations, some of which may reflect conditions such as viral INFECTION, AUTOIMMUNE DISORDERS, and certain kinds of CANCER. Dermatitis may be acute (come on suddenly) or chronic (persist or recur over an extended period of time).

Atopic dermatitis A chronic condition also called eczema, atopic dermatitis typically first appears in infancy or early childhood and often persists, in periods of exacerbation and REMISSION, throughout life. Symptoms include areas of red, cracked, weepy (oozing) sorelike eruptions that eventually crust, scale, and thicken. Itching is intense. The most frequent areas of involvement are the surfaces on the inner (antecubital) surface of the elbows and the back (popliteal) surface of the knees, though atopic dermatitis can affect any part of the body. Atopic dermatitis seems to have a hereditary component, as it runs in families, and is more common in people who have hypersensitivity conditions such as ALLERGIC RHINITIS.

People who have, or who have ever had, atopic dermatitis should *not* receive vaccination against SMALLPOX that uses the vaccinia virus (the vaccine administered by health-care providers in the United States). This vaccine can cause a particularly serious eruption of atopic dermatitis.

Treatments for atopic dermatitis outbreaks include topical skin lubricants, such as ointments and lotions that help the skin retain moisture, and topical CORTICOSTEROID MEDICATIONS. The dermatologist may prescribe a course of oral corticosteroid medication (such as prednisone) for severe or resistant symptoms. Oral ANTIHISTAMINE MEDICATIONS may help control itching. Scratching excoriates the lesions, setting the stage for bacterial infection, which then requires ANTIBIOTIC MEDICATIONS.

Atopic dermatitis outbreaks vary in severity and length. Atopic dermatitis abates in some children as they reach ADOLESCENCE or early adulthood, though dermatologists believe the condition goes into an extended state of remission rather than disappears. In some adults, the only indications that atopic dermatitis persists are fissures and cracks in the skin on the palms of the hands and the soles of the feet, which may appear to be exceedingly dry skin rather than dermatitis. Coating the palms and soles with petroleum jelly at bedtime, protecting the coating with mittens and socks, often helps heal the fissures. About 10 percent of the American population has atopic dermatitis.

Contact dermatitis Numerous environmental substances, from plant resins (poison ivy) to metals (nickel, stainless steel) to bath soaps and laundry detergents, can irritate and inflame the skin. Contact dermatitis may represent an allergic response in which the IMMUNE SYSTEM, particularly the Langerhans cells located in the dermis, overreacts to a substance. Allergic contact dermatitis generally appears within 24 hours of contact, while weeks or even months of exposure to irritants may take place before causing contact dermatitis. The location of the first point of outbreak often helps narrow the field for identifying the cause.

Treatment is twofold: removing the offending irritant or ALLERGEN, and treating the symptoms. Oral antihistamine medications and topical corticosteroids typically reduce itching and inflammation. It may take up to three months for all symptoms of contact dermatitis to resolve. Contact dermatitis can be a matter of OCCUPATIONAL HEALTH AND SAFETY when the offending substance is necessary in the workplace. People who work with glues, paints, metals, plastics, latex rubber, and numerous industrial chemicals commonly develop contact dermatitis.

Exfoliative dermatitis An uncommon but serious form of dermatitis in which the epidermis (outer layer of the skin) becomes inflamed and forms scales that peel away, exfoliative dermatitis nearly always indicates systemic disease, frequently a cancer such as LEUKEMIA, cutaneous T-cell lymphoma (CTCC), or LYMPHOMA. Exfoliative dermatitis may be the earliest sign of PROSTATE CANCER, THYROID CANCER, and COLORECTAL CANCER. It also develops in people who have AIDS, and may occur as an ADVERSE REACTION to numerous medications.

Exfoliative dermatitis begins with patches of skin (lesions) that turn red and itch. Within two weeks the lesions spread to cover nearly the entire surface of the skin except the soles of the feet, palms of the hands, and face (though usually spare the mucous membranes). The scaling and dilation of blood vessels that follow significantly impairs all dermal functions from IMMUNE RESPONSE to thermal regulation (heat loss). Fluid oozes continually from the exposed dermis and the BLOOD vessels are dilated, causing excessive cooling that easily becomes HYPOTHERMIA. Damage to the pro-

tective epidermis exposes the inner layers of skin and tissues to infection.

Treatment aims to restore skin integrity and function as well as to remedy any underlying disorder. Symptomatic treatment typically includes oral antihistamines to control itching, topical corticosteroids to reduce inflammation, and warm baths. Prolonged or chronic exfoliative dermatitis may require IMMUNOSUPPRESSIVE THERAPY such as psoralen plus ultraviolet-A (PUVA) therapy or methotrexate. The success of treatment depends on identifying and treating the underlying cause. Idiopathic exfoliative dermatitis tends to recur, with periods of exacerbation alternating with periods of remission.

Nummular dermatitis Circular lesions about the size of coins that crust and weep are the distinctive hallmark of nummular dermatitis. Researchers do not know what causes the lesions to take such a precise form. Sometimes mistaken for tinea corporis (ringworm) at the onset of an outbreak, the lesions begin as red, raised circles that quickly progress. Usually the lesions remain confined to small areas, and typically recur in the same locations. Outbreaks can cause significant itching. As with other forms of dermatitis, antihistamines and topical corticosteroids help control symptoms. Severe or persistent symptoms may require a course of oral or intramuscular corticosteroids.

Seborrheic dermatitis A common cause of DANDRUFF, seborrheic dermatitis affects the sebaceous structures primarily of the head and face, notably on the scalp, behind the ears, around the eyebrows, and in the beard area on men's faces. Seborrheic dermatitis may also develop on other parts of the body that have numerous sebaceous structures, such as the chest and axilla (underarms), and typically occurs in a symmetrical pattern. Inflammation stimulates the sebaceous glands to increase sebum production, which in turn accelerates the turnover rate of dermal and epidermal cells that plug the sebaceous ducts and HAIR follicles. Key symptoms of seborrheic dermatitis include oily patches of skin that crust, scale, and flake.

Most seborrheic dermatitis is idiopathic (occurs without identifiable cause) and is more common in people between the ages of 20 and 40. Seborrheic dermatitis that occurs later in life may be a sign of PARKINSON'S DISEASE, though researchers do not fully understand this correlation. Treatments for dandruff are often effective for seborrheic dermatitis, and emphasize reducing sebum production and accumulation.

Stasis dermatitis Restricted or damaged peripheral blood circulation allows fluid to collect between the layers of the skin, causing inflammation and itching characteristic of dermatitis. The skin typically becomes discolored, turning reddish brown, and scaly as the condition persists. People who have DIABETES, VARICOSE VEINS, PERIPHERAL VASCULAR DISEASE (PVD), or INTERMITTENT CLAUDICATION have increased risk for stasis dermatitis, as do people who have restricted mobility or are bedridden. The impaired circulation limits the skin's ability to resist or fight infection, and can allow the skin to break down into ulcerations that require aggressive medical intervention. Wearing support hose, elevating the legs when sitting or lying down, and walking are measures that help reduce fluid accumulations (edema).

Symptoms and Diagnostic Path

Though each type of dermatitis has unique symptoms, all types share certain symptoms in common. These include lesions that:

- are erythematous and edematous (reddened and swollen)
- crust, weep, scale, and SCAR
- itch intensely
- recur

The dermatologist often can make the diagnosis based on the appearance, characteristics, and location of the lesions as well as the individual's age and family health history. When the diagnosis is questionable, the dermatologist may biopsy several lesions for further examination under the microscope. Tests for immune response also may be helpful for confirming a diagnosis.

Treatment Options and Outlook

Antihistamine and corticosteroid medications are the mainstay of pharmacological therapy for nearly all forms of dermatitis. Secondary bacterial infections require treatment with antibiotic medications. Most dermatitis is, or becomes, chronic. Treatment approaches strive to minimize the fre-

quency and severity of outbreaks. Though dermatitis is seldom life-threatening, it can significantly interfere with QUALITY OF LIFE. Researchers continue to explore the causes of dermatitis, looking for ways to suppress symptoms.

Risk Factors and Preventive Measures

The key risk factors for dermatitis are family history and existing allergies. Preventive measures focus on minimizing outbreaks and symptoms. Self-care approaches include

- short, warm (not hot) baths or showers
- mild, detergent-free soaps
- lubricating skin lotions, creams, and oils
- nonrestrictive clothing that allows moisture to evaporate
- restricted sun exposure
- resisting scratching

dermatofibroma A noncancerous (benign) tumor that develops in the connective tissue beneath the SKIN, most commonly on the legs and occasionally on the arms. Dermatofibromas are firm, round, and may differ in color from the surrounding skin. Most dermatofibromas cause no symptoms (other than cosmetic) and require no medical intervention unless they become tender or irritated. The dermatologist may opt to remove or scrape down a dermatofibroma in a location where it receives repeated trauma such as from shaving or rubbing against clothing. Dermatofibromas are common in adults.

diaper rash An irritation of the genitals and buttocks in an infant or young child who wears diapers. Diaper RASH may also affect adults who wear adult diapers or other incontinence products. Most diaper rash begins as a reaction to the chemicals in urine or feces, notably ammonia, that comes into contact with the SKIN. The skin typically appears chapped and raw. The involved area is painful and may crack and bleed. Diaper rash that lasts longer than three days often reflects an INFECTION of the skin, commonly FUNGUS (CANDIDIASIS). Untreated, persistent diaper rash may develop macerations that can result in deep ulcerations and CELLULITIS, requiring medical treatment. Mild to moderate diaper rash is very common in children who are not yet toilet trained, with nearly all children experiencing at least one episode. Diaper rash often accompanies DIARRHEA. Diaper rash occurs equally among infants who wear cloth diapers and who wear disposable diapers.

Home treatment successfully eliminates most diaper rash. Methods include

- frequent diaper changes
- cleansing the skin with gentle soap and warm water with each diaper change
- application of a moisture barrier cream or diaper rash product with each diaper change

A doctor should evaluate diaper rash that persists longer than a few days without improvement after home treatment measures.

discoid lupus erythematosus (DLE) A chronic autoimmune disorder, also called cutaneous lupus erythematosus, in which roughly circular, reddened patches (erythematous lesions) form on the SKIN. The lesions are most common on the face, back of the neck, scalp, inner lips and mouth, and outer portions of the auditory (EAR) canals. The INFLAMMATION involves the epidermis, dermis, and HAIR follicles. When the lesions heal they leave permanent scarring, lightened pigmentation, and loss of hair (ALOPECIA) in their wake. Outbreaks may range from localized and sporadic to generalized and persistent. Cigarette smoking, heat, and exposure to sunlight precipitate or exacerbate outbreaks in many people who have DLE. About 5 percent of people who have DLE subsequently develop SYSTEMIC LUPUS ERYTHEMATOSUS (SLE), a generalized autoimmune disorder in

which lesions can attack internal structures as well as the skin.

Symptoms and Diagnostic Path

The characteristic appearance of the skin lesions is a clear diagnostic marker for DLE. Because the same skin lesions can be an early indication of SLE, the diagnostic path includes biopsy of representative lesions as well as BLOOD tests to assess ANTIBODY status. People whose DLE lesions are primarily above the neck usually have isolated DLE. People who have DLE lesions both above and below the neck have increased risk for SLE.

Treatment Options and Outlook

The primary treatment approach for DLE is topical or injected CORTICOSTEROID MEDICATIONS. In the early stages of the condition, topical corticosteroids often limit the lesion's progression. As the condition becomes established, the lesions may not respond as well and the dermatologist may inject a corticosteroid medication directly into the lesion. Some people experience relief with medications otherwise prescribed to treat MALARIA, RHEUMATOID ARTHRITIS, and severe ACNE, as well as medications that act on the IMMUNE SYSTEM such as the corticosteroids and immunomodulators. These medications have potentially serious side effects and interact with numerous other medications. Women who are pregnant or who could become pregnant cannot take many of them, as they cause damage to the developing fetus.

The use of some of these medications is OFF LABEL USE—that is, not a use the US Food and Drug Administration (FDA) has approved though the DRUG itself has FDA approval for other uses. It is important for people who have DLE to discuss with their doctors, and to fully under-stand, the potential benefits and risks of all treatment options. Treatment approaches for DLE target symptoms though do not cure the condition itself.

MEDICATIONS TO TREAT DLE

Anti-Acne (Retinoids)	
isotretinoin	acitretin
etretinate	tazarotene
Antimalarials	
hydroxychloroquine	chloroquine
Corticosteroids	
triamcinolone	hydrocortisone
betamethasone	diflorasone
flumethasone	mometasone
desoximetasone	halcinonide
fluocinonide	amcinonide
Immunomodulators	
interferon	thalidomide
azathioprine	mycophenolate
methotrexate	dapsone

Risk Factors and Preventive Measures

Researchers do not know for certain what autoimmune mechanisms cause the lupus disorders, or what triggers them. Because DLE and SLE seem to run in families, a genetic component is likely. At present there are no known preventive measures. Though women are more likely than men to develop DLE, there are no clear risk factors for the condition other than family history. Early treatment minimizes the residual scarring, atrophy, alopecia (hair loss), and other permanent consequences the lesions can cause.

Cigarette smoking worsens the lesions, so doctors strongly advise people who have DLE and smoke to stop. Sun exposure also increases the frequency and number of lesions; liberal application of high-SPF sunscreen and sun-blocking clothing can mitigate this effect.

ecchymosis The clinical term for a bruise. Ecchymosis occurs when there is bleeding into the layers of the SKIN, causing discoloration and sometimes swelling and discomfort. The injured area typically undergoes several, and sometimes vivid, color changes during the stages of HEALING. Ecchymosis usually results from trauma to the tissue, such as a blow. Ecchymosis may also occur as a symptom of bleeding disorders, LEUKEMIA, LIVER disease, and other health conditions. Ecchymosis that develops without known trauma warrants a doctor's evaluation to determine the underlying cause.

epidermolysis bullosa The collective term for a group of inherited SKIN disorders that result in blisterlike formations (bullae) on the skin. Severity can range from mild (a few bullae) to debilitating (bullae covering large areas of the body). Dermatologists classify epidermolysis bullosa according to the layer of the skin where the bullae originate. There are three general types of epidermolysis bullosa:

- Epidermolysis bullosa simplex involves the epidermis, the skin's outermost layer, and usually results from an autosomal dominance inheritance pattern for the gene that encodes keratin production.
- Junctional epidermolysis bullosa involves the basement membrane, a thin layer of cells that separates the epidermis and the dermis, and usually results from an autosomal recessive inheritance pattern for the gene that encodes protein structures which connect the epidermis and dermis through the basement membrane.
- Dystrophic epidermolysis bullosa involves the basement membrane as well, occurring in either an autosomal dominance or a recessive inheritance pattern for the gene that encodes collagen formation.

In all types, bullae form with friction or irritation to the skin. In the junctional and dystrophic types, this includes the mucous membranes of the gastrointestinal and genitourinary tracts. Healed bullae typically leave scars. The severity of symptoms and disease vary according to the type and, with dystrophic epidermolysis bullosa, the inheritance pattern (dominant or recessive). At present there is no cure for any type of epidermolysis bullosa.

Symptoms and Diagnostic Path

The bullae of epidermolysis bullosa are uniquely characteristic and typically begin in infancy. The skin is frail and may BLISTER or tear upon touch or contact with clothing and bedding. The bullae of epidermolysis bullosa simplex generally affect only the palms of the hands and soles of the feet. The bullae of other types may affect mucous membranes throughout the body. The repeated blistering and HEALING of junctional and dystrophic types causes scarring and tissue damage that often results in deformities. People who have junctional or dystrophic epidermolysis bullosa may also have defects of the tooth enamel and the NAILS, or be missing fingernails or toenails.

The diagnostic path includes examination of the entire skin surface and mucous tissues with biopsy to determine the level of tissue separation

in representative bullae, which distinguishes the general type of epidermolysis bullosa. Molecular examination, including DNA mutation analysis identifies the precise type. CHORIONIC VILLI SAMPLING (CVS) during PREGNANCY (removing a small tissue sample from the edge of the PLACENTA) can identify whether the FETUS has the disorder.

Treatment Options and Outlook

Treatment attempts to minimize or prevent bullae formation, heal bullae that do form, and provide necessary supportive care such as PARENTERAL NUTRITION. Healing mechanisms are often impaired, and ruptured bullae and related tissue damage can leave tissues exposed. Burn therapies such as artificial skin can provide a temporary covering to improve healing. Support groups offer forums for sharing experiences and coping methods.

People who have mild forms of disease may experience few bullae or complications and be able to enjoy fully active lives. More severe forms are debilitating or fatal. It is important though difficult to prevent ruptured bullae from becoming infected. Nutritional deficiencies are common when bullae form along the gastrointestinal mucosa, which may interfere with swallowing (bullae that form in the ESOPHAGUS) or absorption (bullae that form in the SMALL INTESTINE). The risk for squamous cell SKIN CANCER is very high among people who have junctional epidermolysis bullosa, with first appearance often in late ADOLESCENCE. Dermatologists advise frequent skin self-examinations and regular skin examinations by a dermatologist who has clinical experience with epidermolysis bullosa.

Risk Factors and Preventive Measures

Epidermolysis bullosa is a genetic disorder, so the primary risk factor is a family history of the condition. In autosomal recessive INHERITANCE PATTERNS, it is possible for each parent to carry the gene defect yet show no indications of disease or to have a mild form and not realize it. GENETIC TESTING can help families detect the presence of the gene MUTATION, and GENETIC COUNSELING can help couples in making family-planning decisions. Researchers continue to explore GENE THERAPY solutions.

erysipelas A streptococcal INFECTION of the dermis, the middle layer of the SKIN. Infection commonly follows STREP THROAT, with the BACTERIA likely carried on the hands to the skin where a scratch or other breach allows the bacteria to colonize into an infection. The infection presents characteristic symptoms that allow prompt clinical diagnosis. These symptoms include

- redness (erythema), swelling (edema), and PAIN at the site of the infection
- clearly defined and usually raised border between the infection and healthy skin
- swelling of adjacent LYMPH NODES
- FEVER, generalized discomfort, and aching in the muscles and joints

Treatment is a course of ANTIBIOTIC MEDICATIONS, preferably penicillin unless the person is allergic, and medications to relieve pain and fever. Warm compresses help bring blood to the area, improving the effectiveness of the body's IMMUNE RESPONSE to attack the infection and increasing circulation of the antibiotic.

It is important for people to take ANTIBIOTIC MEDICATIONS prescribed to treat erysipelas as the doctor directs, and to use them until all the antibiotic is gone, to completely eradicate the streptococcal BACTERIA.

Prompt medical attention is essential as erysipelas can rapidly invade deeper tissues, causing CELLULITIS and perhaps SEPTICEMIA (bodywide infection). Untreated or undertreated streptococcal infections also present the risk for INFLAMMATION of the HEART valves (RHEUMATIC HEART DISEASE). With treatment, symptoms improve within 72 hours and the erysipelas resolves completely in 10 to 14 days. People who have DIABETES, impaired peripheral circulation, and IMMUNE DISORDERS are at increased risk for erysipelas. Preventive meas-

ures include HAND WASHING after coughing or sneezing.

erythema multiforme A HYPERSENSITIVITY REACTION, commonly to medications and sometimes to viral INFECTION, in which circular, weltlike lesions resembling targets form on the arms, hands, legs, and feet. Lesions also often form on and around the lips and inside the MOUTH. The center of the LESION is typically pale and blistered, surrounded with a reddened (erythematous) middle ring. The outer ring often has a purplish tint, giving it a bruiselike appearance. Lesions typically begin erupting within three days of the causative exposure, rising suddenly. Some people experience tingling, itching, or a burning sensation at the site of the lesion.

Common causes of erythema multiforme include

- infection with the HERPES SIMPLEX VIRUS
- ANTIBIOTIC MEDICATIONS
- ANTISEIZURE MEDICATIONS
- aspirin and NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS)
- numerous other medications

The uniquely characteristic lesions in provide fairly conclusive diagnosis. The causative agent may be clear, such as a recently taken medication, or remain unknown (idiopathic). Most erythema multiforme outbreaks are self-limiting and clear up two to three weeks after exposure to the causative agent ends. Treatment to provide relief from discomfort may include ANTIHISTAMINE MEDICATIONS for itching, ANALGESIC MEDICATIONS for PAIN relief, and topical corticosteroids for INFLAMMATION. Nearly always the lesions heal without scarring or other complications. Prevention of future outbreaks is difficult as there are so many potential causes.

See also TOXIC EPIDERMAL NECROLYSIS; URTICARIA.

erythema nodosum The eruption of red nodules along the top surfaces of the lower legs (shins). Erythema nodosum is nearly always a symptom of an underlying condition, often a streptococcal INFECTION, and represents INFLAMMATION of the fatty tissue at the foundation of the SKIN. Other symptoms include FEVER, PAIN and swelling in the joints, and generalized discomfort and malaise. Erythema nodosum occurs most commonly in young adults between the ages of 18 and 30.

The initial eruption of nodules may clear in six to eight weeks, though outbreaks tend to recur over months to years. Over the course of HEALING the nodules change color from their original bright red to bluish red and ultimately yellow, resembling bruises, before fading completely. The doctor diagnoses erythema nodosum primarily on the basis of its appearance, though may run BLOOD tests to look for evidence of AUTOIMMUNE DISORDERS or infection that may underlie the outbreak. Treatment targets the underlying cause and may include ANTIBIOTIC MEDICATIONS when there is infection or anti-inflammatory agents such as NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) to relieve swelling, pain, and fever.

See also JOINT; NODULE; TUBERCULOSIS.

erythrasma A chronic bacterial INFECTION of the epidermis (outer layer of the SKIN) that produces scaly, brownish red patches that often itch. The patches may occur anywhere on the body though are most common in skin folds and moist areas such as the underarm (axilla) and groin. When

CONDITIONS ASSOCIATED WITH ERYTHEMA NODOSUM

STREP THROAT	rheumatic FEVER	SCARLET FEVER
Hodgkin's LYMPHOMA	Hansen's disease	bacterial infection
fungal INFECTION	adverse reaction to sulfonamides	PREGNANCY
ADVERSE REACTION to sulfonylureas	oral contraceptives	HISTOPLASMOSIS
INFLAMMATORY BOWEL DISEASE (IBD)	non-Hodgkin's lymphoma	SARCOIDOSIS

viewed under ultraviolet light, the areas of infection appear a deep coral color. *Corynebacteria*, BACTERIA normally present on the skin, are responsible for the infection. People who have DIABETES or OBESITY are especially susceptible to erythrasma. Treatment is topical and sometimes oral erythromycin, an antibiotic medication, which completely eliminates the infection within 10 to 14 days. As with all antibiotics, it is important to take the erythromycin (or other prescribed antibiotic) as the doctor directs and until the medication is gone. Erythrasma may recur (come back) if the environment of the skin continues to support the growth of *Corynebacteria*.

Fitzpatrick skin type A commonly used classification system for identifying a person's SKIN characteristics, particularly the likelihood for SUNBURN and developing ACTINIC KERATOSIS and SKIN CANCER. Dermatologists also use Fitzpatrick skin type as a factor in determining appropriate cosmetic procedures to treat skin blemishes and WRINKLES.

folliculitis An infected and inflamed HAIR follicle. Folliculitis may involve a single follicle or a number of follicles in proximity, and begins with a reddened bump at the site of the follicle that soon progresses to a PUSTULE containing a collection of fluid and cells (pus). The site often hurts or itches. Most folliculitis is idiopathic—that is, it develops without identifiable cause. However, a number of risk factors can precipitate its occurrence. Among them are

- OBESITY
- HYPERHIDROSIS
- DIABETES
- DERMATITIS and SKIN irritations
- long-term topical corticosteroid use
- ABRASIONS
- immunosuppressive disorders such as HIV/AIDS

Warm compresses applied to the site several times a day may resolve isolated folliculitis. Folliculitis that persists or involves multiple hair follicles requires treatment with topical and oral ANTIBIOTIC MEDICATIONS. Most folliculitis improves within a few days of antibiotic therapy, though it is important to take the full amount of medication

FITZPATRICK SKIN TYPE CLASSIFICATIONS

Type	Skin characteristics	Sun exposure
type I	very pale or ruddy; numerous freckles	always BURNS, never tans; severe SUNBURN (blisters) with unprotected exposure; high risk for SKIN CANCER
type II	pale or light-toned; some freckles mostly on face, shoulders, arms, hands	usually burns, lightly tans; moderate sunburn (redness) with unprotected exposure; increased risk for skin cancer
type III	olive	sometimes burns, moderately tans; mild sunburn (pinkness) with unprotected exposure; moderate risk for skin cancer
type IV	light brown	seldom burns, easily tans; low risk for skin cancer
type V	brown	rarely burns, darkly tans; seldom develops skin cancer
type VI	dark brown to brownish black	never burns; rarely develops skin cancer

as the doctor directs. In people who frequently have folliculitis or who are on long-term antibiotic therapy such as for ACNE, the INFECTION may resist the common first-line antibiotics, requiring further therapy with a different antibiotic. Folliculitis usually heals without scarring or residual complications.

HOT TUB FOLLICULITIS

The hot, moist environment of a hot tub is the ideal incubator for various BACTERIA, notably the *Pseudomonas aeruginosa*. The warm water of the hot tub opens the pores, giving the bacteria access to the HAIR follicles. When the pores close after leaving the hot tub, they trap *P. aeruginosa,* which thrives in the moist setting. Folliculitis results, often appearing on the SKIN the same pattern of the clothing worn in the tub.

freckles See LENTIGINES.

frostbite Damage to the SKIN that results from prolonged exposure to extremely cold temperatures. Frostbite occurs when the fluid in cells crystallizes into ice, causing the skin and often the underlying tissues to freeze. The fingers, hands, toes, feet, NOSE, and ears are most vulnerable to frostbite. People who have impaired peripheral circulation are at increased risk. Frostbite also can damage blood vessels, interrupting the blood supply. When this occurs, GANGRENE (tissue death) and subsequent loss of the body part are significant threats.

Symptoms and Diagnostic Path

Any loss of feeling following extended exposure to the cold raises suspicion of frostbite and is the first factor to consider when evaluating potential frostbite. The ice crystals that form cause the skin to become hard, pallid, and cold to the touch. There is loss of feeling and function, and the skin may BLISTER. Skin that has remained frostbitten for a long time may already be gangrenous or necrotic (blackened and dead). As it warms, frostbitten

FROSTBITE SEVERITY

Degree of Damage	Characteristics	Recovery Implications
first degree	spots of whitened, hardened SKIN involving primarily the epidermis erythema (redness) of adjacent skin; localized edema (swelling) distorted or absent sense of touch or clumsy movements	recovery with no residual complications
second degree	areas of whitened, hardened skin involving the epidermis and dermis erythema of adjacent skin; regional edema loss of feeling and movement fluid-filled blisters	recovery with some residual complications (scarring)
third degree	white, hard skin with frostbite extending through the layers of the skin and into the subcutaneous tissue regional edema loss of feeling and movement blood-filled blisters	recovery with moderate residual complications (tissue loss and scarring)
fourth degree	white, hard skin with frostbite extending through the skin and into supporting tissues and structures GANGRENE or necrosis; regional edema	significant loss of tissue, with AMPUTATION likely

skin turns red and BURNS or hurts, sometimes severely.

Treatment Options and Outlook

Prompt treatment is essential to save the affected tissue and body parts. When possible, a doctor should evaluate the situation and implement warming procedures for maximum recovery. To protect body parts until the person receives medical treatment, wrap them in sterile bandages (separating the fingers and toes, if affected). When immediate medical attention is not possible, warming the frostbitten areas should only be undertaken when they cannot refreeze.

Refreezing does more damage than allowing the area to remain frozen. Do not thaw frostbite unless the area can remain warm.

To warm frostbite, place the affected parts under gently running warm water for 20 to 30 minutes. The water temperature should be 8º to 10ºF above normal body temperature or about 108ºF, which feels warm but not hot to someone whose skin temperature is normal. For frostbitten ears, cheeks, or nose, apply cloths dipped in warm water. Do not use dry heat, as it will further damage the skin and tissues. Severe frostbite is likely better left for emergency care providers to treat because tissue damage is likely to be extensive.

The thawing process can be extremely painful, and may require PAIN relief medications. Superficial frostbite (first and second degree) usually heals with few or no residual consequences. Frostbite that extends deeper than the layers of the skin (third and fourth degree) can destroy MUSCLE, connective tissue, joints, and BONE, and may necessitate AMPUTATION or surgery to clean away necrotic tissue. A full damage assessment may not be possible for six to eight weeks, as it may take that long for tissue to demonstrate whether it will recover or die.

Risk Factors and Preventive Measures

People who spend extended time outdoors in cold weather, such as for employment or recreation, risk frostbite when exposure time extends beyond what clothing can protect. Wetness increases the risk. People who are very young or very old or who have DIABETES, PERIPHERAL VASCULAR DISEASE (PVD), RAYNAUD'S SYNDROME, untreated or undertreated HYPOTHYROIDISM, OR MALNUTRITION may develop frostbite far more rapidly and severely. Preventive measures include protective clothing appropriate for the weather conditions and limiting exposure when temperatures are extremely cold.

furuncle An infected HAIR follicle, commonly called a boil. A furuncle develops when BACTERIA normally present on the surface of the SKIN (typically staphylococcus) causes a collection of dead cells and fluid (pus) to block the follicle. The blocked follicle becomes reddened, inflamed, enlarged, and usually quite painful. Furuncles are most likely to develop in the underarm area, groin, hairline at the back of the neck, and, in men, the beard area of the face.

Most furuncles improve with frequent applications of moist heat, which helps open the follicle and drain the collected pus. A typical furuncle heals on its own in 7 to 10 days, though a large furuncle may take longer. A furuncle that does not improve within 10 days warrants a doctor's evaluation and may require lancing (a small incision to drain the INFECTION) or ANTIBIOTIC MEDICATIONS. People who have DIABETES or who are IMMUNOCOMPROMISED are more likely to develop furuncles.

Furuncles tend to recur. Preventive measures include reducing irritation from clothing and regular cleansing with an antibacterial soap. Prompt treatment at the earliest indication of a furuncle can minimize or head off the infection's development. A large furuncle may leave a SCAR after it heals, though most furuncles heal without scarring.

goose bumps A bumpy texture to the SKIN, also called gooseflesh, that results when the erector muscles in the HAIR follicles contract, causing the hair to "stand up." Goose bumps occur when a person becomes chilled or fearful, a vestigial response no longer physiologically useful in humans. The physiologic mechanism that causes goose bumps, called the pilomotor REFLEX or pilo-

erection, is involuntary. Researchers believe it is in part the consequence of the release of stress hormones, primarily EPINEPHRINE (also called adrenaline), which stimulates the HYPOTHALAMUS. In other mammals the pilomotor reflex raises the hair or fur for warmth by trapping air near the skin's surface or to present an intimidating appearance by making the animal appear larger than it is. Goose bumps often accompany shivering, rapid and involuntary muscle contraction to generate heat.

granuloma telangiectaticum A noncancerous vascular tumor, also called a lobular capillary hemangioma or GRANULOMA pyogenicum, made up of entangled capillaries. A granuloma telangiectaticum appears suddenly as a shiny red NODULE that bleeds easily with bumping or irritation and may itch or hurt. Doctors typically remove these growths because of their tendency to bleed and to confirm the diagnosis through biopsy (examination of a tissue sample under the microscope). The cause of granuloma telangiectaticum remains uncertain; in some people the growth arises following trauma to the site, though the nodules most often occur without a known precipitating event. The growths may recur.

H

hair The fibers that grow from the hair follicles. Not far above the root of the hair follicle the cells that form the hair fiber are dead, hardened into their shape through compression within the follicle as new cells emerging from the hair's root push them upward. A hair fiber is five or six cells in thickness and varies in length, depending on its location. Hair on the head can grow to several feet in length, whereas the hair of the eyelashes is generally no longer than about a quarter of an inch long. The hair does not require nourishment from the body, though the secretions of the sebaceous glands help moisturize the hair fibers to keep them supple.

Genetic encoding determines the characteristics of the hair, from how rapidly it grows to whether it is curly or straight. Hair covers all SKIN surfaces except the palms of the hands and the soles of the feet, though is most prominent on the head and, after PUBERTY, in the pubic region, on the legs, and under the arms. Men typically have darker, coarser body hair than women. Specialized hairs line the auditory canals and the inside of the NOSE, functioning to remove debris from these structures.

Like the skin, the hair provides clues to the health of the body. Numerous conditions can change the characteristics of the hair. Such changes reflect circumstances that affect the hair follicles in some way, from physical damage, such as BURNS or scars that can destroy follicles, to immune or disease processes that attack the follicles and disrupt hair growth. Physical stress such as the body experiences with major injury, illness, or surgery can cause various changes in the hair, from altered color and consistency to hair loss.

The hair's characteristics also change with aging. By midlife the hair typically starts to lose the melanocytes that give it color. Sebum (the natural oil that lubricates the hair follicle) production slows, allowing the hair to become dry. Sun exposure also can alter the hair, lightening its color or extracting moisture to make it brittle. Hair-care products can help restore moisture to the hair on the head as well as to the skin of the scalp.

hair replacement A surgical procedure, also called hair transplantation, to relocate viable HAIR follicles from sites on the scalp where they are abundant to sites where there has been permanent hair loss. The most common reason for hair replacement is androgenic ALOPECIA (male pattern hair loss). Hair replacement is nearly always a cos-

metic procedure, though may be restorative to correct damage resulting from injuries or BIRTH DEFECTS.

Surgical Procedure

Hair replacement procedures may involve tissue grafts, flaps, expansion, or combinations of these methods. The surgeon will plan the appropriate approach for each individual's situation and hair loss circumstances. The OPERATION is an AMBULATORY SURGERY, performed with local ANESTHESIA and a sedative for comfort. Most people require several operations to establish satisfactory results. Mild to moderate PAIN is common for several days following a hair replacement procedure.

Tissue grafts SKIN grafts were the original hair transplantation method. The surgeon removes a plug or slice of skin from the back or side of the head and transplants it to a hair loss site. The graft may contain from one or two to several hundred hair follicles, depending on the technique and size. With the first replacement procedure the surgeon places the grafts fairly widely apart (about one eighth inch) to allow generous BLOOD circulation. Subsequent grafts fill in the spaces. Generally, a pressure bandage holds the grafts in place for 24 to 48 hours following surgery to help the transplanted skin attach to the new site, and fine sutures (stitches) close the donor sites.

HAIR REPLACEMENT GRAFT TECHNIQUES

Type of Graft	Follicles Contained	Grafts per Session
punch graft	10 to 15	50
micrograft	1 to 2	500 to 700
minigraft	2 to 4	500 to 700
slit graft	4 to 10	500 to 700
strip graft	20 to 40	500 to 700

Tissue flaps A tissue flap relocates a substantial amount of hair-bearing skin to a single recipient site. The surgeon loosens a flap of skin near the area of hair loss, and removes a similarly sized and shaped segment of skin from the hairless scalp. The surgeon leaves one end of the flap attached and pulls the remainder of the flap over the recipient site, suturing it in place. The surgeon also sutures the edges of the donor location, which heals beneath the hair with no visible SCAR. A common variation of tissue flap hair replacement is scalp reduction, in which the surgeon removes more hairless scalp than the replacement flap covers, drawing the edges tight to pull additional hair from the sides of the head higher onto the crown of the head. Tissue flaps generally heal with less chance of rejection than grafts because they remain anchored to their original blood supply.

Tissue expansion Plastic surgeons developed TISSUE EXPANSION techniques to reconstruct major skin damage following trauma such as BURNS or major surgery, then discovered tissue expansion allows natural expansion of hair-bearing scalp for hair replacement. The surgeon loosens a segment of hair-bearing skin adjacent to an area of hairless skin to create a pouch, and inserts a special silicone balloon called a tissue expander.

Over a period of months the surgeon injects saline (sterile saltwater) into the expander, gradually increasing its size. As the expander stretches, the skin grows to accommodate it. When the area produces the desired amount of growth, the surgeon removes the expander, surgically removes a similarly sized and shaped segment of hairless scalp, and pulls the new skin over the area. Tissue expansion can relocate the greatest surface area of hair-bearing skin in a single procedure and produces the most natural-appearing frontal hairline.

Risks and Complications

Risks and complications are slight for hair replacement methods, and include excessive bleeding, INFECTION, and reaction to the anesthetic. The recipient site on the scalp also may reject the replacement tissue. Because relocation traumatizes hair follicles, they immediately enter a resting phase and shed their hair about five to six weeks following relocation. Though this is normal, many people find it alarming and worry that it signals rejection of the new hair. However, with rejection the entire segment of relocated skin fails to grow and eventually sloughs off. The surgeon can generally replace the rejected replacement tissue during the next session of surgery. When they reestablish themselves in their new sites, the follicles return to a growth phase and produce about an inch of new hair within six to eight weeks after the old hair falls out.

Outlook and Lifestyle Modifications

For the first few weeks following surgery the scalp is swollen and tender, and the replacement sites may bleed with strenuous physical activity. Surgeons recommend refraining from intense exercise or activity and contact sports for two or three weeks after the procedure. The scalp remains tender (though the swelling subsides within a few weeks) for up to three or four months, depending on the replacement method. Transplanted hair growth does not look exactly the same as the hair that previously grew from the transplant site, though most people experience satisfactory results when a qualified and experienced cosmetic surgeon performs the surgery. It generally takes a year or two from the final hair replacement procedure to see the full effects.

There must be abundant healthy hair on the back and sides of the head to serve as donor hair. Men in whom male pattern hair loss begins early in life are more likely to experience severe or total hair loss as they age. Satisfactory results from hair replacement surgery are less certain when this is the case, as the transplanted follicles may also experience hair loss. Hair loss from follicles native to the site generally continues, particularly in male pattern hair loss, which can result in irregular growth patterns and the need for further hair replacement.

hidradenitis suppurativa A condition of chronic INFLAMMATION resulting from blockage of the HAIR follicles (follicular occlusion). The inflammation may involve the apocrine glands, SWEAT GLANDS that secrete fluid into the hair follicles. The hair follicles then channel the sweat to the surface of the SKIN. When sebum or cellular debris plugs the apocrine gland's opening, fluid backs up into the gland. The situation results in an INFECTION that produces a hard, painful, reddened NODULE below the skin's surface. Though the nodules will heal in three or four weeks without treatment, they often SCAR and recur. Treatment with oral ANTIBIOTIC MEDICATIONS may help control the condition though does not always clear it up. Occasionally the dermatologist needs to lance (surgically open) the nodule to allow it to drain. Dermatologists do not know what causes hidradenitis suppurativa to develop, though it is more common in people who have OBESITY.

hyperhidrosis Excessive sweating that results from abnormal functioning of the nerves or BLOOD vessels that supply the eccrine SWEAT GLANDS. Hyperhidrosis characteristically involves the hands (palms), feet (soles), and axillae (underarms), though can affect eccrine sweat glands anywhere in the body. The eccrine sweat glands produce most of the body's sweat and play a key role in thermoregulation (regulating body heat). They empty their fluids (perspiration) directly to the SKIN's surface for rapid evaporation and cooling.

Stress and physical activity tend to exacerbate hyperhidrosis, particularly when it affects primarily the hands and feet. The portion of the BRAIN that regulates sweating in these areas, the cerebral cortex, is not part of the body's thermoregulation system but rather responds to emotional signals such as anxiety and fear. Hyperhidrosis may also occur as an undesired SIDE EFFECT of medications or a symptom of metabolic disorders such as HYPERTHYROIDISM and DIABETES, or health conditions such as TUBERCULOSIS and Hodgkin's LYMPHOMA. Most hyperhidrosis that arises from structural or functional anomalies of the nerves or blood vessels first appears in ADOLESCENCE, when the hormonal changes of PUBERTY stimulate sweat gland function. Hyperhidrosis that begins later in life generally arises from underlying health conditions.

Symptoms and Diagnostic Path

The primary symptom of hyperhidrosis is profusely excessive sweating. The hands and feet, when involved, may be continually wet. Sweating from the underarms and other areas of the body typically drenches clothing, requiring frequent clothing changes. The diagnostic path typically includes a comprehensive NEUROLOGIC EXAMINATION and blood tests to measure HORMONE levels. The doctor may conduct further diagnostic procedures, depending on the individual's health circumstances.

Treatment Options and Outlook

Treatment options currently available in the United States include topical products, oral medications, BOTULINUM THERAPY, iontophoresis, and, when other treatments are unsuccessful, surgery.

- Topical products block the pores of the sweat glands. Those commonly used include aluminum chloride preparations, boric or tannic acid solutions, glutaraldehyde, and potassium permanganate. These products may stain the skin and clothing. Most people apply them at night and wash them off in the morning.
- Oral medications interrupt the action of the nerves that regulate sweat gland activity. Those commonly used are anticholinergics such as propantheline and benztropine, which block the action of the NEUROTRANSMITTER acetylcholine. Dermatologists sometimes prescribe other medications such as beta-blockers and calcium channel blockers. These medications may have unacceptable side effects, however, and they are not approved for this use in the United States.
- Iontophoresis uses mild electrical current in a water-based solution to shrink the sweat gland pores and is a treatment option for hyperhidrosis of the hands and feet. Relief generally requires daily treatments over a period of several weeks.
- Botulinum therapy (localized injection of purified botulinum toxin) blocks acetylcholine, interrupting the flow of NERVE signals to the muscles that contract to push fluid from the sweat glands. The effect can last for six months or longer.
- Surgery to sever some of the nerves supplying the sweat glands, or to remove clusters of sweat glands such as in the axillae, is a treatment of last resort for severe hyperhidrosis that does not respond to other treatments. The effects are permanent.

Many people who have hyperhidrosis use combinations of these approaches to control their symptoms. Hyperhidrosis is often deeply embarrassing to those who have it, particularly adolescents. Because stress plays a key role in hyperhidrosis, stress management techniques are often helpful for coping with the condition as well as reducing the stimuli that exacerbate symptoms.

Risk Factors and Preventive Measures

When an underlying health condition is the cause of the hyperhidrosis, treating the condition eliminates the hyperhidrosis. Primary hyperhidrosis is a lifelong condition for which there are no known risk factors or preventive measures.

I–J

ichthyosis A genetic disorder of keratinization in which the cells the SKIN sheds as part of its continual renewal cluster on the skin's surface in scale-like formations. The lesions itch and flake, and the involved surfaces of the skin become very dry, reddened, and inflamed. Ichthyosis may affect limited areas of the skin or most of the skin's surface, depending on which of several GENE mutations is responsible for the condition. Ichthyosis is chronic and lifelong, with symptoms first appearing in early childhood. Ichthyosis may be hereditary or acquired. Symptoms of hereditary ichthyosis are present at birth and can be severe, often affecting the eyes and eyelids.

The dermatologist can usually diagnose ichthyosis on the basis of its appearance, though may biopsy several lesions to confirm the diagnosis. Treatment attempts to restore moisture to the skin as well as to accelerate exfoliation (remove dead cells from the skin's surface). Lotions, creams, and ointments containing lanolin or other emollients help the skin retain moisture, which eases the itching and INFLAMMATION. Topical products that contain fruit acids such as alphahydroxy acid or lactic acid help remove dead cells.

Severe ichthyosis may require topical or oral treatment with a retinoid medication such as isotretinoin. The scaly lesions tend to overlap one another and can trap BACTERIA and other microorganisms normally present on the skin's surface, causing INFECTION that requires treatment with topical or oral ANTIBIOTIC MEDICATIONS. An ophthalmologist should provide monitoring and care to detect and promptly treat EYE symptoms to prevent permanent damage to the CORNEA and to preserve vision.

impetigo A contagious bacterial INFECTION of the SKIN that most commonly affects young children. Staphylococcal or streptococcal BACTERIA are the usual culprits, typically taking advantage of breeches in the skin's integrity that result from rashes, insect bites, and other minor wounds. The infection begins as small blisters, often around the MOUTH, that itch and burn. Scratching or touching the blisters and then touching other parts of the body spreads the infection. Contact also spreads the infection to other people. After two or three days the blisters rupture, ooze, and crust. The crust is characteristically honeylike in color and appearance. The blisters remain contagious as long as they are present.

Treatment is a topical antibiotic applied to the blistered areas. The doctor may also prescribe an oral antibiotic medication when the infection extends to multiple areas of the body. The blisters begin to recede within 24 to 48 hours of initiating treatment, which eases the itching and discomfort. The blisters are no longer contagious at this stage, and generally heal completely within five to seven days. Frequent HAND WASHING with antibacterial soap and warm water helps stop the spread of impetigo among children, family members, and caregivers. Prompt cleansing and treatment of minor skin irritations reduces the opportunity for impetigo to develop.

ingrown hair A new HAIR that curls as it grows, slicing into the side of the hair follicle instead of arising from it to extend above the surface of the SKIN. An ingrown hair forms a painful red bump. The hair may grow its way through the wall of the follicle and above the skin, or may block the folli-

cle, causing INFLAMMATION and INFECTION (FOLLICULITIS). People who have curly or kinky hair are more likely to develop ingrown hairs. Men may develop ingrown hairs in the beard area as a consequence of shaving, sometimes called shaving bumps or shaving rash. ACNE and other inflammatory conditions of the skin that block the follicles can cause ingrown hairs. Moisturizing the skin helps open the follicles, allowing the hair to grow outward. Warm compresses can help release cells and sebum clogging the follicles, releasing the hair. Regular skin cleansing and mild exfoliants also help keep the follicles clear.

ingrown nail A toenail, or less commonly a fingernail, that grows beneath the surrounding SKIN. An ingrown nail, also called onychocryptosis, is painful and easily become infected. Often the tissue around the nail swells and grows over the nail (hypertrophy), further aggravating the site. Ingrown NAILS require medical attention and often minor surgery done in the provider's office. The provider injects the involved finger or toe with an anesthetic to numb it, then clips the corners of the ingrown nail to release it from the skin and trims away the excess tissue. Typically the doctor then applies a caustic solution, usually an acid preparation, to prevent the portion of nail from regrowing.

Tight-fitting shoes are a common cause of ingrown toenails. The shape of the toes also is a factor, with nails that have a pronounced curve being more likely to grow into the side of the toe. A common but ineffective home remedy for ingrown toenails is to cut a "V" into the top edge of the nail with the presumption that doing so will draw the edges of the nail away from the skin as the nail grows. The shape of the nail bed determines the growth pattern of the nail, however. The jagged edges that result at the top of the nail from this method present the potential for tears and snags that can separate the nail from the toe, another painful problem.

In some people ingrown nails tend to recur and may require more aggressive treatment such as removal of additional nail or the entire nail. Most people experience permanent relief after a single treatment to remove the edges of the nail. Podiatrists recommend trimming the nails straight across, with a slight margin over the edge of the toe. People who have DIABETES, PERIPHERAL VASCULAR DISEASE (PVD), or other conditions that impair blood circulation to the feet should inspect their feet daily and see a doctor or podiatrist regularly as well as at the first indication of irritation.

K

Kaposi's sarcoma A CANCER that develops in the connective tissues that support the SKIN, with characteristic lesions on the skin and mucous membranes. There are several types of Kaposi's sarcoma. The two that are most common in the United States are AIDS-related Kaposi's sarcoma and transplant-related Kaposi's sarcoma.

In 1994 researchers discovered that human herpesvirus 8 (HHV-8), sometimes called Kaposi's sarcoma–associated herpesvirus (KSHV), causes Kaposi's sarcoma. However, the path of transmission remains uncertain. Like other herpesvirus strains, HHV-8 can remain dormant in the body for years without manifesting symptoms. A healthy IMMUNE SYSTEM seems to hold HHV-8 in check, preventing it from causing disease. Prolonged compromise of immune function, through conditions such as HIV/AIDS or through IMMUNOSUPPRESSIVE THERAPY such as occurs following ORGAN TRANSPLANTATION, allows HHV-8 to replicate (reproduce itself by taking over healthy cells) and cause Kaposi's sarcoma.

AIDS-related Kaposi's sarcoma Nearly all Kaposi's sarcoma in the United States occurs in people, predominantly men, who have AIDS. Doctors consider the appearance of Kaposi's sarcoma a defining sign that INFECTION with HIV (human immunodeficiency virus) has progressed to the disease state of AIDS. The activation of both HIV and HHV-8 may occur simultaneously, when both are present. Advances in treatment options for HIV/AIDS, notably highly active antiretroviral therapy (HAART), delay the progression of HIV to AIDS and consequently the appearance of Kaposi's sarcoma. About 6 percent of men with HIV/AIDS who receive HAART develop Kaposi's sarcoma, compared to 20 percent among those who do not.

Transplant-related Kaposi's sarcoma People who undergo organ transplantation typically receive immunosuppressive therapy, to prevent organ rejection, for the rest of their lives. The development of Kaposi's sarcoma arises from the immunosuppression, not the organ transplantation. The American Cancer Society estimates that about 1 in 200 transplant recipients taking immunosuppressive therapy to prevent organ rejection develop Kaposi's sarcoma. People who take long-term immunosuppressive therapy for other health conditions are also at risk for Kaposi's sarcoma.

Symptoms and Diagnostic Path

The key symptom of Kaposi's sarcoma is the presence of its characteristic lesions, which are nodular and raised, in people with long-term immunosuppression or who are HIV-positive. The lesions start as small, raised areas and are most common on the face, lower legs and feet, and genitals, though can develop anywhere on the body. They are usually darkly pigmented, often brownish red or purple, and sometimes itch. As they grow, the lesions may block the flow of blood or lymph, causing painful swelling. Lesions sometimes develop within the connective tissues of internal organs such as the LUNGS, where they can cause difficulty BREATHING, or the intestines, where they can cause GASTROINTESTINAL BLEEDING and ILEUS (intestinal obstruction).

The doctor can usually make a definitive diagnosis of Kaposi's sarcoma on the basis of visible lesions and immune or HIV status, with biopsy of a representative lesion to confirm the diagnosis if necessary. A chest X-ray can determine the presence of lesions in the LUNGS. Other imaging studies such as COMPUTED TOMOGRAPHY (CT) SCAN and

ENDOSCOPY can determine whether there are lesions elsewhere in the body, such as in the gastrointestinal tract, when symptoms suggest or the doctor suspects this is the case.

Treatment Options and Outlook

Treatment depends to some extent on whether the Kaposi's sarcoma is AIDS related or transplant related. In either form, methods to remove or reduce the lesions for improved comfort and appearance. Such methods may include

- localized CHEMOTHERAPY (injecting a cytotoxic agent directly into the lesion)
- external-beam RADIATION THERAPY that narrowly targets the lesion
- the topical retinoid preparation alitretinoin (Panretin) applied to the lesion
- surgery to reduce or excise (cut out) the lesion
- liquid nitrogen or cryotherapy, which freezes the lesion

Systemic chemotherapy reduces lesions in recurrent, widespread, or systemic (involving internal organs as well as the skin) disease in AIDS-related Kaposi's sarcoma, though it is not usually an option for transplant-related Kaposi's sarcoma because the immune system cannot withstand the assault. Treatment for Kaposi's sarcoma in people who have received organ transplants is often a delicate balance between suppressing enough immune function to stave off organ rejection and preserving enough immune response to fight INFECTION. Sometimes changing the immunosuppressive agent gives the immune system enough of a boost to fight the lesions, causing them to retreat or disappear.

SYSTEMIC CHEMOTHERAPY AGENTS TO TREAT AIDS-RELATED KAPOSI'S SARCOMA

daunorubicin (DaunoXome)	doxorubicin (Doxil)	paclitaxel (Taxol)

For most cancers, doctors apply an algorithm of symptoms and progression that helps determine effective treatment options and prognosis (potential for improvement). Kaposi's sarcoma occurs nearly always in circumstances of depressed or suppressed immune system function, skewing the conventional cancer-staging algorithms. The AIDS Clinical Trials Group (ACTG) system is the most commonly used staging algorithm for Kaposi's sarcoma associated with AIDS or transplant-related immunosuppression. The ACTG system assesses three factors:

- number of lesions
- CD4 cell count, which represents immune system function
- systemic conditions that indicate compromised immune function

Each factor receives a rating of zero (good) or one (poor), reflecting the likelihood for five-year survival, a standard prognosis marker for cancer. Kaposi's sarcoma of the skin is seldom itself fatal, though the extent of its presence indicates the immune system cannot protect the body from infection. Kaposi's sarcoma of internal organs can be fatal. This cancer is not curable in AIDS or active immunosuppressive therapy, so treatment aims to relieve symptoms.

Risk Factors and Preventive Measures

In the United States, HIV infection is the leading risk factor for Kaposi's sarcoma. Methods to reduce exposure to HIV/AIDS also reduce the risk for Kaposi's sarcoma. Most AIDS-related Kaposi's sarcoma occurs in men who have sex with men, leading researchers to postulate that there is a route of sexual transmission for HHV-8. Safer sex practices are crucial.

As a result of the growing availability and acceptance of organ transplantation, the number of cases of Kaposi's sarcoma among transplant recipients is steadily rising. The risk increases the longer the person receives immunosuppressive therapy. Newer immunosuppressive agents more selectively target the immune functions responsible for organ rejection, leaving other immune functions undisturbed.

keloid An overgrowth of collagen after a wound has finished HEALING. A keloid typically forms as folds or bunches of tissue. Keloids are fibrous, spongy in consistency, and often dark red. They form most often on the earlobes, upper chest, and shoulders though can develop anywhere on the body. Keloids are more common in people who have dark skin, and in people under age 50. Though keloids do not present any health problems, they can become irritated from rubbing on clothing. A corticosteroid medication injected into the keloid often halts its growth and causes the existing excess tissue to recede. The dermatologist can surgically remove large keloids or keloids that recur.

keratinocyte The cell type that makes up most of the epidermis, also called a squamous cell. Keratinocytes originate in the first of the four layers of the epidermis, the stratum basale. Here they either replicate to generate new keratinocytes or migrate upward. Migratory keratinocytes acquire melanin from melanocytes. The keratinocytes carry this pigment to the outer layers of the SKIN, where it appears as the skin's normal color or causes the skin to darken (as in a tan). At each of the epidermis's layers the keratinocytes become more compressed. Their internal structures break down, and the keratin they contain causes them to harden.

At the stratum corneum, the outer layer of the epidermis, the keratinocytes overlap tightly, looking somewhat like irregular shingles when viewed under the microscope. At the culmination of this journey, which takes about four weeks, the keratinocytes die and slough from the skin's surface. The fingernails and toenails are much more tightly compressed and hardened keratinocytes. They do not shed as does the stratum corneum but instead grow forward over the front of the fingers and toes at the rate of about one eighth inch every four to five weeks.

Hyperkeratosis is a state in which the keratinocytes migrate through the epidermis far more rapidly than normal, sometimes cutting the journey to 10 days. This accelerated journey causes more keratinocytes than the body can shed to accumulate in the HAIR follicles and sebaceous structures, causing numerous hyperkeratosis-related conditions from ACNE and atopic DERMATITIS to PSORIASIS and SEBORRHEIC KERATOSIS. Squamous cell carcinoma, a common type of SKIN CANCER, arises from keratinocytes.

For further discussion of keratinocytes within the context of integumentary structure and function please see the overview section "The Integumentary System."

keratoacanthoma A form of squamous cell carcinoma (SKIN CANCER) that appears suddenly and grows rapidly, though has a low rate of METASTASIS (spreading). Like other forms of skin CANCER, keratoacanthoma is the consequence of extensive sun exposure that manifests decades later. Researchers have identified a number of chromosomal abnormalities that appear connected with keratoacanthoma, suggesting a strong genetic component or familial predisposition (tendency of the cancer to run in families).

Most keratoacanthomas develop in people over age 50, though may occur at younger ages in people who are taking IMMUNOSUPPRESSIVE THERAPY (such as following ORGAN TRANSPLANTATION) or who are IMMUNOCOMPROMISED. A keratoacanthoma lesion typically develops on skin surfaces that receive or have received significant sun exposure and may initially appear to be a FURUNCLE (boil) or a cyst. The lesion often appears to heal, though seems to take a long time to do so (up to a year).

Though it appears that keratoacanthoma eventually resolves (heals) on its own, the risk that the lesion could instead be squamous cell carcinoma or that the keratoacanthoma could metastasize causes dermatologists to recommend immediate removal with microscopic examination to confirm the diagnosis. Keratoacanthomas tend to recur. The dermatologist may recommend surgical removal of the lesion or inject it with a chemotherapeutic agent, either of which generally is adequate treatment.

keratosis pilaris A very common condition in which the keratocytes produce excessive keratin, clogging the HAIR follicles and forming small

bumps on the SKIN that resemble GOOSE BUMPS. The bumps may be the same color as the skin or slightly reddened and create a texture like rough sandpaper on the skin's surface. Occasionally the bumps itch. Keratosis pilaris most often affects the lower arms and inner thighs, though can occur anywhere on the body, and is most common among adolescents. Researchers have implicated number of gene mutations for keratosis pilaris.

The eruption and pattern of bumps present a fairly conclusive diagnostic picture. A biopsy can confirm any questionable presentations. Treatment typically consists of measures to increase exfoliation, which clears accumulated cells from the hair follicles. Topical products containing alphahydroxy acids such as lactic acid are often helpful. The dermatologist may prescribe a topical retinoid medication to treat resistant symptoms. Keratosis pilaris becomes increasingly uncommon with age and generally resolves by the early 20s.

L

laser skin resurfacing A method for smoothing scars, ACNE pitting, WRINKLES, and other blemishes from the SKIN, primarily on the face, using a heat (usually carbon dioxide) laser. The laser focuses a high-intensity beam of light that the dermatologist moves across the surface of the skin, precisely targeting the depth and skin areas for resurfacing. This precision control allows the dermatologist to target some areas more deeply than others, accommodating such variations in the skin as fine wrinkles to moderate scars. Like CHEMICAL PEEL and DERMABRASION, laser skin resurfacing achieves skin smoothing by destroying layers of cells. The new skin that grows to replace the destroyed skin is tight and smooth.

The dermatologist performs laser skin resurfacing as an AMBULATORY SURGERY procedure in a clinic, office facility, or an ambulatory surgery facility, typically using local anesthetic to numb the skin and a sedative medication for relaxation and improved comfort. The length of time the procedure requires depends on what kinds of blemishes the dermatologist is treating. The dermatologist may cover the treated surfaces with an ointment and bandages, which remain in place for one or two days.

After the procedure the treated skin surfaces are red, swollen, and tender or painful. After a day or two the skin scabs or crusts, a normal stage in the HEALING process. The dermatologist removes any bandages at this time. As the skin heals the scabs fall away, typically in 10 to 14 days. The new skin is red and shiny, transitioning to normal pigmentation and texture over the following six to eight weeks (though most of the redness subsides in about three weeks). Full HEALING and noticeable improvement take about six months.

The risks of laser skin resurfacing are slight and include excessive bleeding, INFECTION, and pigmentation changes. As with all cosmetic procedures, it is important to fully understand what laser skin resurfacing can and cannot accomplish. Most people who receive treatment from a qualified dermatologist or plastic surgeon are satisfied with the results. Some people may find that the new skin is sensitive to soaps, cleansers, and makeup used before the procedure.

The new skin is very vulnerable to damage from the sun during as well as after healing, requiring protective clothing, such as a wide-brimmed hat or scarf, and high sun protection factor (SPF) sunscreen whenever sun exposure is necessary. The effects of laser skin resurfacing typically last several years, with wrinkles gradually returning as a normal function of the aging process. Alterations such as SCAR revision or removal are permanent.

lentigines Dark spots of varying size on the SKIN, also called freckles, liver spots, or age spots. Lentigines develop as a result of continued sun exposure and indicate damage to the skin. A single spot is a lentigo. Lentigines are often widespread on areas of skin that receive high sun exposure, such as the face and arms, sometimes covering the entire surface of exposed skin. It is important to examine the skin in areas of heavy sun damage, such as those with many lentigines, for signs of SKIN CANCER as most skin cancer arises from such damage.

Cosmetic products such as creams and lotions containing alphahydroxy acid, lactic acid, or other mild fruit acids can lighten lentigines, functioning as a mild CHEMICAL PEEL. These products have a

mild bleaching action that reduces pigmentation in the areas of application. Cosmetic procedures such as dermatologist-performed chemical peel, hydroquinone application (a bleaching agent), or LASER SURGERY can diminish or eliminate lentigines and other blemishes on the face.

lesion A generalized term for any abnormal growth. Lesions can result from injury, disease, or surgery. Some lesions are malignant (cancerous) though most lesions are benign (noncancerous). Numerous types of lesions affect the SKIN. Their characteristics help define and diagnose disorders and conditions of the skin as well as systemic disorders that manifest dermatologic symptoms.

COMMON TYPES OF SKIN LESIONS

ACHROCHORDON	ANGIOMA	basal cell carcinoma
BIRTHMARK	BLISTER	
BULLA	DERMATOFIBROSIS	KELOID
LENTIGINES	MACULE	malignant melanoma
NEVUS	NODULE	
PAPILLOMA	PAPULE	plaque
PUSTULE	SCALE	SCAR
squamous cell carcinoma	TELANGIECTASIS	ulcer

lice See PEDICULOSIS.

lichen planus A common condition affecting the SKIN that appears as small, shiny, reddish purple (violaceous) bumps that itch, sometimes intensely. The bumps grow together in a scalelike pattern that resembles tree lichen. Lichen planus nearly always occurs in adults.

Symptoms and Diagnostic Path

Lichen planus typically erupts on the inner surfaces of the lower arms and wrists, along the shins and inner ankles, and along the lower back. Occasionally lichen planus appears on the scalp, where it can cause temporary or permanent ALOPECIA (hair loss), or affects the fingernails and toenails, causing ridges and grooves. In the MOUTH, lichen planus is light in color and the scaling more diffuse, creating a lacelike pattern lighter in color than the surrounding mucosa. The distinctive color and pattern of the RASH allow the dermatologist to make a quick diagnosis. The doctor may biopsy lichen planus lesions that appear in the mouth, as they resemble other conditions (such as CANDIDIASIS and precancerous lesions) that require different treatment.

Treatment Options and Outlook

Outbreaks of lichen planus typically retreat without medical intervention, though ANTIHISTAMINE MEDICATIONS and topical CORTICOSTEROID MEDICATIONS can help relieve the itching. In severe cases, the dermatologist may prescribe oral corticosteroids such as prednisone to suppress the IMMUNE RESPONSE. An outbreak may last several weeks to several months and typically flares in irregular recurrences over a period of years. Gentle, regular skin cleansing and moisturizing can help to manage and reduce symptoms.

Risk Factors and Preventive Measures

Dermatologists do not know what causes lichen planus, though believe it is an immune response of some sort, either an autoimmune condition or an immune response to a VIRUS, likely with a genetic predisposition. Lichen planus also occurs in HEPATITIS C INFECTION, is an early sign of transplant organ rejection, and is a rare SIDE EFFECT of some medications such as long-term therapy with the antimalarial medication quinidine and some NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) used for OSTEOARTHRITIS. Avoiding exposure to substances that can cause lichen planus, when identified, usually prevents future outbreaks though some people continue to experience cycles of the condition for several years.

lichen simplex chronicus A SKIN condition, sometimes called neurodermatitis, in which an itchy RASH erupts in response to continued scratching of the skin. Over time, the involved areas develop hyperkeratosis, an overgrowth of keratinocytes that gives the areas a scaly, lichen-

like appearance (plaques). Lichen simplex chronicus sometimes develops in areas of the skin that have previously had irritation, such as from DERMATITIS or abrasive injury, or frequently irritated, such as from clothing that rubs or constricts. Stress and strong emotional responses exacerbate the rash and the itching. The condition appears more common in people who have DEPRESSION or anxiety, hence the former term, neurodermatitis, for the condition. Most often, however, there is no clear cause for the condition.

Symptoms and Diagnostic Path

The rash of lichen simplex chronicus begins with small reddened areas (macules) that itch, commonly forming on the neck and the inner surfaces of the arms and legs. Most people who have lichen simplex chronicus describe the itching as intense, such that they are unable to stop scratching. With scratching, the rash becomes more extensive. Many people find the itching more pronounced at night before sleep, creating difficulty falling asleep or staying asleep. The dermatologist typically diagnoses lichen simplex chronicus on the presentation of these symptoms, though may choose to biopsy questionable lesions to confirm the diagnosis.

Treatment Options and Outlook

Treatment targets relieving the symptoms, primarily the itching. The dermatologist may prescribe oral ANTIHISTAMINE MEDICATIONS and topical CORTICOSTEROID MEDICATIONS, which work together to mitigate the IMMUNE SYSTEM's response to the persistent irritation scratching causes. Antihistamine medications are especially helpful at bedtime, when many people find the itching most intense, as they tend to cause drowsiness. Some people benefit from ANTIANXIETY MEDICATIONS. Methods such as VISUALIZATION, BIOFEEDBACK, and ACUPUNCTURE may help. Mild to moderate lichen simplex chronicus generally heals without residual effects, though more severe manifestations may leave scarring and altered pigmentation (either lighter or darker patches of skin in the sites of the healed plaques).

Risk Factors and Preventive Measures

The causes of lichen simplex chronicus remain elusive. Dermatologists disagree on whether the rash or the itching appears first, though the end result is that the rash itches and continued scratching perpetuates the rash. The most important factor is to avoid scratching, as persistent scratching causes other damage to the skin that increases the risk for INFECTION and scarring. In many people, episodes follow stressful experiences. Stress management techniques and relaxation methods provide other means for diffusing the physiologic effects of stress.

M

macule A small SKIN LESION that is flat, smooth, and discolored. Macules are common and may appear as the presenting symptom for numerous dermatologic and other health conditions. Often the only symptom they present themselves is discoloration, though some macules itch or hurt. The discoloration may be hyperpigmentation (darker than the surrounding skin) or hypopigmentation (lighter than the surrounding skin). A macule is the same texture and thickness as the adjacent skin and generally no larger than two inches in length, width, or diameter. The most common macule is a lentigo, or freckle.

malignant melanoma See SKIN CANCER.

melanocyte A type of cell prominent in the dermis (middle layer of the SKIN) that produces melanin, the pigment that gives color to the skin as well as protects the skin from ultraviolet light damage. There are two types of melanin: the dark brown pigment eumelanin and the red/yellow pigment pheomelanin. The skin contains the same number of melanocytes no matter what the individual's natural skin color. The melanocytes in darker skin are more active than those in lighter skin. The eyes and HAIR also contain melanocytes.

Melanogenesis

The exclusive role of melanocytes is to produce melanin (melanogenesis), a somewhat sequential process. To prepare for melanogenesis, the body produces the enzyme tyrosinase. Genetic encoding regulates this process. Tyrosinase initiates conversion of the amino acid tyrosine, which the body synthesizes from dietary proteins such as meats and which the melanocytes store, into dopaquinone. The dopaquinone forms the pigments eumelanin and pheomelanin, which collectively comprise mel-anin.

Exposure to ultraviolet light, notably sunlight, initiates a sequence of hormonal and chemical events that stimulate melanocytes to produce melanin (melanogenesis):

1. Sunlight (or other ultraviolet light exposure) damages the cells of the skin. The damage activates the natural repair mechanisms within the cells, which releases chemicals into the bloodstream that travel to the PITUITARY GLAND.
2. In response the pituitary gland releases melanocyte-stimulating hormone (MSH), to bind with melanocytes.
3. Melanocytes pass packets of melanin molecules to the keratocytes, which carry them to the outer layer of the epidermis as they migrate upward.

The resulting skin color depends on the mix of eumelanin and pheomelanin the melanin contains. The melanin in light skin contains more pheomelanin than eumelanin. In darker skin the balance tips the other way with the melanin in dark skin containing more eumelanin than pheomelanin. In the epidermis, melanin protects the skin from damage by absorbing ultraviolet light. The darker the skin, the less ultraviolet light penetrates the epidermis. In general, it takes about a week of regular sun exposure to generate a tan adequate to begin protecting the skin from further sun damage, though the tan itself signals sun damage.

Dysfunctions of Melanocytes

There are three significant dysfunctions of melanocytes:

- ALBINISM is a deficit or absence of pigmentation (hypopigmentation) caused by a MUTATION in the genetic encoding for tyrosinase. The body may produce little or none of this enzyme, reducing or completely blocking melanogenesis. The dermatologic consequence is extremely light-colored skin that cannot protect itself from ultraviolet light damage.
- VITILIGO is a hypopigmentation disorder of autoimmune origin in which the melanocytes in areas of the skin die, leaving the skin without pigmentation.
- Malignant melanoma is a serious type of SKIN CANCER that arises from melanocytes.

melasma See CHLOASMA.

miliaria Small bumps that form on the SKIN in environmental conditions of high heat and humidity, when the body produces much sweat that cannot evaporate and instead pools on the surface of the skin. The bumps may be red (miliaria rubra) or clear and filled with fluid (miliaria crystallina). Clothing may further inhibit sweat evaporation. The pooling creates irritation and INFLAMMATION that obstructs the sweat glands. Most miliaria, commonly called heat RASH, improves with self-care to cool the body, which causes the SWEAT GLANDS to decrease production. The skin bumps generally go away in three to five days. Newborns are particularly susceptible to miliaria in the first week or two of life. Miliaria also sometimes occurs in people who have high fevers.

Mohs' micrographic surgery A specialized technique for removing certain skin cancers such as basal cell carcinomas and squamous cell carcinomas. In an outpatient OPERATION (AMBULATORY SURGERY) with local anesthetic and a sedative for relaxation if necessary, the dermatologist removes one thin layer of the tumor at a time and examines each specially stained layer under the microscope. The surgery continues until the tissue sample shows a one- to two-millimeter margin of healthy tissue on all borders, ensuring that the dermatologist removes all of the malignancy. Because Mohs' micrographic surgery is so precise it removes only the malignancy, sparing as much surrounding tissue as possible.

By comparison, conventional excision removes the tumor and what the surgeon believes is a reasonable amount of surrounding tissue to provide clean margins, which can result in removing considerably more tissue than just the malignancy. A pathologist later examines frozen sections of the tissue to confirm the margins. With conventional excision there is a change that the margins could be positive (contain cancer cells) and the surgeon would have to do another operation to remove more tissue.

Dermatologists use Mohs' micrographic surgery when the SKIN CANCER is on the face, nose, eyelids, or around the mouth, or if it is a larger, more aggressive cancer on the body. The procedure may take several hours altogether to complete, depending on how many layers of tissue the dermatologist must remove to get clean margins. Many cancers removed using Mohs' micrographic surgery heal with minimal scarring. The dermatologist performing the surgery usually repairs any residual defect as dermatologists also perform reconstructive surgery. Mohs' micrographic surgery has an overall cure rate of 95 percent and up to 99 percent for certain kinds of malignant lesions, the highest for all current forms of treatment for these two types of skin cancer. Frederic E. Mohs, M.D. (1910–2002), discovered the technique while a medical student in the 1930s.

mole See NEVUS.

nails The hardened epidermal layer covering the top surfaces of the tips of the fingers and toes. Nails are made of cornified, compacted SKIN cells (keratinocytes) that grow from the base of the nail (matrix or nail-bed root). Though the cells of the matrix are alive, the cells that make up the nails are dead. New cell growth from the matrix pushes the nail outward across the tip of the finger or toe. In adults the fingernails grow about two tenths inch in a week. The cells the matrix produces today will reach the end of the finger in about six months.

Like the skin, the nails provide insights into the overall health situation of an individual. Certain changes in the nails signal specific health conditions. Such characteristics include

- banding: stripes of dark or light across the width of the nail bed, visible through the nail

HEALTH IMPLICATIONS OF NAIL CHARACTERISTICS

Nail Characteristic	Possible Health Implications
Beau's lines	serious injury or illness that disrupts nail growth
clubbing	chronic pulmonary conditions, HEART FAILURE, low blood oxygen levels
dark band at tops of nails, bottoms of nails normal color (Terry's nails)	age, CANCER, congestive heart failure, DIABETES, CIRRHOSIS, HYPERTHYROIDISM
koilonychia	iron-deficiency ANEMIA
leukonychia	arsenic poisoning, mineral deficiency, trauma to the nail matrix
onycholysis	thyroid disease, fungal INFECTION, PSORIASIS, adverse DRUG reaction
PETECHIAE (pinpoint hemorrhages)	ENDOCARDITIS, THROMBOCYTOPENIA, SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)
stippling	psoriasis, ALOPECIA AREATA, injury to the nail
white band at the bottoms of nails, tops of nails normal color (half-and-half nails)	UREMIA, KIDNEY failure
yellow nail syndrome (yellow-green discoloration consistent through all nails)	chronic pulmonary disorders such as BRONCHITIS and EMPHYSEMA, NICOTINE staining

- Beau's lines: indentations in the nail surface that extend across the width of all the nails at about the same position on each
- clubbing: end of the finger or toe becomes enlarged and the angle between the nail fold and the nail plate exceeds 180 degrees
- discoloration: may be widespread throughout the nail or occur in spots or streaks
- koilonychia: nails soften and the edges rise, leaving a large spoonlike indentation in the center of the nail
- leukonychia: white spots or streaks in the nail
- onycholysis: separation of the nail from the nail bed
- PETECHIAE: red or dark spots beneath the nail
- stippling: the formation of small pits in the surface of the nail

For further discussion of the nails within the context of integumentary structure and function please see the overview section "The Integumentary System."

neurodermatitis See LICHEN SIMPLEX CHRONICUS.

nevus A discolored LESION on the SKIN. Nevi are very common and may take various shapes and colors. Most nevi contain primarily melanocytes and may differ in texture from the surrounding skin. A nevus may be smooth, distinguishable only by its color, or rough and segmented. Some nevi contain coarse HAIR. The most common form of nevus is a mole, a small lesion that can be smooth or raised and is usually darker in color than the surrounding skin. A nevus may be congenital (present at birth) or acquired (develops at any point in the lifespan after birth). Nearly everyone has some nevi by early adulthood.

Giant congenital nevus, a rare presentation of congenital nevus, may cover a large area of the skin's surface. In another uncommon genetic disorder, neurocutaneous melanosis, nevi develop within the structures of the BRAIN and SPINAL CORD. The presence of melanocytes in some NERVOUS SYSTEM tissue is normal and functional. Melanocytes populate the substantia nigra, for example, a structure of the midbrain. The pigmented cells of substantia nigra produce dopamine, a NEUROTRANSMITTER essential for the brain's coordination of MUSCLE function throughout the body. However, melanocytes in other parts of the nervous system can generate overgrowths—nevi—just as they do on the skin. Such nevi cause pressure as they grow, resulting in neurologic symptoms.

Acquired nevi begin to appear during childhood in most people, with the most intense activity occurring in middle adulthood (ages 30 to 50). Though sun exposure plays a role in their development, genetic encoding seems to regulate characteristics such as size, color, shape, and numbers. In the typical structure of the dermis, the layer of skin where melanocytes reside in greatest concentration, melanocytes are frequent but are not in contact with each other. Researchers believe this distribution pattern results from "contact inhibition" genetic encoding. A nevus can form when the contact inhibition lapses, allowing the melanocytes to drift into contact with one another. Sometimes nevi appear after extensive injury to the skin, such as occurs with conditions that cause widespread blistering. This suggests that such injuries disrupt contact inhibition in some way, though the mechanisms through which this occurs remain unknown.

A nevus should have regular borders, consistent coloration, and a symmetrical (balanced) appearance. A doctor should evaluate a nevus that has or develops irregular borders, variable coloration, or an asymmetrical appearance as these characteristics may indicate a nevus that is becoming cancerous.

Though nevi are themselves benign (noncancerous), they can become cancerous over time and particularly with repeated, unprotected sun exposure. Congenital nevi in particular carry an increased risk for malignant melanoma, a serious type of SKIN CANCER. Most often, the only health concerns with nevi are the increased risk for malignancy and cosmetic appearance. The dermatologist may choose to remove nevi that receive frequent irritation, such as those that form in

areas where clothing rubs them. The resulting SCAR may require PLASTIC SURGERY for the desired cosmetic appearance, depending on the size, nature, and location of the nevus. Small nevi heal without noticeable scarring. Nevi do tend to recur after removal.

nodule A small cluster of cells that arises from the subcutaneous or dermis layer of the SKIN and forms a swelling. Nodules are solid and distinct from the surrounding tissue. Most skin nodules arise from causes other than dermatologic, such as neurofibroma and LIPOMA. Nodules may exist in other parts of the body, typically as symptoms of systemic disease.

See also MACULE; PAPULE; PUSTULE.

onychomycosis A common fungal INFECTION, typically CANDIDIASIS or TINEA, of the fingernail or toenail. The infection causes the nail to thicken, discolor, fragment, and peel or crack. Though some people experience itching, PAIN, or other discomfort with onychomycosis, most people seek medical care because of the nail's appearance. Onychomycosis affects the structure and function of the nail, however. Onychomycosis affecting multiple toenails can interfere with proper walking, and onychomycosis of the fingernails may reduce gripping ability and the ability to perform tasks such as typing or keyboarding. The doctor often can make the diagnosis based on the appearance of the NAILS, though may choose to examine tissue samples under the microscope to confirm the presence of the infective FUNGUS.

Eradication of the fungus often requires oral antifungal medication in combination with topical antifungal medication. Onychomycosis can be a stubborn infection, making several courses of treatment necessary. Early diagnosis and treatment affords the most successful results.

P

papilloma A general classification of tumors arising from the epidermis (outer layer of the SKIN) as well as the epithelial layer of the mucous membranes. Warts, HUMAN PAPILLOMAVIRUS (HPV) lesions (also called condylomata or genital warts), and POLYPS are papillomas. Though papillomas are noncancerous (benign), some types of papillomas, notably intestinal polyps, are the foundation for certain cancers. Doctors generally remove polyps and treat HPV infections and lesions because these are among the papillomas that can become cancerous. Many people prefer to have common warts removed for cosmetic purposes. Irritation such as from clothing that rubs or frequent trauma can cause papillomas to bleed.

papule A small, raised bump arising from the epidermis that is distinctive and firm to the touch. Papules may be discolored or the same color as the surrounding SKIN. The presence of papules is a symptom of many dermatologic and other health conditions. Papules that cluster together form a skin plaque, usually taking on a hardened, flaky appearance.

See also MACULE; NODULE; PLAQUE, SKIN; PUSTULE.

paronychia INFLAMMATION and INFECTION of the SKIN that surrounds the NAILS. Paronychia commonly occurs in people who bite their fingernails or the skin around them or who have frequent cuts around their fingernails. Paronychia is common in children who suck their thumbs or fingers. Paronychia of a toenail may accompany an ingrown toenail. Splinters, INSECT BITES AND STINGS, and other injuries around the tips of the fingers or toes can fester, allowing infection to creep under the nail.

Paronychia can be acute (come on suddenly) or chronic (persist or recur over a period of time). Acute paronychia is generally painful and pustular (produces pus). *Staphylococcus aureus,* a strain of BACTERIA that normally lives on the skin, is the usual cause of the infection. Less commonly, a strain of *Streptococcus* or *Pseudomonas* (bacteria), or the FUNGUS (yeast) *Candida albicans,* may be the culprit.

Symptoms of paronychia include redness, swelling, PAIN, and occasionally bleeding or pus discharge. The doctor can diagnosis paronychia based on the symptoms and the history of their development and occurrence. Treatment may include

- warm soaks three to four times a day, keeping the affected finger or toe dry at all other times
- topical antibiotic or ANTIFUNGAL MEDICATION
- oral antibiotic or antifungal medication

Occasionally the doctor may need to lance (make a sterile incision) the infected area to release the pus collected within. The paronychia generally heals within 7 to 10 days, though may recur if related to behaviors or exposures that continue. Untreated paronychia becomes very painful and may cause infection to spread into deeper tissues, with the potential for permanent damage to the nail as well as to tendons, ligaments, MUSCLE, and BONE.

symptoms	PAIN, redness, and swelling SKIN around the nail appears tight and bright red may have pus precipitating trauma (sliver, pulled hangnail, biting the nail or skin) sudden onset	tenderness and swelling of the skin around the nail redness and increased discomfort with prolonged exposure to water (such as washing dishes) ongoing for longer than four to six weeks repeated exposure to water, chemicals, other irritants discolored or thick nail on the affected finger or toe separation of the cuticle from the nail bed
infective agent	*Staphylococcus aureus* *Streptococcus* *Pseudomonas*	*Candida albicans*
medication	oral ANTIBIOTIC MEDICATIONS such as clindamycin, cephalexin, or amoxicillin and clavulanic acid	topical antifungal medication such as miconazole oral antifungal medication such as ketoconazole or fluconazole

small punctures they make through the skin. Lice attach their eggs, called nits, to HAIR shafts. Of the numerous species of lice, three afflict humans:

- *Pediculus humanus capitis*, which infests the scalp
- *Pediculus humanus corporis*, which infests the body
- *Pediculus pubis*, which infests the pubic region

Each species has unique claw and MOUTH structures that allow survival in the particular region of the body, and each species can infest only the body region for which it is adapted. However, infestation with two or more species is common. *Pediculosis* refers collectively to infestation with any species of lice, and affects around 12 million Americans each year.

Pediculosis spreads easily through direct and indirect contact, and is so common among school-age children that schools routinely screen for its presence. Crowded environments, such as schools and dormitories, allow close contact between people, permitting the lice to spread from one person to another. Pediculosis may be present for as long as two months before causing appreciable symptoms, increasing the potential for extending infestation. Head and pubic lice and nits resist the most scrupulous cleansing. Infrequent clothing changes are often a factor with body lice infestation. Poor PERSONAL HYGIENE such as infrequent bathing can allow secondary problems such as INFECTION to develop.

Symptoms and Diagnostic Path

The most common symptom of pediculosis is itching, which is often particularly intense at night when the lice feed. The saliva of the lice contains enzymes to delay coagulation (blood clotting) which irritate the skin. The bites leave reddened papules (raised bumps) that continue to itch. Finding nits (eggs attached to hair shafts) is the conclusive diagnostic marker. Nits are difficult to remove, which helps distinguish them from other matter that might collect on the skin or hair, as well as from conditions such as seborrheic DERMATITIS and common DANDRUFF. Examination with fluorescence (Woods lamp) causes the lice and nits to glow yellow or green.

Treatment Options and Outlook

Treatment for head or pubic infestation combines removing the nits with a fine-tooth comb (nit comb) and shampooing or washing with an insecticide-based product such as permethrin (Nix) or malathion (Ovid). Multiple treatments about a week apart for a month, or until no nits are present, are necessary to cover the lifespan of the louse, which is about 35 days. It is important to

carefully follow the label directions for the product and to leave the product on the hair or skin for the instructed length of time. Most treatment regimens include combing the hair with a nit comb after shampooing. All individuals in the household should receive treatment.

It is also necessary to wash clothing and bed linens in hot water (130°F or more) for at least five minutes, and placing stuffed toys in sealed plastic bags for two weeks. The hot water wash kills any lice or nits, and the plastic bag method deprives any lice or nits that hatch of nourishment. Because body lice live on the clothing rather than the skin, washing the clothing in hot water is usually adequate.

Risk Factors and Preventive Measures

Most pediculosis leaves no residual health consequences, although secondary infections may develop with excessive scratching. However, sexual contact generally transmits pubic pediculosis, which raises concern for SEXUALLY TRANSMITTED DISEASES (STDS). Body lice (*P. humanus corporis*) can carry serious bacterial diseases including typhus.

pemphigus An autoimmune disorder in which large, painful bullae (blisters) form on the SKIN and mucous membranes. The bullae develop within the epidermis, the skin's uppermost layer, giving them a very thin surface. They rupture and tear easily, exposing the skin to INFECTION and interfering with the skin's ability to carry out its numerous functions. The ruptured bullae form crusts while they heal, though typically heal without scarring. Some forms of pemphigus can cover large portions of the skin's surface are potentially fatal. There are three main forms of pemphigus:

- pemphigus vulgaris, the most common form in which bullae develop in the MOUTH and under the eyelids as well as on the skin surfaces of the face, neck, chest, axillae (underarms), and groin
- pemphigus foliaceus, the mildest form in which bullae develop mostly on the skin of the scalp and face though sometimes involve the back and chest
- paraneoplastic pemphigus, which occurs only secondarily to CANCER and can involve the mucous membrane lining the ESOPHAGUS and airways (TRACHEA and bronchi)

Pemphigus occurs when antibodies the IMMUNE SYSTEM produces attack and destroy certain proteins on the surface of epidermal keratinocytes, the skin cells that make up the epidermis, causing them to separate from one another. The proteins are like glues that hold the keratinocytes together. Dermatologists do not know what causes pemphigus to develop as an autoimmune process, though occasionally it occurs as an ADVERSE REACTION to certain medications, notably penicillamine (taken to treat severe RHEUMATOID ARTHRITIS) and carbidopa/levodopa (taken to treat PARKINSON'S DISEASE).

Symptoms and Diagnostic Path

The primary symptom of pemphigus is the appearance of bullae that start as small blisters. In early outbreaks the blisters may rupture and heal without taking the characteristic bulla form. As outbreaks become more frequent and progressive, however, the blisters enlarge over several days to a week. In the early stages of the disorder's manifestation, the pattern and appearance of bullae may be similar to other autoimmune symptoms, notably the sores that can appear with HIV/AIDS. Biopsy of the lesions can help to rule out other causes.

The location and extent of the bullae characterizes the form of pemphigus. Pemphigus vulgaris typically begins with blisters in the mouth, with outbreaks quickly following on other skin surfaces as well as the mucous membranes lining the NOSE and the URETHRA. The bullae of paraneoplastic pemphigus, which only occurs in conjunction with cancer, also originate in the mouth though quickly involve the esophagus as well as the skin. Pemphigus foliaceus bullae are smaller and remain confined primarily to the head (scalp and face), and do not involve the mouth or other mucous membranes.

Treatment Options and Outlook

Treatment targets relief of symptoms during outbreaks and mitigation of future outbreaks to the extent possible. Treatment varies with the form and severity of pemphigus, though typically includes oral or injected CORTICOSTEROID MEDICATIONS along with oral ANALGESIC MEDICATIONS for PAIN relief and ANTIBIOTIC MEDICATIONS to treat infection when necessary. Severe outbreaks may require IMMUNOSUPPRESSIVE MEDICATIONS to subdue the IMMUNE RESPONSE, or PLASMAPHERESIS, a therapy that cleanses the blood's serum of antibodies. Cytotoxic drugs such as those used in CHEMOTHERAPY also improve symptoms in some people with severe outbreaks.

The most serious complication of pemphigus itself is loss of the skin's ability to protect the body from bacterial invasion, resulting in widespread skin or systemic infection. However, pemphigus is a chronic condition that requires ongoing medication therapy. For many people who have pemphigus vulgaris, the more common and more severe form, the most significant complications arise from the long-term use of the medications necessary to control outbreaks. These medications all have serious side effects and adverse consequences for other body structures and functions. Pemphigus that appears as an adverse DRUG reaction typically ends when the person stops taking the medication. Paraneoplastic pemphigus improves with treatment for the underlying cancer, though may cause life-threatening pulmonary complications when it affects the airways.

Risk Factors and Preventive Measures

Because doctors do not know the mechanisms that set pemphigus in motion, there are no identified risk factors. The condition tends to first manifest in people who are age 40 or older, though can occur at any age. Researchers suspect GENE mutations underlie pemphigus as they do other AUTOIMMUNE DISORDERS, though have not yet been able to identify them. Early diagnosis and aggressive treatment are key to mitigating symptoms and outbreaks, improving QUALITY OF LIFE as well as helping preserve other structures and functions. People who have milder forms of pemphigus may go extended periods without symptoms.

petechiae Smooth, reddened, pinpoint lesions that result from microscopic bleeding under the surface of the SKIN. Petechiae most commonly appear on the lower legs though can appear anywhere on the body. The presence of petechiae is a symptom that signals an underlying health condition that causes a low platelet count such as THROMBOCYTOPENIA, LEUKEMIA, MONONUCLEOSIS, or SYSTEMIC LUPUS ERYTHEMATOSUS (SLE). Platelets are the body's first-line response in the COAGULATION process, clumping together (aggregating) to slow bleeding. Antiplatelet therapy such as ASPIRIN THERAPY, often prescribed for people at risk for HEART ATTACK or STROKE, intentionally blocks the actions of platelets and may also result in petechiae. The appearance of petechiae, which often is sudden, requires prompt evaluation from a doctor.

photosensitivity A heightened reaction to sunlight or other ultraviolet light that results in a RASH or SUNBURN at much lower or shorter exposure than would ordinarily cause sunburn. Photosensitivity may develop as a reaction to a medication, such as the antibiotic medication tetracycline or the herbal antidepressant remedy ST. JOHN'S WORT (hypericum), or as a symptom of an underlying health condition such as SYSTEMIC LUPUS ERYTHEMATOSUS (SLE) or ALBINISM. Photosensitivity may manifest as a red, splotchy rash on areas of SKIN exposed to the sun or as a full-fledged sunburn. Rarely, an individual may have an allergic reaction to ultraviolet light that causes the fairly immediate eruption of URTICARIA (hives) with sun exposure.

The dermatologist can diagnose photosensitivity based on its presentation and a history of recent sun exposure. Treatment may include topical or oral ANTIHISTAMINE MEDICATIONS if the rash itches (although topical antihistamines can themselves increase sun sensitivity). Topical CORTICOSTEROID MEDICATIONS often help reduce INFLAMMATION from widespread sunburn. However, the most effective treatment for photosensitivity is preven-

tion. Dermatologists recommend people who are photosensitive:

- wear clothing that covers the arms, legs, head, face, and neck when going outdoors, even when the day is cloudy
- liberally apply sunscreen at least 30 minutes before going outdoors (many dermatologists recommend applying sunscreen after getting out of the shower in the morning so the skin can absorb it) and frequently while outdoors
- avoid exposure during the sun's most intense periods, typically between 10 a.m. and 4 p.m. in most regions of the United States

phototherapy Treatment with ultraviolet light, which suppresses the action of immune cells in the SKIN (T-CELLS). Ultraviolet light also slows the growth rate of keratinocytes, the cells that make up much of the dermis and nearly all of the epidermis, helping reduce symptoms such as plaque formation and scaling. Phototherapy is effective for numerous chronic dermatologic conditions, notably PSORIASIS, VITILIGO, and atopic DERMATITIS. Many people require therapeutic phototherapy to bring symptoms under control, with ongoing maintenance treatments to help prevent recurrent outbreaks or to continue subduing the IMMUNE RESPONSE. With appropriate protection to prevent ultraviolet damage to the eyes and skin, phototherapy has few short-term side effects. Questions remain, however, about long-term consequences such as the same problems that accompany extended sun exposure (notably SKIN CANCER). Dermatologists use three types of phototherapy: ultraviolet B (UVB) phototherapy, psoralen plus ultraviolet A (PUVA) phototherapy, and excimer laser phototherapy.

UVB phototherapy UVB lightwaves are less intense than ultraviolet A (UVA) lightwaves, achieving a therapeutic benefit with low risk of sunburn and other complications. UVB phototherapy was the first therapeutic application of ultraviolet light and remains the most common one in use today. Dermatologists use two forms of UVB phototherapy: broadband, the conventional UVB phototherapy, and narrowband, which employs a narrower width of ultraviolet light. Narrowband UVB phototherapy is often more effective for treating psoriasis, though has a higher risk of sunburn than broadband UVB phototherapy. For UVB phototherapy treatments, the person stands inside a small room called a light box with the areas of skin exposed that are to receive treatment. Other skin surfaces remain clothed or covered, though treatment may be appropriate for nearly the entire body.

PUVA phototherapy PUVA lightwaves provides a stronger, more focused therapeutic effect. UVA lightwaves are more intense than UVB lightwaves. Psoralen is a photosensitive substance taken orally as a pill or applied as a lotion to lesions and desired skin surfaces. Short exposures to UVA lightwaves activate the psoralen, which intensifies the effect. This combination reduces the risk for complications such as sunburn during treatment. However, the skin remains photosensitive for up to 36 hours after treatment, requiring the person to avoid all sun exposure for 12 to 36 hours following a PUVA phototherapy session. The individual must also wear sunglasses after taking oral psoralen because the psoralen tends to accumulate in the retinal tissues of the eyes. Some people have an ADVERSE REACTION to psoralen including NAUSEA, vomiting, itching (PRURITUS), and heightened sensitivity to sun exposure even after PUVA phototherapy ends.

Excimer laser phototherapy Another type of phototherapy is the excimer laser, which emits high-intensity UVB lightwaves that the dermatologist focuses on specific lesions or defined areas of the skin's surface. Such laser phototherapy allows targeted treatment and limits the risk for sunburn, though targeted lesions often acquire deeper pigmentation than the surrounding skin and may SCAR after HEALING. Often the hyperpigmentation fades over time. Dermatologists generally reserve excimer laser phototherapy for conditions that do not respond to other treatments.

piercings Skin piercings for cosmetic purposes have become popular in the United States, especially among young people. Most people who have piercings experience minor complications at

some point. Wearing jewelry in the piercing, which is necessary to maintain the piercing, also establishes circumstances for HYPERSENSITIVITY REACTION and INFECTION. Long-term complications of piercings can include deformity of the tissues at the piercing site and the risk for systemic infection such as HEPATITIS.

Hypersensitivity Response

Contact DERMATITIS, often as a hypersensitivity reaction to the nickel in stainless steel, is the most common dermatologic complication of piercings. In contact dermatitis, the skin at the piercing location becomes red (erythema) and inflamed. It may itch or hurt. The piercing may swell, causing the tissue to close around the jewelry. Removing the jewelry and cleansing the site with an antiseptic solution made for this purpose helps soothe the irritated tissues and reduce INFLAMMATION.

Infection

Infection is a common problem that may develop as a complication of contact dermatitis, as a result of contaminated piercing needles and devices, or as a consequence of improper cleansing after piercing. Contamination is a significant risk with self-piercing. Early detection and treatment is important to prevent the infection from invading deeper tissues. EAR CARTILAGE piercings are particularly vulnerable to infection as well as resistant to treatment for infection, as the BLOOD supply to the area is sparse. Navel and genital piercings also are vulnerable to infection as a result of irritation from clothing and moisture.

Piercing jewelry made of plastic, wood, BONE, and other permeable materials can harbor BACTERIA. Minor infections generally improve with topical ANTIBIOTIC MEDICATIONS. More extensive infections require a doctor's evaluation and often require more involved treatment such as oral antibiotic medications and antiseptic cleansing of the piercing site.

Systemic infection such as hepatitis, and less commonly HIV/AIDS, is a significant risk when reusing or sharing piercing jewelry and needles. The hepatitis VIRUS can live outside the human body for extended periods of time. Piercings in and around the MOUTH carry the risk for bacterial infection that can involve the HEART valves because the mouth has a rich blood supply as well as an abundance of bacteria.

Deformity

Small piercings (16 gauge and smaller) will heal closed without scarring when the person no longer wears jewelry in the piercing to keep it open. Larger piercings (12 gauge and larger) may not heal closed, or may close with puckering of the tissue. Large-gauge piercings may stretch the tissues, such as the earlobes or lips, causing permanent enlargement. Infections, particularly of the ear cartilage, can destroy tissue, requiring PLASTIC SURGERY to restore the appearance and sometimes the function of the tissue. Piercings of the PENIS can damage or destroy erectile tissue, nerves, or the URETHRA. Clitoral piercing can damage nerves and cause structural damage to the CLITORIS and surrounding labia, particularly as a consequence of infection.

Preventing Piercing Complications

Basic hygienic methods can prevent most piercing complications. These methods include

- having piercings done by reputable, experienced professionals who use only disposable needles and equipment
- daily cleansing of piercing sites, such as washing with gentle soap and water during regular showering or bathing, or using a commercially available antiseptic cleansing solution for piercing sites
- frequently changing and cleaning piercing jewelry
- not sharing piercing jewelry
- wearing piercing jewelry made of impermeable materials such as metals

pilonidal disease A chronic condition in which HAIR-filled cysts form at the base of the spine. The cysts typically originate when the SKIN closes to form saclike structures with hair trapped inside. The sac fills with fluid, cells, and other debris. Often there are indentations or pits over the tops of the cysts, and sometimes the hair within the

cyst protrudes out. Pilonidal cysts often remain symptomless, though many become apparent because they are subject to persistent irritation from clothing, movement, and pressure. Extended sitting, clothes that fit tightly across the buttocks, and activities such as bicycling often create awareness of pilonidal cysts.

The key symptoms of pilonidal disease are PAIN, swelling, erythema (redness), and drainage (pus) over the sacrum (tailbone). Often a FEVER accompanies these symptoms, and the person is unable to sit or walk without great discomfort. The doctor often can diagnose pilonidal disease based on the appearance of the cysts and the history of the symptoms. The doctor typically lances (cuts open with a sterile instrument) the cysts to allow them to drain. Large, purulent, or recurrent cysts may require surgery to remove them.

Pilonidal disease tends to be recurrent and persistent, often continuing throughout life. Surgically removed cysts seldom return, though new cysts frequently form in the same proximity. Keeping the area clean and wearing loose-fitting clothing can help prevent pilonidal cysts from becoming irritated. Frequent position changes when sitting and sitz baths (sitting in warm water) help reduce discomfort when cysts are present.

pityriasis rosea A common SKIN RASH in which an outbreak of lesions occurs and resolves over a period of 3 to 12 weeks, generally without treatment or complications. The lesions are characteristically oval with distinct borders and may be smooth (macules), raised (papules), or scaly (plaques). Often the lesions itch and sometimes they cause the skin to be hypersensitive to touch. Doctors believe a VIRUS causes pityriasis rosea.

Symptoms and Diagnostic Path

The primary symptom of pityriasis rosea is an itchy (pruritic) rash that appears on the back, chest, arms, and legs. There is usually an initial outbreak, called a herald LESION, with subsequent eruptions of lesions in other locations. Often the dermatologist will biopsy a lesion to confirm the diagnosis, as well as conduct BLOOD tests to rule out secondary SYPHILIS, which has a rash very similar to that of pityriasis rosea.

Pityriasis rosea is very similar in appearance to the rash that occurs with secondary SYPHILIS. As untreated syphilis has serious health consequences, the diagnostic path should include a blood test to rule out syphilis.

Treatment Options and Outlook

Treatment aims to relieve symptoms. Cool baths and skin moisturizers often are enough to relieve mild pityriasis rosea. Topical and oral ANTIHISTAMINE MEDICATIONS, and sometimes mild CORTICOSTEROID MEDICATIONS, are necessary to control itching. The lesions clear up on their own after about 8 weeks, though in some people the rash and itching may persist for up to 12 weeks.

Risk Factors and Preventive Measures

Doctors do not know what causes pityriasis though strongly suspect a virus. Outbreaks tend to occur among people who are in close proximity, commonly during the winter months. Complications are very uncommon though scratching can open the lesions and allow secondary infection to develop. Pityriasis rosea is a self-limiting condition so recovery is without residual effects.

plaque, skin Raised, hardened, scaly lesions that form on the SKIN. Plaques characterize numerous dermatologic conditions. They may itch, hurt, or flake and may occur in small clusters or cover large areas of skin. Treatment for skin plaques targets the underlying conditions and includes measures to moisturize or soften the skin to help reduce the plaques. Topical CORTICOSTEROID MEDICATIONS or injections of corticosteroids into large plaques may help reduce them more quickly.

pressure sore See DECUBITUS ULCER.

prurigo A chronic condition in which lesions, typically papules or nodules, that itch intensely erupt on the SKIN. The lesions may occur anywhere on the body, though typically form in loca-

tions that allow scratching. Because the cause of prurigo, also called prurigo nodularis, remains unknown, dermatologists do not know whether the lesions develop in response to scratching or whether the itching of the lesions establishes the need to scratch. Whichever is the case, one perpetuates the other. The lesions eventually develop coarse, scaly surfaces. The intense itching drives many people to scratch the lesions until they bleed, which causes scabs to develop. Lesions that heal often leave white scars. An outbreak of lesions may extend over months or even years.

Prurigo is sometimes associated with LIVER disease, KIDNEY disease, HIV/AIDS, atopic DERMATITIS, GENERALIZED ANXIETY DISORDER (GAD), and also DEPRESSION. Most people who develop prurigo are middle-age or older, though occasionally the condition occurs in young people. The diagnostic pathway may include biopsy to rule out other causes for the lesions. Treatment generally incorporates topical CORTICOSTEROID MEDICATIONS and topical or oral ANTIHISTAMINE MEDICATIONS to subdue the itching. The dermatologist may choose to inject large or recurrent lesions with a corticosteroid medication. Some people who have prurigo benefit from psoralen plus ultraviolet A (PUVA) PHOTOTHERAPY or cryotherapy (freezing), which destroys the lesions and allows the skin to heal.

pruritus The clinical term for itching, especially itching that engenders the uncontrollable urge to scratch. Pruritus is a symptom of innumerable health conditions and may be localized (confined to a specific area or to lesions) or generalized (widespread, involving much of the SKIN's surface). The skin may appear reddened (erythema), swollen (edema) or otherwise irritated, or may show no reason for the itching.

The physiologic mechanism of itching is similar to, though distinctive from, that of PAIN. The NERVE cells, called nociceptors, that send itch signals to the BRAIN are scattered throughout the epidermis and upper layer of the dermis. Irritants that contact the epidermal and dermal layers of skin can arouse the nociceptors, coming from the external surface of the skin (such as from lesions that form on the skin) or from within (such as the accumulation of BILIRUBIN, which accounts for the itching that accompanies JAUNDICE). HISTAMINE, which the IMMUNE SYSTEM releases during a HYPERSENSITIVITY REACTION (allergy or ASTHMA), is among the internal stimuli that activate these nociceptors.

The response of scratching is a REFLEX that the autonomic NERVOUS SYSTEM generates in response to itch signals. Researchers theorize that scratching activates a mild pain response that overrides the itch response. Pain and itch appear to use many of the same nociceptors, and pain seems to be the more dominant stimulus. However, many factors contribute to the experience of itching as

well as to its relief. Scratching is also a conscious action, and can itself be an irritant that causes itching. Dermatologic conditions in which the itch/scratch relationship becomes circular include LICHEN SIMPLEX CHRONICUS and PRURIGO.

Pruritus is often an early indication of systemic health conditions such as jaundice or kidney dysfunction, and is a hallmark symptom of dermatologic conditions such as PSORIASIS and DERMATITIS. The diagnostic path depends on the complex of symptoms. Treatment may include topical or systemic ANTIHISTAMINE MEDICATIONS or CORTICOSTEROID MEDICATIONS and other therapies to resolve the underlying condition. It is important to resist the urge to scratch, as scratching further irritates the skin and may open the pathway for INFECTION.

pseudofolliculitis barbae A condition in which large numbers of the hairs in the beard region on a man's face grow inward after shaving, causing irritation and INFLAMMATION. Pseudofolliculitis barbae, sometimes called razor RASH or razor bumps, occurs most frequently in men whose facial HAIR is tightly curled, and is particularly common among African American men. The process of shaving pulls the hairs before cutting them, allowing the cut tips to retreat within the hair follicle. When the facial hair is tightly curled the shaved tips of the hairs, which are pointed and sharp, turn into the sides of the follicle. As they grow they puncture the follicle rather than growing out of the follicle's opening, creating blocked follicles. The entire beard area often becomes involved, causing considerable discomfort and difficulty shaving.

The dermatologist can usually diagnose pseudofolliculitis barbae on the basis of its appearance, though may choose to scrape several of the inflamed papules (bumps) to rule out INFECTION. Shaving with an electric razor, which does not pull and cut the hair as much as a blade razor, may reduce symptoms for some men, though many men experience irritation and inflammation regardless of shaving method. When that is the case, the optimal solution is to stop shaving. Topical preparations such as benzoyl peroxide lotion or tretinoin cream are also sometimes helpful, though may themselves cause SKIN irritation.

psoriasis A common, chronic SKIN condition in which the dermis produces keratinocytes at an accelerated rate. This causes immature keratinocytes, which are still soft, to reach the epidermis (the outer layer of the skin). The excess keratinocytes form lesions, typically scaly plaques, that itch (PRURITUS) or hurt. The accelerated turnover of keratinocytes creates an IMMUNE RESPONSE in the skin that dermatologists refer to as T-CELL activation. The immune response produces INFLAMMATION, the body's attempt to heal the plaques. But like the other components of psoriasis, the T-cell response is out of control and results in exacerbating, rather than relieving, the lesions.

Dermatologists believe GENE mutations establish a predisposition for the accelerations that characterize psoriasis. External or environmental circumstances such as injury, INFECTION, and stress then trigger the dysfunctions in the skin that result in the psoriasis. Psoriasis appears to run in families, suggesting that the mutated genes are inherited. Researchers continue to explore the genetic foundations of psoriasis. Once psoriasis manifests, it remains in a lifelong pattern of outbreak and REMISSION.

Generally, dermatologists classify five types of psoriasis. Psoriasis in any of these types can also cause inflammation of the joints, a form of arthritis called psoriasic arthritis. Dermatologists may also refer to psoriasis according to the parts of the body affected, such as palmar-plantar which affects the palms of the hands and soles of the feet. About 7 million Americans have psoriasis.

Erythrodermic psoriasis In erythrodermic psoriasis, widespread areas of the skin become red and scaly, and often swollen. This is the least common but most severe type of psoriasis. It can develop from any of the other types of psoriasis.

Flexural psoriasis Also called inverse psoriasis, flexural psoriasis forms smooth though itchy lesions in areas such as the axillae (underarms), creases of the leg in the groin, under the breasts, and other skinfold areas. Irritation from rubbing and sweating exacerbates the lesions.

Guttate psoriasis In guttate psoriasis, the second-most common type of psoriasis, the lesions

are small and look as though they were dropped onto the skin. The lesions have raised edges with centers that are somewhat depressed and appear crumpled. Guttate psoriasis is most common on the trunk, arms, legs, and scalp. The lesions itch, and may crack and then crust over before HEALING. Upper respiratory infections such as COLDS or PHARYNGITIS (notably STREP THROAT) often trigger outbreaks of guttate psoriasis.

PSORIASIS AND BLOOD DONATION

Some oral medications for psoriasis stay in the BLOOD for an extended time and have the potential to cause serious BIRTH DEFECTS. Blood banks defer people who take or who have taken these medications from donating blood for periods of time, depending on the medication. People who have taken etretinate at any time, which is no longer available, are permanently deferred because it remains in the blood indefinitely.

Plaque psoriasis The most common form of psoriasis, plaque psoriasis features erythematous (reddened) plaques that typically develop on the knees, elbows, scalp, and trunk. The plaques itch and sometimes hurt and often crack, bleed, and crust. Plaque psoriasis also can affect the fingernails and toenails, causing pitting, deformation, discoloration, and separation from the nail bed. Emotional and physical stress (such as illness or injury) may initiate outbreaks of plaque psoriasis. Some people have few outbreaks and other people have lesions nearly continuously.

Pustular psoriasis The lesions in pustular psoriasis look infected but simply contain fluid mixed with white blood cells, dead skin cells, and other matter that has the appearance of pus. Adverse DRUG reactions and topical irritants often trigger pustular psoriasis.

Symptoms and Diagnostic Path

The dermatologist diagnoses psoriasis primarily on the basis of its symptoms and history, and may choose to biopsy representative lesions to confirm. In its early stages, psoriasis may be difficult to distinguish from DERMATITIS and other skin disorders. The diagnosis becomes more conclusive when other family members have psoriasis.

Treatment Options and Outlook

The extent to which medical treatments can mitigate the symptoms of psoriasis depends on the type and severity of the psoriasis. Unfortunately, psoriasis responds unpredictably to treatment methods, with great individual variation. As well, the lesions may become resistant to specific treatments or medications over time, requiring a shift in therapeutic approach. This results in a trial-and-error approach that often frustrates those who have psoriasis. Dermatologists generally follow a sequential approach of progressively more intense therapy. Many people with moderate to severe psoriasis use a combination of therapies to help control their symptoms. ANTIBIOTIC MEDICATIONS may be necessary to treat secondary infections that affect psoriasis lesions.

Risk Factors and Preventive Measures

Because psoriasis has genetic predisposition, it is not possible to prevent its development. Once pso-

purpura Smooth, moderately sized lesions, typically dark red to reddish purple, that result from bleeding under the surface of the SKIN. Purpura often look like small bruises and may occur anywhere on the body, including mucous membranes. The presence of purpura signals an underlying health condition resulting either from PLATELET deficiency, which delays COAGULATION (the clotting process), or bleeding due to systemic INFLAMMATION or INFECTION. As some of these underlying conditions are serious and potentially life-threatening, the appearance of purpura (except senile purpura and actinic purpura, which are common in aging skin) requires immediate medical evaluation. The doctor can distinguish purpura from other discolorations by applying gentle pressure to them. Purpura remain discolored, while other kinds of lesions often blanch (turn lighter).

pustule A blisterlike formation that contains a pus, thick fluid of white blood cells, cellular debris, and sometimes BACTERIA. Pustules tend to hurt and sometimes itch. They commonly develop in numerous dermatologic conditions ranging from ACNE to FOLLICULITIS to PSORIASIS. Often pustules resolve without medical intervention, going away when the underlying condition causing them is under control. Warm, moist compresses or soaking and sometimes medications to reduce INFLAMMATION or fight INFECTION can speed HEALING. Topical or oral ANTIBIOTIC MEDICATIONS may be necessary when there is infection.

rash A general term for a broad range of SKIN eruptions. A rash is a symptom rather than itself a health condition and may accompany numerous dermatologic or systemic conditions. Viral and bacterial infections, immune and autoimmune responses, toxic contacts, systemic illnesses, chronic health conditions, and PARASITIC INFESTATIONS often cause rashes. Many rashes are so generalized that they are difficult to diagnose in the absence of other symptoms. Some rashes are so distinctive that their diagnosis requires no further symptoms. Nearly all rashes go away when the underlying health condition is resolved. Treatment for the rash may consist of approaches to mitigate symptoms, typically itching, and may include topical and oral ANTIHISTAMINE MEDICATIONS.

rhytidoplasty The clinical term for facelift, an OPERATION to smooth and tighten the SKIN on the face. Rhytidoplasty, also called rhytidectomy, is a cosmetic surgery appropriate for treating moderate to significant WRINKLES and sags on the face. There are numerous variations of rhytidoplasty that target only certain regions of the face or the whole face. Rhytidoplasty is generally an outpatient surgery (AMBULATORY SURGERY) with the person going home the same day. The operation generally takes three to six hours, though can take longer for a complex, total rhytidoplasty. Occasionally the surgeon may prefer to keep the person overnight in the hospital.

Before the operation the surgeon carefully marks the incision lines on the face with a surgical marking pen or permanent marker. Rhytidoplasty involves separating the skin from the underlying tissues, trimming away excess fat as well as skin, and reattaching the skin so it is tighter across the supporting tissues. Depending on the type of operation, the surgeon may also bolster the supporting tissues with suspension sutures to help them "lift" the face.

Swelling, discoloration, and PAIN are common following surgery, though ANALGESIC MEDICATIONS (pain relievers) can mitigate the pain. Many people experience pulling and stretching sensations during HEALING. Skin closures, usually sutures or staples, remain for 7 to 10 days. Bruising and swelling may remain for several weeks, as does numbness of the skin. Full recovery takes several months.

The risks of rhytidoplasty include excessive bleeding during as well as after surgery, INFECTION, permanent loss of sensation or NERVE damage, excessive scarring, separation of the tissues, and tissue death (NECROSIS). It is important to have realistic expectations around what the surgery can and cannot achieve and to understand the range of variation that is possible with regard to the final outcome. Though many people are satisfied with their appearance when healing is complete, there is an element of unpredictability as to the final result. Rhytidoplasty does not prevent further changes, such as those resulting from the natural aging process, from occurring. People who wish to maintain a specific appearance through cosmetic

surgery are likely to require multiple procedures over time. It is important to discuss these factors with the plastic surgeon.

rosacea An inflammatory condition that produces acnelike outbreaks and erythema (redness) on the face. Rosacea, sometimes incorrectly called adult ACNE, occurs primarily in people over age 40 and becomes more common with advancing age. Dermatologists do not know what causes rosacea, though believe it is an interaction between genetic and environmental factors. About 14 million Americans have rosacea. Though more women than men have rosacea, men tend to have more severe symptoms.

Symptoms and Diagnostic Path

The symptoms of rosacea are mild and general at first, often starting with increasingly frequent blushing. Dermatologists believe this early stage of rosacea may persist for years, though not many people seek medical care for it alone. Eventually the condition progresses to outbreaks of pimplelike pustules and other lesions that appear to be acne but resist conventional acne treatments. Most people seek a doctor's evaluation at this stage.

The typical symptoms that bring people to the dermatologist include

- extended flushing of the face and neck that may persist for hours after onset
- papules that erupt in clusters across the cheeks, on the chin and forehead, around the base of the NOSE, and sometimes around the eyelids
- itching and burning of the face, particularly in areas where papules have erupted
- patches of dry flaky skin when the papules retreat
- TELANGIECTASIS (fine BLOOD vessels that appear as red lines beneath the surface of the skin)
- CONJUNCTIVITIS and itchy, dry eyes
- rhinophyma (enlarged and bulbous nose) in advanced or severe rosacea

The dermatologist generally can make the diagnosis on the basis of the appearance and history of the symptoms and the person's age. Other factors that support a rosacea diagnosis include a personal or family health history of AUTOIMMUNE DISORDERS or rosacea symptoms.

Treatment Options and Outlook

Effective treatment for rosacea varies widely; what works for some people may have no effect for others. Dermatologists generally offer a combination approach of topical products and oral ANTIBIOTIC MEDICATIONS that are effective in controlling skin conditions. Most people who have rosacea try a number of treatments to find those that are the most effective.

COMMON TREATMENTS FOR ROSACEA

Topical	
azelaic acid	benzoyl peroxide
clindamycin topical	erythromycin topical
glycolic acid	metronidazole
sulfacetamide	sulfuric solutions
Oral	
doxycycline	erythromycin
minocycline	tetracycline

Laser therapy becomes a treatment option for rhinophyma and can reduce the size and shape of the nose to normal. Laser therapy is also useful for controlling telangiectasis. Treatment for EYE symptoms may include ophthalmic moisturizing solutions and CORTICOSTEROID MEDICATIONS to reduce INFLAMMATION and irritation. As rosacea is a chronic condition with no known cure, treatment is ongoing.

Risk Factors and Preventive Measures

People who are fair-skinned, blond, and blue-eyed seem most likely to develop rosacea. Because dermatologists do not know the precise mechanisms of rosacea, there are no known preventive measures. Factors that can sometimes trigger outbreaks of rosacea, though do not cause rosacea, include

- spicy foods

- CAFFEINE and ALCOHOL
- heat and strenuous physical exercise
- unprotected sun exposure
- strong emotional reactions such as anger, fear, or embarrassment
- hot showers or baths, hot tubs, saunas
- hormones (MENSTRUATION, PREGNANCY, MENOPAUSE)

Actions such as avoiding circumstances that trigger rosacea outbreaks, using sunscreen with a high sun-protection factor (SPF) when outdoors, and maintaining diligent therapeutic approaches can keep rosacea in check for many people who have the condition.

scabies A contagious parasitic infestation with the SKIN mite *Sarcoptes scabei* that typically causes intense itching (PRURITUS) and visible bites or irritation to the skin. The bites create small, reddened papules (bumps) and often a RASH on the surrounding skin that is the burrows the mites make to lay their eggs. The most common sites for scabies are skinfold areas such as in the groin, under the breasts and armpits, between the shoulders, behind the knees, at the creases in the elbows, and on the inner wrists. Itching typically becomes intense at night. Aggressive scratching can cause secondary bacterial infections of the skin to develop. Scabies spreads through close physical contact.

The doctor diagnoses scabies with skin scrapings of the papules or rash. Microscopic examination of the scrapings often reveals eggs or fecal matter from the mites. Applying a lotion that contains a pesticide such as permethrin, lindane, or crotamiton will kill the mites, though the itching may persist for a few days. All members of the household should receive treatment. It is also important to wash clothing, towels, and bed linens in very hot (130°F) water for at least 10 minutes as a precaution to kill any mites these items might be harboring, as mites can live outside the body for up to 36 hours. Reinfestation may occur with reexposure.

scale A SKIN LESION in which keratinocytes clump together instead of falling away from the skin, adhering to the skin. Keratinocytes separated from the epidermis are nearly translucent, often giving scales a silver or white cast. When enough scales accumulate, their weight causes them to finally drop from the skin, often as visible flakes such as characterize DANDRUFF.

scar A formation of fibrous tissue that remains at the site of a healed wound. Though a scar will not entirely match the surrounding tissue, most scars heal to be barely noticeable.

Some scars become overgrown. A hypertrophic scar is enlarged though does not extend beyond the original wound site. Over time, most hypertrophic scars retreat to become less noticeable. The dermatologist may reduce a hypertrophic scar by injecting it with an intralesional corticosteriod medication or with pulsed dye laser treatments. The success of such procedures depends on the location and nature of the hypertrophic scar.

KELOID scars occur when the scar formation process continues after the wound heals. The keloid continues to grow, becoming a spongy LESION that no longer has anything to do with wound HEALING. Keloids can become quite large. The dermatologist may remove keloids that are continually irritated, such as by clothing, or that are cosmetically undesirable. However, keloids tend to recur.

sebaceous glands The small glands that produce sebum, a lipid-based, oily fluid that lubricates the surface of the SKIN. Sebum is mostly the metabolic waste that remains after fat cells break down. Most sebaceous glands empty into HAIR follicles, secreting sebum along the emerging hair shaft. Some sebaceous glands exist independent of hair follicles and secrete sebum directly to the skin's surface, such as those on the glans of the PENIS.

The palms of the hands and the soles of the feet are the only skin surfaces that do not have sebaceous glands.

The oily consistency of sebum gives the skin a highly water-resistant coating. The lubricating qualities of sebum keep the keratinocytes, the cells that make up the epidermis, supple and flexible. Without adequate lubrication the skin becomes dry and the keratinocytes scale and flake, presenting not only an undesirable cosmetic appearance but also compromising the skin's resistance against pathogenic (disease-causing) microorganisms. Sebum also helps regulate the skin's natural flora, the collective of BACTERIA, yeasts, and other microscopic organisms that inhabit the epidermis. These microorganisms draw nutrients from the lipids in the sebum.

For further discussion of the sebaceous glands within the context of integumentary structure and function, please see the overview section, "The Integumentary System."

seborrheic keratosis A condition in which noncancerous (benign) growths arise on the SKIN. The lesions resemble warts though appear pasted on rather than attached to the skin. The lesions are most commonly brown or black, though may be yellow, gray, tan, or other colors. Seborrheic keratosis becomes increasingly common in people age 40 and older. Most people develop multiple lesions. The lesions cause no symptoms beyond their presence, unless frequent irritation causes them to itch, hurt, or bleed.

Seborrheic keratosis requires medical assessment only to ascertain that the lesions are not cancerous, which typically is apparent on the basis of their appearance and history. The doctor should biopsy any lesions that are questionable. There is no medical reason to remove the lesions once diagnosed, however, as they do not turn malignant. People sometimes want lesions removed that are cosmetically undesirable or in locations where they receive frequent irritation such as from clothing. Cryotherapy (freezing), curettage and electrodesiccation (scraping and burning), and shave excision (cutting out; requires no sutures) are the most common methods of removal. Though removed lesions do not recur, others may grow nearby.

skin The body's largest organ, making up the body's covering and about 15 percent of the total body weight The skin's three layers—epidermis, dermis, and subcutaneous layer—help the body maintain its structure; protect against INFECTION; and regulate fluids, electrolytes, and temperature. Numerous health conditions, localized and systemic, can affect the skin and its functions.

The subcutaneous layer, innermost to the body, contains primarily adipose tissue more familiarly called body fat. The dermis, the middle layer, provides the structure of the skin. It contains connective tissue, the SEBACEOUS GLANDS, and an abundant supply of nerves and blood vessels. The dermis nourishes the epidermis above it and attaches to the subcutaneous layer beneath it, holding the skin in place. HAIR follicles and SWEAT GLANDS extend from the epidermis into the dermis and a bit into the subcutaneous layer.

The primary cells of the skin, melanocytes and keratinocytes, originate in the base, or basal, level of the epidermis. Keratinocytes migrate outward to form the upper epidermis, gradually flattening and hardening. The epidermis varies in thickness and other characteristics, accommodating the needs of different body surfaces. The epidermis of the palms of the hands and the soles of the feet is thick and tough, for example, while that of the eyelids is soft and only two or three cells in depth.

The skin is also the body's organ of tactile sensory perception, or touch. Millions of NERVE endings in the skin continually sense environmental factors such as pressure, temperature, moisture. Other specialized nerve cells, called nociceptors, perceive itching and PAIN. Sweat evaporation on the skin's surface is the body's primary cooling mechanism, as well as a secondary mechanism for electrolyte regulation and balance.

For further discussion of the skin within the context of integumentary structure and function, please see the overview section "The Integumentary System."

skin cancer Malignant growth that arises from the epidermis or dermis. There are many types of CANCER that occur in the SKIN. The three most common types of skin cancer are basal cell carcinoma, squamous cell carcinoma, and malignant melanoma. Skin cancer is the most widely diagnosed type of cancer in the United States, with about 1 million new cases each year. The vast majority of skin cancers—basal cell carcinoma and squamous cell carcinoma—are nearly 100 percent curable with early detection and treatment. Malignant melanoma, the least common form of skin cancer, is more dangerous because it tends to metastasize (spread) early in its development, though it also has a high cure rate when detected and treated before it metastasizes.

Cancer experts believe nearly all skin cancer results from sun damage to the cells of the skin. The ultraviolet lightwaves the sun emits cause subtle changes in the ways skin cells function. Over time these changes can result in aberrant growth, causing skin cells to form into cancerous lesions. People with fair skin are most vulnerable to this damage, as their skin produces less melanin. In addition to giving the skin its color, melanin protects the skin from the sun by absorbing the ultraviolet lightwaves that cause damage. A tan paradoxically results from and protects the skin against sun exposure, as sun exposure stimulates melanocytes to produce melanin.

The ultraviolet light used in tanning booths affects the SKIN in the same way as the ultraviolet lightwaves of the sun, and carries the same exposure risk for skin cancer.

The correlation between sun exposure and skin cancer also means that nearly all skin cancers are highly preventable. Cancer experts recommend diligent SUN PROTECTION measures beginning in early childhood in combination with regular skin examinations to detect suspicious growths or changes in existing lesions. Other types of cancer that can affect the skin, but are not primary skin cancers or related to sun exposure, include KAPOSI'S SARCOMA, primarily a manifestation of HIV/AIDS in the United States, and cutaneous T-cell LYMPHOMA.

Basal Cell Carcinoma

Basal cell carcinoma is a cancer of the keratinocytes that form the bottom, or base, of the epidermis, also called basal cells. Most basal cell carcinomas erupt around HAIR follicles, leading researchers to suspect they originate in the follicle

structure or the SEBACEOUS GLAND (sometimes collectively called the pilosebaceous unit). Basal cell carcinomas nearly always arise on sun-exposed skin surfaces, though may also occur on skin exposed to radiation such as for RADIATION THERAPY.

The characteristic symptoms of basal cell carcinoma are

- open sore that does not heal
- reddened or flaky patch that itches or hurts
- shiny, discolored NODULE (bump) that develops on the skin
- pinkish, craterlike structure with raised edges and tiny BLOOD vessels visible in the center
- yellowish, waxy area that resembles a scar though gradually enlarges and may itch

Though basal cell carcinomas rarely metastasize, they do spread within the epidermis and can cause considerable damage to the skin. Doctors diagnose about 800,000 Americans with basal cell carcinoma each year, making it the most common cancer of any type. A person who has one basal cell carcinoma is likely to develop others, though removed tumors seldom recur. Basal cell carcinoma is uncommon in dark-skinned people.

Squamous Cell Carcinoma

Squamous cell carcinoma is a cancer of the keratinocytes in the upper layer of the epidermis, formerly called squamous cells because of their squamous, or squashed, appearance. Nearly all squamous cell carcinoma evolves from ACTINIC KERATOSIS (though not all actinic keratosis lesions become cancer). Because of this, doctors consider actinic lesions precancerous and remove them to end their progression, effectively thwarting the cancer's development. Squamous cell carcinoma can but does not often metastasize. Sun damage causes most squamous cell carcinoma, though tumors can form in sites of continual irritation.

The characteristic symptoms of squamous cell carcinoma are

- crusted, raised growth resembling a WART that easily or frequently bleeds
- patch of red, flaky skin that oozes or bleeds
- sore that bleeds and crusts but does not go away
- ulceration on the lips that resembles a COLD SORE but does not heal

Though most commonly a cancer of the surface skin (particularly sun-exposed), squamous cell carcinoma also can develop in the mucous membranes. Untreated squamous cell carcinoma will eventually grow downward to penetrate the dermis and subcutaneous layer, and may spread to LYMPH structures that enable widespread metastasis. Doctors diagnose about 200,000 Americans with squamous cell carcinoma each year. Though squamous cell carcinoma is less common in dark-skinned than in light-skinned people, among skin cancers in dark-skinned people squamous cell carcinoma is the most common.

Malignant Melanoma

Malignant melanoma arises from melanocytes, the cells that produce melanin. Benign skin lesions such as nevi (moles) composed of melanocytes are often the staging sites for malignant melanoma. Malignant melanoma can develop and metastasize quickly. Diligent monitoring for changes in existing lesions such as moles is the most effective method for early detection and diagnosis. Doctors classify malignant melanoma by growth pattern (such as nodular, superficial, or spreading) or by depth of invasion, metastasis, and nodal involvement. Small, localized malignant melanomas are about 90 percent curable with early diagnosis and treatment. Widely metastasized malignant melanoma is usually fatal.

The characteristic symptoms of malignant melanoma are

- change in the size, symmetry, color, or texture of an existing NEVUS (mole)
- bleeding or oozing from an existing nevus
- a new nevus that emerges and grows rapidly, especially one that has asymmetrical shape, irregular borders, multiple colors, or exceeds one quarter inch in diameter (the ABCD criteria)

Doctors diagnose about 50,000 Americans with malignant melanoma each year, many of whom have moderate to advanced cancer by the time of diagnosis.

ABCD CRITERIA FOR MALIGNANT MELANOMA

A = asymmetry; halves do not match
B = borders; edges are irregular or vague
C = color; two or more colors are present
D = diameter; larger than one quarter inch

Symptoms and Diagnostic Path

Symptoms vary among the types of skin cancer, though generally any wound or sore that does not heal or mole that changes appearance is suspect. The diagnostic path typically includes biopsy of suspicious lesions. The dermatologist may remove very small lesions without biopsy, as doing so effectively removes any cancer that is present. Biopsy identifies the type of cancer present, which determines the appropriate course of treatment.

CHARACTERISTIC SKIN CANCER SYMPTOMS

Type of Skin Cancer	Characteristic Symptoms
basal cell carcinoma	sore that does not heal persistent red or flaky patch that itches shiny, discolored NODULE vascular crater yellowish, waxy, itchy plaque
squamous cell carcinoma	wartlike lesion that bleeds flaky patch that bleeds sore that repeatedly bleeds and crusts lip ulceration that does not heal
malignant melanoma	ABCD criteria: • asymmetrical appearance • irregular borders • multiple colors • diameter greater than one quarter inch

Treatment Options and Outlook

The preferred treatment for nearly all skin cancer is surgical removal, which may include various methods such as curettage and electrodesiccation (scraping and cauterization), excision (cutting out), and MOHS' MICROGRAPHIC SURGERY. Microscopic examination of the removed LESION confirms the diagnosis and type of cancer. Malignant melanoma requires extensive excision, with wide margins and possible removal of nearby LYMPH NODES, and may require follow-up CHEMOTHERAPY if the cancer has metastasized. Dermatologists may use cryotherapy (liquid nitrogen) to remove precancerous lesions, such as those of actinic keratosis, and very small lesions that appear suspicious. Other treatment options may include topical imiquimod (Aldara) cream and RADIATION THERAPY.

Risk Factors and Preventive Measures

The single-most important risk factor for skin cancer is excessive sun exposure. People born before the 1980s have the highest risk for skin cancers because they grew up before sunscreen products became available. Skin cancers tend to manifest several decades after the exposures that damaged the skin, making it important for people age 40 and older to have yearly skin examinations from a physician and to perform monthly SKIN SELF-EXAMINATION. People who have had skin cancers removed may need more frequent physician evaluation. The most effective preventive measures are those that safeguard the skin from sun damage. These measures include

- limit sun exposure during peak ultraviolet intensity (10 a.m. to 2 p.m. in most of the United States)
- wear protective clothing to cover the skin
- apply sunscreen liberally and frequently before and during sun exposure

skin replacement A procedure for restoring SKIN to areas of the body where there has been extensive damage and loss of skin. BURNS, major trauma, surgery, varicose ulcers, and decubitus ulcers are among the conditions that require skin replacement. Skin-replacement techniques may use skin grafts or synthetic skin products for temporary or permanent reconstruction.

Skin Grafts

There are three main sources for skin grafts:

- autograft, which harvests skin from one location on the person's body and transplants to another for permanent skin replacement

- allograft, which uses donor skin harvested from a cadaver to create temporary protection while the wound heals enough to accept a permanent graft
- xenograft, which uses specially prepared skin from an animal, usually a pig (porcine xenograft), to create temporary protection while the wound heals enough to accept a permanent graft

An autograft has the highest rate of success because it is the person's own tissue. A skin graft may be full thickness, which includes the complete epidermal and dermal layers, or split thickness, which includes the epidermal and upper dermal layer. A full-thickness graft generally produces a better cosmetic result though carries a higher risk of failure. A split-thickness graft generally adheres, or "takes," better though may heal somewhat irregularly.

Synthetic Skin

Synthetic skin uses materials crafted in the laboratory to create a substitute skin that may serve as a temporary covering or a matrix to support permanent new skin growth. Typically the matrix consists of two layers: one that the new cells grow into and that remains a permanent part of the skin and the other one, usually made of silicone or a similarly inert material, the surgeon removes when HEALING is well established. The new skin grows through the synthetic matrix, absorbing it into its structure.

Surgical Procedure

Skin replacement may be an outpatient or inpatient OPERATION, depending on the nature of the wound. If using an autograft, the surgeon first harvests the graft from the donor site. With an autograft or allograft, the surgeon typically uses a device called a mesher to put tiny holes evenly throughout the graft. This meshing allows the graft to stretch to cover a larger area. The holes also allow fluid to drain from the site, improving healing. After about 36 hours, the graft begins to develop new BLOOD vessels that tether it to the underlying tissue and provide a source of nourishment. Xenografts typically arrive already meshed and ready to place, needing only for the surgeon to trim them to the appropriate size. Synthetic grafts do not require meshing and are also ready to place. TISSUE EXPANSION is a method that allows the surgeon to literally stretch the growth pattern of existing skin to grow extra skin the surgeon can then harvest and place where needed. It takes several months to grow enough skin to use for a graft.

Risks and Complications

The main risk of skin replacement is graft failure, which can occur regardless of the graft source. Numerous factors contribute to graft success or failure. The graft may fail to develop an adequate blood supply or the match between the donor graft and the recipient site may be not quite right. The underlying tissue foundation may not be adequate to support new skin growth. Other potential complications include excessive bleeding during or after surgery and INFECTION.

Outlook and Lifestyle Modifications

Small grafts that heal without complications may require few lifestyle changes. Large wounds may require extended rehabilitation and significant lifestyle modifications. With more extensive skin replacement, there may be continued care needs. The overall outlook depends more on the reason for the skin replacement than the replacement itself. The recipient site remains more vulnerable than native skin to damage from sun exposure and trauma.

skin self-examination A method for early detection of suspicious and possibly cancerous lesions on the SKIN. Health experts recommend skin self-examination monthly for adults. Doing skin self-examination takes 5 to 10 minutes and requires privacy to fully undress, a full-length mirror, and a handheld mirror. Many people find it convenient to do a skin self-examination before or after bathing or showering. Use the mirrors to visualize and examine the entire skin surface including the bottoms of the feet and the genitals. A handheld hair dryer may help to examine the scalp. Look for skin blemishes and moles, and compare them to the ABCD SKIN CANCER screening characteristics

ABCD SKIN EXAMINATION

	Characteristic	Normal	Suspicious
A	asymmetry	matching halves (symmetrical)	unequal or nonmatching halves (asymmetrical)
B	border	smooth, even edges	ragged, notched, or otherwise uneven edges
C	color	single shade of brown	varied shades of brown; multiple colors
D	diameter	less than one quarter inch	larger than one quarter inch

for malignant melanoma. After doing several skin self-examinations, most people are familiar with their usual lesions and blemishes and can quickly identify any changes that have taken place since the previous self-exam. A dermatologist should evaluate any suspicious findings.

staphylococcal scalded skin syndrome A potentially life-threatening bacterial INFECTION of the skin that most commonly affects infants and young children. *Staphylococcus aureus* is the infective agent. The infection is systemic, causing eruptions on the skin that give the appearance of scalding. A single LESION heralds the onset of the infection, with multiple lesions rapidly emerging. The lesions are scarlet red and quickly BLISTER. The blisters (bullae) are very fragile and peel away from the skin with touch. The lesions spread to be contiguous with one another, covering large portions of the body. The loss of skin exposes the body to other pathogens that can cause complicating infections and means the body cannot maintain proper thermal or fluid regulation. Prompt diagnosis and treatment with ANTIBIOTIC MEDICATIONS is essential. Most children fully recover with appropriate treatment. The infection is highly contagious. Diligent HAND WASHING is crucial for caregivers and family members.

Stevens-Johnson syndrome See TOXIC EPIDERMAL NECROLYSIS.

stretch marks Irregular, discolored streaks or lines in the SKIN. Stretch marks represent, as the name suggests, changes in the tissue structure and appearance that result from the skin stretching and separating from the underlying supportive tissues. Such stretching most commonly occurs with PREGNANCY, BREAST augmentation surgery, and weight gain and loss, and affects the abdomen, upper arms, thighs, and breasts. Early stretch marks appear pink; mature stretch marks are generally pale. In addition to the altered pigmentation, stretch marks may have a different texture than the surrounding skin. Stretch marks are cosmetic and do not affect health or reflect health conditions. Cosmetic treatments to minimize the appearance of stretch marks include laser therapy and topical products such as glycolic lotions and tretinoin cream.

sunburn Damage to the epidermis and sometimes the dermis, the top and middle layers of the SKIN, as a consequence of extended, unprotected sun exposure. The sun emits several wavelengths of ultraviolet light. Those that reach the earth's surface are ultraviolet A (UVA) and ultraviolet B (UVB). Each affects the skin in different ways. UVA activates melanocytes, the cells that produce melanin (pigment) and may produce a thermal (heat) response that causes the skin to turn red. Though the skin may feel hot, this is not actually sunburn but rather a thermal (heat) response.

Sunburn is a delayed response to UVB exposure. UVB lightwaves do not activate the melanocytes but instead affect keratinocytes. When the epidermis (skin's outer layer) contains deeply pigmented keratinocytes, such as in a person who has dark skin or a tan from previous sun exposure, the pigment (melanin) absorbs the UVB and the keratinocytes escape damage. When the skin is light, melanin distribution is also light and there is little absorption of UVB.

The keratinocytes bear the brunt of the exposure, and about 8 to 12 hours later show the consequences. The damaged cells release toxins and other substances that draw increased BLOOD flow to the dermis. The additional blood flow causes the skin to become red (erythema). These toxins irritate the nerve endings in the epidermis and dermis, causing PAIN. Fluid may accumulate between the cells (edema), causing swelling. With more severe damage, fluid-filled blisters form on the skin. Discomfort peaks about 48 hours after exposure. At about this same time, the melanocytes have infused keratinocytes migrating from the dermis to the epidermis with melanin, giving them a darker pigment that will offer better protection than their predecessors had.

The most effective treatment for sunburn is a combination of moisturizing lotion or gel such as aloe vera to soothe the irritated skin and a nonsteroidal anti-inflammatory drug (NSAID) such as ibuprofen to relieve INFLAMMATION and pain. Most sunburn discomfort resolves in three to five days. Badly sunburned skin that has blistered is likely to peel at this point and requires gentle cleansing to minimize the risk for bacterial INFECTION until the new skin completely heals. Researchers now believe one significant sunburn is sufficient to lay the groundwork for skin cancer decades later. Repeated mild to moderate sunburns appear to have similar effect. Sunscreens and protective clothing worn during sun exposure can protect against sunburn.

sun protection Methods to safeguard the SKIN from SUNBURN and sun damage. Though the body requires a certain amount of sun exposure to produce certain vitamins (such as vitamin D) and help eliminate chemical wastes from the body, ultraviolet light is a potential hazard for the cells. Melanin production, which results in darkening the skin, is the body's primary method for protecting itself. The lighter a person's natural skin color, however, the less effective this method. Many health conditions that affect the skin, most notably SKIN CANCER, result from overexposure to the sun and in particular to ultraviolet B (UVB) light.

Protective Clothing

Clothing that covers or shades the skin surfaces is the most effective protection from sun exposure and can block more than 90 percent of the sun's ultraviolet light, though it is still possible to acquire a sunburn through clothing. Fabric with a tight weave is more effective than fabric with a loose weave. Many items currently manufactured specifically for outdoor activities now use yarns and weaving techniques that substantially block ultraviolet light. Manufacturers use ultraviolet-protection factor (UPF) ratings to designate the extent of the fabric's ability to prevent ultraviolet light penetration. The higher the UPF rating, the more effective the protection. Solid-weave, broad-brimmed hats help protect the scalp and shelter the ears, NOSE, and back of the neck. Technical gear for many outdoor sports, such as bicycling and kayaking, includes gloves that protect the hands from friction and pressure as well as sun exposure. Sunglasses that block UVA and UVB light are necessary to shelter the eyes.

A sunscreen product's SPF rating applies only to UVB blocking, so it is important to read the product label to determine what protection the product can provide.

Sunscreen

Sunscreens that chemically block ultraviolet light from penetrating the skin's surface became available in the 1980s. These chemicals work by absorbing the light so it does not reach the cells. Most sunscreens block UVB; some also block UVA. A sunscreen's sun-protection factor (SPF) rating, provides a general idea of how long the product can provide protection based on a time-related formula. In general, a fair-skinned person will get a sunburn after about 10 minutes of unprotected exposure to the sun. A sunscreen's SPF rating is a multiplier of that marker. A sunscreen with an SPF rating of 15, for example, theoretically permits 15 times as long in the sun before burning, or 150 minutes. A sunscreen with an SPF of 30 would allow 300 minutes. These are general guidelines, however, and dermatologists recommend applying more sunscreen about every two

hours during exposure (as well as SPF lip balms to protect the lips). Dermatologists recommend sunscreens that block both UVA and UVB lightwaves.

Because both sunscreen use and skin cancer are on the rise, some researchers have questioned whether sunscreens cause, rather than prevent, skin cancer. Though there are few clinical studies of such a correlation, so far there is no evidence to support this concern. Nor is there evidence to support claims that sunscreens promote estrogenic activity in the body, another concern that some people have raised. Health experts agree that proper application of sunscreen is the most effective defense to protect the skin from damage.

Time of Exposure

The sun's ultraviolet light is most intense from 10 a.m. to 2 p.m. in the United States. Health experts recommend staying out of the sun as much as possible during that period of time, especially during summer months. When this is not practical, dermatologists recommend combining protective clothing and sunscreen for maximum protection.

sweat glands Structures within the dermis layer of the SKIN that produce sweat as part of the body's temperature-regulation mechanisms. There are two kinds of sweat glands—eccrine and apocrine, both of which arise from the dermis.

Eccrine sweat glands are functional from shortly after birth and are present in all skin. An individual has between two and three million eccrine sweat glands that produce about 20 liters of sweat in 24 hours and can double or triple their production rate during strenuous exercise or heat conditions. Eccrine sweat glands open through pores directly onto the surface of the skin (pores), releasing sweat for rapid evaporation to cool the skin and lower body temperature.

Apocrine sweat glands are present only under the arms and in the pubic region, though are abundant in these regions. Although present from birth, they are nonfunctional until PUBERTY activates them. The apocrine sweat glands empty into HAIR follicles rather than directly onto the skin's surface. The sweat the apocrine glands produce contains lipids and proteins, which helps the sweat mix with the sebaceous fluids in the hair follicles to reach the skin's surface. BACTERIA on the surface of the skin consume the lipids and proteins, creating waste byproducts that produce the characteristic odor associated with sweating.

For further discussion of the sweat glands within the context of integumentary structure and function please see the overview section "The Integumentary System."

tattoos A form of body art in which decorative inks injected into the dermis permanently stain the SKIN. Though the needles are solid, they create puncture wounds that then fill with ink. The cells and intracellular spaces of the dermis absorb the ink. The health implications of tattoos are twofold: potential complications at the time of tattooing and the challenges of tattoo removal.

Commercial tattoo artists use mechanical needles that rapidly inject inks. The needles and the ink packets are sterile and for one-time use. Though inks are generally of natural origins, some people have adverse reactions to them that can cause swelling, INFLAMMATION, and scarring. Though many tattoo artists follow appropriate antiseptic procedures, many others do not. Most US states do not have regulations or procedures to establish health standards or confirm their practice.

The most common risk arising from improper skin and equipment cleansing is bacterial INFECTION of the tattooed site, which may require treatment with ANTIBIOTIC MEDICATIONS. A less common though far more serious infection risk is that of HEPATITIS and HIV/AIDS, both of which are bloodborne viral infections. Reusing needles and inks passes any VIRUS present to subsequent clients. Improperly cleaning the tattooing equipment also allows viruses to linger, with the potential of passing them on.

Tattoo removal is far less certain than tattooing. Most methods cause significant scarring. A form of laser therapy called Q-switched laser offers the least destructive means for removing tattoos. Lasers can destroy the structure of some inks without damaging the surrounding cells. The body's normal processes then remove the ink fragments as cellular debris. However, this process is most effective with black and blue inks, and least effective with yellow, red, and orange. Different wavelengths of laser are necessary for the various colors, so tattoo removal may involve several sessions. Seldom can the laser remove all color, though it often can remove enough color for the tattoo to appear only as a slight discoloration of the skin. It is possible for the pigment to darken in the skin surface surrounding the tattoo, in response to the laser. Scarring and infection also remain slight risks. Other methods of tattoo removal, such as DERMABRASION and excision, may more successfully remove the full tattoo though leave considerable scarring. With these methods, skin grafts are sometimes necessary.

telangiectasis A weblike network of BLOOD vessels that becomes visible just below the surface of the SKIN, commonly called spider veins. Sometimes telangiectasis is present from birth or early childhood as a BIRTHMARK, though more commonly develops later in life as a manifestation of chronic sun exposure. Telangiectasis generally has no adverse health effects, though many people find the lesions cosmetically unacceptable. For telangiectasis on the face, dermatologists use laser therapy or fine cautery. For spider veins on the legs, the most common treatment is sclerotherapy in which the dermatologist injects the telangiectasis with a chemical that irritates the blood vessels, causing them to SCAR. Over time the discoloration fades. Laser therapy may be a therapeutic option for some telangiectasis lesions.

tinea A common fungal INFECTION of the SKIN, involving the layers (including the hair and nails) that are cornified (composed of dead keratinocytes). Several species of fungi, known collectively as dermatophytes, cause tinea infection (also called dermatophytosis). People commonly refer to some forms of tinea as ringworm because the lesions have the appearance of worms ringed beneath the surface of the skin. Though descriptive this is a misnomer as tinea has nothing to do with worms. There are numerous designations of tinea based on where it appears on the body, though the same group of dermatophytes can cause any of tinea's presentations.

Tinea Infection	Common Name	Body Region Affected
tinea barbae	ringworm	beard area of the face
tinea capitis	ringworm	scalp
tinea cruris	jock itch	genitals
tinea corporis	ringworm	central trunk, arms, and legs
tinea pedis	athlete's foot	bottom of the foot and between the toes

Tinea is fairly contagious and spreads from person to person as well as through contact with surfaces, such as shower floors or soil, that can harbor the fungi. Dermatophytes can exist outside the body for a considerable length of time and thrive in environments that are warm and moist.

Symptoms and Diagnostic Path

The symptoms of tinea vary somewhat according to the part of the body affected, though generally include

- itching (PRURITUS), which may be intense, or PAIN
- redness (erythema)
- lesions that may appear as papules, vesicles, or plaques
- cracking or scaling of the lesions
- irregular HAIR loss (ALOPECIA) when the site of the infection is the scalp

The diagnostic path is generally straightforward. The doctor may take small scrapings of affected tissue to examine under a microscope. Such examination reveals the dermatophytes or evidence of their presence, which is conclusive for diagnosis. Inability to identify evidence of dermatophytes points to other causes for the symptoms.

Treatment Options and Outlook

Topical ANTIFUNGAL MEDICATIONS often effectively treat all forms of tinea except those involving the hair or NAILS. Prescription antifungal medications produce the most reliable results; over-the-counter products may require multiple applications. Because many people who acquire tinea continue the activities that resulted in exposure, reinfection is common. Pervasive or resistant tinea may require oral antifungal medications to attack the infection systemically. Oral antifungal therapy is necessary to eradicate tinea that involves the hair or the nails. Treatment may require up to eight weeks for some infections, particularly those involving the nails and the feet (tinea pedis).

COMMON ANTIFUNGAL MEDICATIONS FOR TREATING TINEA

econazole (topical)	fluconazole (oral)
griseofulvin (oral)	itraconazole (oral)
ketoconazole (topical and oral)	miconazole (topical)
naftifine (topical)	oxiconazole (topical)
sertaconazole (topical)	terbinafine (topical and oral)

Risk Factors and Preventive Measures

Common environmental settings in which dermatophytes thrive include communal showers, spas, and swimming pools. Wearing water socks or sandals when walking on wet surfaces helps protect the feet from contact with the fungi. Tinea can be an opportunistic infection in people who are IMMUNOCOMPROMISED, such as those taking IMMUNOSUPPRESSIVE THERAPY following ORGAN TRANSPLANTATION or who have HIV/AIDS.

tinea versicolor A fungal INFECTION of the SKIN that causes areas of altered pigmentation, usually darkened patches. Unlike other forms of TINEA,

tinea versicolor is not contagious. The FUNGUS responsible, *Malassezia furfur*, is normally present on the skin (NORMAL FLORA). Dermatologists do not know why the fungus causes infection in some people and not in others, though they suspect the infection is opportunistic in being able to gain a foothold when other challenges are occupying the IMMUNE SYSTEM. Treatment is typically a combination of topical and oral ANTIFUNGAL MEDICATIONS. As *M. furfur* is normal flora, tinea versicolor tends to recur in people who are susceptible to it. When recurrences are frequent, the dermatologist may prescribe prophylactic antifungal therapy.

tissue expansion A method for growing additional SKIN to use for autologous (self) skin grafts. Autologous grafts have the best rate of success when transplanted because they are native to the body and present no risk for graft rejection. Tissue expansion is a common method for many reconstructive surgery procedures, though requires adequate areas of healthy skin.

For tissue expansion, the surgeon makes a small incision to create a pouch or pocket in healthy skin and inserts a balloonlike pouch called a tissue expander. The surgeon then adds a small amount of saline, through a special valve, every few days or so over a period of several months. The expander encourages the skin to grow to cover it, slightly accelerating the rate of growth over that which would normally occur. When the new growth of skin reaches the desired surface area, the surgeon removes the expander and can harvest the skin to transplant elsewhere on the body. Tissue expansion grafts are highly successful for repairing skin surfaces damaged or lost to severe BURNS or injuries. Some HAIR TRANSPLANTATION methods also use tissue expansion to grow additional skin that contains healthy hair follicles.

As with any surgery, the primary risks associated with tissue expansion are INFECTION and excessive bleeding. The tissue expander generally creates a conspicuous bulge in the surface of the skin, though the skin profile at the growth site returns to normal when the surgeon removes the expander. The surgeon uses appropriate techniques to minimize scarring at the harvesting site as well as during placement of the new skin.

toxic epidermal necrolysis A life-threatening inflammatory condition affecting the SKIN and underlying connective tissues, also called Stevens-Johnson syndrome. Toxic epidermal necrolysis usually results as an adverse DRUG reaction though may occur as a complication of INFECTION or CANCER. Doctors believe toxic epidermal necrolysis develops when an external event triggers the mechanism for programmed cell death (apoptosis), causing massive numbers of keratinocytes (the cells that primarily comprise the skin) to die. This in turn activates the body's IMMUNE RESPONSE, which attacks the dying cells. The massive death of keratinocytes results in large segments of skin sloughing off, leaving the underlying tissue exposed. Toxic epidermal necrolysis typically evolves over a period of 10 to 14 days, though once the skin eruptions begin deterioration is rapid.

Diagnosis is by skin biopsy, which shows the characteristic pattern of cell destruction and abundance of killer T-cells. In most situations the first line of treatment is plasmapheresis, a process somewhat similar to dialysis in which a mechanical BLOOD separator removes the serum and replaces it with donor serum. Plasmapheresis helps clear antibodies from the serum, reducing the immune response. Other treatments include frequent surgical débridement of skin surfaces, skin grafts to cover denuded surfaces, and precise fluid and electrolyte replacement.

Toxic epidermal necrolysis has a survival rate of about 60 percent. Those who survive often have long-term complications and face a challenging road to rehabilitation and recovery. The massive loss of skin causes extensive scarring similar to that of serious BURNS. The eyes also experience damage as the sloughing affects the conjunctiva and sclera (EYE tissues).

urticaria The clinical term for hives, an outbreak of wheals on the SKIN's surface. Acute urticaria, which comes on suddenly, typically signals a HYPERSENSITIVITY REACTION. The wheals contain fluid

the IMMUNE RESPONSE draws from the cells of the skin. They itch, often intensely (PRURITUS), and may appear and recede in various locations on the body (migration).

BREATHING difficulties with urticaria may indicate ANAPHYLAXIS, a life-threatening hypersensitivity reaction causing swelling of the airways that requires emergency medical care.

When urticaria manifests, the first focus is on subduing the response to relieve the symptoms and prevent complications. The doctor may administer an EPINEPHRINE injection to thwart a hypersensitivity response that appears to be intensifying or if the urticaria progresses. Most urticaria responds fairly quickly to ANTIHISTAMINE MEDICATIONS such as diphenhydramine (Benadryl) or hydroxyzine (Vistaril), which the doctor can administer by injection for severe urticaria. The wheals generally retreat within 6 to 8 hours and are entirely gone in about 36 hours with antihistamine therapy. Most people recover fully and can avoid future episodes by avoiding exposure to the substance that caused the reaction.

Potential complications associated with urticaria are uncommon though can be life-threatening. ANGIOEDEMA occurs when fluid accumulates in tissues other than the skin; most doctors consider it a progressive form of urticaria. Angioedema can affect internal structures, causing pressure and swelling that affects the ability of vital organs to function. When angioedema affects the airways it can cause BREATHING difficulties and ANAPHYLAXIS, the most serious hypersensitivity reaction. These complications occur only with repeat exposure to the substance causing the reaction.

Urticaria represents an IMMUNE RESPONSE in which the immune system releases IMMUNOGLOBULIN E (IgE), which causes mast cells to release HISTAMINE. The histamine draws fluid into the tissues. Numerous drugs, foods, environmental factors such as pollen and animal dander, and health conditions may cause urticaria. It is important to attempt to identify the causative factor to prevent recurrences. Hypersensitivity responses, which people also call allergic reactions, tend to intensify with repeated exposure to the substance.

A similar release of IgE occurs with chronic urticaria, as an immune-mediated response related to serious illnesses that challenge the immune system such as cancer. AUTOIMMUNE DISORDERS that affect the connective tissue, such as SYSTEMIC LUPUS ERYTHEMATOSUS (SLE), AMYLOIDOSIS, and RHEUMATOID ARTHRITIS, can also cause chronic urticaria, as can exposure to extreme heat or cold. As with acute urticaria, treatment for chronic urticaria first targets symptom relief.

vesicle A small, blisterlike LESION on the SKIN that contains serous fluid. Vesicles typically occur in clusters and indicate INFECTION, such as with HERPES SIMPLEX VIRUS (HSV), or irritation, such as results from contact with poison ivy. Skin vesicles often hurt or itch. Treatment may include topical medications to relieve discomfort, with oral ANALGESIC MEDICATIONS (PAIN relievers) or ANTIHISTAMINE MEDICATIONS (to relieve itching) as necessary. Vesicles begin to recede and heal when the underlying circumstance causing them begins to resolve. Vesicles usually do not rupture or tear. During HEALING the body reabsorbs the serous fluid they contain, giving the appearance that the vesicles wither away until all that remains is a thin crust that eventually falls off.

In other contexts within the human body, a vesicle is a small saclike or pocketlike structure in an organ, such as the seminal vesicles in the male reproductive system.

vitiligo A condition of hypopigmentation in which melanocytes die in patches of SKIN, leaving macules that are pale and depigmented. Dermatologists believe vitiligo is an autoimmune disorder in which the IMMUNE SYSTEM produces antibodies that attack melanocytes, the skin cells responsible for producing pigment. Vitiligo affects people of all races and ethic backgrounds, though is more conspicuous in people who have darker skin.

There appears to be no pattern to the presentation of vitiligo, which may affect small areas or nearly the entire skin surface. The depigmented areas have no other symptoms—that is, they do not cause itching or PAIN. Vitiligo occurs more frequently in people who have other AUTOIMMUNE DISORDERS such as ALOPECIA AREATA. Vitiligo is also associated with ADDISON'S DISEASE (a disorder of the ADRENAL GLANDS), HYPERTHYROIDISM, DIABETES, and pernicious ANEMIA.

Symptoms and Diagnostic Path

In most people who develop vitiligo, the areas of depigmentation generally appear slowly and start with small patches of skin. Some people do not develop more than a few such patches, while other people eventually develop large and numerous patches of depigmentation. In most people, the depigmentation is roughly symmetrical on both sides of the body, though in some people it affects only one side. The appearance of the depigmented areas is generally diagnostic as this is a unique symptom of vitiligo. The most common sites for depigmentation are the face, hands, arms, legs, and genitals.

Often there was a precipitating factor, such as a severe SUNBURN or other trauma to the skin, within several months of the start of symptoms. Serious physical injury or illness may also precipitate symptoms. The dermatologist may biopsy a representative LESION to rule out other causes. Sometimes blood tests will show the presence of antibodies, which strongly supports the diagnosis of an autoimmune disorder.

Treatment Options and Outlook

The cosmetic aspects of vitiligo are often the most disturbing feature of vitiligo for people who have the disorder, and most treatments target cosmetic improvement. Most aim to slow the progression of the depigmentation or to darken the appearance of depigmented areas and include topical CORTICOSTEROID MEDICATIONS, micropigmentation (therapeutic tattooing), and psoralen plus ultraviolet A (PUVA) PHOTOTHERAPY. Skin grafts are sometimes

an option for small areas of depigmentation, though are expensive and entail numerous risks. Cosmetics to cover depigmented areas work well for some people.

Another therapeutic approach is to create hypopigmentation consistently, lightening all of the skin using topical bleaching agents such as monobenzone to make the depigmented areas less conspicuous. Such lightening is permanent, and establishes heightened sensitivity to sun exposure with the risk for severe sunburn. The functional disturbances to the skin also have significant implications for health, as the depigmented areas cannot protect from sun damage. Protective, full-cover clothing and high sun-protection factor (SPF) sunscreens are necessary to provide this protection.

In most people, vitiligo progresses despite treatment. One of the most challenging dimensions to vitiligo, as with other dermatologic conditions that have similarly conspicuous symptoms, is the sense of social isolation and embarrassment many people who have the condition feel. Vitiligo is especially difficult for adolescents and young adults to manage. Support groups are often helpful for coping.

Risk Factors and Preventive Measures

Because dermatologists do not know what causes vitiligo to start, there are few known preventive measures. It does appear that significant trauma to the skin, such as a sunburn that blisters and peels, can trigger vitiligo. Most dermatologists believe GENE MUTATION is the underlying cause, as is the case with many autoimmune disorders, though researchers have yet to verify this. Limiting sun exposure by wearing protective clothing and sunscreen may slow the progression of vitiligo.

wart A growth, typically rough and raised, that appears on the SKIN. The HUMAN PAPILLOMAVIRUS (HPV), which has numerous strains, causes common warts as well as variations including genital warts (a common sexually transmitted disease) and plantar warts which appear on the soles (plantar surfaces) of the feet. Because common warts are viral, physical contact can spread them to other locations on the affected person's body. However, common warts rarely spread to other people.

Symptoms and Diagnostic Path

Most common warts begin with a small, rough, raised bumps that can be the same color as the surrounding skin or discolored (typically pale). As they grow they take on the characteristic appearance of warts. Small dark dots sometimes appear inside the wart, which are clotted blood vessels though people commonly call them wart seeds. The "seed" of the wart is the HPV, and it is not visible. Warts seldom hurt or itch, though may do either as well as bleed when they are in locations that expose them to frequent irritation.

Treatment Options and Outlook

From a medical perspective, warts are harmless and do not require treatment. Because common warts continue to spread, however, it is prudent to remove them when they are small and few. Though the health consequence of warts is primarily cosmetic, warts that cluster in areas such as around the fingertips can create functional interference. Common therapies the dermatologist may use for removing warts include

- cryotherapy, such as treatment with liquid nitrogen, which freezes the wart
- electrodesiccation, which cauterizes or burns off the wart
- cantharidin, a topical chemical solution that forms a BLISTER which raises the wart from the skin
- topical salicylic acid, which chemically destroys the wart

Surgical remedies such as excision or laser therapy are effective and may be necessary for warts that resist other efforts, though they have substantially greater risks, including INFECTION and scarring. Oddly enough, an application of duct tape over the wart appears as successful as any other therapy for causing common warts to resolve. Most over-the-counter products for wart removal require multiple applications though are ultimately successful for those who are patient. Because they are viral, common warts tend to recur for as long as the HPV remains in the body, and HPV is extraordinarily difficult to eradicate.

Risk Factors and Preventive Measures

The risk factor for common warts is exposure to HPV, which is pervasive. Preventive measures include frequent and regular HAND WASHING and refraining from picking at or scratching existing warts. Prompt treatment to remove warts while they are small and restricted to a fairly contained area helps to limit their spread.

wheal A raised, blisterlike LESION on the SKIN that usually results from an intradermal injection such as for allergy skin testing or the tuberculin skin test. Wheals also may occur in response to insect stings and topical allergic reactions (URTICARIA or

hives). Wheals associated with urticaria typically itch, sometimes intensely. Wheals usually do not rupture or tear, and gradually fade to smooth, red areas (macules) before disappearing entirely as the body absorbs the fluid they contain.

whitlow An INFECTION at the end of the finger, or less commonly the end of a toe, that contains pus and is very painful. The area is inflamed, enlarged, erythematous (reddened), and often oozing. A common cause of whitlow is infection with the HERPES SIMPLEX VIRUS (HSV), conveyed to the finger via contact with infectious secretions from oral herpes infections or genital herpes lesions. Some doctors use the terms *whitlow* and *paronychia* interchangeably, whereas others use whitlow to refer to HSV infection and paronychia to refer to bacterial infection. It is important to distinguish between the causes of the infection as the treatment approach is different. Herpetic whitlow features the vesicles characteristic of HSV infection, and treatment is primarily to relieve symptoms. Bacterial whitlow lacks vesicles and treatment requires ANTIBIOTIC MEDICATIONS.

wrinkles Furrows or channels in the SKIN, typically resulting from repeated movements, such as facial expressions (for example, crow's feet and laugh lines), or from long-term exposure to sun and wind. Aging is the single-most significant factor that causes wrinkles. Wrinkles increase with age as the skin loses collagen and subsequently resiliency. As well, the skin and the cutaneous tissue layer that supports it both thin, providing less support.

People who have light-colored skin tend to have more wrinkles than people who have darker skin. Smoking ages the skin considerably, increasing the depth and number of wrinkles. Extensive wrinkles may signal substantial sun damage that is an alert for SKIN CANCER. Rapid or major weight loss also causes wrinkles, as the skin that stretched to accommodate the extra weight suddenly has no underlying support so it sags, bags, and wrinkles. Prematurely wrinkled skin has less ability to protect itself from the sun because its layers are thinner and contain fewer cells, which means less melanin to shield the skin from ultraviolet radiation.

For many people, wrinkles are cosmetically undesirable. Dermatologists offer a number of solutions to reduce the appearance of wrinkles. These include

- For a CHEMICAL PEEL, the dermatologist applies a caustic solution to the skin, causing the epidermis, and in a deep chemical peel the dermis, to slough away. The new skin that forms beneath is tighter, pulling the surface of the skin smooth.
- For DERMABRASION, the dermatologist mechanically removes the top layers of skin (with local Anesthesia), using a device similar to a small grinder or sander to strip away the epidermis.
- For LASER SKIN RESURFACING, the dermatologist uses a heat laser to "burn" away the top layers of the skin. This technique allows the dermatologist to precisely control the depth and extent of skin removal as well as to target some areas for deeper penetration and others for lighter penetration.
- For BOTULINUM THERAPY, the dermatologist injects purified botulinum toxin into the muscles beneath the skin. This paralyzes them and keeps them from contracting. The paralysis keeps the person from forming wrinkles. Botulinum therapy lasts three to four months on average, depending on the location and the person's natural skin-aging tendencies.
- For BLEPHAROPLASTY and RHYTIDOPLASTY, a surgeon performs cosmetic surgery operations to remove wrinkles and tighten the skin around the eyes (blepharoplasty) and the overall face (rhytidoplasty).

Though it is not possible to totally prevent wrinkles because they develop as a function of aging, it is possible to reduce their numbers and effects. Preventive measures include

- drink plenty of water to keep the skin well hydrated
- use topical moisturizers and emollients to hold moisture in the skin

- limit sun exposure, and wear protective clothing and sunscreen when outdoors
- stop smoking and avoid exposure to environmental cigarette smoke
- eat nutritiously, especially fruits and vegetables that supply B vitamins and vitamin C, antioxidants that may help prevent skin damage due to sun exposure

Numerous over-the-counter products and preparations purport to "cure" wrinkles. At best this is false advertising, as wrinkles are as inevitable as aging. However, products that add moisture and vitamins to the skin may be nonetheless beneficial for the skin.

xanthoma A fatty deposit that forms a benign (noncancerous) LESION beneath the SKIN, though also may occur in other tissues. Xanthomas develop in people who have chronic, untreated HYPERLIPIDEMIA (elevated BLOOD cholesterol and triglycerides levels). In their most common form, xanthomas appear as yellowish blebs beneath the skin, typically rounded or oblong, that protrude as nodules or papules. Xanthomas that form on the eyelids, a common presentation, are xanthelasmas. Most xanthomas do not cause symptoms though may be cosmetically undesirable. Eruptive xanthomas may occur in clusters, typically occurring on the shoulders and inner surfaces of the arms, and often itch.

The most significant feature of xanthoma is the underlying lipid disorder, which signals increased risk for CORONARY ARTERY DISEASE (CAD) and HEART ATTACK. Many people who develop xanthomas have familial lipid disorders that result in unusually elevated levels of triglycerides and very low density lipoprotein cholesterol (VLDL-C) or low density lipoprotein cholesterol (LDL-C). These elevations are markers for serious CARDIOVASCULAR DISEASE (CVD) and require prompt medical treatment. Lowering the blood lipid levels helps prevent further xanthomas from developing, though has no effect on existing xanthomas.

A xanthoma may create functional interference depending on its location. Xanthelasmas on or near the eyelids can interfere with proper vision, for example, and xanthomas on the hands may cause irritation and PAIN during tasks that require manual dexterity. Many people choose to have xanthomas removed for cosmetic purposes. Several options are available for removing xanthomas, including cryotherapy (freezing), electrodesiccation (cauterizing), excision (cutting out), and LASER SURGERY. The site usually heals without scarring, although xanthomas tend to recur.

THE NERVOUS SYSTEM

The NERVOUS SYSTEM directs the functions, voluntary and involuntary, of the body through an intricate network of specialized cells (neurons) that convey information in the form of electrochemical messages. Practitioners who diagnose and treat conditions of the nervous system are neurologists, neurosurgeons, and neuropsychiatrists. This section, "The Nervous System," presents a discussion of the structure of the BRAIN and nerves, an overview of neurologic functions in health and the disorders that occur as a result of physiologic (organic) dysfunction of the brain and nerves, and entries about the health conditions that can affect neurologic function.

Conditions involving the nervous system often directly involve other body systems as well. Entries for neuromuscular disorders and neuropsychiatric disorders in which the origins or symptoms are primarily neurologic appear in this section, "The Nervous System." Entries for neuromuscular disorders in which the origins or symptoms are primarily muscular appear in the section "The Musculoskeletal System." The section "Psychiatric Conditions and Psychological Issues" contains entries about disturbances of mood, emotion, personality, and mental health and illness.

Functions of the Nervous System

The nervous system regulates and directs the functions of the body, processing billions of biochemical messages—bits of information traveling between the brain and the body—every minute. It is the earliest system to develop in the EMBRYO. The cells that will become the nervous system begin to separate and distinguish themselves about 14 days after CONCEPTION. During the following 7 days, the neural tube, the rudiment of the central nervous system, takes shape. By seven weeks of gestation, the neural tube has evolved into the SPINAL CORD and the brain. And by birth, the nervous system is anatomically complete.

tional divisions, the nervous system operates so efficiently that most of the time its myriad activities take place virtually unnoticed. The nervous system contains two major divisions: the CENTRAL NERVOUS SYSTEM and the PERIPHERAL NERVOUS SYSTEM.

The brain and spinal cord make up the central nervous system. The brain's main divisions are the cerebral cortex (cerebrum), cerebellum, and brainstem. The cerebral cortex is the largest and most complex part of the brain, accounting for 85 percent of the brain's mass and conducting all functions of consciousness and voluntary action. The cerebral cortex filters, sorts, and manages information about the body's experiences in its external environment. It is the center of thought, reason, intellect, emotion, judgment, personality, mood, behavior, and movement. The cerebral cortex also integrates many of the functions of other divisions of the nervous system and initiates voluntary movement.

CEREBRAL DOMINANCE

One or the other cerebral hemisphere is contralaterally dominant in nearly everyone. The most prominent feature of cerebral dominance is handedness. In about 85 percent of people, the left hemisphere of the cerebral cortex is dominant: they are right-handed (and usually right-footed and right-eyed). About 10 percent of people are right-hemisphere dominant: they are left-handed (and usually left-footed and left-eyed). About 5 percent of people appear to use either side of the body with equal ease: they are ambidextrous.

Structurally the cerebral cortex consists of two matched halves: the right hemisphere and the left hemisphere. A band of NERVE fibers, the corpus callosum, connects the two hemispheres at the bottom of the deep fissure that separates them. The functions of the hemispheres are contralateral to the body—that is, the right hemisphere controls the left side of the body and the left hemisphere controls the right side of the body. Matching pairs of lobes—frontal, temporal, parietal, and occipital—form the structure of each hemisphere, with each lobe specializing in certain functions. Though each pair of lobes handles similar operations, the right and left lobes conduct different aspects of those operations. Right hemisphere lobe operations tend to be spatial and conceptual, whereas left hemisphere lobe operations tend to be linear and logical. Regions of the frontal lobes work together to collect, assimilate, and integrate the results.

The cerebellum, a small structure at the back of the brain, coordinates motor function (movement). It receives a constant flow information from the cerebral cortex, the basal ganglia (a collection of nerve fibers on the basal, or bottom, surface of the cerebral cortex, where the planning and initiation of motor function takes place), the brainstem, and the body about the body's relationship to its external environment and sends in return a constant flow of instructions to seamlessly carry out tasks ranging from threading a needle to running a marathon. Like the cerebral cortex, the cerebellum has two hemispheres but operates ipsilaterally. The cerebellum manages balance, coordination, speed, direction, and the smoothness of movements.

The brainstem, an elongated, bulbous structure between the cerebral cortex and the spinal cord, maintains the functions of survival and connects the brain with the spinal cord. The primary structures of the brainstem are the pons, and midbrain, medulla oblongata. The pons functions as a bridge connecting the cerebellum, the cerebral cortex, and the spinal cord. The medulla oblongata is the segue from the brain to the spinal cord. It is responsible for the beating of the HEART, BREATHING, BLOOD PRESSURE, BLOOD flow, and many reflexes (automatic, survival-oriented reactions to environmental stimuli). The 2nd through the 12th pairs of CRANIAL NERVES originate in the brainstem. Injuries to the brainstem can be debilitating or fatal.

BILLIONS AND BILLIONS OF BRAIN CELLS

At the completion of its structural development just before birth, the BRAIN contains more than 100 billion neurons (NERVE cells) and about 50 times as many glial cells (cells that support the neurons). The longest neuronal axons, the threadlike fibers that carry nerve impulses away from the NEURON, reach from the brain to the base of the SPINAL CORD and extend nearly five feet in an adult.

The spinal cord, the body's largest nerve, is the thoroughfare of communication between the brain and the body. It extends from the second cervical vertebra to the second lumbar vertebra, a distance of about 20 inches in an adult. The bones of the spinal column, the vertebrae, enclose and protect the spinal cord. The spinal cord controls the reflexes of URINATION and defecation as well as of MUSCLE stretch (the automatic responses of muscle cells that allow movement).

All nervous system structures and functions outside the central nervous system belong to the peripheral nervous system: the cranial nerves, the spinal nerves, and their numerous branches. The 12 paired cranial nerves arise from the base of the brain and the brainstem. They convey sensory and motor signals to and from the structures of the head and face, one of each pair going to each side. The 31 paired spinal nerves branch from the spinal cord at each vertebra, carrying sensory and motor signals to and from the rest of the body.

Within the peripheral nervous system are two main subdivisions: the somatic nervous system, which handles voluntary functions such as movement, and the autonomic nervous system, which handles involuntary functions such as digestion. The autonomic nervous system has two further subdivisions. The sympathetic nervous system is made up of the nerves that serve the structures of the main trunk (thoracic and lumbar regions). The parasympathetic nervous system is made up of the nerves that serve the neck and head and the sacral region of the trunk.

DIVISIONS OF THE NERVOUS SYSTEM

CENTRAL NERVOUS SYSTEM: BRAIN and SPINAL CORD

PERIPHERAL NERVOUS SYSTEM: cranial nerves, SPINAL NERVES, and their branches

- somatic NERVOUS SYSTEM: voluntary functions
- autonomic nervous system: involuntary functions
  - † sympathetic nervous system: main trunk
  - † parasympathetic nervous system: head and sacral region

Nervous system communication: neurons, ions, and neurotransmitters The basic structure of function in the nervous system is the neuron, a specialized cell capable of sending and receiving electrochemical impulses that initiate or inhibit actions. What makes the neuron special are the filaments that extend from its cell body. A single such filament, the axon, extends from the cell body to carry nerve impulses from the neuron. From one to numerous other filamental processes, the dendrites, branch from other sites on the cell membrane to capture nerve impulses coming to the neuron. Like electrical wires, neurons would "short" if they came into contact with each other. Microscopic channels—synapses—help neurons keep safe distance from each other. Axons and dendrites reach toward, but do not touch, each other in the synapses.

WHITE MATTER AND GRAY MATTER

A fatty substance, myelin, coats most axons to insulate and protect them. The myelin gives the axons a whitish color. NERVE tissue in the BRAIN and SPINAL CORD, which is primarily a collection of axons, is white matter. The cell bodies of neurons are dark and grayish in color. Nerve tissue in the brain and spinal cord that is primarily a collection of NEURON cell bodies is gray matter.

Electrically charged chemical molecules—ions—are within and surround a neuron. Among the significant ions, sodium, potassium, and calcium are positive ions and chloride is a negative ion. Microscopic channels in the neuron's cell membrane, called ion channels, selectively allow ions to enter and leave the neuron. Each ion channel is specific for an ion—that is, calcium ion channels allow passage only of calcium ions and sodium ion channels allow passage only of sodium ions. When a neuron is at rest, the total charge of the ions within its membrane is negative relative to the ions outside its membrane. As well, there are more potassium ions within the cell body and more sodium ions outside the cell.

When a stimulus triggers an electrical impulse, the first stage of neuronal communication, the impulse causes sodium ion channels to open. Sodium ions rush into the neuron cell body, changing the neuron's polarity to become positive relative to the surrounding environment. The electrical impulse rides the wave of polarity down the axon of the sending neuron. About the time the impulse reaches the presynaptic terminals at the end of the axon, potassium ion channels open and potassium enters the cell body. In exchange,

because only so many ions can be inside the cell body, sodium ions leave. To restore itself to negative polarity the cell body activates a burst of energy to "pump" more sodium ions out, at an exchange rate of three sodium ions out for every two potassium ions in.

Meanwhile, back at the synaptic terminals another conversion is taking place. The synaptic terminals contain tiny storage pockets called vesicles that hold NEUROTRANSMITTER molecules. The electrical impulse causes the synaptic vesicle to release a neurotransmitter molecule. The neurotransmitter molecule crosses the synapse and binds with a NEURORECEPTOR on a dendrite of the receiving neuron. The binding either causes or blocks an action.

The longer the neurotransmitter molecules remain in the synapse the more neuroreceptors they can bind. As a safety mechanism, the neurotransmitter's presence in the synapse stimulates the synaptic vesicles to reuptake (recycle) the remaining neurotransmitter, containing the potential for binding. Further stimuli are then necessary to continue. The neuron sending a message is the presynaptic neuron; the neuron receiving a message is the postsynaptic neuron. Some neurologic conditions affect the functioning of presynaptic neurons and others affect the functioning of postsynaptic neurons.

NEURONAL PATHWAYS: THE BRAIN'S ENDLESS CAPACITY TO LEARN

The adult BRAIN contains 60 to 200 trillion synapses. Synapses represent the networks of axons that neurons develop to form neuronal pathways, the routes by which neurons communicate with one another in expedited fashion. Even though all the neurons the brain will ever have are present at birth, the brain has an endless capacity to create new neuronal pathways and thus "grow" its ability to learn.

Many medications work by inhibiting (blocking) or expediting the reuptake process to extend or shorten, respectively, the time the neurotransmitter is active. Selective serotonin reuptake inhibitors (SSRIs), for example, are ANTIDEPRESSANT MEDICATIONS that work by blocking serotonin reuptake. Serotonin is a neurotransmitter that facilitates neuron communication in areas of the brain related to mood. The acetylcholinesterase inhibitors, medications to treat ALZHEIMER'S DISEASE, work by blocking the enzyme that breaks down the neurotransmitter acetylcholine. This action extends the presence of acetylcholine in the synapses, increasing neuroreceptor binding. Acetylcholine facilitates neuron communication in areas of the brain that process cognitive functions and memory. Medications may also masquerade as neurotransmitters to bind with neuroreceptors. Therapies for PARKINSON'S DISEASE, a degenerative condition that results from depletion of the neurotransmitter DOPAMINE in the brain, are among the most effective applications of this approach.

Health and Disorders of the Nervous System

The most significant health risks the nervous system faces occur before birth. The most vulnerable period in nervous system development takes place before most women have missed a menstrual period or suspect they are pregnant. Within the first three weeks after conception, the rudimentary nervous system, the neural tube, forms and rapidly differentiates into the brain and spinal cord. Numerous factors, environmental and genetic, can disrupt this process to cause cephalic disorders (structural defects of the brain) or SPINA BIFIDA (structural defects of the spinal cord). CEREBRAL PALSY is the most common developmental disturbance of the nervous system.

FOLIC ACID AND NEURAL DEVELOPMENT

Folic acid is crucial for proper development of the NERVOUS SYSTEM early in PREGNANCY, especially at the time of CONCEPTION through the first trimester. Numerous studies show that taking folic acid supplements before and during pregnancy can prevent 70 percent of NEURAL TUBE DEFECTS. Health experts recommend that all women of childbearing age take 400 micrograms of folic acid supplement daily regardless of whether they are trying actively to become pregnant.

From birth through midlife, injury becomes the most worrisome threat to the nervous system. Young people are especially vulnerable to TRAUMATIC BRAIN INJURY (TBI) and SPINAL CORD INJURY; 80

percent of spinal cord injuries occur in people who are between the ages of 15 and 30. Many of these ACCIDENTAL INJURIES are preventable. Many of the illnesses that threatened not only nervous system function but often life itself—POLIOMYELITIS, ENCEPHALITIS, MENINGITIS—in previous generations are now either preventable or treatable.

Systemic health conditions shift to the forefront of concern with the approach of late age. CARDIOVASCULAR DISEASE (CVD), endocrine disorders, pulmonary disease, and disorders of METABOLISM arising from LIVER and kidney disease become more prevalent with advancing age. All of these conditions have the potential to affect nervous system function. STROKE, a consequence of cardiovascular disease, is the leading cause of disability resulting from damage to the brain. Metabolic disorders such as chronic CIRRHOSIS and DIABETES may disrupt the body's biochemical balances to the extent of creating brain dysfunction (ENCEPHALOPATHY). Health conditions that directly affect the nervous system also become more frequent with increasing age. The most common—and disabling—such conditions are Alzheimer's disease, Parkinson's disease, and DEMENTIA. Alzheimer's disease alone affects as many as 50 percent of people age 85 and older.

Traditions in Medical History

The earliest medical writings of Eastern and Western physicians document nervous system conditions such as epilepsy (SEIZURE DISORDERS) and surgical treatments that involved boring through the skull, probably to relieve pressure resulting from head trauma. Healed wounds in skulls, clearly made by intent, remain as archaeological evidence that physicians of antiquity were somewhat sophisticated, as well as successful, in their methods. Mummified remains reveal that poliomyelitis—which approached worldwide eradication in 2005 through vaccination efforts, with the exception of a few pockets where the disease remained endemic—was fairly common among ancient Mesopotamians and Egyptians.

The Greek physician and philosopher Hippocrates, the father of modern medicine, was the first to determine the brain's responsibility for consciousness and control of the body. The inability to directly explore the structure and function of the brain resulted in centuries of misunderstandings, however. The first accurate representations emerged when in 1543 Andreas Vesalius (1514–1564) published the landmark manuscript *De humani corporis fabrica libri septum,* more familiarly known today as *The Fabric of the Human Body*. The manuscript presented the first drawings of the human brain based on dissection and physical examination.

Breakthrough Research and Treatment Advances

Today some of the greatest advances in understanding of brain and nervous system structure and function come from research in genetics and molecular medicine. HUNTINGTON'S DISEASE was one of the first neurologic disorders for which researchers established a conclusive genetic foundation. In the 1990s researchers uncovered mutations in genes responsible for Parkinson's disease, Alzheimer's disease, and Lewy body dementia.

There is great hope that such discoveries will lead to effective treatments for these and other degenerative neurologic conditions.

Other research focuses on replacing lost or damaged nervous system tissue. STEM CELL transplantation, still experimental, shows promise for treating conditions such as Parkinson's disease, Alzheimer's disease, MULTIPLE SCLEROSIS, AMYOTROPHIC LATERAL SCLEROSIS (ALS), and spinal cord injury. Researchers are also combining GENE and molecular technologies to cultivate neurons in the laboratory with the hope of providing additional sources of transplantable cells.

Other breakthroughs involve new understanding about how the brain functions. Highly sophisticated imaging technologies such as POSITRON EMISSION TOMOGRAPHY (PET) SCAN and SINGLE PHOTON EMISSION COMPUTED TOMOGRAPHY (SPECT) SCAN allow researchers to observe changes in the brain during brain activity. Such observations have provided insights into the processes of memory and cognitive function and offer an objective means for assessing the effectiveness of therapeutic approaches for neurologic disorders such as Alzheimer's disease, Parkinson's disease, and seizure disorders.

In the 1980s scientists discovered the brain has the ability to reorganize the way it functions to some degree, allowing different areas of the brain to take over for certain areas that become damaged. Whether this process permits the brain to default to abandoned pathways or to create new pathways remains unknown. Researchers continue to explore the mechanisms of this reorganization, hopeful that further discoveries will lead to therapies to retrain the brain after stroke or traumatic brain injury and perhaps to compensate for functional losses due to disease processes such as those that occur with multiple sclerosis and Alzheimer's disease.

A

aging, neurologic changes that occur with A rudimentary NERVOUS SYSTEM is among the first structures to form as a new life begins. The CENTRAL NERVOUS SYSTEM begins to form about two weeks after CONCEPTION, arising from a cluster of specialized cells called the ectoderm. Its physical and functional development is about 60 percent complete by birth, 80 percent complete by age three, and finally reaches completion at the end of ADOLESCENCE. Though the full complement of neurons is in place by early childhood, the BRAIN continues to establish new pathways for NEURON communication for most of life.

The Prenatal Nervous System

The first recognizable neurologic structure is apparent 21 days after conception when the cells of the ectoderm grow and divide to form the neural tube, a primitive structure of NERVE tissue. Over the following four weeks the neural tube elongates and closes at each end to form the SPINAL CORD and the brain, a process called neuronal migration. This is one of the most sensitive times in embryonic development. NEURAL TUBE DEFECTS—such as SPINA BIFIDA and anencephaly, which result when one or the other end of the neural tube fails to close—are among the most common BIRTH DEFECTS involving the nervous system.

The brain grows by 50,000 neurons a second during most of this migration period, forming the brain's three major divisions—prosencephalon (forebrain), mesencephalon (midbrain), and rhombencephalon (hindbrain)—which themselves grow and divide to form the core structures of the brain. From the spinal cord, the SPINAL NERVES and PERIPHERAL NERVES begin to tendril out to the organs and structures of the body, establishing motor and sensory innervations that will carry nerve impulses to and from the body throughout life.

The Early Childhood Nervous System

The brain continues to add new cells at an astonishing rate, doubling in size from birth by the time a child reaches 18 months of age. Intense learning takes place during this period, during which the brain acquires the foundations of language, sensory interpretation, and motor skills. Interruptions of these processes can have serious and lifelong consequences. Studies with animals show, for example, that depriving the brain of visual input during the time the brain is establishing the pathways for interpreting visual signals results in permanent blindness even though the structural components of vision—the EYE, OPTIC NERVE, and brain regions—are intact.

Throughout childhood brain neurons continue to expand the connections they make with each other, laying down the hundreds of thousands of pathways necessary for learning and remembering. These neuronal networks provide shortcuts that allow the brain to carry out familiar functions with great speed and efficiency. The foundations of language and motor movement develop and evolve during this period of expansion. Though researchers agree it is never to late for the brain to learn, it is during the years of childhood that the brain is most receptive.

The Adolescent Nervous System

During adolescence (between the ages of 12 and 20) axons continue to grow and branch, most notably from the neurons of the frontal lobes, which are responsible for many of the functions of cognition and behavior, and to lesser extent from neurons in other areas of the brain. This is the

final stage of functional organization of the brain's processes and mechanisms. The numbers of neuroreceptors on the surfaces of neurons also increase dramatically, particularly those for DOPAMINE which is the primary brain NEUROTRANSMITTER for functions of cognition and behavior. This axonal growth makes the adolescent brain especially vulnerable to the neurotoxic effects of ALCOHOL and drugs. Damage that disrupts axonal growth during adolescence often has complex and permanent, consequences for brain function during the rest of life.

The Elderly Nervous System

The brain remains capable of carrying out its functions across the lifespan unless injury or disease interrupts. But by old age the likelihood of injury, disease, and general health problems is higher than any other stage of life. Many diseases common in old age affect the brain and nervous system even when they primarily involve other body systems. CARDIOVASCULAR DISEASE (CVD), for example, may change the BLOOD flow to the brain. HYPERTENSION (high BLOOD PRESSURE), one of the most common forms of cardiovascular disease, is the leading cause of STROKE; and stroke is the leading cause of disabling brain injury. DIABETES damages the delicate blood vessels that nourish the peripheral nerves, most notably damaging sensory perception—the ability of distant body parts such as the feet to send PAIN signals to the brain (peripheral NEUROPATHY). Chronic CIRRHOSIS creates widespread metabolic imbalances in the body that alter brain functions from cognition to motor movement (hepatic ENCEPHALOPATHY).

The likelihood of neurologic disease also increases with age. Conditions such as ALZHEIMER'S DISEASE, PARKINSON'S DISEASE, HUNTINGTON'S DISEASE, DEMENTIA, CREUTZFELDT-JAKOB DISEASE (CJD), TREMOR DISORDERS, and ORGANIC BRAIN SYNDROME seldom develop in people under the age of 50. As many as half those age 85 and older have Alzheimer's disease, however. Progressive neurologic conditions that begin earlier in life, such as MULTIPLE SCLEROSIS, tend to exhibit the most severe of their symptoms as age advances. Such changes are generally irreversible.

Neurons, like other cells, die throughout life. Researchers believe such cell death is a form of culling that helps the brain maintain its efficiency. By old age the cumulative effect of this cell death results in decreased brain tissue. Imaging procedures such as MAGNETIC RESONANCE IMAGING (MRI) show the ventricles (spaces) are larger in the brain of a 70-year-old person than a 30-year-old person. The numbers of sensory nerve receptors in the body (peripheral nerve structures) also begin to decline, reducing to some extent the sensory input that reaches the brain.

But these changes are not sufficient, in themselves, to significantly diminish the brain's functions. Indeed, recent research suggests the brain gets "smarter" with age, developing shortcuts and efficiencies in the ways that it processes information. Many people reach age 80 and beyond with relative good memory, cognition, and independence. Though physical changes do take place in the brain with aging, researchers believe neurologic deficiency is *not* inherently a normal dimension of aging.

Alzheimer's disease A progressive, degenerative condition that causes irreversible loss of cognitive and memory functions. The hallmarks of the disease are the diminished production of acetylcholine, a NEUROTRANSMITTER essential for cognitive function, and the formation of amyloid plaques (abnormal protein deposits) and neurofibrillary tangles (resulting from another protein, tau), within the BRAIN. These formations interfere with normal NEURON communication and literally "scramble" NERVE signals. Alzheimer's disease is typically a condition of aging, primarily affecting people age 70 and older, though an early-onset form of the disease may strike people who are in their 40s or 50s. Early-onset Alzheimer's disease tends to progress more rapidly. More than 4 million Americans have Alzheimer's disease.

The causes of Alzheimer's disease remain unclear, though GENE MUTATION is emerging as a leading candidate. In the 1990s researchers correlated mutations in the apolipoprotein E (apoE) gene on CHROMOSOME 19 with the tendency, depending on the ALLELE (form of the gene) inherited, to develop Alzheimer's disease in old age.

People with one allele pairing appear less likely to develop the disease, and those with other allele pairings seem more likely. Researchers believe there are other genes that may affect a person's GENETIC PREDISPOSITION for Alzheimer's disease, though developing the disease is an interaction among environmental factors, such as the individual's overall health status and lifestyle habits, and genetic factors.

Early-onset Alzheimer's disease, in which symptoms appear before the age of 60 (often in the 40s and 50s), is the only form of Alzheimer's disease researchers know for certain is hereditary. It occurs as a result of mutated genes on chromosomes 1, 14, and 21 that cause alterations in proteins that have key functions in the brain in regard to regulating amyloid. The mutations occur in an autosomal dominant INHERITANCE PATTERN, which means each child of a person who has the gene mutation has a 50 percent chance of inheriting the gene. In this form of Alzheimer's disease, also called familial Alzheimer's disease, it appears that inheriting any one of the mutated genes establishes the certainty of developing the disease. Researchers are sure that variables of personal health play a significant role in whether any given individual develops the disease, though they do not yet know what those variables are.

Symptoms and Diagnostic Path

Early symptoms of Alzheimer's disease tend to be vague and inconsistent deviations from the known and familiar. Though memory loss is the most familiar symptom, it is more than simply misplacing one's car keys or forgetting an appointment. A person may travel the same route to and from the store, for example, and then become completely lost. Early symptoms that can suggest Alzheimer's disease include

- confusion when following directions
- forgetting familiar people and places
- inability to write a check or count out money to pay for purchases
- repeatedly asking the same questions or telling the same information
- inability to prepare meals or perform common household tasks
- stops speaking in the middle of sentences or conversations

Later symptoms become more pronounced and limit independent functioning. Later symptoms of Alzheimer's disease include

- DEMENTIA
- forgetting to eat or drink
- engaging in socially inappropriate behavior such as public MASTURBATION
- disorientation
- inability to recognize people and places and sometimes self

The diagnostic path includes a comprehensive medical examination, thorough NEUROLOGIC EXAMINATION, ELECTROENCEPHALOGRAM (EEG), and usually imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN to rule out other possible causes (such as BRAIN TUMOR or STROKE) that could cause the symptoms.

Diagnosis of Alzheimer's disease is primarily clinical, as only examination of brain tissue at autopsy following death can provide definitive evidence of the hallmark amyloid plaques and neurofibrillary tangles. The person's age, the gradual progression of symptoms, and ruling out other possible causes of the symptoms lead the neurologist to the diagnosis of Alzheimer's disease. POSITRON EMISSION TOMOGRAPHY (PET) SCAN and SINGLE-PHOTON EMISSION TOMOGRAPHY (SPECT) SCAN often can show the progression of damage within the brain as Alzheimer's disease advances. This can help confirm the diagnosis and monitor the effectiveness of medications in slowing the deterioration.

Treatment Options and Outlook

In the 1990s the US Food and Drug Administration (FDA) approved a new class of drugs, acetylcholinesterase inhibitors, to treat Alzheimer's disease. These drugs, such as donepezil (Aricept) and rivastigmine (Exelon), prevent the enzyme acetylcholinesterase from metabolizing (breaking down) acetylcholine. This action extends the length of time acetylcholine remains available to neurons, compensating to a certain degree for the diminishing amounts of acetylcholine the brain

produces as Alzheimer's disease progresses. Eventually acetylcholine production drops below the level at which extending its presence is useful, however, making these medications most effective in the early to middle stages of the disease.

There is some evidence that GINKGO BILOBA, a botanical supplement, improves the cognitive and memory symptoms of early to middle Alzheimer's disease in some people. Ginkgo biloba has no known effect on neurotransmitters directly; its action appears to be that it improves the circulation of BLOOD throughout the brain. This possibly broadens the areas of the brain that participate in cognitive functions. However, ginkgo biloba also affects COAGULATION (the processes of clotting). People who take anticoagulant medications, including daily ASPIRIN THERAPY, should not take ginkgo biloba unless their doctors approve and determine there are no interactions likely with prescribed medications.

Other treatments for Alzheimer's disease are primarily supportive and may include OCCUPATIONAL THERAPY to provide methods for maintaining cognitive function and memory for as long as possible. Activities that use these functions, such as crossword puzzles and reading, seem helpful. Some studies show that daily physical exercise, such as walking, slows the progression of Alzheimer's disease, though the mechanisms through which it may do so remain unknown.

Alzheimer's disease is challenging and emotionally draining for family members and friends who participate in caregiving. Most people want to maintain their loved ones at home for as long as possible, such that it often takes a traumatic event to force the recognition that the person requires more extensive care. Specialized Alzheimer's care facilities provide the staffing and environment to keep the person with Alzheimer's disease safe. SUPPORT GROUPS for family members and caregivers provide forums for sharing information and understanding. Because Alzheimer's disease is progressive and incurable, it is important for families to discuss key END OF LIFE CONCERNS with the person before impairment becomes significant. Most people prefer to make decisions about their own care and are more comfortable when they can feel confident their desires will shape the care they receive.

Risk Factors and Preventive Measures

Age is the primary risk factor for Alzheimer's disease. Though researchers have investigated numerous apparent correlations between environmental exposures (such as to aluminum) and Alzheimer's disease, they have not been able to substantiate them. Genetic factors are likely significant contributors. Except for early-onset Alzheimer's disease, however, the role of the genetic component of Alzheimer's disease remains uncertain. Researchers discovered in the early 2000s that people taking statin medications (such as lovastatin) to lower blood cholesterol levels have a much lower rate of Alzheimer's disease than people who do not take these medications, and they continue to investigate what correlations may exist.

At present, however, there are no measures known to prevent Alzheimer's disease. Because environmental factors such as overall personal health, nutrition, and lifestyle likely contribute in some fashion to conditions that allow Alzheimer's disease to develop, health experts encourage nutritious EATING HABITS, daily physical activity, and other lifestyle measures to maintain optimal health.

amnesia See MEMORY AND MEMORY IMPAIRMENT.

amyotrophic lateral sclerosis (ALS) A progressive, degenerative disorder in which motor neurons (NERVE cells in the SPINAL CORD that are responsible for movement) die, resulting in loss of voluntary MUSCLE function. ALS does not affect involuntary muscle function or other neurologic structures. Other names for ALS include Lou Gehrig's disease, Charcot's disease, and motor NEURON disease. ALS affects half again as many men as women and typically appears in people who are between the ages of 40 and 60.

Though ALS ultimately affects all voluntary muscle function, it typically begins in one of the three types of motor neurons:

- upper motor neurons, which regulate voluntary muscle function in the upper extremities

- lower motor neurons, which regulate voluntary muscle function in the lower extremities
- bulbar motor neurons, which affect the functions of structures in the BRAIN that regulate coordination of movement throughout the body

As motor neurons die the muscles they control can no longer function. As ALS progresses and muscle cells become inactive, the muscles atrophy (waste away). These events in combination result in the debilitating loss of mobility. Regardless of the disease's point of origin, it eventually affects all voluntary muscles in the body. Because the bulbar structures in the brain additionally have functions related to emotion, loss of emotional control is also common particularly in the disease's later stages. Researchers do not know what causes motor neurons to die, nor do they know the precise mechanisms by which cell death occurs.

Symptoms and Diagnostic Path

The development of symptoms varies with the first location of motor neuron loss. Early symptoms of ALS are generally vague, sporadic, and asymmetrical (one-sided). Among them are

- muscle cramps
- emotional inappropriateness and lability (mood swings)
- difficulty speaking, notably slurred speech
- excessive salivation (SIALORRHEA) and difficulty swallowing

Symptoms gradually progress, often over the course of several years, to a level at which they interfere with normal activities. The diagnostic path generally starts with BLOOD tests to assess thyroid and parathyroid function and to detect any presence of heavy metals, notably lead. HYPERTHYROIDISM, HYPERPARATHYROIDISM, and lead poisoning can cause symptoms similar to those of ALS. The diagnostic path also includes electromyography (EMG) to assess muscle function in affected as well as unaffected limbs. The neurologist may further conduct diagnostic imaging procedures of the brain and spinal cord, such as MAGNETIC RESONANCE IMAGING (MRI) of the cervical spine, to rule out other causes of the symptoms. There are no definitive diagnostic tests for ALS.

LOU GEHRIG'S DISEASE

Amyotrophic lateral sclerosis (ALS) struck American baseball legend Lou Gehrig (1903–1941) at the height of his record-setting career. After Gehrig struggled for more than a year with the progressive loss of neuromuscular function characteristic of ALS, doctors made the diagnosis. Gehrig remained a public figure even as his health deteriorated, drawing attention to the disease that finally claimed his life at the age of 38. Americans more familiarly know ALS as Lou Gehrig's disease. However, French neurologist Jean-Martin Charcot (1825–1893) first described the symptoms of this rare condition in 1869. Doctors in France and much of Europe refer to ALS as Charcot disease.

Treatment Options and Outlook

At present treatment for ALS is primarily supportive; there is no cure. The medication riluzole, which blocks release of the NEUROTRANSMITTER glutamate, often can slow the progression of symptoms. Glutamate stimulates activity in the brain, which correspondingly increases nerve signals to parts of the body such as the muscles. People who have ALS tend to have elevated blood levels of glutamate, and some research suggests glutamate overstimulation may damage motor neurons. Researchers do not know what causes the elevation, however, or whether it contributes to or results from the ALS. The neurologist may prescribe other medications such as baclofen and tizanidine to treat muscle spasms and anticholinergic medications to control excessive salivation.

The progressive loss of muscle control eventually affects vital functions such as swallowing, which affects the ability to eat, and BREATHING. Important treatment decisions as ALS progresses include choices around the insertion of a permanent feeding tube, called a percutaneous endoscopic gastrotomy (PEG) tube, to provide adequate nutrition and assistive breathing devices, including MECHANICAL VENTILATION. Some people who have ALS choose full support to extend life as long as possible and others opt for only those supportive

measures that provide the QUALITY OF LIFE that is acceptable to them. Treatment decisions are uniquely individual.

About 40 percent of people who have ALS live 5 to 10 years after diagnosis, and 10 percent survive longer than 10 years. Pulmonary failure and its complications are usually the cause of death. Because ALS is a fatal disease, those who have it should discuss their treatment preferences and END OF LIFE CONCERNS with their physicians and family members, and establish their desires in writing through advance directives such as medical power of attorney and living will.

Risk Factors and Preventive Measures

ALS appears to be familial (hereditary) in about 20 percent of people who develop it, occurring in an autosomal dominant INHERITANCE PATTERN. Neurologists classify the remaining 80 percent as sporadic. Family history is the strongest individual risk factor for developing ALS. Epidemiologists can identify trends in which pockets of ALS occur, suggesting there are common risk factors for sporadic ALS. As yet no clear evidence has emerged that identifies these risk factors or that establishes any explanation for why only a small percentage of people exposed to the same circumstances develop ALS. Some research suggests ALS may have components of autoimmune and mitochondrial dysfunction, though the causes and mechanisms of ALS remain unknown. There are no known measures to prevent ALS.

aphasia Loss of the ability to use language. Aphasia results from damage to the areas of the BRAIN responsible for language, often due to STROKE. Because these areas of the brain are functional rather than structural, doctors cannot predict the extent to which injury will affect language. Other causes of aphasia include BRAIN TUMOR and TRAUMATIC BRAIN INJURY (TBI). Aphasia sometimes occurs in the later stages of neurodegenerative disorders such as ALZHEIMER'S DISEASE and PARKINSON'S DISEASE. It may involve any individual aspect or combination of aspects of the abilities to speak, read, write, and understand language.

In most people the left brain contains the functional centers responsible for speech and language, so stroke or other injury affecting the left brain may produce aphasia, ranging from limited (certain kinds of words or expressions) to global (complete inability to communicate through language). These functional centers conduct all brain activity related to language concepts, including expression such as through SIGN LANGUAGE, not only through speech. Severe damage to these centers appears to prevent the person also from engaging in pantomime and other methods of communication, creating significant disability.

People with mild to moderate aphasia typically have difficulty articulating and understanding the correct words for objects and activities as well as in structuring words they do understand into sentences. Speech and language therapy can help people with mild to moderate aphasia use their remaining language functions to their best ability and learn alternate means of expression. Family and friends can assist by developing mechanisms for interpreting and understanding the person's expressions.

See also APRAXIA; ATAXIA; SPEECH DISORDERS.

apraxia The inability to engage in learned patterns of voluntary MUSCLE activity though the capability (muscle function) is present. Apraxia, also called dyspraxia, may affect various functions and tasks that require voluntary muscle activity. Among them speaking (verbal apraxia, sometimes called apraxia of speech), clapping hands or brushing the TEETH (limb apraxia), swallowing or whistling (buccofacial apraxia), using implements such as eating utensils or hand tools (motor apraxia), and moving the eyes to follow an object (occulomotor apraxia). Verbal apraxia is the most common form of this neurologic disorder.

Verbal Apraxia in Children

Developmental verbal apraxia in children results from injury, often unidentified as to its nature and cause, to the BRAIN regions and neural pathways that produce speech. Verbal apraxia begins to show symptoms between the ages of 18 and 30 months, the age in normal development at which

a child has acquired a vocabulary of several dozen to several hundred words and can speak in simple sentences. Symptoms of verbal apraxia include

- unable to shape the lips and MOUTH to form words
- appears to hear and understand but does not verbalize in response
- verbalizes only certain sounds or words
- makes inconsistent mistakes in speech

These characteristic symptoms distinguish verbal apraxia from developmental delays in speech, in which the child's language skills evolve more slowly than normal but are otherwise typical and complete. The diagnostic path includes a comprehensive speech and language evaluation as well as an assessment for HEARING LOSS. Early recognition and diagnosis allow appropriate early intervention, which focuses on training the brain to use different language pathways. Treatment is more likely to succeed when the brain is still learning these pathways. Rerouted language pathways appear to remain as redirected, becoming the "normal" language pathways for the individual, and the person speaks and otherwise manages language skills in an age-appropriate manner. However, the ultimate success of treatment depends on the nature, location, and extent of the injury to the brain, factors the neurologist often does not know.

Verbal Apraxia in Adults

Acquired verbal apraxia in adults most commonly results as a consequence of STROKE or TRAUMATIC BRAIN INJURY (TBI). The person knows what he or she wants to say but cannot formulate the words, says the wrong words, or articulates sounds that are not words (gibberish). The person knows the right words and is aware his or her words are wrong but cannot correct them. Often the mistakes in speech are inconsistent; the person may one time speak flawlessly and the next be unable to articulate recognizable words. The person may also speak with incorrect inflection and intonation, such that the rhythm of speech does not match the words. Verbal apraxia is extremely frustrating for the person who has it.

The diagnostic path typically includes imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN to identify the area of injury as well as to determine, when unknown, the cause of the injury. Aggressive speech therapy may improve speech over time. However, severe apraxia, especially when coupled with muscle weakness, may not respond to treatment. In such circumstances the emphasis shifts to teaching the person to communicate through other means such as writing or pictures. Some people experience spontaneous recovery from acquired verbal apraxia, though neurologists do not know what causes this to happen or how it happens.

ataxia The inability to coordinate voluntary fine-motor movement. Ataxia may be acquired or inherited and has varied presentations. Gait and balance disturbances (difficulty with walking) are the most common symptoms. Depending on the form of ataxia, other symptoms may include disturbances of EYE movements, sensory perception, and cognition. The diagnostic path includes diagnostic imaging procedures such as MAGNETIC RESONANCE IMAGING (MRI) and COMPUTED TOMOGRAPHY (CT) SCAN to rule out other causes of the symptoms. Personal health history and family medical history are important.

Acquired ataxia most commonly occurs as a result of injury to the cerebellum (the division of the BRAIN responsible for fine motor movement), SPINAL CORD, or SPINAL NERVES. It may also develop as a consequence of long-term ALCOHOLISM and MULTIPLE SCLEROSIS. These forms of ataxia tend to be persistent or slowly progressive, depending on the underlying cause. Acute (sudden onset) acquired ataxia may develop following a viral INFECTION such as CHICKENPOX and EPSTEIN-BARR VIRUS. No treatment is necessary for acute acquired ataxia, as normal movement and coordination generally return within several months.

Hereditary ataxia may occur in various inheritance patterns and tends to be slowly progressive. There are several forms of hereditary ataxia, the most common of which are ataxia telangiectasia and Friedreich ataxia. Hereditary ataxia typically begins to show symptoms in early childhood when the child begins to walk. Most people retain

the ability to walk for 10 to 15 years after symptoms begin and maintain limited independence with assisted mobility (such as a wheelchair) for another 10 years or longer.

athetosis Slow, writhing, involuntary, often continuous movements of the hands and fingers and occasionally the upper extremities. Athetosis occurs as a result of damage to the basal ganglia, NERVE structures deep in the BRAIN that regulate voluntary movement. Athetosis occurs in about 5 percent of people who have CEREBRAL PALSY and also as a consequence of hepatic ENCEPHALOPATHY (damage to the structures of the brain resulting from LIVER FAILURE) or encephalopathy due to drug toxicity (including ANTIPSYCHOTIC MEDICATIONS and medications to treat PARKINSON'S DISEASE), ENCEPHALITIS (INFLAMMATION of the brain), and HUNTINGTON'S DISEASE. Athetosis often occurs in combination with CHOREA (choreoathetosis).

The diagnostic path relies on physician observation in combination with health history. Imaging procedures such as MAGNETIC RESONANCE IMAGING (MRI) and SINGLE-PHOTON EMISSION COMPUTED TOMOGRAPHY (SPECT) sometimes show the lesion (damaged tissue) within the brain. Treatment for athetosis depends on the underlying cause and may include

- MUSCLE RELAXANT MEDICATIONS such as diazepam (Valium) and clonazepam (Klonopin)
- OCCUPATIONAL THERAPY to teach adaptive skills and improve MUSCLE control
- DEEP BRAIN STIMULATION, which alters the electrical output of the basal ganglia and related structures
- RHIZOTOMY, a surgical OPERATION in which the neurosurgeon selectively severs root fibers of the SPINAL NERVES that serve the affected areas of the body

Outcome also depends on the underlying cause. Surgery is often effective at eliminating athetosis when the cause is cerebral palsy. A combination of methods often achieves relief when other causes are responsible.

B

Bell's palsy Damage to the seventh cranial nerve (facial NERVE) that results in partial to complete PARALYSIS of the facial structures on the affected side. Palsy is an antiquated term for paralysis. The paralysis is usually temporary, though it may take up to six months (and occasionally longer) for nerve function to return to normal. Bell's palsy is the most common form of facial paralysis, affecting more than 40,000 Americans each year.

The facial nerve has both motor and sensory functions. It controls all of the muscles in the face, the tiny MUSCLE that moves the stapes BONE in the middle EAR, the muscles that regulate the flow of tears from the tear glands (lacrimal glands), and the muscles that regulate the flow of saliva from the SALIVARY GLANDS. The facial nerve also conveys sensory signals for taste from the tongue to the BRAIN. One facial nerve serves each side of the face. The facial nerve runs from the base of the brain through a channel (the fallopian canal) in the cranial (skull) bones to its emergence at the base of the earlobe, where it divides into numerous branches that extend across the face.

The damage that results in Bell's palsy typically occurs within the fallopian canal. Researchers suspect viral INFECTION is the primary culprit, as Bell's palsy often follows a viral infection such as INFLUENZA, MENINGITIS, and HERPES SIMPLEX. Trauma to the head that compresses the facial nerve within the fallopian canal and extended irritation such as may occur with prolonged exposure to intense wind are also circumstances that can cause Bell's palsy.

Symptoms and Diagnostic Path

The most prominent feature of Bell's palsy is facial distortion resulting from paralysis of the muscles on the affected side of the face. Rarely, symptoms may involve both sides of the face. Symptoms include

- drooping of the eyelid and corner of the MOUTH
- loss of control of the facial muscles
- numbness
- excessive tearing of the EYE
- drooling (SIALORRHEA)
- HEARING LOSS or ear PAIN
- disturbances of taste

The PARALYSIS and other symptoms of Bell's palsy strike suddenly, often mimicking those of STROKE. For this reason, immediate medical assessment is crucial. Stroke is life-threatening and urgent treatment can make the difference for optimal recovery.

The diagnostic path includes a NEUROLOGIC EXAMINATION and assessment of personal health history, particularly for any recent viral infections or circumstances that cause compression or inflammation of the facial nerve. The doctor may conduct imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN, or MAGNETIC RESONANCE IMAGING (MRI) to rule out stroke, tumor, BRAIN HEMORRHAGE, and other possible causes of the symptoms. An electromyogram (EMG) may show the extent to which the nerve damage affects the facial muscles. The doctor makes the diagnosis of Bell's palsy after ruling out other possible conditions.

Treatment Options and Outlook

Treatment for Bell's palsy targets the cause of the nerve damage when the cause persists, which may

include anti-inflammatory medications to relieve swelling or ANTIVIRAL MEDICATIONS when a VIRUS appears to be the culprit. It is important to protect the eye when the paralysis affects the muscles controlling the eyelid, as the eyelid may not blink or close. The doctor may prescribe topical ophthalmic medications and protection for the eye such as an eye shield. Other therapies are primarily supportive, such as speech and swallowing therapy. Some people benefit from MASSAGE THERAPY of the face, PHYSICAL THERAPY, and ACUPUNCTURE to relieve symptoms and maintain muscle tone and health while the damage to the facial nerve heals.

About 85 percent of people recover with minimal or no residual effects. The remainder experience improvement though may have persistent paralysis and loss of function, including hearing impairment. Rarely, Bell's palsy results in significant, permanent loss of function and feeling. In such circumstances doctors may recommend corrective surgery to restore the protective capability of the eyelid as well as function and appearance of the mouth. The symptoms of Bell's palsy may take two weeks to six months or longer to fully resolve.

Risk Factors and Preventive Measures

People who have DIABETES and women who are in the third trimester of PREGNANCY are significantly more likely to develop Bell's palsy. Bell's palsy is more common as well in people who have MULTIPLE SCLEROSIS or who are IMMUNOCOMPROMISED. Researchers do not know why these circumstances increase vulnerability to Bell's palsy. There are no known preventive measures for Bell's palsy.

blood–brain barrier A protective mechanism that regulates the size of molecules that may pass from the bloodstream to the BRAIN. A layer of cells called the endothelium lines the inner channel of the body's tiniest BLOOD vessels, the capillaries. The endothelium functions somewhat like a net. In parts of the body other than the brain, the cells of the endothelium are wider apart, forming a looser net that allows NUTRIENTS, chemicals, and other substances to pass into the spaces between cells. From these spaces the substances can enter the cells that need them.

In the brain the capillary endothelium is compact, its cells forming a tight net to restrict substances from crossing into the intracellular spaces. Glial cells, cells within the brain that support neurons, also participate in the blood–brain barrier, although researchers do not fully understand the mechanisms through which they do so. In some areas of the brain the blood–brain barrier is looser, allowing substances to more easily cross (though not as easily as in the body). Among these areas are the:

- area postrema, commonly called the NAUSEA center, which allows toxins in the bloodstream to rapidly trigger the vomiting REFLEX
- pineal region, the area surrounding the PINEAL GLAND
- pituitary region, the area surrounding the PITUITARY GLAND

The blood–brain barrier permits the brain to maintain balances of neurotransmitters, GLUCOSE, electrolytes, fluid, and other substances that differ from those of the body and are essential for proper brain function. The blood–brain barrier also prevents many PATHOGENS (notably BACTERIA and viruses) from entering the brain, helping reduce the likelihood of INFECTION. Many drugs are unable to cross the blood–brain barrier, though those that can include barbiturates. The body must metabolize drugs that cannot cross the blood–brain barrier, such as ANTIBIOTIC MEDICATIONS to treat infection and levodopa (a precursor of DOPAMINE taken to treat PARKINSON'S DISEASE), into substances small enough to cross the capillary endothelium to enter the brain. Thus, though it is primarily protective, the blood–brain barrier sometimes impedes therapeutic efforts. Conditions such as HYPERTENSION (high BLOOD PRESSURE, which can cause microscopic ruptures in the capillaries), STROKE, and penetrating trauma to the brain can disrupt the blood–brain barrier by allowing blood to come in direct contact with brain tissues.

brain The structural and functional hub of the NERVOUS SYSTEM. The brain regulates the body's functions, voluntary and involuntary. The adult brain is a mass of soft, spongy tissue that weighs about three pounds. It receives 20 percent of the body's BLOOD flow and consumes 20 percent of the body's oxygen supply. The brain and the SPINAL CORD collectively make up the CENTRAL NERVOUS SYSTEM.

The brain resides within the enclosure of the cranium (skull). The cranium's fused bones limit the portals of direct access to the brain. The largest such portal is the foramen magnum, the opening in the occipital bones through which the spinal cord passes. Other smaller passages provide pathways for the CRANIAL NERVES, which terminate in the structures of the brainstem and the underside of the brain. Three layers of membranes, the MENINGES, wrap around the brain for further physical protection. CEREBROSPINAL FLUID circulates between the meninges, cushioning the brain as well as maintaining its biochemical balance. The BLOOD–BRAIN BARRIER, a specialized layer of cells lining the blood vessels that serve the brain, adds a final level of security by limiting the substances that can pass between the blood and the brain.

The Brain's Structure

Neurons (NERVE cells) and glial cells (support cells) form the tissue of the brain. Neurons transmit electrical impulses (nerve signals). Glial cells (also called neuroglia) make myelin, a fatty protein coating that nourishes and insulates neurons. Though the brain contains its full complement of neurons by about age three, glial cells grow and divide throughout life. Though neurons do not grow or divide, they do continue to form new connections (synapses or synaptic circuits) throughout life by extending and branching their axons, the fibers that carry nerve impulses from the NEURON to a synapse (a microscopic channel that separates one neuron from another).

Areas of the brain that contain high concentrations of neuron bodies, such as the cerebral cortex and the basal ganglia, are the gray matter, so-named because these areas are dark in color. Areas of the brain such as the inner cerebrum and the brainstem that are primarily concentrations of axons, the pathways by which neurons communicate, are the white matter. Myelin, which encases and insulates the axons to contain the electrical impulses they transmit, gives the axons their white appearance. The fully developed adult brain contains about 100 billion neurons and up to 50 times as many glial cells.

The brain's three main structural components are the forebrain (prosencephalon), midbrain (mesencephalon), and hindbrain (rhombencephalon). Each of these divisions has further structural as well as functional subdivisions, making the brain the most complex organ of the body. For the most part the brain is a paired organ, with its two halves, the right hemisphere and the left hemisphere, roughly symmetrical in physical structure though not in function. A connecting bridge of neuronal tissue, the corpus callosum, allows the hemispheres to communicate with each other.

Within the structure of the brain are four connected spaces, called ventricles, that produce and contain cerebrospinal fluid. The lateral ventricles, also called the first and second ventricles, are the largest and contact the frontal, temporal, and occipital lobes. The third ventricle is a small space that joins with the lateral ventricles along the midline of the brain and the fourth ventricle, also small, is at the back of the brainstem and joins with the subarachnoid mater (the middle of the meninges).

The Forebrain

The forebrain is the largest of the brain's structural divisions, making up about 85 percent of the brain's mass and weight. Its composition is primarily gray matter—neuron bodies. The forebrain's subdivisions are the telencephalon and the diencephalon. The first cranial nerve, the olfactory nerve, arises from the telencephalon. The second cranial nerve, the OPTIC NERVE, originates in the diencephalon. The forebrain also contains the lateral ventricles and the third ventricle.

The telencephalon, which makes up the bulk of the forebrain, contains the:

- cerebral cortex, also called the cerebrum, which handles all of the body's functions related to conscious activity, from thought and behavior to movement and balance

- basal ganglia, collections of nerve fibers that direct motor functions related to complex movement, including the coordination of muscles and speed with which movements take place; among the basal ganglia are the caudate nucleus, putamen (corpus striatum), globus pallidus, and subthalamic nucleus
- amygdala, a pair of almond-shaped collections of neurons (nuclei) in the temporal lobes with functions related to emotion and the storage of new memories
- hippocampus, a collection of neurons in each temporal lobe with functions related to memory (especially storage and retrieval of long-term memories) and learning

The cerebral cortex features a complex structure of folds (gyri) and fissures (sulci). Each cerebral hemisphere contains four lobes—frontal, parietal, temporal, and occipital—that conduct the brain's cognitive, emotional, behavioral, analytical, interpretive, sensory, and motor activities. Though there is some overlap among the lobes in the kinds of information they process and the ways they process it, each lobe has specific functions. As well, the corresponding lobes of each hemisphere have complementary functions. The lobes of the left hemisphere handle more of the tasks and activities of logic, sequence, order, analysis, and verbal communication. The lobes of the right hemisphere handle more of the tasks and activities of emotion, imagination, intuition, and nonverbal communication.

The primary structures of the diencephalon are the:

- HYPOTHALAMUS, a mix of endocrine and nerve tissues that integrates many of the neurologic

and HORMONE functions of basic survival (such as body temperature regulation)

- thalamus, a small structure that filters and sorts (modulates) sensory impulses that enter and the motor impulses that leave the brain

The diencephalon incorporates the olfactory and optic tracts (origins and pathways of the first and second cranial nerves, respectively). Also within the diencephalon are the PITUITARY GLAND and PINEAL GLAND.

The Midbrain

The midbrain, also called the brainstem, is the point of origin for the third cranial nerve (oculomotor nerve) and the fourth cranial nerve (trochlear nerve). It is the neuronal bridge that joins the forebrain, hindbrain, and spinal cord. The midbrain controls primitive survival functions such as BREATHING and heartbeat. It also contains a cluster of cells called the substantia nigra which secrete DOPAMINE, a NEUROTRANSMITTER essential for movement. The death of cells in the substantia nigra causes PARKINSON'S DISEASE.

The Hindbrain

The hindbrain is beneath and to the back of the forebrain. Its two substructures are the metencephalon and the myelencephalon, which control numerous bodily functions essential for survival. The fourth ventricles are also located within the hindbrain.

The metencephalon is the point of origin for the fifth (trigeminal), sixth (abducens), seventh (facial), and eighth (vestibulocochlear) cranial nerves. The metencephalon contains the:

- cerebellum, which directs and coordinated voluntary MUSCLE function; it receives sensory input from the vestibular structures of the inner EAR (balance) and from peripheral proprioceptors (specialized sensory nerve endings in the limbs) that report the body's spatial orientation within its environment
- pons, which connects the medulla oblongata and the cerebellum with the cerebrum and from which the fifth (trigeminal), sixth (abducens), seventh (facial), and cochlear segment of the eighth (vestibulocochlear) cranial nerves originate

The myelencephalon contains the medulla oblongata, which connects the brainstem and the spinal cord. The ninth (glossopharyngeal), tenth (vagus), eleventh (spinal accessory), and twelfth (hypoglossal) cranial nerves arise from the medulla oblongata. The fourth ventricle is within the medulla oblongata. The medulla oblongata regulates BLOOD PRESSURE, HEART RATE, RESPIRATORY RATE, digestion, and elimination (URINATION and defecation), as well as reflexive actions such as sneezing and coughing.

Neuron Communication in the Brain

Brain neurons communicate with one another through electrical impulses and biochemical facilitators called neurotransmitters. Neurotransmitters conduct or block the impulse's travel across a synapse. Each brain neuron has up to 10,000 synapses, which make up its neuronal pathways; the brain overall has 50 to 200 trillion synapses. The brain sends and receives nerve impulses contralaterally—that is, the brain's right hemisphere handles functions dealing with the left side of the body and its left hemisphere handles functions dealing with the right side of the body. The brain receives sensory nerve signals from the body, which its various regions and areas process and assimilate. The brain sends motor nerve signals to the body in response.

Recent research suggests the brain appears to continually adapt and adjust its neuronal, or synaptic, pathways by extending and branching existing axons and shutting down axon branches it no longer uses. This process of continual pruning seems aimed at keeping the brain's neuronal communications streamlined and efficient and perhaps also at compensating for diminishment that may occur through aging. Though the brain is most receptive to learning during the childhood years when the establishment of synaptic pathways is at its peak, the brain remains capable of learning for the duration of the lifespan.

Health Conditions and the Brain

The brain is vulnerable to the effects of health conditions that affect other body systems as well

as to disease and injury that affects it directly. CARDIOVASCULAR DISEASE (CVD) is perhaps the most significant general health risk for the brain. Conditions such as ATHEROSCLEROSIS, CORONARY ARTERY DISEASE (CAD), and HEART FAILURE can diminish the flow of blood to the brain. HYPERTENSION (high blood pressure) is the leading cause of STROKE; stroke, in turn, is the leading cause of irreversible brain injury. Conditions that affect the body's metabolic state and balance, such as chronic CIRRHOSIS and DIABETES, may alter the brain's biochemical balance to the extent of disrupting brain function (ENCEPHALOPATHY). Direct injury to the brain may result from INFECTION (ENCEPHALITIS), BRAIN TUMOR (including metastatic cancer), traumatic injury, and neurodegenerative diseases such as ALZHEIMER'S DISEASE and Parkinson's disease.

brain death The permanent cessation of BRAIN function commonly accepted as the indication that life has ended. The American Academy of Neurology has established guidelines for determining whether brain death has occurred that form the basis for the criteria health-care providers in the United States apply. However, the criteria vary among states in the United States as well as among countries. In general doctors make a declaration of brain death only when there is clear and unquestionable cause for and evidence of irreversible loss of brain function, and a series of procedures consistently support the determination that all brain function is absent and has no possibility of returning. The concept and establishment of brain death has medical, legal, ethical, moral, and for many people religious components.

The need to establish brain death arises when a person has suffered catastrophic injuries, such as in a motor vehicle accident, or a catastrophic health crisis, such as HEART ATTACK or STROKE, that deprives the brain of oxygen for an extended period. Emergency treatment may place the person on life support, with MECHANICAL VENTILATION to maintain BREATHING. Removing life support generally requires medical consensus that brain death has occurred. The declaration of brain death is also necessary to harvest organs such as the HEART for ORGAN TRANSPLANTATION. In most circumstances a person's next of kin, family members, or person designated with medical power of attorney must authorize cessation of life support even with a declaration of brain death.

brain hemorrhage Significant loss of BLOOD within the cranium or the tissues of the BRAIN. Most brain hemorrhages occur suddenly and unexpectedly. Occasionally brain hemorrhage may be chronic, such as when slow bleeding takes place through a small rupture in an ANEURYSM.

Brain hemorrhage has two major consequences, each of which can be life-threatening: It deprives the brain of vital oxygen and it causes increased pressure within the skull. Brain hemor-

rhage may result from trauma to the brain or from the rupturing of a blood vessel (hemorrhagic STROKE), and may occur within the tissues of the brain, between the inside of the cranium (skull) and the MENINGES (membranes that enclose and protect the brain), or between the layers of the meninges. Doctors designate the kind of bleeding by its location, which also provides clues as to the cause of the bleeding. A brain hematoma is a collection of blood, though many people use the terms *hemorrhage* and *hematoma* interchangeably in referring to bleeding in the brain.

Suspected brain hemorrhage is a potentially life-threatening emergency that requires immediate medical evaluation and treatment.

Symptoms and Diagnostic Path

Symptoms of brain hemorrhage are very much the same regardless of the location of the bleeding. They include

- severe HEADACHE that may come on suddenly or come and go
- weakness or numbness (especially if only on one side of the body)
- difficulty forming words, using the right words, or understanding what others are saying
- NAUSEA and VOMITING
- irritability
- seizures
- fluctuations in consciousness and cognitive function

The diagnostic path typically begins with a NEUROLOGIC EXAMINATION and COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) of the head. These procedures can nearly always confirm the diagnosis of brain hemorrhage as well as pinpoint its location and provide information for the neurologist to assess the severity of the bleeding and potential extent of damage. Because the standard of treatment for stroke that results from a blood clot in a blood vessel is thrombolytic medications to dissolve the clot, doctors conduct these procedures with urgency so they can initiate the appropriate treatment.

Treatment Options and Outlook

Rapid treatment is essential to stop the bleeding and relieve pressure within the brain. In many situations such treatment is emergency surgery to repair the bleeding blood vessels and drain the collected blood. The risk of dying from intracerebral hemorrhage (hemorrhagic stroke) is particularly high because the bleeding is often extensive and directly damages vital areas of the brain. The extent of residual damage after successful treatment depends on many factors and may not be

KINDS OF BRAIN HEMORRHAGE

Brain Hemorrhage	Location	Likely Causes or Contributing Factors
epidural	between the cranium and the dura mater (above the MENINGES)	blunt trauma to the head bleeding disorders
subdural	between the dura mater and the arachnoid mater (the outermost and middle meninges)	blunt trauma to the head
subarachnoid	between the arachnoid mater and the pia mater (the middle and innermost meninges)	ruptured ANEURYSM blunt trauma to the head
intracerebral	within the tissues of the BRAIN	HYPERTENSION ATHEROSCLEROSIS ruptured aneurysm ruptured vascular malformation

apparent for weeks to months after the bleeding. Some people have significant permanent consequences such as PARALYSIS, SEIZURE DISORDERS, and cognitive dysfunction. Many people who recover have minimal permanent consequences, particularly when diagnosis and treatment are immediate. PHYSICAL THERAPY, OCCUPATIONAL THERAPY, and speech therapy help restore maximum function.

Risk Factors and Preventive Measures

Trauma to the head, such as may occur in MOTOR VEHICLE ACCIDENTS or falls, is the most common cause of brain hemorrhage. Proper restraints (seat belts and car seats) and helmets worn during activities such as bicycle riding and downhill skiing, help reduce the risk for head injury. Young children and elderly adults are at highest risk for head injury due to falls. HYPERTENSION (high BLOOD PRESSURE) is the most significant preventable risk factor for intracerebral hemorrhage (bleeding within the tissues of the brain). Lifestyle factors such as cigarette smoking, which causes changes in the structure of the walls of the arteries, and lack of regular physical activity can exacerbate the effects of hypertension. People who take anticoagulant medications ("blood thinners") or who consume excessive amounts of ALCOHOL have increased risk for brain hemorrhage because these substances slow the blood's ability to clot. People who have MARFAN SYNDROME also have increased risk for brain hemorrhage as this congenital disorder causes abnormalities in the blood vessel structures.

brain tumor An abnormal growth that arises within the tissues of the BRAIN. Brain tumors may be noncancerous or cancerous, and cancerous brain tumors may be primary (originate in the brain) or metastatic (spread to the brain from cancer that originates elsewhere in the body). About 75 percent of cancerous brain tumors are metastatic. Primary brain cancer very seldom spreads beyond the CENTRAL NERVOUS SYSTEM (brain and SPINAL CORD). In general noncancerous brain tumors are easier to treat than primary cancerous brain tumors because they tend to remain contained.

However, the tumor's size and location are often the more relevant factors in determining treatment options and prognosis (prospects for recovery). Because the cranium, which houses the brain, is a closed space, any extra mass within it puts pressure on the tissues of the brain that can cause serious damage or death. Though all of the brain is important, some areas are vital to sustain the functions of life. A tumor growing in such an area, such as the brainstem, may become life-threatening more quickly than a tumor growing elsewhere in the brain. As well, some areas of the brain, again such as the brainstem, are inoperable—that is, a neurosurgeon cannot get to the tumor to remove it. Neurologists grade (classify) brain tumors according to their cells of origin, size, likelihood to grow in size, and likelihood to infiltrate (spread into) the tissues and supportive structures of the brain. Many brain tumors contain a combination of cell types.

TYPES OF BRAIN TUMORS

astrocytoma	chordoma
craniopharyngioma	dermoid cyst
ependymoma	epidermoid cyst
ganglioglioma	ganglioneuroma
glioblastoma	glioblastoma multiforme (GBM)
glioma	hemangioblastoma
medulloblastoma (MDL)	meningioma
neuroglioma	oligodendroglioma
pineal germinoma	pituitary ADENOMA
primary malignant lymphoma	primitive neuroectodermal tumor (PNET)

Symptoms and Diagnostic Path

The symptoms of a brain tumor depend on the tumor's location and the parts of the brain the tumor's presence affects. Though HEADACHE can be among the symptoms of brain tumor, most headaches, even those that are severe, do *not* indicate a brain tumor. Disturbances of balance, motor control (movement and coordination), special senses (sight, smell, taste, and hearing), cognitive function, memory, and emotions are common general symptoms of brain tumors. Brain tumors may also cause seizures, NAUSEA and VOMITING, and weakness or PARALYSIS on one side of the body.

The diagnostic path begins with a PERSONAL HEALTH HISTORY and NEUROLOGIC EXAMINATION, with

BRAIN TUMOR SYMPTOMS AND SIGNS

Tumor Location	Common Symptoms and Signs
cerebrum—frontal lobe	erratic behavior emotional outbursts cognitive dysfunction memory dysfunction altered sense of smell vision impairment hemiplegia or hemiparesis (PARALYSIS or weakness on one side of the body) awkward, uncoordinated movement seizures
cerebrum—occipital lobe	loss of vision in the upper half or the lower half of the field of vision seizures
cerebrum—parietal lobe	difficulty with language and speech loss of the ability to write seizures loss of PROPRIOCEPTION (spatial orientation)
cerebrum—temporal lobe	seizures disturbances of language processing and articulation
eighth cranial NERVE (vestibulocochlear nerve)	tinnitus (ringing in the ears) HEARING LOSS
midline (center of the ventral surface of the BRAIN)	persistent HEADACHE NAUSEA NYSTAGMUS vision disturbances erratic behavior or personality changes
cerebellum	awkward, staggering gait swaying when standing lack of coordination
brainstem	irritability inability to concentrate headache that is especially severe upon waking disturbances of vision and EYE function nausea and vomiting MUSCLE weakness

imaging procedures such as MAGNETIC RESONANCE IMAGING (MRI) and COMPUTED TOMOGRAPHY (CT) SCAN to examine the brain's structure. Most tumors are detectable with these procedures. However, the neurosurgeon must take a sample of the tumor's cells (biopsy) to determine the type of tumor and whether it is cancerous or noncancerous. When the tumor is near the surface of the brain, the neurosurgeon can usually reach it via craniotomy (drilling or cutting a small hole through the cra-

nium). Deeper tumors may require guided stereotactic techniques in which the neurosurgeon uses an imaging procedure such as MRI to guide the insertion of a biopsy instrument to the tumor with minimal disturbance of other brain tissue. Laboratory examination of the tumor's cells combined with the visual images of the CT scan or MRI help the neurosurgeon identify and grade the tumor.

Treatment Options and Outlook

The tumor's type, grade, and location determine the appropriate treatment options. Whenever possible, surgery to remove a primary tumor (or as much of it as possible) is the preferred treatment. However, tumors that deeply infiltrate brain tissue, are very large, intertwine with BLOOD vessels, or are located in vital areas may be inoperable. As well, surgery is generally not a viable option for metastatic brain tumors. RADIATION THERAPY can kill tumor cells to shrink or eradicate the tumor. Most often, treatment combines surgery and radiation therapy. Outcomes are most promising when treatment can remove 90 percent or more of the tumor.

CHEMOTHERAPY is not generally an effective treatment for primary brain tumors because it has no effect on noncancerous tumors and because primary brain cancer typically remains contained within the brain, making it unnecessary to expose the entire body to the effects of chemotherapy. Chemotherapy may be the treatment of choice for metastatic brain cancer, however, and for certain brain cancers in very young children. For people who have brain tumors beyond the reach of current treatment options, neurologists and oncologists may recommend clinical trials that are investigating new treatments. It is important to fully understand both the risks and the potential benefits of investigational treatments before agreeing to participate in a clinical trial. Among the most promising investigational treatments are medications that specifically target certain kinds of cells such as cancer cells.

Metastatic brain cancer is very difficult to treat because the cancer is generally widespread throughout the body by the time it appears in the brain. Treatment must target the original cancer as well as the metastatic brain tumor. Chemotherapy and radiation therapy are sometimes effective in achieving REMISSION of cancers that have metastasized to the brain, though in general the outlook is not favorable for metastatic brain cancer.

Risk Factors and Preventive Measures

Neurologists do not know what causes primary brain tumors to develop. There is evidence that exposure to certain toxic chemicals, notably vinyl chloride, increases the risk for primary brain cancer. However, the correlations are not as yet conclusive. Primary brain tumors, cancerous and noncancerous, occur in people of all ages and about equally in men and women. Early diagnosis allows the widest range of treatment options, and early treatment offers the best opportunity for a positive outcome. There are no known measures to prevent brain tumors. However, lifestyle measures such as nutritious EATING HABITS, daily physical exercise, maintaining healthy weight, and not smoking all help support the body's natural IMMUNE SYSTEM efforts to resist disease and maintain the body in optimal health.

central nervous system The collective structures of the BRAIN and SPINAL CORD, exclusive of the CRANIAL NERVES and SPINAL NERVES (the cranial nerves and the spinal nerves, along with their branches, make up the PERIPHERAL NERVOUS SYSTEM). The central nervous system functions as the master control center for the body, maintaining processes to support basic survival as well as conducting complex voluntary and conscious activities. The cranium (skull) and spinal column (vertebrae) enclose and protect the central nervous system.

cerebral palsy Disturbances of motor movement resulting from damage to the structures of the BRAIN responsible for movement, notably the basal ganglia. About 500,000 Americans, children and adults, have cerebral palsy. Cerebral palsy is permanent though nonprogressive (does not worsen over time). Though cerebral palsy often is congenital (present at birth) and may result from GENE MUTATION, it is not hereditary (passed from parents to child).

Neurologists believe about 90 percent of the damage that results in cerebral palsy occurs in PREGNANCY during the development of the NERVOUS SYSTEM, sometimes long before birth. Known causes of such damage include INFECTION, such as RUBELLA (German MEASLES) and TOXOPLASMOSIS, in the mother during pregnancy and interruptions of BLOOD flow to the developing fetus. These events may disrupt critical stages of brain development. The most vulnerable times are 3 to 20 gestational weeks, 26 to 34 gestational weeks, and 36 to 40 gestational weeks.

About 10 percent of cerebral palsy occurs as a result of injuries that occur during or after birth that deprive the brain of oxygen (HYPOXIA). Other known causes of cerebral palsy acquired in the early postnatal period include untreated NEONATAL JAUNDICE (JAUNDICE of the newborn), Rh factor BLOOD TYPE incompatibility, and head injury such as may occur in MOTOR VEHICLE ACCIDENTS or falls. Most often the causes of cerebral palsy in an individual remain uncertain and likely represent a combination of circumstances (multiple factors).

Cerebral palsy has widely variable presentations. These presentations help determine the stage of development—prenatal, perinatal, or postnatal—in which the damage to the brain occurs. Other conditions that often accompany cerebral palsy include HEARING LOSS, VISION IMPAIRMENT, developmental disorders, LEARNING DISORDERS, intellectual impairment, and SEIZURE DISORDERS. These conditions reflect damage to other structures of the brain that may have occurred as a result of exposure to the same event or circumstance responsible for the cerebral palsy (especially hypoxia). Doctors classify the forms of cerebral palsy according to the pattern of symptoms present. The four general classifications currently in use are spastic, athetoid (dyskinetic), ataxic, and mixed.

Spastic cerebral palsy Spastic cerebral palsy affects about 70 percent of those who have cerebral palsy and is the "classic" form first documented by English physician William Little in the mid-1800s. In spastic cerebral palsy the affected muscles are in a state of continuous contraction, causing them to feel and appear stiff. Spasticity affects motor movement and balance. Over time

the spastic muscles tend to remain fixed in their positions (contractures) as the contracted MUSCLE fibers eventually shorten. There are four forms of spastic cerebral palsy that affect the body in different ways:

- Spastic diplegia affects both arms and both legs, though it affects the legs more severely. The legs of people who have spastic diplegic cerebral palsy often turn in at the knees and cross with walking, causing a characteristic, awkward "scissors gait." Balance and sustained movement may be difficult. Severe leg involvement may result in the inability to walk. When arm involvement is moderate to severe, the person may need assistance to eat, bathe, dress, and carry out many of the functions of daily living.
- Spastic hemiplegia (also called spastic hemiparesis) affects the arm, trunk, and leg on one side of the body. Balance is generally better than with spastic diplegia because one side of the body functions normally, though gait is awkward. Spastic hemiplegia may also affect one side of the face, sometimes resulting in speech, eating, and swallowing difficulties. Some people who have spastic hemiplegic cerebral palsy experience tremors (uncontrollable shaking) on the affected side of the body.
- Spastic paraplegia (also called spastic paraparesis) affects only the legs. As with spastic diplegia, movement when walking may be awkward. Balance is generally better, though, because the arms and upper body function normally and can to some extend offset the dysfunctions of the lower body.
- Spastic quadriplegia (also called spastic quadriparesis) affects the entire body—face, arms, trunk, legs—with equal severity. People who have mild spastic quadriplegic cerebral palsy may function relatively normally, though people who have moderate to severe damage may be relatively immobilized and dependent on others for care.

Athetoid cerebral palsy Athetoid, or dyskinetic, cerebral palsy causes persistent, involuntary movements that are slow, rhythmic, and writhing. About 15 percent of people who have cerebral palsy have this form, which most commonly affects the arms and legs though also can involve the face. Facial involvement typically results in speech, eating, and swallowing difficulties. The movements generally subside during sleep and often intensify during emotional experiences.

Ataxic cerebral palsy Ataxic cerebral palsy is the least common form of cerebral palsy, affecting only about 5 percent of people who have cerebral palsy. Ataxic cerebral palsy affects a person's balance and coordination, causing the person to adopt a wide stance and gait. In this form of cerebral palsy muscle tone may be normal, increased, or decreased. Tasks that require rapid or prolonged movements are often the most difficult. People who have ataxic cerebral palsy may also have intention tremors, in which their arms or legs shake uncontrollably with purposeful movement such as taking a step or reaching for an object.

Mixed cerebral palsy About 10 percent of people who have cerebral palsy have a mix of the standard forms. The most common mixed form is spastic and athetoid, in which the person has both stiff, contracted muscles and involuntary, writhing movement. Mixed forms of cerebral palsy also range from mild to severe, though are more likely to interfere with mobility and independence at less severe levels because of the multiple effects.

Symptoms and Diagnostic Path

The symptoms of cerebral palsy generally do not become apparent until an infant is 2 months to 2 years old. Neurologists have identified hand preference before age 12 months as one of the first indications of spastic hemiplegic cerebral palsy; in the course of normal development a child does not acquire hand preference until older than 12 months. Infants who have cerebral palsy may reach developmental markers, such as sitting unassisted or rolling over, more slowly than normal. Some have obvious hypertonicity (tense muscles) or hypotonicity (flaccid muscles).

The pediatrician closely monitors a child at risk for cerebral palsy, regularly assessing motor skills, reflexes, and other dimensions of growth and development. Common at-risk factors include low birth weight, preterm (premature) delivery, seizure disorders, severe neonatal jaundice, Rh incompatibility, and a history of difficulties during

pregnancy. The doctor may conduct diagnostic imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN and MAGNETIC RESONANCE IMAGING (MRI) to visualize the structures of the brain. An ELECTROENCEPHALOGRAM (EEG) helps identify electrical irregularities in the brain that may identify structural abnormalities. Though none of these tests conclusively diagnoses cerebral palsy, the tests help rule out other possible causes of symptoms.

As the child grows older the symptoms of cerebral palsy often become unmistakable. Among them are

- spasticity and contractures of the limbs
- inability to crawl or walk
- vision impairment
- hearing loss
- swallowing and speech difficulties
- SIALORRHEA (drooling)
- URINARY INCONTINENCE

The severity of symptoms does not worsen, though symptoms may change over time. With some forms of cerebral palsy, notably spastic hemiplegic, symptoms may change from day to day. Spasticity may develop into contractures. However, the person's overall neuromuscular status remains unchanged. The doctor may conduct repeated NEUROLOGIC EXAMINATION and diagnostic procedures to monitor any changes in symptoms, though generally can make a firm diagnosis when the child is age three to five years.

Treatment Options and Outlook

Cerebral palsy is irreversible. Treatment targets relieving symptoms and may include medications to relieve spasticity (such as baclofen), tremors, sialorrhea, and muscle tenseness. Many people take combinations of medications tailored to their specific needs and symptoms. People who have severe spastic cerebral palsy may benefit from injections of medication into the fluid around the SPINAL CORD, which allows higher concentrations of the medication to reach the NERVE cells than the person could otherwise tolerate.

PHYSICAL THERAPY can specifically target particular muscle groups and developmental delays, and

KNOWN RISK FACTORS FOR CEREBRAL PALSY

Risk Factor	Preventive Measures
maternal RUBELLA (viral INFECTION)	rubella VACCINE before PREGNANCY
maternal TOXOPLASMOSIS (protozoan infection)	avoid contact with cat feces (such as when cleaning a litter box or working in an outdoor garden) thoroughly cook pork and lamb
preterm delivery low birth weight	appropriate and consistent PRENATAL CARE appropriate nutrition diligent management of DIABETES avoid smoking avoid drinking ALCOHOL
Rh incompatibility	Rh screening before pregnancy Rh serum to mother after birth of Rh-incompatible child to protect future children
NEONATAL JAUNDICE	PHOTOTHERAPY
head injury	methods to reduce risks for falling appropriate infant restraints in motor vehicles

is especially effective when children who have cerebral palsy are young. Parents and physical therapists work together with stretching exercises to keep muscles from contracting and activities that improve coordination and balance. Speech and swallowing therapy teaches methods for gaining optimal muscle control. Physical therapy is often a long-term, even lifelong, process with specific methods for the stages of development a child goes through during the process of growing up. Continued physical therapy often is helpful for adults who have cerebral palsy, helping to keep them as independent as possible.

Surgical approaches include THALAMOTOMY (targeted ablation, or destruction) of cells in the thalamus, a brainstem structure that helps regulate voluntary movement, operations to lengthen contracted muscles, and RHIZOTOMY (selectively cutting segments of spinal nerve roots to block nerve signals to reduce spasticity). Many people who have cerebral palsy are able to live fairly independently with assistive devices and mobility aids. Computers are especially valuable tools, with adaptive technology to allow a person who has extreme mobility limitations to communicate.

Risk Factors and Preventive Measures

Most often doctors do not know the exact causes of cerebral palsy, even when they can correlate the presentation to specific windows of prenatal development or to perinatal or postnatal events. Appropriate and consistent PRENATAL CARE helps a woman maintain a pregnancy that is as healthy as possible, reducing the risk not only for cerebral palsy but also for other complications and conditions that could harm the unborn child. Among the known causes of cerebral palsy, some are preventable and others are not.

cerebrospinal fluid The liquid that circulates between the arachnoid mater and pia mater, the middle and inner MENINGES surrounding the BRAIN and SPINAL CORD. Its purpose is to cushion and protect these structures. Specialized cells that line the choroid plexuses (ventricular structures within the brain) produce cerebrospinal fluid at a rate of about 500 milliliters (mL) every 24 hours, though the amount of cerebrospinal fluid in circulation is only 150 mL. The vascular arachnoid mater absorbs cerebrospinal fluid into the BLOOD circulation. Cerebrospinal fluid is 99 percent water that contains electrolytes, GLUCOSE (sugar), and proteins. The composition, color, and pressure of cerebrospinal fluid are important diagnostic characteristics, which a neurologist may assess using LUMBAR PUNCTURE. In health cerebrospinal fluid is sterile so the presence of BACTERIA or another PATHOGEN is diagnostic of INFECTION.

CEREBROSPINAL FLUID

chorea Rapid, irregular, and involuntary movements that occur as a result of damage to structures of the BRAIN, notably the basal ganglia and subthalamic nucleus, that regulate voluntary MUSCLE function. The word *chorea* is from the Greek word for "dance." Researchers believe chorea represents damage to the mechanisms within these structures that ordinarily suppress extraneous NERVE signals to the muscles. Such damage allows the signals through, creating confused and excessive motor response. Chorea often occurs in combination with ATHETOSIS (called choreoathetosis) and is a symptom rather than a condition.

Chorea usually involves the arms and legs though may also involve the face and trunk. The movements of chorea appear randomly and seem to flow from one part of the body to the other,

though often are abrupt and exaggerated. In its mildest form chorea appears as restless fidgeting; in its most severe form (called ballism) chorea prevents mobility and actions such as holding objects. Chorea occurs in numerous neurologic conditions, including HUNTINGTON'S DISEASE (formerly called Huntington's chorea), PARKINSON'S DISEASE, SYSTEMIC LUPUS ERYTHEMATOSUS (SLE), untreated NEONATAL JAUNDICE (kernicterus), RETINITIS PIGMENTOSA, and CEREBRAL PALSY. Some research suggests autoimmune processes contribute to some forms of chorea. One form of chorea, Sydenham's chorea, results from streptococcal INFECTION that migrates to the brain after untreated or undertreated STREP THROAT.

The diagnostic path depends on whether there are known neurologic conditions or the chorea is a new symptom occurring without a known underlying neurologic cause. In the latter situation the doctor conducts generalized BLOOD tests to measure thyroid HORMONE levels, electrolyte levels, cell composition of the blood, and antibodies for streptococcus. The clinician may also conduct diagnostic imaging procedures such as MAGNETIC RESONANCE IMAGING (MRI) and COMPUTED TOMOGRAPHY (CT) SCAN to assess the brain's structure. Such procedures will show tumors, STROKE, and anatomic abnormalities that could be responsible for the chorea.

Treatment may include ANTIBIOTIC MEDICATIONS when blood tests identify, or the doctor suspects, strep infection. Antiseizure medications, MUSCLE RELAXANT MEDICATIONS, and some of the ANTIPSYCHOTIC MEDICATIONS (notably haloperidol) often relieve the chorea. Forms of chorea that result from transient conditions typically improve or go away within weeks to months. Forms of chorea that result from permanent damage, such as TRAUMATIC BRAIN INJURY (TBI) or HYPOXIA (extended oxygen deprivation), or from degenerative conditions, such as Huntington's disease, do not improve and may worsen as the underlying neurologic condition progresses.

cognitive function and dysfunction The abilities to think, reason, concentrate, process language, and remember are key functions of the BRAIN. Numerous metabolic and neurologic conditions affect these functions, some transiently and others permanently. Medications may also alter cognitive function, either intentionally (as with the acetylcholinesterase inhibitors to treat ALZHEIMER'S DISEASE) or as undesired side effects. Adequate cognitive function is essential for learning as well as for independent living.

The two frontal lobes of the cerebrum conduct most of the functions of cognition, with the other cerebral lobes contributing processes such as sensory input and behavioral cues. The prefrontal areas of the frontal lobes are the most active in regard to cognitive functions, performing functions related to analytic thought, judgment, and concentration. Other areas of the frontal lobes regulate motor movement necessary for language expression and speech. The temporal lobes, located beneath and somewhat behind the frontal lobes, interpret language input and recall memories. One temporal lobe also contains the speech center. The structures of the limbic system, notably the amygdala and the hippocampus, control the storage of recent memories.

Symptoms and Diagnostic Path

The symptoms of cognitive dysfunction vary according to the damaged area of the brain. Symptoms tend to appear gradually when the cause of the damage is a progressive neurologic disorder. A person in the early stages of cognitive loss may:

- become easily confused
- get lost on familiar routes
- be unable to perform tasks such as using a checkbook or reading a book
- say the wrong words
- fail to remember recent events

When the cause of cognitive dysfunction is damage to the brain that occurs as a result of TRAUMATIC BRAIN INJURY (TBI) or STROKE, the cognitive loss is generally obvious though may improve over time and with treatment. The diagnostic path begins with a comprehensive medical examination, including assessment of PERSONAL HEALTH HISTORY, and a general NEUROLOGIC EXAMINATION. The

COGNITIVE FUNCTIONS OF KEY BRAIN AREAS

Brain Area	Key Cognitive Functions	Indications of Damage
cerebrum—frontal lobes	logic analytic thought judgment concentration language formation and expression planning organization	inability to conduct tasks such as simple math or preparing meals cannot get from one place to another, such as home to the store cannot follow directions or instructions difficulty finding the right words to speak or write short, fragmented attention span inability to assess right and wrong
cerebrum—temporal lobes	language interpretation memory recall	inability to understand what others say cannot remember previously learned information
cerebrum—parietal lobes	PROPRIOCEPTION (awareness of body's location in its physical environment)	inability to write
cerebrum—occipital lobes	visual interpretation	inability to read
amygdala/hippocampus	memory storage	cannot remember recent events cannot learn new information

findings determine subsequent diagnostic procedures, which often include COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) to visualize brain structure and ELECTROENCEPHALOGRAM (EEG) to evaluate the brain's electrical activity. Cognitive assessment testing measures the ability to perform analytic and computational tasks; recall information; and orient to time, place, and current events.

CONDITIONS THAT MAY AFFECT COGNITIVE FUNCTION

ALZHEIMER'S DISEASE	BRAIN HEMORRHAGE
BRAIN TUMOR	CREUTZFELDT-JAKOB DISEASE (CJD)
DEMENTIA	HUNTINGTON'S DISEASE
HYPOGLYCEMIA	medication side effects
MULTIPLE SCLEROSIS	ORGANIC BRAIN SYNDROME
PARKINSON'S DISEASE	sleep deprivation
STROKE	TRAUMATIC BRAIN INJURY (TBI)

Treatment Options and Outlook

Treatment approaches target the underlying causes of cognitive dysfunction. Stopping medications and correcting metabolic disorders that disrupt thinking or memory result in rapid turnaround of symptoms arising from these causes. Because many of the areas of the brain involved in cognition are functional rather than anatomic divisions, their locations vary somewhat among individuals. This is one of the factors that creates challenge for neurologists when assessing the extent of damage and the potential for recovery of functions when the cause of the damage is injury to the brain. In most people, recovery reaches its maximum level in about two years from the time of injury. Targeted, persistent PHYSICAL THERAPY and OCCUPATIONAL THERAPY can help the brain "reprogram" to use other areas for some cognitive functions.

When the cause of cognitive loss is a progressive neurologic disorder, treatment efforts are primarily supportive and aim to maintain independent functioning for as long as possible. Medications such as acetylcholinesterase inhibitors sometimes improve symptoms in people who have Alzheimer's disease though are less predictably effective in other degenerative disorders that affect cognitive function. Other medications may improve psychiatric stability, motor function,

and related symptoms that contribute to cognition, improving the person's overall ability to engage in cognitive activities.

Risk Factors and Preventive Measures

Brain damage resulting from stroke or TBI is the leading cause of cognitive dysfunction among adults in the United States. Preventive measures that target these events correspondingly lower the likelihood of cognitive dysfunction. For stroke such measures include appropriate treatment for HYPERTENSION (high BLOOD PRESSURE) and DIABETES, the leading causes of stroke. For TBI such measures include appropriate protective devices such as seat belts in vehicles and helmets for activities that entail risk for contact injuries to the head.

There is some evidence that the herbal supplement GINKGO BILOBA helps maintain alertness and cognitive function in people who are healthy and may improve concentration and cognition in people who have mild forms of cognitive dysfunction or memory impairment. However, neither prescription medications nor herbal products have the ability to fully restore cognitive functions lost to permanent brain damage such as occurs with Alzheimer's disease or TBI.

coma A sustained state of loss of CONSCIOUSNESS from which a person cannot be aroused. When in a coma a person does not respond to any external stimuli, including PAIN. REFLEX responses may or may not be present, depending on the depth of the loss of consciousness. Some comas are reversible with immediate and appropriate medical intervention. However, irreversible coma typically leads to PERSISTENT VEGETATIVE STATE or BRAIN DEATH.

COMMON CAUSES OF COMA

BRAIN HEMORRHAGE	CARDIAC ARREST
DRUG OVERDOSE	ENCEPHALITIS
excessive ALCOHOL consumption	hepatic ENCEPHALOPATHY
HYPERGLYCEMIA	hypoglycemia
STROKE	toxic exposure
TRAUMATIC BRAIN INJURY (TBI)	untreated HYPOTHYROIDISM
UREMIA	

Neurologists may use various assessment approaches, such as the Glasgow Coma Scale or the Rancho Los Amigos Scale (RLAS), to evaluate the depth of a coma and the extent of damage to the BRAIN that the coma represents.

See also ANESTHESIA; DELIRIUM; UNCONSCIOUSNESS.

concussion An injury to the BRAIN resulting from a blow to the head. The blow causes the brain to jolt against the inside of the cranium (skull), causing BLOOD vessels within the brain tissue to rupture. Often these are small blood vessels and the bleeding is comparable to that of minor bruising, though any damage within the brain may have potentially serious consequences, depending on its location. Brain tissue may also swell as a protective response to traumatic injury. Concussion is the most common head injury.

Symptoms and Diagnostic Path

The symptoms of concussion vary with the severity of the blow. The symptoms of mild to moderate concussion typically include

- HEADACHE
- dizziness
- confusion or disorientation
- vision changes or disturbances such as "seeing stars" or seeing double (DIPLOPIA)
- ringing in the ears (TINNITUS)
- brief loss of memory, especially of the incident causing the concussion

The symptoms of mild to moderate concussion typically go away in 15 minutes to several hours. Symptoms that are more extensive suggest severe concussion and typically include

- severe headache
- one pupil larger than the other
- NAUSEA and VOMITING
- drowsiness or inability to stay awake
- persistent confusion
- irritability, agitation, or emotional instability
- weakness on one side of the body

A person may have a reddened area, a bruise, or swelling at the site of impact, although often

there are no outward indications that a concussion has occurred.

Because the potential for serious BRAIN damage exists even with an apparently minor concussion, a person who experiences a blow to the head that results in loss of CONSCIOUSNESS or symptoms of concussion that last longer than 15 minutes should undergo examination by a physician.

The diagnostic path includes a basic NEUROLOGIC EXAMINATION to assess the person's level of CONSCIOUSNESS and REFLEX responses. The doctor may conduct diagnostic imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) to determine whether there is active bleeding within the brain and to assess the extent of damaged tissue when the concussion is severe. The doctor may also conduct an ELECTROENCEPHALOGRAM (EEG) to assess the brain's electrical activity.

GRADING OF CONCUSSION

grade 1	brief confusion but no loss of CONSCIOUSNESS
grade 2	extended confusion and little or no memory of the event that caused the concussion but no loss of consciousness
grade 3	loss of consciousness lasting a few minutes to several hours with brief to extended confusion upon return of consciousness and no memory of the event that caused the concussion

Treatment Options and Outlook

Treatment is generally watchful waiting. The doctor may choose to hospitalize the person for close medical observation or may recommend regularly arousing the person for 24 to 48 hours to monitor the person's ability to exhibit full consciousness. Most concussions are mild and recovery is complete. However, severe or repeated concussions can lead to permanent brain damage or even death. It is important to monitor a person who has had a concussion for changes in alertness, behavior, and symptoms such as headache and to seek medical reevaluation if they occur.

Risk Factors and Preventive Measures

The most common causes of concussion are MOTOR VEHICLE ACCIDENTS, team sports (especially contact sports such as football and boxing), bicycle accidents, and shaking an infant or young child.

Never shake an infant or young child, even in play. Infants and young children are particularly vulnerable to BRAIN injury that can occurs with forceful shaking (shaken baby syndrome). The damage can cause concussion or, when severe, be permanent or fatal.

Collisions and crashes when downhill skiing, snowboarding, roller skating, inline skating, and skateboarding are also common causes of concussion. Measures to reduce the risk for concussion and other injuries include using appropriate personal protective equipment and devices, such as safety belts and helmets; following safety procedures and regulations; and proper training and technique when participating in sporting activities.

consciousness A state of awareness of one's external environment, typically when a person is awake and the cerebrum (the largest part of the BRAIN responsible for sensory, voluntary, and cognitive functions) is fully functional. Most researchers believe consciousness results from the interactions of physiology, chemistry, cognition, and memory. However, scientists do not fully understand how consciousness occurs. A clinical assessment of consciousness typically incorporates measures of how well a person is oriented to current events and surroundings. Altered states of consciousness range from sleep, from which a person is easily aroused, to COMA, from which a person cannot be aroused. A network of nerves in the brainstem, midbrain, and cerebral cortex, the reticular-activating system (RAS), is primarily responsible for regulating the level of consciousness.

cranial nerves The 12 paired nerves that originate within the cranium (skull). The cranial nerves convey sensory signals and control motor functions primarily for the head, neck, and face. Cranial NERVE X, also called the vagus nerve, serves the organs of the trunk as well. The cranial nerves and the SPINAL NERVES combined make up the PERIPHERAL NERVOUS SYSTEM, dividing and branching throughout the body to extend nerve fibers to all tissues.

When identifying the cranial nerves numerically, neurologists generally use Roman numerals I through XII to refer to the cranial nerves or designate them as first cranial nerve, second cranial nerve, and so forth. The numbers of the cranial nerves designate the cranial nerves in order from the front to the back of the BRAIN and brainstem. Cranial nerve IV, the trochlear nerve, is the smallest, and cranial nerve V, the trigeminal nerve, is the largest of the cranial nerves. Cranial nerve X has the most diverse and extensive functions.

Types of Cranial Nerves

Cranial nerves are sensory, motor, or mixed (convey both sensory and motor signals). Sensory nerves or nerve components are afferent; they conduct signals from the body to the brain and may be general (conveying sensory information such as temperature and PAIN) or special (conveying sensory information for sight, hearing, taste, or smell). Motor nerves or nerve components are efferent; they conduct signals from the brain to the body and may be somatic (serving striated or voluntary MUSCLE), visceral (serving the smooth muscle of internal organs), or branchial (serving the structures that arise from the embryonic gill arches, which are primarily the structures of the lower face, jaw, and THROAT). The cranial nerves cross before leaving the brain and brainstem, serving structures on the opposite side of the body.

Origins and Paths of the Cranial Nerves

Cranial nerves I and II are special sensory nerves. The first cranial nerves, the olfactory nerves, originate in the olfactory bulbs at the front of the brain, in a region sometimes called the rhinencephalon. The olfactory nerve fibers unify to become the olfactory tracts as they pass along the underside of the brain and terminate in the olfactory epithelium, a structure of hairlike extensions which respond to scent molecules that enter the NOSE. The second cranial nerves, the optic nerves, originate at the front of the brain near the olfactory bulbs. The OPTIC NERVE fibers converge into the optic tracts that terminate as they enter the retinas of the eyes.

Cranial nerves VIII, the vestibulocochlear nerves, are the third purely sensory pair of cranial nerves and arise from the brainstem near the juncture of the pons and the medulla oblongata. The vestibulocochlear nerve travels parallel to cranial nerve VII, the facial nerve, through a portion of the fallopian channel (a narrow tunnel through the cranium) as each leaves the brain. Each vestibulocochlear nerve has two branches, one that terminates within the cochlea, responsible for hearing, and one that terminates within the structures of the vestibule, responsible for balance.

Cranial nerve pairs III through VII and IX through XII originate from clusters of cells within structures of the brainstem. Cranial nerves III (oculomotor nerves), IV, VI (abducens nerves), XI (spinal accessory nerves), and XII (hypoglossal nerves) have purely motor functions. The remaining cranial nerves—V, VII, IX (glossopharyngeal), and X—have mixed sensory and motor functions.

Conditions That Can Affect the Cranial Nerves

Damage to the cranial nerves may result from trauma, INFLAMMATION, INFECTION, AUTOIMMUNE DISORDERS, and tumors. Depending on the nerve affected the consequences may be disturbances of sensory perceptions, such as altered taste or diminished smell, or disturbances of motor function, such as the facial PARALYSIS of BELL'S PALSY (damage to cranial nerve VII). HERPES ZOSTER (shingles) frequently affects cranial nerve V, causing extreme pain along the involved DERMATOME (pattern of nerves) of the face. ACOUSTIC NEUROMA is a noncancerous, slow-growing tumor affecting cranial nerve VIII that causes progressive HEARING LOSS.

Creutzfeldt-Jakob disease (CJD) A rare degenerative, and at present fatal, BRAIN condition that results from the distortion and malfunction of proteins in the brain. Protein particles called prions appear to be the responsible agents. Prions are infectious, meaning they can pass from one person to another to cause disease. CJD is a brain-wasting disease that destroys brain tissue, leaving spongelike holes throughout the brain. Doctors diagnose about 300 cases of CJD a year in the United States, though many researchers feel this is an inaccurate representation of how many people develop the condition because diagnosis can take place only by examining brain tissue at autopsy. Autopsy is not a standard procedure in the United States or in most countries.

Though known to doctors for more than a century, CJD came to international prominence in the early 1990s with the discovery that a form of prion infection in cows, bovine spongiform encephalopathy (BSE), could be transmitted to humans through consumption of meat in which the nervous tissues present in the meat contained infectious prions (infectious prions occur only in nervous tissue). Researchers designated this form as variant CJD (vCJD) to distinguish it from the classic form of CJD.

Another form of CJD is iatrogenic CJD in which an individual acquires the disease as a result of medical treatments using tissues from a cadaver donor with had undiagnosed CJD. Current methods for harvesting such tissues and substances, notably dura mater for transplantation and human growth HORMONE (hGH) extracted from cadaver PITUITARY GLAND, now include procedures to reduce the risk for INFECTION.

CJD is a difficult disease to track to its origins because the time from onset to show of symptoms can be several decades. Before BSE (also called "mad cow disease") focused attention on CJD, doctors believed the malformed proteins characteristic of CJD occurred spontaneously in individuals who perhaps had a GENETIC PREDISPOSITION for such damage or had unknown environmental exposure that set the chain of events in motion. Some forms of CJD appear to have a genetic component as they tend to run in families, and researchers have identified GENE mutations that produce the defective proteins.

The discovery of infectious prions has caused some researchers to suspect that these protein particles cause nearly all CJD. Researchers do not know, however, how most people would acquire infectious prions. Only about 110 people worldwide (mostly in England where BSE first surfaced) are known to have died from CJD acquired through eating BSE-contaminated beef. About 150 people worldwide are known to have died from iatrogenic CJD acquired through medical procedures. Health-care providers and suppliers of donor tissues and products now follow more stringent preparation and sterilization techniques to kill infectious prions. These measures significantly reduce, though do not eliminate, the risk of acquired CJD.

Symptoms and Diagnostic Path

Though the incubation period for CJD is typically very long (10 to 25 years), once symptoms develop the course of the disease is quite rapid. Symptoms tend to appear with dramatic suddenness and include

- erratic behavior and emotional outbursts
- memory disturbances
- DEMENTIA
- loss of motor function (jerky movements and unsteady gait)
- cognitive dysfunction

The diagnostic path includes a comprehensive PERSONAL HEALTH HISTORY to determine any family history or exposures that suggest CJD as well as imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN and MAGNETIC RESONANCE IMAGING (MRI), which can show the damage in the brain. The neurologist makes the diagnosis on the basis of clinical findings, including the progression of symptoms, after ruling out other causes. Definitive diagnosis can be made only by analysis of brain tissue after death.

Treatment Options and Outlook

All forms of CJD are, at present, progressive and fatal. Treatment is primarily palliative, aiming to improve the person's comfort and QUALITY OF LIFE to the extent possible. CJD typically results in loss

of neurologic function that leads to death within two years after symptoms appear.

Risk Factors and Preventive Measures

Because the transmission of prion infections remains uncertain, the United States and many countries in Europe have imposed strict guidelines for tissue and blood donation. Health experts disagree as to whether there is a risk for acquiring CJD through donated blood and blood products, though the risk has been well established for certain kinds of tissues and extracted substances. Many countries now have strict regulations for the raising and slaughtering of cattle, as well as testing for the presence of BSE. These regulations are constantly evolving.

deep brain stimulation A surgical procedure to treat tremors in disorders such as PARKINSON'S DISEASE and benign essential tremor. In such conditions, researchers believe the BRAIN structures responsible for fine motor movement become unable to block extraneous NERVE signals, allowing far more nerve signals to reach the muscles. The overstimulation results in the tremors. Deep brain stimulation generally becomes a viable treatment option when noninvasive measures are no longer successful in controlling tremors and the tremors are severe enough to disrupt daily living. The neurosurgeon implants a thin wire with electrodes at the tip into the thalamus or subthalamic nucleus, structures of the brainstem responsible for fine motor movement. A battery-powered pulse generator then sends electrical signals to the electrodes. The signals block the thalamus or subthalamic nucleus from sending extraneous nerve signals to the muscles, which slows or stops the tremors.

The first step of deep brain stimulation surgery is the placement of a stereotactic halo, a circular brace the neurosurgeon attaches to the person's skull with local anesthetic to numb the areas of the skull where the halo attaches. The halo holds the instruments in precise position during the OPERATION. The second step of the surgery is implanting the electrodes. After injecting a local anesthetic to numb the SKIN and periosteum covering the cranium (which are the only areas that contain nerves sensitive to PAIN), the neurosurgeon drills a tiny hole and inserts a very thin insulated wire, feeding it slowly to the thalamus or subthalamic nucleus, using MAGNETIC RESONANCE IMAGING (MRI) to visualize and guide the path of the wire.

The person remains conscious and relatively aware during this part of the surgery, so he or she can respond to the neurosurgeon's directions and report any unusual effects. The neurosurgeon typically has the person hold a small object to monitor improvement of the tremors with the electrode's placement and activation. During the third and final stage of the operation the neurosurgeon implants the pulse generator into a pocket of tissue beneath the clavicle (collarbone) under local or sometimes general ANESTHESIA and runs the other end of the insulated wire under the skin to connect at the pulse generator. The neurosurgeon uses a computer to program the pulse generator to deliver the appropriate STRENGTH and rate of electrical impulses.

The operation lasts about 90 minutes. The neurosurgeon removes the stereotactic halo when the operation is finished. Minor side effects, usually temporary, may include tingling and balance disturbances from the wire passing through the brain. Complications are rare; when they do occur they may include excessive bleeding and postoperative INFECTION. Most people return to full and regular activities within two weeks. The batteries in the pulse generator last about five years, after which the neurosurgeon replaces the pulse generator and batteries together. Deep brain stimulation typically provides long-term relief from tremors, though in degenerative conditions such as Parkinson's disease the benefit eventually diminishes as the condition progresses.

delirium A state of extreme confusion generally resulting from reversible causes. Delirium appears to result from multiple imbalances in the brain's neurotransmitters. The causes of these imbalances are generally multiple or complex, such as the

metabolic disruptions that are the hallmark of withdrawal from prolonged ALCOHOL INTOXICATION (delirium tremens). Other metabolic disturbances, such as occur with LIVER FAILURE (hepatic ENCEPHALOPATHY) or ketoacidosis of DIABETES, also cause delirium. Some people experience delirium as a reaction to general ANESTHESIA or certain medications, or as a consequence of very high FEVER. People who are elderly are more vulnerable to delirium, though delirium may occur at any age.

The presentation of delirium, which varies widely, is often difficult to distinguish from that of disorders such as DEMENTIA. A person experiencing delirium may exhibit DELUSION, HALLUCINATION, disorientation, restlessness, and inability to concentrate. The person's recent health history, including history of substance abuse or ALCOHOLISM, generally provides the determining information. BLOOD tests may show electrolyte or GLUCOSE (sugar) imbalances. The diagnostic path focuses on finding the underlying cause. Delirium nearly always resolves when the doctor identifies and treats the underlying cause.

See also COGNITIVE FUNCTION AND DYSFUNCTION; PSYCHOSIS.

dementia The loss of cognitive function resulting from changes in the structure of or damage to the BRAIN. Metabolic disturbances that create biochemical imbalances in the body, such as chronic CIRRHOSIS, may alter the brain's biochemistry as well, establishing transient dementia (dementia that goes away when the underlying imbalance returns to normal). An ADVERSE REACTION to medication or interaction among medications may also produce symptoms of dementia that typically end when the person stops taking the medication. Most often, however, dementia represents permanent loss of abilities related to thought, memory, logic, analysis, calculation, planning, and organization.

Degenerative neurologic disease ALZHEIMER'S DISEASE, PARKINSON'S DISEASE, HUNTINGTON'S DISEASE, and other progressive, degenerative conditions affecting the brain are the primary causes of dementia. These conditions cause the death of neurons in areas of the brain that conduct cognitive activities and are the most common causes of dementia.

Lewy body dementia Lewy bodies are abnormal protein deposits that form in the structures of the midbrain. Because the midbrain handles functions related to basic emotional response (such as fear and anger) and basic motor function, Lewy body dementia typically produces symptoms that appear a blend of Parkinson's disease and Alzheimer's disease. Some researchers believe the three conditions may share common origins, though the mechanisms of their relationship remain undetermined.

Vascular dementia STROKE, TRANSIENT ISCHEMIC ATTACK (TIA), BRAIN HEMORRHAGE, carotid ATHEROSCLEROSIS, and cerebral vascular disease (atherosclerosis affecting the arteries within the brain) deprive areas of the brain of the BLOOD supply they require to remain functional. Brain neurons can survive only a short time (three minutes or less) without oxygen; the body cannot replace lost neurons as it can certain other types of cells.

Traumatic brain injury Injury to the brain such as may occur in MOTOR VEHICLE ACCIDENTS may permanently damage areas of the brain. TRAUMATIC BRAIN INJURY (TBI) is the most common cause of dementia in people under age 60. Depending on the extent and location of the injury, it is sometimes possible to retrain other areas of the brain to carry out some of the lost cognitive functions.

Symptoms and Diagnostic Path

The symptoms of dementia may appear gradually or suddenly depending on the cause. They typically include

- loss of memory, which may manifest in terms of forgetfulness, failure to recognize familiar people and places, and inability to carry out familiar activities such as cooking or driving to the store
- inappropriate behavior, such as outbursts of anger
- inability to find the right words when speaking
- personality changes
- inability to make basic decisions, such as which shirt to wear or what to eat
- pronounced decline in PERSONAL HYGIENE (bathing and wearing clean clothes)

The diagnostic path begins with a comprehensive medical examination to look for common and

easily remedied causes for the symptoms. Among such causes might be undiagnosed conditions such as HYPOTHYROIDISM, DIABETES, vitamin B_{12} deficiency, neurosyphilis, and medication reactions or interactions. The doctor will also take a careful medical history, looking for evidence of recent injury or trauma or of family history of conditions such as Parkinson's disease and Alzheimer disease. The doctor may conduct diagnostic imaging procedures such as MAGNETIC RESONANCE IMAGING (MRI) and COMPUTED TOMOGRAPHY (CT) SCAN to rule out BRAIN TUMOR, brain hemorrhage, or stroke. Dementia is generally a clinical diagnosis based on symptoms and on ruling out treatable causes of the symptoms.

Treatment Options and Outlook

Treatment and outlook vary with the cause of the dementia. Metabolic dementia is often transient, with normal brain function returning when treatment restores the body's metabolic balance. Dementia that results from injury to the brain or neurodegenerative conditions such as Alzheimer's disease is generally permanent. Treatment aims to improve remaining cognitive abilities through activities that use and exercise the brain, such as reading and crossword puzzles. Adaptive measures may also help, such as writing out instructions or drawing maps or pictures. Persistent, and particularly progressive, dementia may result in loss of independent function.

Risk Factors and Preventive Measures

Age is the primary risk factor for dementia. About half of people over age 85 have Alzheimer's disease, the leading cause of dementia. Lewy body dementia and vascular dementia also become significantly more common with advanced age. Appropriate medical and lifestyle management of conditions such as HYPERTENSION (high BLOOD PRESSURE), atherosclerosis, LIVER disease, and diabetes helps mitigate their health consequences.

dermatome A region of the body a specific, single spinal NERVE root serves. The SPINAL NERVES convey motor signals to and sensory signals from the body. The body's dermatome pattern is fairly consistent among individuals though each person has subtle unique characteristics. Identifying the involved dermatome for chronic PAIN, MUSCLE weakness, or PARALYSIS helps the neurologist determine the region of the spine where the damage originates. This is particularly useful for therapies such as NEURAL BLOCKADE (NERVE BLOCK) and RHIZOTOMY, which are treatments for intractable pain or spasticity. The body's dermatome has the appearance of a topographic map when rendered as a visual representation.

A dermatome is also a bladed surgical instrument used to remove very thin layers of SKIN such as for skin transplantation.

dyskinesia Abnormal, involuntary movements. Dyskinesia results from damage to the structures within the BRAIN responsible for motor movement and coordination, notably the basal ganglia. ATHETOSIS, CHOREA, DYSTONIA, MYOCLONUS, tics, and tremors are all forms of dyskinesia that may appear in neurologic disorders such as PARKINSON'S DISEASE, HUNTINGTON'S DISEASE, TOURETTE'S SYNDROME, RESTLESS LEGS SYNDROME, CEREBRAL PALSY, and essential benign tremor. Abnormally slow movements are bradykinetic (bradykinesia) and abnormally rapid movements are hyperkinetic (hyperkinesis). It is common for people who have neuromotor disorders to have more than one form of dyskinesia. Medications such as anticholinergics and MUSCLE relaxants can sometimes improve dyskinesia.

Tardive dyskinesia is a form of dyskinesia that develops with long-term use of DOPAMINE antagonist medications, which block dopamine from reaching dopamine receptors in the brain. Dopamine antagonists are the convention of treatment for Parkinson's disease. Many ANTIPSYCHOTIC MEDICATIONS to treat SCHIZOPHRENIA and other serious psychiatric illnesses also are dopamine antagonists. Tardive dyskinesia is often irreversible.

electroencephalogram (EEG) A diagnostic procedure that records the electrical activity of the BRAIN. The neurologist uses EEG to assess the brain's function. Electrodes attached to the scalp detect the brain's electrical impulses and carry the signals to the EEG machine. An amplifier converts the impulses into patterns that the machine records either in analog form (in which styluses create tracings on a slowly moving roll of paper) or digital form (in which a computer creates an electronic record).

Reasons for Doing This Test

Neurologic conditions, from BRAIN HEMORRHAGE to BRAIN TUMOR to SEIZURE DISORDERS, cause predictable and detectable deviations from the normal electrical patterns. EEG also shows the level of electrical activity in the brain of a person who is UNCONSCIOUS, in a COMA, or in a PERSISTENT VEGETATIVE STATE. The neurologist must interpret the EEG findings in context with the person's age, PERSONAL HEALTH HISTORY, medications, and other clinical findings to arrive at a diagnosis.

Preparation, Procedure, and Recovery

EEG generally requires no preparation or recovery and does not cause discomfort. To conduct the EEG, the technologist first measures the scalp to determine the sites for placing the electrodes. The sites represent a standard pattern, the most common of which is called the 10/20 system in reference to the relationships among the sites. A key of letters and numbers denote the lobe and the electrode's position. The technologist then attaches electrodes to locations on the scalp. Small dots of glue hold the electrodes in place; the glue may be difficult to remove when the EEG is over. During the EEG the person lies on a table in a quiet, darkened room while the technologist allows the EEG machine to record the electrical impulses the electrodes pick up and conduct to the machine. The technologist may use flashing or steady light to stimulate areas of the brain. A typical diagnostic EEG of the brain may take 15 to 90 minutes to complete.

The different regions of the brain generate characteristic patterns of electrical activity, measured in Hertz (Hz). EEG typically captures five types of electrical activity or brain waves:

- Alpha waves are 8 to 13 Hz, originate from the forward lobes, normally are present only when the eyes are closed, and form a moderate-amplitude symmetrical pattern.
- Beta waves are 2 to 13 Hz, originate from the back lobes, normally are present during wakefulness, and form a low-amplitude symmetrical pattern.
- Delta waves are 0 to 4 Hz, normally are present only during deep sleep, and form a high-amplitude symmetrical pattern.
- Theta waves are 4 to 8 Hz, normally are present during the transition from wakefulness to sleep, and form a moderate-amplitude erratic pattern.
- A pattern of spikes and waves is always abnormal, features erratic amplitude and cycle, and typically indicates a seizure disorder.

Risks and Complications

There are no risks or complications from EEG. There is no discomfort from attaching the electrodes or during the recording process. Sometimes removing the electrodes pulls the HAIR, and the

glue used to attach the electrodes to the scalp may be difficult to cleanse from the hair.

encephalopathy Widespread (as opposed to localized) dysfunction of the BRAIN. Encephalopathy may be short term and temporary or result from irreversible damage to the brain such as can occur with metabolic, infectious, and degenerative diseases. Symptoms of encephalopathy include

- personality changes
- mood swings
- cognitive dysfunction
- memory impairment
- slurred speech
- disorientation
- UNCONSCIOUSNESS or COMA

The diagnostic path begins with a comprehensive medical examination, discussion of PERSONAL HEALTH HISTORY, and basic NEUROLOGIC EXAMINATION. BLOOD tests to measure electrolytes, enzymes, blood composition, GLUCOSE and INSULIN levels, and HORMONE levels can provide clues as to whether there is a condition of metabolic imbalance. The doctor may conduct diagnostic imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) to visualize the structures of the brain and detect any abnormalities.

Treatment targets the underlying condition. Some forms of encephalopathy are reversible, though encephalopathy may be an end-stage circumstance in conditions such as LIVER failure or RENAL FAILURE. Encephalopathy resulting from degenerative neurologic conditions such as CREUTZFELDT-JAKOB DISEASE (CJD) is not reversible. Many people who recover from encephalopathy have no long-term residual effects. Some people may have persistent symptoms such as cognitive dysfunction or mood swings, or may develop SEIZURE DISORDERS.

Guillain-Barré syndrome A rare disorder in which the IMMUNE SYSTEM attacks the myelin sheaths of the PERIPHERAL NERVES, causing weakness or PARALYSIS, diminished reflexes, and loss of feeling. The loss of myelin strips the NERVE axons of insulation, inhibiting their ability to conduct electrical impulses. Doctors do not know what causes Guillain-Barré syndrome but believe it is a complication of bacterial or viral INFECTION. The most common association is with *Campylobacter jejuni*, which causes the foodborne illness CAMPYLOBACTERIOSIS. Other associations are with INFLUENZA, PNEUMONIA, GASTROENTERITIS, and some vaccinations.

Symptoms and Diagnostic Path

Symptoms typically are acute, beginning 7 to 10 days after the precipitating event (such as viral infection) and reaching peak severity within 14 days. Commonly, tingling and weakness, and sometimes PAIN, begin with the feet and move symmetrically up the body. The weakness may become paralysis, depending on the extent of demyelinization that takes place. Some people experience mild symptoms and others experience symptoms that result in complete paralysis including respiratory distress. Some people experience irregularities in HEART RATE, RESPIRATION RATE, BLOOD PRESSURE, and other autonomic functions. About half of people who develop Guillain-Barré syndrome have moderate to severe pain with movement.

The diagnostic path includes careful assessment of recent PERSONAL HEALTH HISTORY, notably for viral or bacterial infection, and procedures such as LUMBAR PUNCTURE, nerve conduction studies, and COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) to rule out other causes of the symptoms. Though there is no single conclusive test for Guillain-Barré syndrome, the pattern of symptoms and findings allow the neurologist to make a clinical diagnosis.

Treatment Options and Outlook

Treatment is primarily supportive though some people improve with intravenous IMMUNOGLOBULIN, which helps restore normal immune system function, or plasmapheresis, which removes antibodies from the BLOOD. Most people require hospitalization. About 30 percent of people require temporary MECHANICAL VENTILATION until function returns to the muscles that conduct breathing.

About 85 percent of people make a complete recovery, without residual effects, in six months to a year though may need PHYSICAL THERAPY and other supportive treatment to regain MUSCLE STRENGTH and function. About 10 percent of people have residual neurologic complications such as altered sensation or weakness of the hands and feet. Very rarely, paralysis persists. Guillain-Barré syndrome is fatal in about 5 percent of people, usually in those who are older (age 65 or more) or who experience very rapid progression to complete paralysis and respiratory failure.

Risk Factors and Preventive Measures

About two thirds of people recall a viral or bacterial infection within 2 to 12 weeks of their neurologic symptoms. The most significant risk for Guillain-Barré syndrome is *C. jejuni* infection (campylobacteriosis). CYTOMEGALOVIRUS (CMV), EPSTEIN-BARR VIRUS (infectious mononucleosis), and varicella-zoster virus (CHICKENPOX) are other infections commonly associated with Guillain-Barré syndrome. There are no measures known to prevent the syndrome.

Huntington's disease An inherited, degenerative disorder of structures in the BRAIN that regulate movement, mood and personality, and cognitive function and memory. Huntington's disease follows an autosomal dominant INHERITANCE PATTERN, with each child of an affected parent having a 50 percent chance of inheriting the GENE MUTATION that allows the condition to develop. The defective gene is IT-15 on CHROMOSOME 4. It causes an alteration in a protein called the Huntington protein that has a key, though poorly understood, role in maintaining the putamen and the caudate nucleus, two structures within the basal ganglia. All people have the Huntington protein; the protein's function becomes defective when the gene that regulates it is mutated. People who have the mutation for Huntington's disease will develop the disorder, generally in midlife though occasionally the disorder manifests in late ADOLESCENCE (juvenile Huntington's disease).

Symptoms and Diagnostic Path

Early symptoms of Huntington's disease are general and may not appear related. They include

- irritability
- DEPRESSION, BIPOLAR DISORDER, or anxiety
- anger and hostility
- diminished energy
- disturbances of balance and coordination
- forgetfulness
- inability to concentrate
- delusions and hallucinations

As the disease progresses the neuromuscular symptoms become more pronounced and include DYSKINESIA (notably CHOREA and ATHETOSIS) and DYSTONIA. Cognitive dysfunction also becomes prominent, and the person may no longer recognize familiar places and people. PSYCHOSIS may also increase.

The diagnostic path includes a comprehensive medical examination, detailed exploration of PERSONAL HEALTH HISTORY and FAMILY MEDICAL PEDIGREE, and NEUROLOGIC EXAMINATION. Diagnostic imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) may show changes in the brain characteristic of Huntington's disease though these changes are not conclusively diagnostic. The only certain diagnostic procedure is GENETIC TESTING, done from a sample of BLOOD, to determine whether the IT-15 gene is defective.

Treatment Options and Outlook

Huntington's disease is progressive and fatal, generally causing death 15 to 30 years after the onset of symptoms. Treatment aims to improve symptoms and QUALITY OF LIFE. Treatment may include ANTIPSYCHOTIC MEDICATIONS, ANTIDEPRESSANT MEDICATIONS, ANTIANXIETY MEDICATIONS, and BOTULINUM THERAPY to relieve dystonia. Therapeutic needs and effectiveness changes as the disease progresses. Emotional support through counseling and SUPPORT GROUPS is often helpful for the person who has Huntington's disease and for family members and caregivers. Most people who develop Huntington's disease can remain active and independent for 10 years or so after the onset of symptoms.

Risk Factors and Preventive Measures

The only risk for Huntington's disease is genetic. As yet researchers do not know how to prevent Huntington's disease from developing in those who carry the mutated gene. Genetic testing to detect the presence of the gene in people who have a family history of Huntington's disease but have no symptoms themselves is available; however, it is because there are no known treatments for the disorder. Though finding the gene is normal is a great relief, learning one carries the mutated gene is often a difficult challenge. Some people prefer to know so they can make appropriate plans and decisions, including family planning. Health experts strongly recommend GENETIC COUNSELING for people who have family history of Huntington's disease or symptoms that suggest Huntington's disease.

hydrocephaly Excessive cerebrospinal fluid within the cranium (skull). Hydrocephaly, also called hydrocephalus, may develop for numerous reasons, such as congenital BRAIN defects, TRAU-

MATIC BRAIN INJURY (TBI), meningitis, subarachnoid hemmorage, and brain tumors. Untreated or uncontrolled hydrocephaly places pressure on the structures of the brain and can displace brain tissue, causing permanent damage to the brain. In an infant whose cranium has not yet fused, hydrocephaly may cause the head to enlarge as the pressure of the excessive fluid pushes the bones outward.

Hydrocephaly occurs when the brain's ventricles produce too much CEREBROSPINAL FLUID or there is an obstruction that blocks the flow of the fluid through the ventricles and spinal canal. Diagnostic prenatal ULTRASOUND often detects hydrocephaly in an unborn child. After birth or in adults, MAGNETIC RESONANCE IMAGING (MRI) or COMPUTED TOMOGRAPHY (CT) SCAN can identify hydrocephaly, which most commonly occurs as a complication of INFECTION or blunt trauma (closed injury) to the brain. Symptoms are difficult to distinguish from those of the underlying condition, though may include severe HEADACHE, NAUSEA, and VOMITING.

Treatment for hydrocephaly is usually surgery to place a shunt in the brain ventricle to drain the excessive cerebrospinal fluid. The shunt is a small, rigid catheter that attaches to a one-way valve (to prevent cerebrospinal fluid from flowing back into the brain). The valve in turn attaches to a long, thin, flexible catheter that the surgeon channels beneath the SKIN to drain into the peritoneal cavity. The body then absorbs the fluid. Treatment also targets any underlying causes for the hydrocephaly. Usually the shunt is a permanent therapy, though may require periodic replacement. The risks of shunting are postoperative infection and deterioration of the shunt, valve, or catheter.

L

learning disorders Difficulties with cognitive functions such as analytical thinking, reading, writing, speech, listening, comprehension, and memory. Learning disorders are neurologic and arise from physical disturbances in BRAIN function. Such disturbances may be due to abnormalities in brain structure that occur during fetal development, injuries to the brain that result from oxygen deprivation during PREGNANCY or CHILDBIRTH, or TRAUMATIC BRAIN INJURY (TBI) during childhood. Frequently, however, the reason for a learning disorder remains unknown. Though social factors influence the extent to which a person who has learning disorders is able to overcome challenges, such factors do not cause learning disorders.

Symptoms and Diagnostic Path

Often the first indication of a learning disorder is a gap between a child's abilities and the abilities that are normal for the child's age. Depending on the type of disorder, this gap may become apparent early in childhood or be detected when the child starts school. Symptoms may include a child's inability to

- speak in sentences by age 3
- speak clearly enough for others to understand by age 3
- tie shoes and fasten buttons by age 5
- sit still through the reading of a short story by age 5
- read and write as expected for age or grade level

Some learning disorders also involve deficits in motor skills and physical coordination. Because the rate and nature child development varies widely, diagnosing learning disorders is often challenging. The diagnostic path may incorporate numerous approaches including neurologic, vision, hearing, and speech pathology evaluations; psychologic testing; achievement testing; and classroom observation. It may be difficult to reach a clear diagnosis; test results may be inconclusive or inconsistent. In the United States, diagnostic testing and remedial or adaptive educational services are available at no cost to families for all children from birth to age 21.

Treatment Options and Outlook

Treatment is often multidisciplinary, integrating alternate learning approaches with appropriate PHYSICAL THERAPY, speech pathology, OCCUPATIONAL THERAPY, and counseling. Treatment efforts may involve the entire family. The rate and extent of progress varies widely and depends on multiple factors. Many people learn to compensate for their learning disorders to the extent that they are able to lead normal, productive lives. For some people, learning disorders present lifelong challenge.

Risk Factors and Preventive Measures

Because learning disorders result from neurologic damage, they are very seldom preventable. Appropriate PRENATAL CARE is important to provide optimal opportunity for healthy fetal development and growth. Appropriate care during childbirth and in the immediate newborn stage is especially crucial. Some learning disorders, such as dyslexia (difficulty reading), appear to run in families, leading researchers to believe genetic components may be involved.

lumbar puncture A diagnostic procedure, colloquially called spinal tap, in which the doctor inserts a needle between the lumbar vertebrae in the lower back to withdraw CEREBROSPINAL FLUID from the spinal canal for laboratory examination. The point of entry into the spinal canal is below the end of the SPINAL CORD, so there is no risk of the needle entering the spinal cord.

Reasons for Doing This Test

Cerebrospinal fluid may contain BACTERIA, BLOOD, or alterations of its composition that may suggest or confirm numerous conditions affecting the BRAIN and spinal cord such as INFECTION, INFLAMMATION, cancer, certain brain tumors, BRAIN HEMORRHAGE, and MULTIPLE SCLEROSIS. Lumbar puncture may also return negative results that rule out such conditions. The doctor may use therapeutic lumbar puncture to administer medications, such as baclofen as treatment for severe spasticity due to cerebral palsy or other neurologic disorders, or CHEMOTHERAPY drugs for certain cancers affecting the brain or spinal cord.

Preparation, Procedure, and Recovery

There is no advance preparation for lumbar puncture. Immediately before the procedure the doctor cleanses the area where the needle will enter the spinal canal. The person may lie on his or her side with knees drawn to chest, or sit with the head on a pillow that is resting on a table. These postures bend the spine in such a way as to open the spaces between the vertebrae. The doctor administers a local anesthetic to numb the SKIN at the insertion site. The doctor measures the pressure of the cerebrospinal fluid immediately upon the needle's entry, then allows small samples of fluid, usually about three milliliters total, to drip through the needle into collection containers. The laboratory will run different tests on each sample.

Some people experience discomfort or tingling sensations when the doctor inserts the needle into the spinal canal; occasionally the needle contacts a spinal NERVE rootlet. When finished collecting fluid samples, the doctor withdraws the needle and puts a pressure bandage over the site. Some doctors recommend lying flat in bed for three to four hours after the lumbar puncture to reduce the risk for postlumbar puncture HEADACHE, though lying flat does not always prevent this common complication. The brain's ventricles continuously replenish cerebrospinal fluid, completely replacing the full volume circulating in the brain and spinal cord three to four times a day.

The entire procedure takes about 20 minutes. Some results may be available from the laboratory within a few hours, while other results may take several days to several weeks, depending on what tests the doctor requested.

Risks and Complications

The primary risk of lumbar puncture is introducing bacteria into the cerebrospinal fluid that causes infection, which occurs rarely. Some people experience bleeding after the procedure. Headache is the most common complication, affecting about one fourth of people who have lumbar puncture. The headache may be mild to severe and typically lasts 24 to 48 hours. Unfortunately PAIN-relief medications (ANALGESIC MEDICATIONS) do not usually help the headache. Tiredness and backache are also common for a day or two after the procedure.

M

memory and memory impairment The abilities to recall past events and to anticipate future events are hallmarks of the human experience and their diminishment an indication of various disorders that affect BRAIN function. Memory is the process by which the brain stores and retrieves information. Memory impairment may affect the processes of memory storage, memory retrieval, or both, and may be temporary or permanent.

Mechanisms of Memory Storage and Retrieval

The brain manages memories through multiple processes, both organic and functional, that involve numerous areas of its lobes and structures. Most researchers believe the brain stores memories in bits and fragments, which it then reassembles when recalling a specific memory. Cognitive processes (thought and analysis) and emotion significantly shape memory storage and recall, even, some experts believe, to the extent of causing memory errors and false memories. Such memory mistakes can occur when the brain blends events in the processes of storing and retrieving. Accordingly, there is much controversy among medical as well as legal professionals about the objectivity and precision of memory.

Storing memories begins with sensory or emotional NERVE impulses that travel to the brain. Different areas of the brain receive, interpret, and encode (prepare for storage) the various kinds of nerve impulses that arrive. Memory is either short-term (transient) or long-term (relatively permanent). Bridging the two is working memory, through which the brain encodes information to allow its storage in long-term memory. The extent to which a person gives attention to incoming information helps determine whether and how the information enters memory. The hippocampus, an area of the temporal lobe, is essential for forming new memories. The hippocampus also is the area of the brain responsible for emotion and emotional expression.

The mechanisms of short-term memory—information the brain retains for seconds to minutes, such as the name of the waiter taking a menu order or the amount of a purchase—appear to create only temporary shifts in neuronal connections. The information has transient (and often time-limited) value so the brain gives it transient attention. The mechanisms of long-term memory—memory of events and people from days to decades ago—create permanent changes in the neuronal pathways among cells in the regions of the brain that participate in memory storage and retrieval. Once formed, these pathways appear to remain intact and fully functional even when there is no retrieval for extended periods of the memories they connect.

Researchers categorize long-term memory as either explicit (also called declarative) or implicit (also called nondeclarative or procedural). Explicit memory requires conscious attention to recall information, such as when taking a test or telling the story of a childhood event. Explicit memory appears to involve primarily the frontal, temporal, and parietal lobes of the cerebral cortex. Implicit memory contains information the brain retrieves and acts on automatically, without conscious attention. Riding a bicycle, playing a musical instrument, driving a car, and throwing a ball are common functions of implicit memory. Implicit memory involves primarily the prefrontal cerebral cortex and the cerebellum, which coordinate voluntary MUSCLE activity, and the amygdala, a small almond-shaped structure in front of the hippocampus that governs fear and fear response.

The amygdala also appears to be where face recognition, in conjunction with emotional associations such as love or fear, takes place.

Memory retrieval requires activating, or stimulating, the neuronal pathways that connect the stored information. This involves interactions among neurotransmitters, hormones, and electrical impulses, though precisely how these interactions happen remains a mystery. Some memory retrieval occurs in response to external cues and stimuli, such as responding to questions or seeing a familiar face. Implicit memory retrieval appears activated by exposure to a circumstance, for example getting on a bicycle or behind the wheel of a car. Explicit memories are more complex. Those with strong emotional connections seem more rapidly and vividly recalled.

Causes of Memory Impairment

Everyone experiences occasional forgetfulness, most commonly with respect to recent information. Such forgetfulness may range from the names of newly introduced people to where the car keys are or the driving route to give a coworker a ride home. Many researchers believe such forgetfulness represents an incompletion in the brain's processes for establishing neuronal pathways. Only when information becomes repetitious does the brain create connections among neurons to accommodate it. The more frequently a person encounters the same information (such as a person's name), the more complete the neuronal connections among the various regions of the brain that store the information. Forgetfulness may also represent the brain's efforts to "clean house" and maintain efficiency by purging unused or extraneous information.

Memory impairment occurs when the brain cannot establish new neuronal pathways to store new memories or use existing neuronal pathways to retrieve memories already stored. A person experiencing memory impairment may be unable to remember the names of close family members or how to drive home from the store. Though memory and cognition (thought and reason) are distinct functions within the brain, neither is especially effective without the other. Correspondingly, cognitive dysfunction and memory impairment often occur together. Because researchers do not fully understand the mechanisms of memory, they do not fully understand how memory impairment occurs.

The quality of memory, particularly short-term memory, normally diminishes somewhat with advanced age (age 70 and beyond). Though forgetfulness tends to become more common as people get older, significant memory impairment is *not* an inherent dimension of aging. Much age-associated memory impairment results from conditions that occur with aging. ATHEROSCLEROSIS, in which plaque deposits accumulate in the walls of the arteries to narrow the passageways for BLOOD, is among the leading causes of impaired memory in older adults. Neurologic disorders that affect memory, such as ALZHEIMER'S DISEASE and DEMENTIA, almost exclusively occur in people over age 60.

Circumstances that can affect memory in people of any age include BRAIN TUMOR, INFECTION such as ENCEPHALITIS or MENINGITIS, systemic neurologic conditions such as MULTIPLE SCLEROSIS, and disorders that alter the body's chemical balance such as LIVER disease or untreated metabolic disorders. Memory impairment may be transitory (come and go, such as with a TRANSIENT ISCHEMIC ATTACK [TIA]), may return when treatment resolves the underlying cause (such as when the brain heals after an infection or surgery), or may be permanent (which occurs when there is tissue damage or loss in areas of the brain that perform functions of memory, such as often occurs with STROKE or TRAUMATIC BRAIN INJURY [TBI]).

Amnesia and *memory loss* are common terms for disturbances of memory. Amnesia is the inability to recall past information or to remember information relevant to the future, such as appointments. Amnesia may result from the inability to

retrieve existing memories or to store new memories, and may be temporary (such as following CONCUSSION) or permanent. Memory loss is an imprecise term that usually refers to the permanent inability to retrieve information from long-term memory.

Symptoms and Diagnostic Path

It is normal for people to forget recent information such as where they placed the car keys or phone numbers they use infrequently. Forgetfulness crosses the line to memory impairment when a person cannot remember information essential for daily activities, such as familiar faces and names or where he or she lives. The diagnostic path includes a comprehensive medical examination, neurologic examination, and imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN to identify possible organic causes within the brain. Functional magnetic resonance imaging (fMRI), a dynamic variation of MAGNETIC RESONANCE IMAGING (MRI) that shows the functional activity of the brain, may show areas of diminished activity during memory tasks. Memory and cognitive tests help identify the kinds of memory affected and define remaining memory functions.

Treatment Options and Outlook

Treatment for memory impairment depends on the underlying cause. Memory functions lost due to injury or infection such as encephalitis often return as the brain heals. The return commonly takes place in fragments, often with older memories (such as from childhood) emerging first. Memory impairment due to conditions such as stroke or Alzheimer's disease is generally permanent. Medications such as the acetylcholinesterase inhibitors doctors prescribe to treat Alzheimer's disease improve memory and cognition in many people in the early to middle stages of the condition though do not appear especially effective in treating memory impairment resulting from other causes. Permanent memory impairment may also be progressive, as occurs with degenerative conditions such as Alzheimer's disease and PARKINSON'S DISEASE.

Exercising memory and cognition, such as with crossword puzzles and other activities that require storage and recall of information, helps keep these abilities as functional as possible in healthy aging as well as when health conditions exist that have the potential to impair memory. Memory specialists can help individuals develop methods and approaches to maintain optimal memory capability as well as to accommodate memory impairment. The herbal products GINKGO BILOBA and GINSENG may improve circulation to the brain, resulting in overall improvement of memory and cognitive functions.

Risk Factors and Preventive Measures

Diseases, systemic and neurologic, and injuries to the brain are the primary risk factors for memory impairment. To a great extent, injuries to the brain that might result in impaired memory are preventable through safety measures, such as wearing appropriate protective headgear and avoiding activities with a high risk for head injury. Lifestyle factors influence some conditions that can cause memory impairment, such as HEART ATTACK and stroke. Chronic ALCOHOLISM contributes to episodic as well as progressive memory loss. Family history may be a risk factor for neurologic conditions such as Alzheimer's disease and dementia, for which there are no known measures of prevention.

meninges The connective tissue membranes that enclose and protect the BRAIN and SPINAL CORD (collectively called the CENTRAL NERVOUS SYSTEM). There are three meninges:

- The dura mater is the tough, outermost meninx. It has two layers, a fibrous outer layer that attaches to the inside of the cranium (skull bones) and a soft inner layer that contains an extensive network of BLOOD vessels. The dura mater sometimes folds back on itself (dural reflections) or its layers separate to form pockets (dural sinuses).
- The arachnoid mater is the middle meninx.
- The innermost meninx is the pia mater, a tissue-like membrane that covers the surface of the brain.

CEREBROSPINAL FLUID circulates between the arachnoid mater and the pia mater, in an envelope-like pocket called the subarachnoid space.

DURA MATER GRAFTS AND CJD

For several decades neurosurgeons have used grafts of dura mater acquired from cadaver donors to replace dura mater removed during neurosurgery or in circumstances of extensive injury to the BRAIN. In the late 1990s researchers traced several cases of CREUTZFELDT-JAKOB DISEASE (CJD) to the grafts, which had been harvested from individuals who turned out to have CJD. US Food and Drug Administration (FDA) regulations now establish strict criteria for the harvesting and processing of dura mater grafts to reduce the risk of transmitting infectious conditions such as CJD.

For further discussion of the meninges within the context of the structures and functions of the NERVOUS SYSTEM, please see the overview section "The Nervous System."

multiple sclerosis A chronic, progressive demyelinating disorder that affects the CENTRAL NERVOUS SYSTEM (BRAIN and SPINAL CORD) and the CRANIAL NERVES, notably the optic nerves. Though the cause of multiple sclerosis remains unknown, most researchers believe the condition is an autoimmune disorders in which the body's IMMUNE RESPONSE attacks myelin, the fatty substance that coats nerves. The areas under attack become inflamed and separate from the nerves, and as they heal scars form. Over time the SCAR tissue damages the nerves and disrupts the passage of electrical impulses. The progression of demyelination is generally slow, occurring over several decades. There is wide variation in the severity of multiple sclerosis among individuals. Some people experience few symptoms and negligible interference with their regular activities and other people lose control of muscles and mobility.

Symptoms and Diagnostic Path

One of the earliest signs of multiple sclerosis is RETROBULBAR NEURITIS, an INFLAMMATION of the OPTIC NERVE (second cranial NERVE) that impairs vision. Indications of retrobulbar neuritis include DIPLOPIA (double vision), blurred vision, impaired color vision and scotomas (blind spots in the field of vision). Other symptoms are neurologic and include

- weakness and lack of coordination in the arm or leg on one side of the body
- gait disturbances such as stumbling
- transient PARESTHESIA (tingling or numbness that comes and goes without apparent cause) on one side of the body
- intermittent loss of BLADDER control (URINARY INCONTINENCE)
- emotional lability
- VERTIGO and dizziness
- fatigue
- SEXUAL DYSFUNCTION (notably ERECTILE DYSFUNCTION in men)

Because symptoms are typically transient they often occur over a number of years before a person seeks medical attention for them. The diagnosis is primarily one of exclusion so the diagnostic path includes a general medical examination, BLOOD tests, NEUROLOGIC EXAMINATION, LUMBAR PUNCTURE, and imaging procedures such as MAGNETIC RESONANCE IMAGING (MRI) of the brain to rule out other potential causes, such as BRAIN TUMOR, of symptoms. Imaging procedures, especially MRI, also may show the lesions (scarring) that characterize multiple sclerosis. However, there is no conclusive diagnostic test for multiple sclerosis and a person may seek medical care for a number of years before doctors feel confident making the diagnosis.

Heat often worsens the symptoms of multiple sclerosis. For this reason, doctors advise against hot tubs, saunas, exposure to hot weather, and hot showers or baths.

Treatment Options and Outlook

For most people the course of multiple sclerosis is one of alternating relapse and REMISSION, without predictability for the frequency or duration of either. Treatment depends on the severity and frequency of symptoms. People who have mild

MEDICATIONS TO TREAT MULTIPLE SCLEROSIS

Drug or Medication	Course of Action	Concerns/Side Effects
interferon beta 1a (Rebif) interferon beta 1b (Betaseron)	genetically engineered proteins that direct IMMUNE SYSTEM responses against viruses enhances natural immune function	may cause development of antibodies NAUSEA, VOMITING, MUSCLE aches (flu-like symptoms) requires weekly intramuscular injections
glatiramer (Copaxone)	block IMMUNE RESPONSE from attacking myelin alternative to beta INTERFERONS	flushing, shortness of breath requires daily subcutaneous injection
corticosteroids (prednisone, prednisolone, dexamethasone)	suppress immune response reduce INFLAMMATION	HYPERTENSION OSTEOPOROSIS increased risk for INFECTION
selective serotonin reuptake inhibitor (SSRI) antidepressants (fluoxetine, sertraline, venlafaxine, parocetine)	stabilize emotions reduce DEPRESSION	drowsiness, dry MOUTH, sexual side effects interactions with other medications cannot take with tricyclic antidepressants
tricyclic antidepressants (amitriptyline, nortriptyline, imipramine, doxepin)	reduce PAIN reduce DEPRESSION	drowsiness, dry mouth, sexual side effects interactions with other medications cannot take with SSRI antidepressants
muscle relaxants (baclofen, tizanidine, diazepam, clonazepam)	reduce muscle spasms	drowsiness muscle weakness
BOTULINUM THERAPY	spasticity that does not respond to other treatment temporarily paralyzes muscles into which it is injected	may cause weakness in injected muscles
ANTIVIRAL MEDICATIONS (acyclovir, Famvir, valacyclovir, amantadine)	improve immune system response to viruses	may slow attacks
modafinil	reduce drowsiness	HEADACHE difficulty sleeping
ANALGESIC MEDICATIONS (acetaminophen, NONSTEROIDAL ANTI-INFLAMMATORY DRUGS [NSAIDS])	relieve pain reduce inflammation	STOMACH irritation (NSAIDS)
mitoxantrone (Novantrone)	CHEMOTHERAPY agent slows attacks on myelin extends periods of remission	intravenous injection every three months for up to three years nausea, vomiting muscle aches may increase risk for cardiovascular disease

episodes of symptoms with extended period of remission, treatment may consist of watchful waiting and approaches to relieve symptoms that become troublesome. People who have moderate to severe episodes of symptoms with short periods of remission may improve with medications specifically for multiple sclerosis. Because these medications have significant side effects, cannot reverse neurologic damage that has already occurred, or halt the progression of multiple sclerosis, doctors reserve their use for people whose symptoms are debilitating. Other medications can suppress the body's immune response, helping slow the attacks.

Lifestyle factors such as nutritious EATING HABITS and daily physical activity help maintain motor functions and coordination. WEIGHT LOSS AND WEIGHT MANAGEMENT are essential for people who have multiple sclerosis, as maintaining appropriate body weight reduces the workload of the muscles. Regular physical exercise also helps to counter DEPRESSION. Most people are able to continue with physical activities they enjoyed before developing multiple sclerosis. Because heat exacerbates symptoms, people who live in warmer climates may want to use the cooler early morning or late evening hours for physical activities outdoors, and use indoor air-conditioned facilities at other times. Swimming provides good aerobic conditioning as well as the opportunity to strengthen weakened muscles in an environment of reduced resistance.

Though it is progressive, multiple sclerosis generally does not cause death or shorten life expectancy. Most people who have multiple sclerosis are able to participate in the work and leisure activities they enjoy when the condition is in remission, and periods of remission may last 10 years or longer. People who have more aggressive forms of multiple sclerosis may progress to assisted mobility within a shorter period of time than people who have the more classic, slowly progressive forms of the condition.

Risk Factors and Preventive Measures

Multiple sclerosis affects twice as many women as men and most commonly makes its first appearance between the ages of 20 and 40 years. It is likely that external environment (such as climate) and genetics both influence the development of multiple sclerosis, as the condition is far less common in tropical regions of the world and more likely to occur when other family members have the condition. However, researchers do not fully understand the connections among these factors. Some researchers believe there may also be involvement of an as yet undetected VIRUS. There are no known measures for preventing multiple sclerosis.

myoclonus Involuntary and episodic contractions, twitching, or spasms of MUSCLE groups. Harmless manifestations of myoclonus include brief HICCUPS or the rapid jerking people may experience when falling asleep (sometimes called sleep starts). Myoclonus also may be a symptom of injury to motor neurons, to the NERVE cells in the SPINAL CORD that direct voluntary movement, or to parts of the BRAIN that participate in movement. Myoclonus occurs as rapid, jolt-like episodes and may take various forms that include the following:

- Action myoclonus occurs or intensifies during attempts at voluntary movement, such as walking or eating. It most commonly develops after circumstances of extended oxygen deprivation to the brain (HYPOXIA), such as may occur with STROKE, HEART ATTACK, or near drowning.
- Essential myoclonus is not associated with any detectable neurologic injury or dysfunction to account for the symptoms.
- Stimulus-sensitive myoclonus occurs as an apparent HYPERSENSITIVITY REACTION (neurologic) to external stimuli, such as sounds and lights.
- Sleep myoclonus occurs when sleep starts become excessive and disruptive to sleep. Some neurologists believe sleep myoclonus is a form of stimulus-sensitive myoclonus in which the person may or may not recognize the external stimuli that trigger the myoclonic episodes.
- Cortical reflex myoclonus, reticular reflex myoclonus, and progressive myoclonus epilepsy, are SEIZURE DISORDERS that include myoclonus among their symptoms.

- Palatal myoclonus occurs when the muscles of the soft palate at the back of the MOUTH contract rapidly and rhythmically though usually without disrupting the ability to swallow or speak.

The pattern and consistency of the myoclonic episodes help the neurologist determine the underlying cause or location of the neurologic injury (sometimes called a LESION). The diagnostic path typically includes a comprehensive NEUROLOGIC EXAMINATION and imaging procedures such as MAGNETIC RESONANCE IMAGING (MRI) or COMPUTED TOMOGRAPHY (CT) SCAN to locate or rule out neurologic damage. The neurologist may also conduct an electromyogram (EMG) to assess the activity of the affected muscle groups. Treatment aims to reduce the symptoms and typically includes combinations of muscle relaxants and antiseizure medications. Finding a therapeutically effective balance of medications is often a trial-and-error process. Most people who have myoclonus require lifelong treatment.

narcolepsy A sleep disorder in which a person feels chronically tired and sleep deprived, and may experience uncontrollable episodes of falling asleep during the day. People who have narcolepsy have disturbed sleep patterns while falling asleep, often experiencing premature sleep PARALYSIS (an inability to move which normally occurs in rapid eye movement [REM] sleep as a protective mechanism to keep the body from enacting dreams), hypnagogic hallucinations (inability to distinguish between dreamlike images and reality when falling asleep), and daytime cataplexy (sudden, brief episodes of MUSCLE weakness or inability to move). As well, the person experiences abnormal and very short REM sleep periods (detected through diagnostic sleep studies) that prevent restful sleep. Researchers believe narcolepsy is far more common than diagnosis data suggest because many people do not seek medical evaluation or treatment.

The diagnostic path includes a general medical examination and basic NEUROLOGIC EXAMINATION to evaluate overall health and neurologic function. Diagnostic sleep studies reveal the characteristic traits of narcolepsy, distinguishing the disorder from other SLEEP DISORDERS. Treatment is a combination of medications that may include

- AMPHETAMINES (STIMULANTS) to diminish daytime sleepiness
- modafinil, a nonamphetamine DRUG that targets different BRAIN functions from amphetamines to improve daytime alertness
- sleep medications such as flurazepam and other benzodiazepine drugs to encourage relaxation when falling asleep
- tricyclic antidepressants such as imipramine and desipramine to improve REM sleep

Some people also benefit from scheduled short naps throughout the day, which may provide restful sleep as well as decrease feelings of sleepiness. Researchers do not know what causes narcolepsy, though there is some evidence that it may be an AUTOIMMUNE disorder because there seems to be involvement of HUMAN LEUKOCYTE ANTIGENS (HLAS), which are fundamental to the IMMUNE RESPONSE. There is also some evidence that people who have narcolepsy have reduced levels of a neuroprotein called hypocretin. However, researchers do not know what these correlations mean or how they cause narcolepsy. Narcolepsy is a lifelong condition.

nerve An organization of connected neurons that conducts electrical impulses, typically forming the structure of a fiber. The nerve fibers may be microscopic, such as the nerves that carry impulses from the fingertips to the BRAIN, or clearly visible to the EYE, such as the SPINAL CORD. The PERIPHERAL NERVES originate in the brain, brainstem, and SPINAL CORD and extend to their destinations in the body. A cluster or mass of nerves located outside the CENTRAL NERVOUS SYSTEM (brain and spinal cord) is a ganglion.

For further discussion of nerves within the context of the structures and functions of the nervous system, please see the overview section "The Nervous System."

nervous system The BRAIN and network of nerves that convey electrical impulses to and from

all structures in the body. The two major divisions of the nervous system are the CENTRAL NERVOUS SYSTEM and the PERIPHERAL NERVOUS SYSTEM. The central nervous system consists of the brain and SPINAL CORD. The peripheral nervous system consists of all other NERVE structures, including the CRANIAL NERVES, the SPINAL NERVES, and the PERIPHERAL NERVES.

neuralgia PAIN that occurs along a DERMATOME (the tract of a NERVE). Neuralgia is often severe, sharp, and brief (each episode lasting 15 seconds or less) though repetitive. The most common causes of neuralgia are INFECTION (notably HERPES ZOSTER, also called postherpetic neuralgia) and compression (a "pinched" nerve). DIABETES, untreated (tertiary) SYPHILIS, MULTIPLE SCLEROSIS, and PORPHYRIA are among the health conditions that can cause neuralgia. Exposure to toxins, notably heavy metals such as arsenic and lead, may cause certain forms of neuralgia. Often, however, the doctor cannot identify the cause of neuralgia. Neuralgia may affect any dermatome in the body. Those most often affected are the CRANIAL NERVES that serve the face and head (especially the glossopharyngeal, trigeminal, facial, and occipital), the intercostal nerves (ribs), and the posterior tibial nerve (ankle and foot).

Symptoms and Diagnostic Path

Neuralgia typically begins with sudden, sharp pain along the affected dermatome. The attacks may be momentarily disabling and last 10 to 15 seconds. However, a person may experience dozens of sequential attacks in episodes, with periods of REMISSION during which there is no pain. The pain is

- always in the same location
- near the surface rather than deep in the body
- often intense and intermittent, though sometimes continuous

Sometimes touching a particular area on the SKIN or actions, such as chewing trigger, attacks of pain. The diagnostic path includes a NEUROLOGIC EXAMINATION and often electromyogram (EMG) to assess the function of the nerves in the affected area. The neurologist may conduct diagnostic imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) to determine whether there is compression of the affected nerve, such as from a tumor, or to rule out other possible causes of the pain.

Treatment Options and Outlook

Treatment targets the cause when known, such as PHYSICAL THERAPY or surgery to relieve compression against a nerve, removal from exposure to potential toxins, or ANTIVIRAL MEDICATIONS for postherpetic neuralgia. Tricyclic antidepressants are particularly effective for relieving the pain of trigeminal neuralgia. Other medications to relieve pain include nonnarcotic and narcotic oral ANALGESIC MEDICATIONS, topical analgesics such as capsaicin, certain antiseizure medications, topical lidocaine patches, corticosteroid/lidocaine injections as neural blockades (nerve blocks) and TRIGGER-POINT INJECTION. These and other treatments can provide relief from the symptoms of neuralgia for most people. Taking medications, even narcotic analgesics, on a regular schedule is usually more effective than waiting until pain occurs or becomes intolerable. ACUPUNCTURE and BIOFEEDBACK are also effective for some people.

Postherpetic neuralgia generally improves and often resolves (goes away) within 2 to 12 months as the underlying damage to the involved dermatome heals. Neuralgia due to other causes may persist, particularly if the cause is chronic (such as diabetes or MULTIPLE SCLEROSIS). When medications and other therapies cannot control the pain (intractable neuralgia), the neurologist or pain specialist may recommend RHIZOTOMY, a surgical OPERATION to cut the nerve rootlets responsible for conducting the pain impulses. Such intervention usually, though not always, ends the pain though may also alter sensory perception along the dermatome.

Risk Factors and Preventive Measures

Age is the most significant risk factor for neuralgia, particularly postherpetic neuralgia. Reduced immune function, especially in people who have HIV/AIDS or take IMMUNOSUPPRESSIVE THERAPY such as

after ORGAN TRANSPLANTATION, allows the dormant varicella-zoster VIRUS to emerge and cause shingles. Injuries to the nerves, such as repetitious motion and compression injuries, also become more common with advancing age.

Antiviral medications, such as acyclovir or famciclovir, taken within 72 hours of the onset of herpes zoster symptoms may be effective in preventing postherpetic neuralgia. Without antiviral therapy, about 20 percent of people who develop herpes zoster infection subsequently develop postherpetic neuralgia. The extent to which antiviral therapy for the herpes zoster affects the likelihood of developing postherpetic neuralgia remains unknown. Other preventive measures include prompt treatment of NEURITIS (INFLAMMATION of a nerve), appropriate intake of vitamin B_{12} (which is vital for proper nerve function), and avoidance of toxins that can damage the nerves.

neuritis INFLAMMATION of a NERVE. Neuritis is usually an indication of an underlying injury or disease process such as irritation, compression, or INFECTION of the involved nerve. The most common symptom is PARESTHESIA (tingling) though some people may experience PAIN (NEURALGIA) or numbness. The diagnostic path is primarily clinical, based on the person's symptoms and a NEUROLOGIC EXAMINATION. PAPILLITIS and RETROBULBAR NEURITIS, inflammations involving different parts of the OPTIC NERVE, can result in vision loss. Retrobulbar neuritis can be an early sign of MULTIPLE SCLEROSIS. Treatment targets the underlying cause and may include anti-inflammatory medications or ANTIBIOTIC MEDICATIONS; when the cause is compression due to an entrapment syndrome (such as CARPAL TUNNEL SYNDROME), surgery may be necessary to relieve the compression.

neurofibromatosis A genetic disorder in which tumors (neurofibromas) form within the tissues and structures of the NERVOUS SYSTEM. There are two primary forms of neurofibromatosis, both of which occur in an autosomal dominant INHERITANCE PATTERN. The tumors, notably those that involve the SKIN, are initially benign (noncancerous) though have a high risk for turning cancerous. Neurofibromatosis type 1 (NF-1) is the more common form; it generates dozens of tiny tumors. Neurofibromatosis type 2 (NF-2) primarily involves the SPINAL CORD and eighth cranial NERVE (vestibulocochlear nerve). Both forms of neurofibromatosis may also involve the BONE, skin, MUSCLE, and connective tissue as well as the BRAIN and the visceral organs.

The earliest sign of neurofibromatosis is often lightly colored patches of skin (café au lait macules). Many people who have NF-1 develop numerous small growths that look like moles (nevi). However, it is possible to press these tumors below the surface of the skin as though turning them into themselves (called a buttonhole effect), whereas moles and similar growths are firm and remain above the skin's surface when pressed. Tumors of NF-2 that arise in the spinal cord may cause deformity of the spine and SCOLIOSIS.

Because the neurofibromas often develop within the tissues of the brain, other symptoms may include seizures, intellectual impairment, and disturbances of motor function. Other symptoms depend on the locations of the tumors. The diagnostic path includes a comprehensive FAMILY MEDICAL HISTORY; immediate family members who have similar symptoms or a diagnosis of neurofibromatosis make the diagnosis fairly conclusive. A NEUROLOGIC EXAMINATION and imaging procedures such as MAGNETIC RESONANCE IMAGING (MRI) and COMPUTED TOMOGRAPHY (CT) SCAN of the brain may reveal tumors.

The preferred treatment is surgery to remove the tumors whenever practical, and close monitoring of tumors that the surgeon cannot remove to assess any changes that could indicate developing malignancies. Unfortunately the tumors tend to recur. Left untreated, however, the tumors often cause deformity of the tissues and structures in which they are growing. As well, the risk for malignancy is very high. Health experts strongly recommend GENETIC COUNSELING for people diagnosed with neurofibromatosis.

neurologic examination A series of basic diagnostic procedures that help the neurologist assess an individual's neurologic status. A fundamental dimension of the neurologic examination is observation, through which the neurologist can gain much information about a person's mental status (cognition and memory), motor function (balance, coordination, STRENGTH), and sensory perception (touch, vision, hearing). Specific procedures include testing the reflexes, response to specific sensory stimuli (soft touch, PAIN, vibration, particular smells or tastes), and the ability to carry out directed movements (such as tracking the movement of an object or touching specific body locations). The neurologist generally performs basic tests of VISUAL ACUITY and field of vision, hearing, and examination of the inner EYE.

Basic assessment of cognitive function and memory may include reading, spelling, and drawing activities. Tasks such as unbuttoning and buttoning, writing one's signature, and handling small objects test dexterity and fine motor movement. The ways in which a person stands, walks, and rises from and lowers to sitting and prone positions help the neurologist further assess MUSCLE strength, coordination, and PROPRIOCEPTION (awareness of the body's position relative to its environment). The neurologist may conduct other evaluations and procedures, including more extensive cognitive testing, depending on basic findings. A basic neurologic examination may take about 20 minutes for the neurologist to complete.

neuron A NERVE cell. A neuron consists of a cell body, nucleus containing the cell's DNA, cytoplasm, organelles (structures within the cytoplasm that conduct functions such as energy production), axons (fibers that carry nerve impulses away from the neuron), and dendrites (rootlike structures that receive the nerve impulses). A myelin sheath (coating of myelin, a fatty substance) may enclose a neuron's axon, insulating it to maintain the integrity of the nerve impulses the axon carries. Dendrites do not have myelin sheaths. An axon may extend several inches to several feet, while dendrites remain close to the neuron's cell body. Axons and dendrites extend into spaces around the neurons called synaptic corridors. The end of the axon branches into numerous extensions called presynaptic terminals. The gap between an axon of one neuron and the dendrites of another neuron is a synapse.

Neurons communicate (conduct nerve impulses) through an electrochemical process called action potential, an exchange of electrically charged particles (ions) across the cell's membrane. A neuron at rest contains a negative charge within its membrane though the environment outside the cell membrane carries a positive charge. A nerve impulse creates a surge or spike of electrical energy that causes ion channels in the cell membrane to open. At the same time the neuron releases a chemical messenger, a NEUROTRANSMITTER.

The neurotransmitter binds with the appropriate NEURORECEPTOR on the dendrites of the neuron intended to receive the nerve impulse. The type of neuron—for example, motor or sensory—determines which neurotransmitters and neuroreceptors are present. As the neuron's polarity changes (the neuron achieves action potential), the electrical impulse moves to the neuron. The process takes only a minuscule fraction of a second to complete. An enzyme then initiates reuptake (recycling) of the neurotransmitter, setting the stage for the next cycle. Neurons align in neuronal pathways that facilitate the conduction of nerve impulses for optimal efficiency.

Neurons are the oldest cells in the body. Most develop in the early to middle stages of gestation, with the final surge of neuron production taking place shortly before birth. The body's full complement of neurons is present at birth, the majority of which survive and function for the course of a full lifetime. The body cannot replace neurons that die, and neurons do die at a fairly consistent rate, barring injury or disease, of about one per day throughout life.

See also CELL STRUCTURE AND FUNCTION.

neuropathy Dysfunction of or damage to the PERIPHERAL NERVES. Neuropathy may be temporary or permanent and may result from numerous causes, such as INFECTION, compression, degenerative disease processes, and AUTOIMMUNE DISORDERS. Neuropathy may involve only a single peripheral

NERVE (as in compression) or multiple peripheral nerves, either in a pattern (as in RAYNAUD'S SYNDROME or shingles) or diffusely throughout the body (as in neuropathy of DIABETES). Neurologists classify the more than 100 forms of neuropathy into broad categories according to the type of nerve affected—motor, sensory, mixed, and autonomic.

The symptoms of neuropathy vary widely with the nerves affected and extent of the condition causing the neuropathy. PAIN, MUSCLE weakness or loss of muscle function, disturbances of sensory perception, and dysfunction of autonomic processes such as digestion are among the myriad symptoms that can occur with neuropathy. The diagnostic path typically seeks to identify the underlying cause of the damage, which then becomes the target for treatment methods. Some neuropathies resolve (go away) with appropriate treatment, though often there is some residual damage as the nerves are delicate and the body cannot replace neurons that die.

Because pain is a common symptom of neuropathy, treatment often includes medications such as analgesics, tricyclic antidepressants, certain antiseizure medications, injected anesthetics and corticosteroids, and topical anesthetics or analgesics (lidocaine or capsaicin). Surgery may be appropriate to relieve compression against a nerve or to sever the nerve when other treatments fail to relieve incapacitating pain. Noninvasive approaches to pain management that are sometimes effective include BIOFEEDBACK and ACUPUNCTURE.

neuroreceptor A molecular structure on the surface of a cell membrane that accepts (binds with) a NEUROTRANSMITTER (chemical messenger). Nearly always a neuroreceptor is specific for only one neurotransmitter. The common analogy is that a neuroreceptor functions like a lock and a neurotransmitter functions like a key; only the correct key can open the lock. Neuroreceptors tend to align along the cell membrane such that they match across cells, facilitating communication between cells. Most cells contain numerous and different neuroreceptors. Drugs may also bind with neuroreceptors, causing an effect (partial or complete) that emulates that of the matching neurotransmitter (agonist) or that blocks the neuroreceptor from accepting the neurotransmitter (antagonist). Some neuroreceptors have multiple binding sites that accept different chemicals (such as neurotransmitters, drugs, and ions).

For further discussion of neuroreceptors within the context of the structures and functions of the nervous system, please see the overview section "The Nervous System."

neurotransmitter A chemical that facilitates the passage of NERVE impulses among neurons. A neurotransmitter may allow or block the travel of a nerve impulse. Neurons store the chemical components of their neurotransmitters in microscopic structures called the synaptic vesicles, synthesizing the appropriate neurotransmitter when conducting a nerve impulse. The sending NEURON's axon releases the neurotransmitter into the synapse (space between neurons). The neurotransmitter crosses the synapse to bind with the appropriate NEURORECEPTOR on the dendrites of the receiving

neuron. Hormones may also function as neurotransmitters.

The appropriate balance of neurotransmitters is essential for neurologic function, as some neurotransmitters are excitory (allow nerve impulses to move from one neuron to another) and others are inhibitory (block nerve impulses). Neurotransmitters have specific functions. The BLOOD–BRAIN BARRIER allows the NERVOUS SYSTEM to maintain different levels of neurotransmitters in the BRAIN and in the body. Acetylcholine, for example, is essential in the brain for functions of cognition and memory. A diminished level of acetylcholine in the brain is among the hallmark characteristics of ALZHEIMER'S DISEASE. DOPAMINE is critical for movement; PARKINSON'S DISEASE develops when the cells in the brain that produce dopamine die. Dopamine also facilitates nerve impulses that activate the brain's pleasure centers. Monoamine oxidase (MAO), serotonin, and NOREPINEPHRINE are key to mood. ANTIDEPRESSANT MEDICATIONS act by altering the balance of these three chemicals in the brain. In the body, acetylcholine conducts electrical impulses between neurons and MUSCLE cells to facilitate movement. EPINEPHRINE and norepinephrine conduct electrical impulses in the HEART.

For further discussion of neurotransmitters within the context of the structures and functions of the nervous system, please see the overview section, "The Nervous System."

organic brain syndrome A collective term for disorders of cognition (thought and logic) and memory that arise from physical changes that take place in the BRAIN. Numerous neurologic and metabolic disorders can cause organic brain syndrome, as can head trauma and INFECTION, such as ENCEPHALITIS. Organic brain syndrome sometimes becomes an ambiguous diagnosis when there are few distinct or apparent causes to explain mental deterioration in people who are elderly. However, the physical changes that occur in the brain to produce organic brain syndrome are more common in old age though are not inevitable aspects of aging.

COMMON DISORDERS ASSOCIATED WITH ORGANIC BRAIN SYNDROME

ALZHEIMER'S DISEASE	DEMENTIA
ENCEPHALITIS	HEART ATTACK
hepatic NEUROPATHY	HUNTINGTON'S DISEASE
HYDROCEPHALY	HYPOXIA
long-term ALCOHOLISM	MENINGITIS
PARKINSON'S DISEASE	SEPTICEMIA
STROKE	substance abuse
TRANSIENT ISCHEMIC ATTACK (TIA)	TRAUMATIC BRAIN INJURY (TBI)

Symptoms and Diagnostic Path

The presentation and severity of symptoms varies with the underlying condition and other health factors. Symptoms extend over time and often worsen with time. Key symptoms include

- confusion, disorientation, and DELIRIUM
- difficulty carrying out tasks that require thought, logic, and reasoning such as shopping or traveling to and from home
- diminished ability to interact with others in social settings
- diminished ability to independently carry out activities of daily living such as bathing, dressing, and preparing meals
- lapses of memory, especially inability to remember recent events

The diagnostic path begins with a ROUTINE MEDICAL EXAMINATION to assess health overall and a NEUROLOGIC EXAMINATION to evaluate brain function and cognitive abilities. Because symptoms can result from electrolyte imbalance, HORMONE disturbances, high or low BLOOD GLUCOSE (sugar) levels, and other factors, the routine medical examination typically includes a complete blood count (CBC) and other blood tests. The doctor may also conduct a basic cardiovascular evaluation, including ELECTROCARDIOGRAM (ECG) and measurement of BLOOD PRESSURE. A number of health conditions that can cause cognitive disturbances become more common with advanced age, some of which are easily treatable such as HYPOTHYROIDISM, HYPERTENSION, ADRENAL INSUFFICIENCY, and cardiac ARRHYTHMIA. The doctor may also conduct diagnostic imaging procedures such as COMPUTED TOMOGRA-

PHY (CT) SCAN OR MAGNETIC RESONANCE IMAGING (MRI) to evaluate the brain and its blood flow.

Treatment Options and Outlook

Treatment targets the underlying condition when appropriate and otherwise focuses on maintaining QUALITY OF LIFE. Recent research shows that daily physical activity such as walking may slow the progression of disorders such as ALZHEIMER'S DISEASE and other degenerative disorders that produce organic brain syndrome symptoms. Adequate nutrition is also essential. Medications such as antidepressants and antipsychotics may help moderate behaviors and improve the person's sense of well-being. Medications to treat Alzheimer's disease, called acetylcholinesterase inhibitors, may improve cognitive ability or at least delay the progression of its decline. Because organic brain syndrome tends to be progressive, family members need to plan for ongoing care and support.

Risk Factors and Preventive Measures

Organic brain syndrome is most common among people 70 years of age and older because many of the conditions that produce the symptoms of organic brain syndrome become more common with advanced age. Mitigating the risk factors for these conditions, which range from CARDIOVASCULAR DISEASE (CVD) to DIABETES to chronic LIVER disease, reduces the likelihood for developing cognitive impairments due to physical changes in the brain. Lifestyle measures such as nutritious EATING HABITS, daily physical activity, not smoking, and maintaining healthy weight further contribute to neurologic as well as overall health. Activities that make use of logic and reasoning, such as reading and crossword puzzles, may help maintain mental acuity.

P

pallidotomy A surgical procedure in which the neurosurgeon destroys a portion of the globus pallidus, a structure of the midbrain that participates in regulating motor movement. Researchers in the 1950s discovered that pallidotomy could significantly reduce symptoms of PARKINSON'S DISEASE such as MUSCLE rigidity, DYSKINESIA, and gait freezing (akinesia). Until recent advances in technology, however, the risks of the surgery were greater than the benefits. Current neurosurgery techniques use MAGNETIC RESONANCE IMAGING (MRI) to locate the globus pallidus and precisely guide the insertion and placement of a thin probe the neurosurgeon uses to ablate (destroy) a few cells at a time until the OPERATION achieves the desired result. This minimizes the risk of damage to adjacent structures of the BRAIN. The person remains conscious and responds with movements as the neurosurgeon directs.

The first step of the surgery is the placement of a stereotactic halo, a circular brace attached to the skull (done under local anesthetic). The halo holds the instruments in precise position during the operation. The second step of the surgery is the ablation, or destruction of tissue in the globus pallidus. After injecting a local anesthetic to numb the SKIN and periosteum covering the cranium, the only areas that contain nerves sensitive to PAIN, the neurosurgeon drills a tiny hole and inserts the probe, feeding it slowly to the globus pallidus with MRI visualization. The operation takes 45 to 90 minutes, with improvement apparent immediately. The neurosurgeon removes the stereotactic halo when the operation is finished. Complications are rare; when they do occur they may include excessive bleeding, postoperative INFECTION, and visual disturbances (the path to the globus pallidus runs very near the optic tract). Most people return to full and regular activities within two weeks.

The effects of pallidotomy are permanent, though they do not affect the progression of the Parkinson's disease. As Parkinson's disease progresses, however, symptoms reemerge. Pallidotomy is not very effective as treatment for other movement disorders.

paralysis The loss of motor function as a result of damage (injury or disease) to the BRAIN or SPINAL CORD. STROKE and trauma are the most common causes of paralysis. Paralysis may also occur with INFECTION such as POLIOMYELITIS, complications of illness such as GUILLAIN-BARRÉ SYNDROME, and neurologic disorders such as AMYOTROPHIC LATERAL SCLEROSIS (ALS) and BELL'S PALSY. Paralysis may affect one side of the body (hemiplegia), the lower body (paraplegia), or the entire body (quadriplegia), depending on the location of the damage. Some paralysis is temporary, with function returning when the underlying condition resolves (such as with Bell's palsy and some kinds of BRAIN HEMORRHAGE). In other circumstances, such as when injury destroys NERVE tissue or structures, paralysis is permanent.

Symptoms and Diagnostic Path

The primary symptom of paralysis is loss of MUSCLE function. In most cases, paralysis comes on quickly. Some people also experience disturbance or loss of sensory perception, depending on the cause of the damage. The diagnostic path generally begins with COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) to identify any correctable or treatable cause for the paralysis and

to assess the extent of damage. Prompt intervention is essential for recovery from conditions such as brain hemorrhage, stroke, BRAIN TUMOR, and compression of the spinal cord.

Treatment Options and Outlook

When possible, treatment attempts to remove or mitigate the source of the paralysis. Such efforts might include surgery to remove a tumor or collected BLOOD (as in subdural HEMATOMA) or other fluid that accumulates within the cranium (HYDROCEPHALY). Rapid treatment can halt and even reverse the effects of stroke due to cerebral infarction (blood clot in the brain). Once paralysis becomes permanent, the emphasis of treatment shifts to maintaining optimal function of remaining motor abilities and learning methods of accommodation. PHYSICAL THERAPY and OCCUPATIONAL THERAPY are essential dimensions of such treatment. Many people who have partial paralysis are able to return to independent living and often to their jobs and many of their favorite activities. Mobility aids such as wheelchairs, crutches, canes or walking sticks, walkers, and braces improve independence and QUALITY OF LIFE.

Risk Factors and Preventive Measures

The risk factors for paralysis are those of the underlying causes of damage to the brain and spinal cord. Traumatic injury is the most significant risk factor for people under age 30 years, particularly young men. Conditions such as stroke, neurologic disorders, and tumors become more common causes of paralysis among people age 50 years and older. Preventive measures include seat belt use, protective headgear for activities such as bicycling and downhill skiing, and prudent judgment when swimming and diving. Lifestyle choices such as nutritious EATING HABITS, not smoking, and daily physical activity help reduce the risk for conditions such as stroke. Other causes of paralysis, such as CEREBRAL PALSY or ALS, are not preventable.

paresthesia The sensation of tingling or burning in a particular part or region of the body. Paresthesia is a symptom of damage, temporary or permanent, to a NERVE or group of nerves. The "pins and needles" feeling in a hand or foot that "falls asleep" is a common experience of transient, or temporary, paresthesia that results from compression of the nerves such as from the limb being tucked under the body during sleep or when sitting for an extended period without moving. CARPAL TUNNEL SYNDROME and ROTATOR CUFF IMPINGEMENT SYNDROME are among the common conditions that cause compression of the nerves through swelling and entrapment.

Pathologic paresthesia—parethesia arising from disease or injury—often occurs with PERIPHERAL VASCULAR DISEASE (PVD) or NEUROPATHY of DIABETES, conditions in which impaired BLOOD circulation causes damage to the PERIPHERAL NERVES of the hands and feet. Deficiency of B vitamins, especially B_{12}, and HEAVY-METAL POISONING (for example, arsenic or mercury) affects the myelin sheathing of nerves and commonly results in paresthesia. Paresthesia is also a symptom of numerous neurologic disorders and conditions and may occur in conjunction with NEURALGIA (PAIN along a nerve tract). Treatment for chronic or persistent paresthesia targets the underlying cause and may range from noninvasive methods such as BIOFEEDBACK and HYPNOSIS to therapeutic interventions such as medications or surgery.

Parkinson's disease A degenerative neuromuscular disorder that results from the progressive loss of neurons within the structures of the midbrain, notably the substantia nigra, that produce DOPAMINE, a NEUROTRANSMITTER essential for MUSCLE function. The loss of muscle function affects both voluntary (movement) and involuntary (swallowing, digestion, urination) activities.

Symptoms and Diagnostic Path

Symptoms become apparent when the number of dopamine-producing cells drops to about 20 percent of normal and typically include

- resting tremor usually affecting the fingers, hands, feet, and occasionally the MOUTH
- bradykinesia (slowed movement)
- stiffness and rigidity of the muscles

- shuffling, hunched posture when walking (Parkinsonian gait)
- loss of balance, especially when changing direction during walking

Other symptoms develop as the condition progresses and may include SIALORRHEA (excessive drooling), HYPERHIDROSIS (excessive sweating), BLEPHAROSPASM, and difficulty speaking and swallowing. There is no definitive diagnostic test for Parkinson's disease, so the diagnostic path considers both personal health history and clinical findings. The neurologist may conduct imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN and MAGNETIC RESONANCE IMAGING (MRI) to rule out other causes of the symptoms, such as BRAIN TUMOR or STROKE.

Treatment Options and Outlook

Treatment targets the symptoms. Some medications replace dopamine or function as dopamine agonists to activate dopamine receptors. The antiviral medication amantadine improves symptoms in some people. Response to medications is highly individual. The neurologist chooses medication combinations according to the person's age, general health status, apparent rate of progression, and other factors. Most people take combinations of medications to address different aspects of the condition and to offset the side effects of some medications. The person eventually becomes resistant to levodopa, a dopamine precursor that currently is the only dopamine-replacement DRUG available. A person who has Parkinson's disease can typically take levodopa for five to seven years.

The US Food and Drug Administration (FDA) recently approved the surgical treatment DEEP BRAIN STIMULATION (DBS) as a treatment for Parkinson's disease that no longer responds to medications. In DBS, the neurosurgeon implants an electrode deep into the BRAIN near the thalamus (a structure with an integral role in movement and motor function). The electrodes connect to a pulse generator, similar in concept to a HEART PACEMAKER, implanted in a small pocket of tissue. The neurologist programs the pulse generator to deliver regular electrical impulses that subdue dyskinesias, rigidity, and tremors. DBS can provide relief from symptoms for a year or two with reprogramming to adjust the intervals and intensity of the electrical impulses.

Parkinson's disease typically progresses over several decades. With early treatment many people can remain symptom free for years. As the number of dopamine-producing cells in the brain continues to decline, however, medications to treat Parkinson's disease become less effective and eventually do not work at all. Though Parkinson's disease continues to progress, it is not fatal for most people when the age of onset is 60 or later.

Risk Factors and Preventive Measures

Researchers do not know what causes Parkinson's disease, though it does appear to run in some families. The most significant risk factor for Parkinson's disease is advancing age, as neurologists diagnose the condition most frequently in people who are age 60 or older. Researchers believe most early-onset Parkinson's disease, which often begins in the 30s or 40s, is genetic. There are no measures known to prevent Parkinson's disease.

peripheral nerves The nerves that branch from the CENTRAL NERVOUS SYSTEM to serve the body. The primary peripheral nerves are the CRANIAL NERVES and the SPINAL NERVES, which branch into smaller and numerous nerves that extend to all parts of the body. The peripheral nerves may be visible to the unaided EYE, as are the cranial nerves and the spinal nerves, or microscopic, as are the tiny nerves that serve areas such as the fingertips. Sensory nerves carry signals to the BRAIN and motor nerves carry signals to the body. Some nerves have both functions.

For further discussion of the peripheral nerves within the context of the structures and functions of the nervous system, please see the overview section "The Nervous System."

See also SPINAL CORD.

peripheral nervous system The CRANIAL NERVES, SPINAL NERVES, and their extensions. The peripheral nervous system has two major subdivisions: the

somatic NERVOUS SYSTEM and the autonomic nervous system. The nerves of the somatic nervous system are both sensory (conduct signals from the body to the BRAIN) and motor (carry signals from the brain to the structures of the body that are under voluntary control). The nerves of the autonomic nervous system regulate involuntary functions such as HEART RATE and digestion as well as the endocrine and exocrine glands. The autonomic nervous system has two further subdivisions: the sympathetic nerves (which serve the thorax and lumbar region) and parasympathetic nerves (which serve the head and sacral region.

For further discussion of the peripheral nervous system within the context of the structures and functions of the nervous system as a whole, please see the overview section "The Nervous System."

persistent vegetative state An extended state of unconsciousness in which higher BRAIN activity (cerebral cortex function) is negligible or lost though the brainstem continues to operate to sustain the vital functions of living such as breathing, HEART RATE, and BLOOD PRESSURE. Basic motor function, such as spontaneous though undirected movement, may also occur as the brainstem is responsible for some motor functions. The person may also make sounds, move the eyes, and move the MOUTH. However, there is no recognition of or purpose to these actions, and the person cannot follow instructions to move in certain ways and does not speak, drink, or eat.

A person may remain in a persistent vegetative state for months, years, or decades with adequate nutritional support. Though in general the longer a person remains in a persistent vegetative state the less likely he or she will recover conscious function, occasionally individuals emerge after extended periods. The likelihood of recovery depends on the extent and nature of damage to the cerebral cortex, which imaging procedures such as MAGNETIC RESONANCE IMAGING (MRI) and COMPUTED TOMOGRAPHY (CT) SCAN can help assess. Persistent vegetative state raises many medical, legal, and ethical concerns for health-care providers as well as family members in regard to how long to sustain life through supportive measures.

poliomyelitis A contagious viral INFECTION, often called simply polio, that affects the nerves and motor function throughout the body. Poliomyelitis is rare today in the United States and other developed countries as a result of aggressive vaccination programs. The first injectable VACCINE to prevent poliomyelitis became available in 1955; a more effective oral vaccine (modified live VIRUS) became available in 1963. The last known "wild" poliomyelitis infection occurred in the United States in 1979. Subsequent poliomyelitis illness resulted from infections acquired in other countries or from exposure of the nonvaccinated to the oral vaccine. The switch to an enhanced inactive (killed) poliovirus vaccine (IPV), capable of providing lifelong immunity, in 1987 eliminated the latter as a cause of poliomyelitis. Oral poliovirus vaccine is no longer available in the United States. Three strains of poliovirus can cause infection. The complete vaccination series consists of four doses of vaccine, one for each strain and a final booster.

Adults who travel to parts of the world where poliomyelitis remains endemic (notably Africa and Southeast Asia) should receive either the complete inactive poliovirus vaccine (IPV) series, if never vaccinated or previous vaccination status is unknown, or an IPV booster otherwise.

Most poliomyelitis is either subclinical (no symptoms) or nonparalytic (runs a course of illness with symptoms similar to those of INFLUENZA). Paralytic poliomyelitis, which affects the BRAIN and SPINAL CORD, occurs in about 2 percent of infections. Among those who develop paralytic poliomyelitis, the risk for death due to PARALYSIS of the muscles of BREATHING and residual paralysis after recovery from the infection are high. More than 90 percent of people who develop nonparalytic poliomyelitis, which affects PERIPHERAL NERVES, recover without complications.

In the late 1970s health experts began tracking the emergence of some polio-like symptoms, such as MUSCLE weakness and generalized fatigue, in

people who had recovered from childhood poliomyelitis. Though researchers do not fully understand what causes postpolio syndrome, it appears to result from damage the poliovirus caused to motor neurons during the active infection rather than a recurrent or new poliomyelitis infection. About one in four people who recover from paralytic poliomyelitis develops postpolio syndrome 10 to 40 years later.

Symptoms and Diagnostic Path

Subclinical poliomyelitis is a very mild infection that does not cause symptoms. The symptoms of nonparalytic poliomyelitis are similar to those of influenza and include

- NAUSEA, VOMITING, and DIARRHEA
- moderate FEVER
- muscle aches and weakness
- extreme fatigue
- irritability
- muscle aches in the lower back and calves
- painful SKIN RASH

The course of nonparalytic illness runs about two weeks, during which symptoms gradually subside. The symptoms of paralytic poliomyelitis are far more severe and are similar to those of MENINGITIS or ENCEPHALITIS. They include

- moderate to high fever
- stiffness and pain in the neck and upper back
- HEADACHE
- rapid onset of muscle weakness that may progress to paralysis within hours
- muscle PAIN and cramping throughout the body
- extreme irritability

The diagnostic path begins with a PERSONAL HEALTH HISTORY to determine the likelihood and circumstances of exposure to the poliovirus. The presence of poliovirus in CEREBROSPINAL FLUID obtained via LUMBAR PUNCTURE confirms the diagnosis.

Treatment Options and Outlook

Treatment is supportive while the infection runs its course, which is typically two to three weeks. Such support may include medications to relieve muscle SPASM and pain, improve gastrointestinal and urinary function, and treat secondary bacterial infections (commonly affecting the urinary tract and the upper respiratory tract). Paralysis that affects breathing may require MECHANICAL VENTILATION.

Most people who survive the course of the disease recover, though many have residual complications such as partial paralysis or muscle deformities that result from the extensive damage to motor neurons. When damage is high in the spinal cord, the person may experience continued difficulty breathing or relatively complete paralysis.

Risk Factors and Preventive Measures

Vaccination prevents infection with the poliovirus; poliomyelitis occurs only in people who have not received proper vaccination or who received vaccination in childhood and travel in later adulthood to parts of the world where poliomyelitis remains endemic (notably Africa and Southeast Asia).

R

reflex An involuntary response to a stimulus that produces a limited and predictable action. Some reflexes are present only in early infancy and are survival-related, such as the rooting reflex, which guides an infant to locate the nipple for BREASTFEEDING, or the startle (Moro) reflex, in which an infant makes a grasping motion with the arms and legs in response to stimulation that suggests falling. Other reflexes that represent normal neurologic function in infancy may reappear later in life as signs of neurologic damage, such as Babinski's reflex (a spreading of the toes with firm stimulation of the sole of the foot). Reflexes that remain throughout life generally protect the body in some way, such as the gag reflex (which helps prevent large objects from entering the throat) and the corneal reflex (in which contact with the CORNEA causes the eyelid to close). The SPINAL CORD manages most reflexes.

A reflex represents a complete circuit of stimulus, sensory NERVE function, spinal cord (and sometimes BRAIN) participation, and motor nerve function. Neurologists call this circuit a reflex arc. Abnormal reflex responses indicate interruption of the arc and damage to the neurologic structures. A number of reflexes become abnormal when there is TRAUMATIC BRAIN INJURY (TBI) or SPINAL CORD INJURY, for example, or in neurologic disorders that damage brain and nerve tissue such as PARKINSON'S DISEASE and MULTIPLE SCLEROSIS.

See also NEUROLOGIC EXAMINATION.

restless legs syndrome A chronic disturbance of the PERIPHERAL NERVES in the legs that causes symptoms of burning, irritation, itching, crawling sensations, and often PAIN. Accompanying these discomforts is the urge to move the legs, which diminishes the symptoms. Restless legs syndrome is most problematic at night because it interferes with sleep. Neurologists do not know what causes restless legs syndrome, though many believe it is a movement disorder arising from dysfunction of the structures in the midbrain that regulate motor function. Many people receive relief when taking medications used to treat PARKINSON'S DISEASE such as DOPAMINE agonists and levodopa, suggesting disturbances of neurotransmitters such as dopamine and acetylcholine create subtle disruptions of motor response. Restless legs syndrome is also common in people who have Parkinson's disease.

The diagnostic path incorporates a comprehensive NEUROLOGIC EXAMINATION primarily to rule out other potential causes for the symptoms. The neurologist may conduct electromyogram (EMG) studies of the muscles in the legs to evaluate their responses to NERVE impulses. Sleep studies often reveal the extent to which the symptoms interfere with sleep. Treatment may include a combination of medications, such as dopamine agonists, MUSCLE relaxants, sleep aids, and ANALGESIC MEDICATIONS for pain relief. Some people experience relief from symptoms and improved sleep with alternative therapies such as ACUPUNCTURE and BIOFEEDBACK.

Restless legs syndrome affects 12 to 20 million Americans. Many people who have restless legs syndrome do not seek medical care because they do not know there are treatments available to ease their symptoms. Restless legs syndrome is chronic, often developing in midlife or later. There are no known measures to prevent restless legs syndrome.

Reye's syndrome A rare complication of certain viral infections in children, notably CHICKENPOX,

upper respiratory INFECTION, and INFLUENZA (the flu). Researchers do not know what causes Reye's syndrome to develop though it is significantly more likely to occur in children who receive aspirin or bismuth subsalicylate (Pepto Bismol) to treat the symptoms of their viral infections.

There is a strong correlation between aspirin and other salicylates (such as bismuth subsalicylate, better known as the trade product Pepto Bismol) and Reye's syndrome in children. Do *not* give these products to children who may have viral infections.

Though Reye's syndrome affects multiple organ systems, the most serious consequence (and usually the first indication of the syndrome's appearance) is ENCEPHALOPATHY (disturbances of BRAIN function). Early diagnosis and aggressive therapeutic intervention are essential to prevent or manage metabolic and neurologic complications. Reye's syndrome can be fatal.

Symptoms and Diagnostic Path

The first symptoms of Reye's syndrome are those of encephalopathy developing within a week of a viral infection. These symptoms include

- confusion
- memory disturbances
- agitation
- progressive UNCONSCIOUSNESS

Reye's syndrome causes excessive deposits of fatty acids in the LIVER; thus liver biopsy provides the definitive diagnosis. The deposits interfere with the liver's ability to function, resulting in systemic metabolic disturbances, such as electrolyte and enzyme imbalances, that are apparent from BLOOD tests. Deposits of fatty acids may accumulate in other organs as well, such as the HEART, KIDNEYS, and PANCREAS.

Treatment Options and Outlook

A child who has Reye's syndrome requires hospitalization in the intensive care unit. Because the cause of Reye's syndrome remains unknown, treatment is supportive and aims to manage the constellation of metabolic disturbances that typify the syndrome. These metabolic disturbances often cause serious complications such as ARRHYTHMIA (abnormal electrical activity in the heart) and HYPOTENSION (low BLOOD PRESSURE). Kidney function also may suffer, leading to RENAL FAILURE.

Overall about 75 percent of children survive Reye's syndrome; about two thirds of survivors have no long-term consequences. When such consequences occur, they may include SEIZURE DISORDERS, intellectual impairment, and neuromuscular dysfunction. The later the stage of Reye's syndrome at the time of diagnosis, the higher the risk for complications, including death.

Risk Factors and Preventive Measures

Reye's syndrome occurs nearly exclusively in children under age 15 years and develops during the course of a viral infection. IMMUNIZATION for influenza and chickenpox can prevent these infections, which are commonly associated with Reye's syndrome. There are no known measures for preventing Reye's syndrome. Early diagnosis and aggressive treatment are essential for optimal recovery.

rhizotomy A surgical OPERATION to selectively sever segments (rootlets) of the dorsal (back) or ventral (front) roots of a spinal NERVE to treat intractable and debilitating PAIN or spasticity such as may occur with neuromuscular disorders. The operation reduces the number of nerve impulses the nerve roots convey. Rhizotomy may be an appropriate treatment for CEREBRAL PALSY, SPINAL CORD INJURY, and other conditions that generate DYSTONIA, CHOREA, or ATHETOSIS. Rhizotomy generally becomes a therapeutic option only when other methods have failed to control symptoms, though may be an earlier recommendation for certain presentations of spastic cerebral palsy. The neurosurgeon performs the operation with the person under general ANESTHESIA. Risks and complications of rhizotomy include excessive bleeding, postoperative INFECTION, altered sensory perception in the affected limb (usually foot or leg), and, rarely, PARALYSIS.

S

seizure disorders Abnormal discharge of electrical activity in certain areas of the BRAIN that causes various involuntary consequences. Most seizures originate in areas of the cerebral cortex.

Seizure disorders may occur spontaneously (without identifiable cause) or as a consequence of damage to the brain such as TRAUMATIC BRAIN INJURY (TBI) or CEREBRAL PALSY. Among the more common forms of seizure disorders are

- epilepsy, in which seizures are recurrent and often frequent
- absence seizures, in which the person experiences very brief episodes of loss of consciousness though often is unaware they occur
- clonic–tonic seizures, in which the person loses consciousness and there is convulsive movement of the legs and arms
- focal seizures, in which the person may or may not lose consciousness and the seizure affects a specific and localized part of the body

Seizures generally end within a minute and do not themselves harm injuries may occur if a person falls or has a seizure in a hazardous location such as a swimming pool. There is no reason to intervene with a person who is having a seizure, other than for safety. Some people, especially children, may have seizures during FEVER. Such seizures, called febrile seizures, do not indicate the person has a seizure disorder.

Symptoms and Diagnostic Path

Seizure disorders run the gamut from causing barely noticeable to disabling symptoms. The diagnostic path includes a thorough PERSONAL HEALTH HISTORY, NEUROLOGIC EXAMINATION, ELECTROENCEPHALOGRAM (EEG), and diagnostic imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI). The EEG typically shows irregularities in electrical activity even when the person is not having seizures. Because sleep deprivation makes the brain more sensitive to electrical activity, the neurologist may request the person remain awake for 24 hours before the EEG. These procedures are generally conclusive for diagnosing seizure disorders.

Treatment Options and Outlook

Antiseizure medications are the mainstay of treatment for seizure disorders. Often a person may require two or more medications that have different actions to adequately suppress inappropriate electrical activity in the brain and prevent seizures from occurring. Because antiseizure medications alter the brain's biochemistry and have potentially serious side effects, neurologists tend not to treat a single episode of seizure but opt instead to take an approach of watchful waiting.

MEDICATIONS TO TREAT SEIZURE DISORDERS

carbamazepine (Tegretol)	gabapentin (Neurontin)
lamotrigine (Lamictal)	levetiracetam (Keppra)
oxcarbazepine (Trileptal)	phenobarbital
phenytoin (Dilantin)	tiagabine (Gabitril)
topiramate (Topamax)	valproic acid (Depakote)
zonisamide (Zonegran)	

Treatment is generally long-term, though children may outgrow certain kinds of seizure disorders. Medications successfully prevent seizures in most people, though require regular monitoring to ensure that BLOOD concentrations remain therapeutic. Dysfunctions of the LIVER and KIDNEYS are the most significant side effects of antiseizure

medications. Surgery to interrupt electrical activity in the brain is sometimes an option for intractable seizures (seizures that fail to respond to medication therapy).

Risk Factors and Preventive Measures

Neurologists do not know the cause of most seizure disorders; thus there are no measures known to prevent them from developing. People who have recurrent seizures or do not experience full suppression of seizures with treatment should not drive or engage in other activities that can put them or others at risk. Many states have laws that regulate the conditions under which a person who has a seizure disorder may obtain a driver's license; such laws vary among states.

spina bifida A form of neural tube defect in which the distal (lower) portion of the neural tube fails to close early in embryonic development. In very mild spina bifida the defect may be unapparent and cause no problems. Severe spina bifida leaves the SPINAL CORD partially or completely exposed, resulting in numerous complications that often include deformity and PARALYSIS. Doctors identify three forms of spina bifida:

- Spina bifida occulta is the most common and the mildest form. Only a small portion of a single vertebra fails to close properly. The spinal cord and the SPINAL NERVES develop correctly. The surface of the spine looks and feels normal, and the person has no symptoms.
- Meningocele is when the meninges (membranes that enclose the spinal cord) protrude under the surface of the SKIN through the incompletely closed vertebrae (usually two or more). The spinal cord and spinal nerves develop correctly, however.
- Myelomeningocele is the most severe form. The spinal canal is open and exposed along the lower spine. The spinal cord and meninges typically appear as a saclike structure, which may be under or on top of the skin. The spinal cord and spinal nerves do not develop correctly, and often there are deformities of the pelvis, abdominal and pelvic organs, and lower limbs.

Meningocele and myelomeningocele are rare. Myelomeningocele can be life threatening, depending on its location and the extent of exposure of the spinal cord, which presents a significant risk for INFECTION (MENINGITIS or ENCEPHALITIS).

Symptoms and Diagnostic Path

Diagnostic prenatal ULTRASOUND detects many neural tube defects before birth. At birth, symptoms of meningocele and myelomeningocele are apparent as deformities of the spine. COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) help the neurosurgeon assess the extent of the damage and plan an appropriate course of treatment.

Treatment Options and Outlook

Spina bifida occulta requires no treatment. Surgery is necessary to repair meningocele, though nearly always recovery is complete. Meningocele repair often heals with minimal or no residual consequences, and the child grows up with normal neurologic function. Complex surgery often is necessary to repair myelomeningocele, and residual complications are usually extensive. Ongoing complications include paralysis, deformity, and HYDROCEPHALY (excessive CEREBROSPINAL FLUID) that requires a shunt. Children born with myelomeningocele require lifetime medical and supportive care. Many have permanent URINARY INCONTINENCE and FECAL INCONTINENCE because the lower spinal cord, which is nonfunctional, regulates urination and defecation. Some may learn to walk with crutches or braces. Developmental delays and LEARNING DISORDERS are common.

Risk Factors and Preventive Measures

Folic acid supplementation greatly reduces the risk for neural tube defects such as spina bifida, perhaps by 70 percent. Health experts recommend that all women of childbearing ability and age take daily folic acid supplement regardless of their pregnancy plans, as the most important period of supplementation appears to be the four to six weeks before CONCEPTION through the first trimester of pregnancy. Some antiseizure medications (notably valproic acid), DIABETES, and OBESITY increase the risk for neural tube defects. Though most spina bifida seems to occur spontaneously,

women who have had one child with spina bifida are more likely to have others. Researchers are not certain whether the connection is genetic or environmental.

spinal cord The largest NERVE in the body, extending from the base of the BRAIN (medulla oblongata) through the spinal canal to the second lumbar vertebra. The average adult spinal cord is 16 to 20 inches long and about the thickness of a man's thumb. The outer structure of the spinal cord is white matter (myelinated neuronal axons); the inner structure is gray matter (NEURON cell bodies). The inner gray matter is roughly the shape of an H, with the horns extending to the roots of the 31 pairs of SPINAL NERVES that branch from the spinal cord.

The spinal cord is the primary neurologic conduit between the body and the brain. It transmits motor nerve impulses from the brain to the body and sensory nerve impulses from the body to the brain. The spinal cord also has rudimentary filtering and control functions, responding to certain kinds of nerve impulses, and serves as the center for reflexes related to urination, defecation, and MUSCLE stretch (essential for movement and balance).

The spinal column, a sequence of joined vertebrae, encloses and protects the spinal cord. CARTILAGE cushions between each vertebra (vertebral disks) allow the spine to flex and twist without jeopardizing the spinal cord. Significant trauma, such as may occur in an automobile accident, can compress, bruise, or sever the spinal cord. Such injuries cause paralysis. A severed spinal cord cannot regenerate, though sometimes partial to full function returns with release of the source of compression or after HEALING of a bruise. Tumors may also compress the spinal cord.

For further discussion of the spinal cord within the context of the structures and functions of the nervous system, please see the overview section "The Nervous System."

spinal cord injury Traumatic damage to the SPINAL CORD, usually the result of a blow to the spine or sudden, forceful twisting. MOTOR VEHICLE ACCIDENTS account for 40 percent and VIOLENCE (gunshot and knife wounds) accounts for 25 percent of spinal cord injuries in the United States. Other common causes are diving into shallow water, sports-related injuries, and significant falls. More than 80 percent of those who experience spinal cord injuries are men, more than half of whom are under age 30.

SPINAL CORD injury is a medical emergency that requires immediate treatment at a neurologic trauma center. It is critical that only properly trained medical personnel attempt to move someone who may have suffered a spinal cord injury.

Such injuries typically cause the vertebrae to compress the spinal cord, damaging the long axons that make up the spinal cord's white matter. The axons are the fibers that extend from neurons in the BRAIN and brainstem. This type of injury, which neurologists classify as incomplete, permits some NERVE impulses to travel the spinal cord and is sometimes recoverable. Much less commonly, trauma partially or completely severs the spinal cord. A complete spinal cord injury exists when no nerve impulses can travel through or around the point of trauma. Circumstances that increase the damage include bleeding, which can increase pressure and/or directly damage neurons, and a surge of neurotransmitters, notably glutamate, at the site of the injury, which overwhelms and kills neurons.

Symptoms and Diagnostic Path

The primary symptom of spinal cord injury is immediate PARALYSIS below the point of trauma. When the injury is high on the spinal cord, above the lumbar vertebrae, the paralysis may affect the DIAPHRAGM and muscles of the chest, preventing the mechanics of BREATHING from taking place. Injury at the cervical level is most severe; injury at the C1 or C2 level is usually not survivable because this is the level of neurologic functions

that support survival such as respiration, BLOOD PRESSURE, and HEART RATE. COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) can show the full extent of the injury.

Treatment Options and Outlook

The standard of care is to administer an intravenous corticosteroid medication, methylprednisolone, within eight hours of a spinal cord. The methylprednisolone reduces the body's natural inflammatory response, lessening the risk for added pressure within the spinal canal and the direct damage to neurons that INFLAMMATION causes. Other treatment options may include surgery to stabilize the spine and remove any BONE fragments or debris from the spinal canal or using braces to immobilize the spine. Supportive measures such as MECHANICAL VENTILATION may be necessary, depending on the level of the injury.

Ongoing treatment typically includes early and aggressive PHYSICAL THERAPY, OCCUPATIONAL THERAPY, and other rehabilitation approaches to maintain MUSCLE tone and STRENGTH as well as to restore as much independence as possible. Much of this treatment may take place at an inpatient rehabilitation center that specializes in spinal cord injuries. Many people are able to recover to a reasonable level of function through the use of mobility aids and assistive devices. When the injury is incomplete, full recovery is sometimes possible. However, it is difficult for neurologists to predict what level of recovery is likely. An individual's general health condition, motivation, and persistence are important influences.

Risk Factors and Preventive Measures

Measures that reduce the risks for spinal cord injury are those that lower the likelihood of motor vehicle accidents. Many of these risks are behaviors such as excessive speed, driving while intoxicated, and failure to wear seat belts. Proper technique and equipment for athletic activities such as horseback riding, downhill skiing, bicycling, and contact sports help improve the safety of participating in these events.

spinal nerves The 31 paired nerves that branch from the SPINAL CORD, extending into the body to form the PERIPHERAL NERVES. The spinal nerves and the CRANIAL NERVES together make up the PERIPHERAL NERVOUS SYSTEM. The spinal nerves emerge from the gray matter of the spinal cord in two roots. The ventral (anterior or front) spinal NERVE root is the motor portion of the spinal nerve that carries nerve impulses from the BRAIN and spinal cord to the peripheral body. The dorsal (posterior or back) spinal nerve root is the sensory portion of the spinal nerve that carries nerve impulses from the body to the spinal cord and brain. Each spinal nerve root immediately branches into several rootlets, which subsequently give rise to the peripheral nerves that serve the body (excluding the head and face).

SPINAL NERVE PAIRS

cervical: 8 pairs, designated C1 through C8
thoracic: 12 pairs, designated T1 through T12
lumbar: 5 pairs, designated L1 through L5
sacral: 5 pairs, designated S1 through S5
coccygeal: 1 pair, designated CO1

Spinal nerve pairs C1 through C4 serve the neck and are collectively referred to as the cervical plexus. Spinal nerve pairs C5 through T1 serve the upper extremities and main trunk and are collectively known as the thoracic plexus. Spinal nerve pairs L1 through L5 (the dorsal roots of L4 and L5) serve the lower back and legs and are collectively referred to as the lumbar plexus. Spinal nerve pairs L4 (the ventral roots of L4 and L5) through S3 serve the structures of the lower abdomen and are collectively known as the sacral plexus. Spinal nerve pairs S4, S5, and CO1 serve the structures of the pelvis, including the genitals, and are collectively known as the pudendal plexus.

stupor A state in which a person is unaware of and does not interact with the external environ-

ment except when vigorously stimulated to brief arousal. Stupor is very near COMA on the scale of CONSCIOUSNESS. Stupor may result from numerous circumstances, including HYPOGLYCEMIA (low BLOOD GLUCOSE level), INTOXICATION, HYPOXIA (lack of oxygen), injury (TRAUMATIC BRAIN INJURY [TBI] or CONCUSSION), ENCEPHALOPATHY, seizures, DRUG overdose, and poisoning. Because some causes of stupor are potentially lethal, doctors attempt to identify them quickly. Treatment depends on underlying cause.

thalamotomy A surgical procedure in which the neurosurgeon destroys a small portion of the THALAMUS, which plays a role in certain kinds of motor movement. Thalamotomy may be an appropriate treatment for tremor-predominant PARKINSON'S DISEASE, tremor disorders such as benign essential tremor, and DYSTONIA. Neurosurgeons first performed thalamotomy in the 1950s. Until recent advances in technology, however, the risks of the surgery (especially damage to adjacent BRAIN structures) were far greater than the benefits. Current neurosurgery techniques use MAGNETIC RESONANCE IMAGING (MRI) to locate the portions of the thalamus that participate in movement, typically the ventral intermediate (VIM) nucleus. The neurosurgeon then uses MRI to precisely guide the insertion and placement of a thin probe into the VIM. A burst of heat through the electrode ablates, or destroys, a few cells at a time until the OPERATION achieves the desired result. The person remains conscious during the operation and responds with movements as the neurosurgeon directs.

The first step of thalamotomy is the placement of a stereotactic halo, a circular brace the neurosurgeon attaches to the skull (done under local anesthetic). The halo holds the instruments steady and in precise position during the operation. The neurosurgeon uses a local anesthetic to numb the SKIN and periosteum covering the cranium, the only areas that contain nerves sensitive to PAIN, and drills a small hole in the BONE. The neurosurgeon slowly feeds the probe toward the thalamus, using MRI to guide the process. The operation takes 60 to 90 minutes, and improvement is apparent immediately. The neurosurgeon removes the stereotactic halo when the operation is completed. Complications are rare; when they do occur they may include excessive bleeding, postoperative INFECTION, and stimulation of taste or visual disturbances (due to the probe passing near or through these areas of the brain). Most people return to full and regular activities in about two weeks.

The effects of thalamotomy are permanent and may end symptoms for some people, especially those who have benign essential tremor. Symptoms often reemerge when the underlying condition is progressive. However, thalamotomy is not very effective treatment for the DYSKINESIA of classic Parkinson's disease.

tic An involuntary MUSCLE SPASM that typically occurs repetitiously and spontaneously. Tics most commonly involve muscle groups in the face and neck and may appear purposeful, such as an eyelid tic that gives the appearance of winking or a tic involving the muscles around the MOUTH that causes a person to look as though he or she were grimacing. Vocal tics are spasms that involve the VOCAL CORDS and produce noises such as grunts. Tics are very common, especially in childhood, and in isolation usually have no neurologic significance. Some people experience tics during times of anxiety. Tics that persist or occur in conjunction with other symptoms may indicate a compressed NERVE or an underlying neurologic or neuromuscular condition. Tic disorders that reflect neurologic disturbances include TOURETTE'S SYNDROME and tic douloureux (more commonly called trigeminal NEURALGIA).

See also CEREBRAL PALSY; DYSKINESIA.

Tourette's syndrome A neurologic disorder in which a person experiences an array of tics (involuntary and repetitive movements). Researchers believe Tourette's syndrome results from subtle imbalances of neurotransmitters in the BRAIN. The imbalances cause disturbances of motor function that affect the muscles of movement as well as functions of articulation and vocalization. Most people who have Tourette's syndrome experience simple neuromuscular tics such as involuntary movements of the eyelids or MOUTH, or even the head and extremities. Some people also experience vocal tics, in which they express noises such as grunts and coughs. And some people experience articulation tics in which they speak words, sometimes obscenities, involuntarily and often loudly, as though the words erupted from them. Although these tics have the appearance of conscious behavior (and some people can temporarily suppress them through conscious effort), they are involuntary neurologic disturbances.

There are no clear diagnostic markers for Tourette's syndrome. Symptoms typically begin in childhood, around age seven or eight, and peak during ADOLESCENCE before trailing off. Many people who have Tourette's syndrome have few episodes of tics after they reach midlife, though neurologists consider Tourette's syndrome a chronic, lifelong condition. When evaluating the symptoms of Tourette's syndrome, the neurologist may conduct numerous tests and procedures to rule out other potential causes, including psychiatric illness, of the symptoms. The neurologist will generally make the diagnosis of Tourette's syndrome after ruling out such possibilities and when symptoms persist for a year or longer.

Many people who have Tourette's syndrome respond to combinations of medications including ANTIPSYCHOTIC MEDICATIONS, ANTIDEPRESSANT MEDICATIONS, STIMULANTS, and the BLOOD PRESSURE medication clonidine (Catapres). All of these medications have varied effects on neurotransmitters and the brain's biochemical balance. Though it may take a period of trial and error to find the combination that is most effective for each individual, nearly everyone who has Tourette's syndrome experiences diminished symptoms with appropriate treatment. Though the tics, especially the vocalizations and articulations, can be disconcerting, Tourette's syndrome does not result from significant neurologic damage and does not threaten health or well-being. SUPPORT GROUPS and therapists can help people develop COPING MECHANISMS for living with Tourette's syndrome. Because stress and anxiety exacerbate symptoms, people who have Tourette's syndrome generally benefit from stress reduction methods and approaches such as BIOFEEDBACK.

traumatic brain injury (TBI) Damage, often permanent, to the BRAIN that results from trauma, blunt or open. TBI may be acute (occur suddenly) or chronic (occur over time as a result of cumulative injuries). Acute TBI most often occurs from a blow to the head, such as from a significant fall or collision. Open trauma to the head, such as gunshot wound, may also result in acute TBI. Chronic TBI develops in people who receive repeated blows to the head, such as athletes who participate in contact or collision sports. Boxing, soccer, and American football are the leading causes of chronic TBI in the United States. The effects of TBI may range from mild disturbances of thought or movement to incapacitating loss of cognitive and motor function or PERSISTENT VEGETATIVE STATE.

Shaken baby syndrome, a form of CHILD ABUSE, is a significant and preventable cause of TRAUMATIC BRAIN INJURY (TBI) in young children. Children are especially vulnerable to brain injury and may experience permanent damage or die from events that would not harm an adult.

Symptoms and Diagnostic Path

Symptoms of TBI may be vague and mild or sudden and severe. Common symptoms include

- significant or persistent HEADACHE
- loss of CONSCIOUSNESS
- unequal dilation of the pupils
- weakness or PARALYSIS on one side of the body
- blurred or double vision (DIPLOPIA)

- ringing in the ears (TINNITUS)
- progressive loss of cognitive function and memory
- seizures
- personality changes

The diagnostic path begins with an assessment of any history of trauma to the head, such as falls or MOTOR VEHICLE ACCIDENTS. When a single event is not apparent, the doctor will look for cumulative injury. A NEUROLOGIC EXAMINATION can identify signs of sensory or motor disturbances that suggest the areas of the brain where there may be injury. Diagnostic imaging procedures, such as COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI), often reveal signs of injury such as subdural or intracranial HEMATOMA, cranial FRACTURE, or altered brain structure. ELECTROENCEPHALOGRAM (EEG) may provide further evidence in the form of abnormal electrical activity in certain areas of the brain.

Treatment Options and Outlook

Treatment depends on the cause and extent of the injury. Surgery is often necessary to drain collected BLOOD (hematoma), relieve pressure, remove BONE fragments or other matter when there is an open wound, or repair damaged blood vessels. Most treatment targets maintaining and restoring brain function through PHYSICAL THERAPY, OCCUPATIONAL THERAPY, and speech therapy. A person may need to relearn basic activities of daily living, or to use his or her nondominant hand. Rehabilitation may also target lost abilities such as reading or writing. The extent of recovery depends on the nature of the injury and the person's overall health status and age. Though traumatic brain injury typically results in some degree of permanent symptoms, many people are able to recover enough to return to an acceptable level of independent living.

Significant injury may result in COMA (UNCONSCIOUSNESS that extends for a few hours to a month) or persistent vegetative state (unconsciousness that persists beyond a month). Though CT scan or MRI can help the neurologist monitor the state of physical damage within the brain, it is difficult to project the likelihood for recovery. A person can remain in a persistent vegetative state for months to years.

Risk Factors and Preventive Measures

Blows to the head are the primary risk factor for traumatic brain injury. Preventive measures include wearing seat belts, helmets, and other protective equipment. Appropriate training and methods reduce the risk for head injuries that occur during sporting events and competitive athletics.

tremor disorders Conditions in which there is damage to the areas of the BRAIN that regulate or coordinate movement, resulting in involuntary, rhythmic back-and-forth movements of the extremities (most commonly the hands) and sometimes the head. Such damage may result from STROKE; injury; or, some researchers speculate, the cumulative effect of NEURON loss over the course of the lifetime. Tremor disorders become increasingly common with advancing age. The most common tremor disorder is benign essential tremor, which affects about five million Americans most of whom are age 60 or older.

BENIGN ESSENTIAL TREMOR VERSUS PARKINSON'S DISEASE

Though tremor is a symptom of PARKINSON'S DISEASE, Parkinson's disease is not a tremor disorder and tremor disorders do not indicate a person has Parkinson's disease. The tremors that characterize Parkinson's disease are most intense when the hands are still and diminish with activity. Tremors of benign essential tremor are most intense during activity and may entirely disappear when the affected limbs are at rest.

Symptoms and Diagnostic Path

Tremors tend to develop gradually and may worsen during times of stress or anxiety. They first appear as mild and intermittent trembling. Over time the movement becomes more clearly rhythmic and begins to interfere with tasks such as holding a pen to write. Tremors may also affect the VOCAL CORDS, making the voice sound wavering. This is the point at which people tend to seek

medical care. The diagnostic path begins with a complete PERSONAL HEALTH HISTORY and family health history. The neurologist conducts a NEUROLOGIC EXAMINATION, and may conduct COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) of the brain to look for changes that suggest other causes for the tremors. The diagnosis combines the neurologist's clinical observations about the characteristics of the tremor with negative findings for other causes.

Treatment Options and Outlook

Medications to mitigate tremors include beta blockers such as propanolol, certain ANTISEIZURE MEDICATIONS (notably primidone), and MUSCLE relaxants such as alprazolam. BOTULINUM THERAPY, in which the neurologist injects botulinum toxin into affected muscles to paralyze them, can provide long-term relief for some people. Surgical interventions such as DEEP BRAIN STIMULATION and THALAMOTOMY may be options for tremors that fail to respond to less invasive treatments. Most people are able to find treatments that minimize the extent to which tremors interfere with their daily activities.

Risk Factors and Preventive Measures

Benign essential tremor appears to run in families. About half of tremor disorders appear to occur in people who mutations in one or both of two genes, *etm1* and *etm2*. Researchers suspect as yet unidentified mutations in other genes are responsible for tremor disorders in people who do not have *etm1* or *etm2* mutations. Other tremor disorders may have genetic components as well. Tremor disorders are far more common in people who are older than age 60 than in those who are younger. However, there are no known measures to prevent tremor disorders.

unconsciousness A state in which a person is unaware of and does not interact with the external environment. The most common experiences of unconsciousness are sleep, fainting (SYNCOPE), and general ANESTHESIA. Unconsciousness may also occur with CONCUSSION, seizures, HYPOTENSION (low BLOOD PRESSURE), ENCEPHALITIS, ENCEPHALOPATHY, and INTOXICATION. Most people are easily aroused from the unconsciousness of sleep though people who are unconsciousness due to other causes may not arouse until or if the underlying cause resolves.

THE MUSCULOSKELETAL SYSTEM

The musculoskeletal system encompasses the bones, muscles, tendons, ligaments, and fasciae. Practitioners who diagnose and treat health conditions of the musculoskeletal system are orthopedists (also called orthopedic surgeons). Orthopedists may further specialize in sports medicine or physiatry (rehabilitative medicine).

This section, "The Musculoskeletal System," present a discussion of the structure and function of the bones, muscles, and other connective tissues. It also contains entries about the health conditions that can affect musculoskeletal function.The section "The Nervous System" contains entries for conditions that affect musculoskeletal function but are primarily neurologic in nature.

Functions of the Musculoskeletal System

The musculoskeletal system gives the body form and structure, protects the internal organs, and provides movement. It determines body height and mass. It is the foundation for facial features, hand characteristics, and athletic ability. The bones of the SKELETON form the core of the structural body; the muscles build the body's outward appearance. In tandem, the bones and the muscles carry the body through life.

A soft start: the skeleton's origins The SKELETON arises from the mesoderm very early in embryonic development, taking rudimentary form at about three weeks of gestational age. Hyaline CARTILAGE, a tough, dense type of connective tissue, forms the template that will become the ossified (mineral-hardened) skeleton. Though the process of ossification begins before birth, the greater percentage of the skeleton is still cartilage at birth to facilitate passage through the birth canal.

After birth an intricate, HORMONE-regulated process immediately sets about to convert cartilage cells (chondrocytes) to BONE cells (osteocytes). This process of ossification takes the first two decades of life to reach fruition. Bone tissue continues to grow and change throughout life even after bone size reaches stability through another process called bone remodeling, in which bone-building cells (osteoblasts) create new bone structure in synchronization with bone-destroying cells (osteoclasts) which remove old bone structure.

Framework: the skeleton The 206 bones of the adult human skeleton give the body shape, protection, and mobility. There are two divisions of the skeleton:

- The axial skeleton forms the body's central alignment; its bones are primarily those of support and shelter.
- The appendicular skeleton "hangs from" the axial skeleton; its bones are primarily those of movement.

Bones provide the structure that gives the body resistance against gravity and makes movement possible. Long bones, such as those in the arms and legs, function as levers for the skeletal muscles to generate movement and locomotion. A honeycombed structure within the long bones reduces their density and weight while increasing their STRENGTH. The compact construction of short bones, such as those in the hands and feet, supports functions that require greater strength and less leverage. Flat bones, such as the scapulae (shoulder blades) and pelvis (hip bones), provide surface area for firmly anchoring the large skeletal muscles that make movement possible.

Some bones function as armor, protecting vital structures and organs. The smooth, thick bones of the skull completely encase the BRAIN in a chamber that has few natural points of entry. Vertebrae separated by cushions of cartilage enclose the SPINAL CORD, their irregular shapes deflecting access while at the same time permitting FLEXIBILITY. The ribs form a cage that contains the HEART and LUNGS, providing a framework for the bellows-like action of the lungs with the thick sternum like a shield to shelter the heart.

Form and function: the muscles The 650 or so muscles in the body give the body shape and make movement, including locomotion, possible. The skeletal muscles cover and protect the bones, attaching directly to them. Muscles also support and protect other structures such as BLOOD vessels and nerves. Most skeletal muscles work in opposing pairs, with one MUSCLE group contracting and the other relaxing in synchronization to permit the balanced, coordinated, and smooth move-

ments necessary for all body mobility from sitting to running.

Muscle cells form collective structures, muscle fibers, that are the functional units of movement. NERVE impulses from motor neurons (nerve cells that direct movement) travel from the NERVOUS SYSTEM to the muscle fibers. The NEUROTRANSMITTER acetylcholine facilitates the transfer of the impulse from the NEURON to the muscle fiber. Some muscle fibers remain in a state of partial contraction, providing muscle tone that supports posture. Other muscle fibers contract and relax in rapid sequence, providing muscle strength.

Connecting structures: tendons, ligaments, and fasciae Specialized structures of connective tissue join the bones and the muscles. Tendons, fibrous bands that arise from muscle, join muscle to bone. Ligaments are tough and sinewy; they connect bones to each other. Sheetlike FASCIA covers the muscles, connecting muscle to muscle and muscle to SKIN.

Articulating interfaces: the joints The ends of the bones come together in various ways that facilitate their movement. Hinge joints, such as the knee and the elbow, allow flexion and extension. Ball and socket joints, such as the hips and shoulders, allow rotational movement. The joints of the cranium—called sutures—are fused, allowing no movement at all. The vertebrae—the bones of the spine—have slight movement between each but collectively allow the body to bend in half.

Most joints contain cartilage, the body's most dense type of connective tissue, to cushion and protect the bones. Cartilage is very smooth, almost slick, permitting movement with minimal resistance. Synovial fluid lubricates larger joints, further reducing friction. A thin coat of cartilage covers the caps of the long bones in the arms and the legs. Thick pads of cartilage cushion the knees and the vertebrae, joints that bear considerable force with movement such as walking.

Biomechanics of movement Movement is a function of leverage and resistance that represents a complex and intricate interaction among the nerves, muscles, connective tissues, and bones. The cerebral cortex coordinates the numerous processes that make movement possible, integrating external sensory data with internal messages. A specialized sensory process, PROPRIOCEPTION, establishes unconscious awareness of the body's location within its physical environment. Proprioception helps the brain interpret and respond to the myriad messages about the body's relation to gravity and speed.

Harder than bone: the teeth The TEETH are the hardest structures in the body, formed of calcium and other minerals with a nearly impermeable enamel coating. The jaw bones—the maxilla (upper jaw) and the mandible (lower jaw)—anchor the teeth. Like most mammals, humans have two sets of teeth, the deciduous (sometimes called primary, milk, or baby teeth) and the permanent. Deciduous teeth begin to erupt through the gum line at about age four months; they drop out and permanent teeth replace them starting at about age six or seven years. The adult mouth contains 32 permanent teeth, generally occurring in pairs on each side of the mouth. They are of three major structures:

- Incisors and cuspids have sharp surfaces for cutting; these teeth are in the front of the mouth.
- Molars have flat surfaces for grinding and crushing; these teeth are in the back of the mouth.
- Bicuspids, sometimes called premolars, function somewhat as transitional structures, capable of secondary biting and preliminary chewing; they are in the middle of the jaw line.

Within the calcium cap is the tooth's living tissue, the pulp. Hollow extensions penetrate deep into the bones of the jaw, their protective canals encasing the nerves and blood vessels that supply the pulp. Chips and cracks in the enamel occur over time, weakening its protection and allowing BACTERIA to penetrate and begin to destroy the calcium cap, exposing the inner pulp. This kind of damage—dental caries (cavities)—is the leading oral health challenge. The teeth also facilitate speech, functioning like reflective walls to amplify sound and providing resistance for the tongue as it reshapes sound into words.

Health and Disorders of the Musculoskeletal System

The musculoskeletal system carries the human body hundreds of thousands of miles in the course of a typical lifetime. Trauma notwithstanding, it

does so with few "maintenance" requirements and little complaining. Proper nutrition and regular physical exercise are about all the bones, muscles, and connective structures require for most of life. However, the musculoskeletal system is vulnerable to numerous hereditary, congenital, and acquired health conditions. Trauma is the most significant risk to the musculoskeletal structures, particularly the limbs and joints. Sprains, strains, and fractures are common injuries. Over time, the repeated trauma of daily function also takes its toll. OSTEOARTHRITIS, the consequence of degenerative damage to the joints, is the most common musculoskeletal ailment, affecting as many as 60 million Americans.

Hereditary and congenital disorders can affect both the structure and function of the musculoskeletal system—and by extension, of other systems of the body as well. Connective tissue, the foundation of the musculoskeletal system, exists in nearly every body structure. Disorders of connective tissue such as MARFAN SYNDROME affect not only the skeleton and muscles but the walls of the arteries and the structure of organs. Though many movement disorders are neurologic in origin, disorders of muscle function such as MUSCULAR DYSTROPHY also affect mobility and motor function.

Traditions in Medical History

Not until the end of the Renaissance did physicians and scientists fully understand the structure of the human musculoskeletal system. The skeleton represented death; only without flesh was it visible. Seeing a bone, even in life, was never a good thing. Fractures, particularly compound fractures in which the bone ends broke through the surface of the skin, were frequently fatal. INFECTION was nearly inescapable. Fractures that did not kill often maimed; ancient doctors had little knowledge of biomechanics and without guidance from technology commonplace today, setting a fracture was at best an imprecise art.

The discovery of the X-RAY—electromagnetic energy capable of penetrating soft tissue—in the late 19th century finally gave doctors a means to examine the bones of living people. With X-ray doctors could see the bone ends of fractures and realign those ends for proper HEALING, and orthopedic medicine was born. Today X-ray remains the quintessential diagnostic tool for skeletal injuries.

Breakthrough Research and Treatment Advances

Today's technology allows incredible visualization of musculoskeletal structures, well beyond the black-and-white X-ray, and of musculoskeletal functions—with minimal intrusion into the body. Nucleotide bone scans, MAGNETIC RESONANCE IMAGING (MRI), ULTRASOUND, and COMPUTED TOMOGRAPHY (CT) SCAN allow doctors to "see" injuries such as torn ligaments, ruptured tendons, and stress fractures. Arthroscopy uses fiberoptic technology to

view the inside of a JOINT, providing a method of minimally invasive visualization for diagnostic and therapeutic purposes.

As in most areas of health and medicine, the most significant breakthroughs in research and treatment for musculoskeletal conditions comes from new discoveries in genetics. Researchers have identified many of the GENE mutations responsible for muscular dystrophy, for example. Though GENE THERAPY as treatment for genetically based musculoskeletal conditions remains experimental, the potential is great for treatments that can reverse the effects of gene mutations to halt and correct disease processes.

A

Achilles tendon A thick, strong band of connective tissue at the back of the heel that joins the gastrocnemius and soleus muscles of the calf (back of the lower leg) to the calcaneus (heel BONE). The Achilles TENDON makes possible extension of the foot, a necessary element of walking, running, and jumping. A sharp tap to the Achilles tendon with a REFLEX mallet causes the foot to jerk downward; this is the Achilles tendon reflex. Motor NEURON diseases such as AMYOTROPHIC LATERAL SCLEROSIS (ALS) and post-polio syndrome produce abnormal Achilles tendon reflex responses.

Injury to the Achilles tendon affects the ability to move the foot down. The Achilles tendon is vulnerable to damage during running and jumping, and especially "plant and twist" kinds of movements, common in numerous sports such as baseball, basketball, tennis, soccer, football, and running. The tendon may become inflamed (TENDONITIS) or tear (rupture).

For further discussion of the Achilles tendon within the context of musculoskeletal structure and function, please see the overview section "The Musculoskeletal System."

See also ACHILLES TENDON INJURY; LIGAMENT; POLIOMYELITIS.

Achilles tendon injury Traumatic damage to the ACHILLES TENDON, the broad band of connective tissue that joins the calf muscles to the heel of the foot. The most common Achilles TENDON injury is INFLAMMATION, called Achilles TENDONITIS, tends to develop somewhat gradually as an overuse injury. A tear in the Achilles tendon, called a rupture, generally happens suddenly during an athletic activity or event. Extended running, especially uphill or in shoes with flat heels (such as racing flats), and jumping are activities that place the Achilles tendon at risk for injury.

Achilles tendonitis causes PAIN and tenderness to touch at the base of the calf muscles on the back of the leg. The inflamed area may appear swollen. Though the pain may restrict the ability to use the foot and ankle, the mechanical functions of the Achilles tendon remain intact, and the person can perform the movements necessary to walk. Achilles tendonitis may follow a competitive event that places high stress on the legs, such as a race, or may develop during a new training regimen.

An Achilles rupture occurs suddenly during movement that stresses the Achilles tendon, such as running. The Achilles tendon is especially vulnerable to quick movements that place extreme stress on it, such as a "plant and twist" maneuver in sports such as tennis, soccer, basketball, soccer, and football. Runners may tear the Achilles tendon when starting from blocks or when accelerating for the finish. The injury causes a popping sensation, followed by pain and an inability to move the ankle and foot very well. When the tear is complete, severing the Achilles tendon, the person cannot point the foot downward to perform the basic movements of walking. Pain is most often at the back of the heel.

The ability to move the foot is generally the distinguishing factor between Achilles tendonitis and Achilles tendon rupture. The doctor's examination includes testing the Achilles tendon reflex, probing for areas of sensitivity (palpable divot), and watching the person move the feet with the legs dangling (seated on an examination table) and when walking. Diagnostic imaging procedures such as MAGNETIC RESONANCE IMAGING (MRI) and

ULTRASOUND can confirm the diagnosis though usually are not necessary unless the doctor suspects a complete rupture and needs to assess the extent and location of damage before surgery to repair it.

Most Achilles tendon injuries heal with ice, rest, and NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) to reduce inflammation and pain. The doctor may choose to cast the lower leg and foot to immobilize the ankle when the injury is severe. Surgery is usually necessary to repair significant or total Achilles tendon rupture. HEALING is complete when the person can move the injured foot with the same ease and range of motion as the uninjured foot, which may take six weeks to three months for repair and six months for rehabilitation, depending on the injury's severity. Swimming is an excellent activity for rehabilitation, as it allows full range of motion and use of the Achilles tendon without impact.

Stretching and WARM-UP before athletic activities, including WALKING FOR FITNESS, are the most effective methods for reducing the risk of injury to the Achilles tendon. People who have tight calf muscles or previous Achilles tendon injury benefit from regular stretching (once or twice daily) regardless of athletic activity.

achondroplasia A genetic disorder in which the rate CARTILAGE cells (chondrocytes) convert to BONE cells is greatly slower than normal, resulting in skeletal abnormalities such as shortened limbs and diminished height. Achondroplasia is the most common cause of SKELETAL DYSPLASIA, commonly called dwarfism. Though achondroplasia can occur as an autosomal dominant inherited genetic disorder, it more commonly occurs as a spontaneous MUTATION of a GENE on CHROMOSOME 4 that encodes fibroblast growth factors, the proteins that regulate cartilage cell conversion. Prenatal testing can identify whether a FETUS has achondroplasia, though doctors generally offer the test only when there is reason to suspect the condition could be present or along with other GENETIC TESTING. Because infants born with achondroplasia have distinctive physical features, the disorder is obvious at birth.

The characteristics of achondroplasia include

- enlarged head and prominent forehead
- short arms and legs
- short hands and short, thick fingers with a distinct separation between the middle and ring fingers
- abnormalities in the opening at the base of the BRAIN, the foramen magnum, and in the vertebrae that compress the SPINAL CORD, affecting BREATHING
- craniofacial anomalies such as narrow nasal passages, flat NOSE, and short jaw

Evaluation for an infant born with achondroplasia typically includes COMPUTED TOMOGRAPHY (CT) SCAN, ULTRASOUND, or MAGNETIC RESONANCE IMAGING (MRI) to evaluate the extent of skeletal anomalies, especially those that may affect the spinal cord and thus vital functions such as breathing. Some infants also have or develop HYDROCEPHALY (fluid accumulation within the cranium), which may require a shunt for draining the excess fluid. As they grow, children who have achondroplasia are vulnerable to KYPHOSIS (a hump in the upper back) and LORDOSIS (curvature of the lower spine). They are also susceptible to frequent OTITIS media (middle EAR INFECTION) because the shortened facial structures mean the eustachian tubes, valvelike structures between the middle ear and the THROAT, are also shorter than normal and do not function properly.

Though some children may benefit from bone-lengthening operations, in most situations there are no treatments to normalize the development of bone. Bone-lengthening surgery is extensive and expensive, has significant risk for side effects (such as infection and permanent damage to the bones), and is controversial among medical experts. Some specialists use HUMAN GROWTH HORMONE (HGH) SUPPLEMENT early in the child's life, though this is also controversial and does not produce predictable results. Adults who have achondroplasia generally reach a maximum height of about four feet.

adhesive capsulitis A condition in which the JOINT capsule of the shoulder joint fuses (adheres)

to the head of the humerus (long BONE of the upper arm), causing PAIN and constricting range of motion. Doctors do not know what causes adhesive capsulitis, commonly called frozen shoulder. The condition may be primary, in which there are no contributory conditions, or secondary, in which other conditions exist that may cause changes that allow adhesive capsulitis to develop. Adhesive capsulitis affects women somewhat more frequently than men and typically occurs in people over age 50.

Symptoms and Diagnostic Path

Adhesive capsulitis begins with acute pain in one shoulder that occurs for no obvious cause. Within weeks to months adhesions (scarlike tissue) develop that progressively limit the affected shoulder's range of motion. Most people first notice restricted movement when trying to reach up and behind, such as combing the HAIR, and when trying to reach back and behind, such as for a wallet in the pocket. The adhesions and range of motion restrictions progress until the person has very limited use of the shoulder. In most people the adhesions gradually lessen and the pain subsides over a period of one to three years. Doctors sometimes refer to the three stages of adhesive capsulitis as freezing, frozen, and thawing.

The pattern of symptoms is generally distinctive enough to allow diagnosis. The doctor may choose to perform diagnostic imaging procedures such as X-RAY or MAGNETIC RESONANCE IMAGING (MRI) to rule out other possible causes of the symptoms.

Treatment Options and Outlook

Because adhesive capsulitis is nearly always self-limiting, treatment primarily targets pain relief. Analgesic medications, heat, and PHYSICAL THERAPY in combination may improve range of motion. When symptoms are severe and do not respond to these measures, the doctor may recommend arthroscopic surgery to release the contractures. In most people such surgery relieves the pain and improves range of motion.

The entire course of adhesive capsulitis, treated nonsurgically, typically spans 1½ to 3 years, after which about half of people recover completely with no residual pain or restrictions on range of motion. In some people range of motion improves though remains limited. A few people experience residual pain and contractures that result in long-term disability.

Risk Factors and Preventive Measures

Conditions that appear to increase the risk for adhesive capsulitis include HYPERTHYROIDISM (overactive THYROID GLAND), DIABETES, and HYPERLIPIDEMIA (elevated CHOLESTEROL BLOOD LEVELS and TRIGLYCERIDE BLOOD LEVEL). Adhesive capsulitis is also more common in people who have SPINAL CORD INJURY, PARKINSON'S DISEASE, certain forms of NEUROPATHY, and traumatic injury to the structures of the shoulder. Despite these correlations, doctors do not know what initiates the onset of adhesive capsulitis and therefore do not know what measures may prevent its development.

aging, musculoskeletal changes that occur with

The muscles, connective tissues, and SKELETON arise from the mesoderm in the EMBRYO at about two weeks of gestational age. The skeleton's first form is as fibrous membranes (the bones of the cranium) or CARTILAGE. Through a process called ossification or osteogenesis, cartilage cells (chondrocytes) convert to BONE cells (osteoblasts, osteocytes, and osteoclasts). This early ossification uses the fibrous membrane (called intramembranous ossification) or the cartilage skeleton (called endochondral ossification) as a mold or template. Bone cells replace the connective tissue cells to form the bone matrix.

Areas of specialized bone tissue called secondary ossification centers form in the long bones; these become the epiphyses or growth plates. After birth the epiphysis extends through the growth of cartilage, which ossification then replaces as bone. The process extends through nearly the first two decades of life. Disorders of ossification include ACHONDROPLASIA, MARFAN SYNDROME, ACROMEGALY, and OSTEOGENESIS IMPERFECTA.

MUSCLE structures gain definition, mass, and STRENGTH as growth occurs. By four months of age a healthy infant can support his or her head and at about six months can sit unsupported and roll over from front to back or back to front. Between 8 and 12 months, an infant begins to crawl, throw

things, and pull into a standing position. By 14 months most infants are walking on their own, and by 18 months can run and jump. Motor skills—the ability to use the musculoskeletal system for mobility—continue to evolve throughout childhood. These skills, along with muscle mass and BONE DENSITY, peak in the late 20s.

By age 40, musculoskeletal structures and functions begin to decline. Joints begin to show the effects of wear. One health consequence of this is OSTEOARTHRITIS, which can become severe enough to warrant JOINT REPLACEMENT. Softening of the ligaments and other connective tissues makes joints more vulnerable to injury. Muscle mass and bone density gradually decrease, as does strength and FLEXIBILITY. In women these decreases become dramatic with MENOPAUSE, with the sudden and significant decline in estrogen. (Estrogen is one of the hormones that influences the movement of calcium between the BLOOD circulation and the bones.) The rate of decrease remains fairly constant in men, who have inherently larger amounts of muscle and bone.

However, by about age 75 or 80 gender differences balance out. Men and women alike have significantly less muscle tissue and bone structure, increasing susceptibility to injury from falls and other accidents. Though bone remodeling continues, it proceeds at a much slower pace. Other changes in the body may result in bone resorption outpacing bone rebuilding. The risk for neuromuscular disorders such as PARKINSON'S DISEASE also rises. At age 80, a woman may have lost four inches or more of her height as a consequence of musculoskeletal changes. Men also lose height, though typically not as dramatically.

amputation Removal or loss of a limb or body part. Amputation may be surgical, in which the removal is intentional to treat a disease condition, or traumatic, in which accidental injury results in the loss of the body part. Most amputations involve digits (fingers and toes) and limbs. In the United States, complications of DIABETES account for the majority of surgical amputations of the foot and lower leg; traumatic injury accounts for most upper extremity amputations. Other causes of amputation include uncontrollable OSTEOMYELITIS (INFECTION of the BONE), severe PERIPHERAL VASCULAR DISEASE (PVD), and tumors.

US surgeons perform nearly 200,000 amputations each year. Surgical amputation is a treatment of last resort, becoming an option only when other treatments fail and leaving the limb threatens the person's health. Surgical amputation is a major OPERATION performed in a hospital. For most amputations the person stays 2 to 10 days in the hospital.

Surgical Procedure

With the person asleep under general ANESTHESIA, the surgeon cuts through the SKIN and MUSCLE to reach the bone, structuring the incisions so tissue remains to create a flap that covers the surgical wound. The surgeon may need to use a saw to cut the bone, though in some circumstances the amputation takes place at the JOINT (called a disarticulation). For limb amputation the surgeon shapes the bone ends and remaining tissue to support a prosthesis.

When there is no infection or risk for infection is minimal, the surgeon closes the surgical wound by suturing the muscles together around the bone and pulling tissue and skin over the end in a flap.

Risks and Complications

The primary risks of amputation are excessive bleeding during surgery and infection and poor HEALING after surgery. The risk for infection is highest in people who have problems with BLOOD circulation in the extremities, such as may occur in PVD or diabetes. People who have diabetes may be slow to heal from the surgery of amputation, usually an extension of the complications of diabetes that made necessary the limb amputation. Complications such as failure to heal or spreading GANGRENE (dead tissue) require a follow-up surgery to attempt to improve the surgical wound for better healing.

Outlook and Lifestyle Modifications

Recovery and limitations depend on the type of amputation and the underlying health conditions. With focused PHYSICAL THERAPY and OCCUPATIONAL

THERAPY, most people can return to a satisfactory level of function and participation in many of the activities they previously enjoyed. A PROSTHETIC LIMB often allows nearly normal function. Adaptive devices and equipment can improve safety, mobility, and independence. People who have amputations as a result of severe chronic disease such as diabetes or PVD often find they have better QUALITY OF LIFE after amputation because the remaining tissue of the limb is healthy.

Amputation may be emotionally difficult for the person as well as for his or her loved ones. The loss of a body part may affect the person's self-image and self-esteem. Some people feel guilty about their health situations, and others feel angry or depressed. The health-care team generally includes a social worker or psychologist to help the person go through the grieving process and cope with the range of feelings and emotions.

ankle injuries Sprains and fractures of the ankle resulting from accidental trauma. The ankle is vulnerable to twisting under the pressure of sudden, unexpected movement. Though ankle injuries are common ATHLETIC INJURIES, they also occur during routine activities such as stepping off a curb, walking on uneven surfaces, and walking in high heels. OBESITY AND HEALTH conditions that impair balance increase the risk for ankle injuries. Doctors in the United States treat about 4 million ankle injuries each year, most of which are sprains (injury to ligaments and tendons).

Three bones come together to form the ankle: the tibia and fibula, the long bones of the lower leg, and the talus, a platform-like BONE that forms the back of the foot. Three sets of strong ligaments hold these bones in place; equally strong muscles and tendons give the ankle range of motion. This structure is necessary because the ankle bears the body's weight. Transferring that weight from one foot to the other when walking places the equivalent of 1½ times the body's weight on the weight-bearing ankle and foot.

Most ankle injuries occur when the foot rolls inward, which stretches, tears, or otherwise damages structures on the outside of the ankle; these are lateral or inversion injuries. When the foot rolls outward, the damage occurs to the structures on the inside of the foot; these are medial or eversion injuries. A sharp blow or twist can break the base of the tibia or more commonly the fibula (the smaller of the lower leg bones). A severe LIGAMENT stretch or tear can pull a piece of the bone away, called an avulsion FRACTURE. Repeated stress such as occurs with intense running or jumping can cause stress fractures in the bones of the ankle or OSTEOARTHRITIS within the ankle JOINT.

Symptoms and Diagnostic Path

PAIN and swelling after a sudden twist or blow to the ankle are the typical symptoms of ankle injury. Both can be intense, and most people are reluctant to or cannot bear weight on the affected ankle. There is a strong correlation between the severity of symptoms, including the ability to walk or bear weight, and the type or seriousness of injury. When it is possible to bear weight on the ankle immediately following the injury and there is no pain to the lower portion of the fibula, fracture is unlikely. The doctor may order an X-ray of the ankle to rule out fracture.

Treatment Options and Outlook

The mainstay of treatment for ankle injuries of any kind is RICE—rest, ice, compression, and elevation. An elastic wrap may help support the injured ankle, though caution is necessary to make sure the wrap is not too tight, particularly during the first 48 hours when the ankle may continue to swell. The doctor may choose to cast a serious sprain. Fractures require casting or surgery or both. Casting is generally adequate for simple fracture in which the broken bone remains nondisplaced (stays in relative alignment). Displaced, comminuted, and open fractures typically require pins, screws, or plates to hold the bones in place while they heal. Sometimes this hardware remains in place and sometimes the surgeon removes it when HEALING is complete, depending on the nature of the fracture.

Most simple strains (injury to the muscles and tendons) heal in 4 to 6 weeks. A simple sprain (injury to the ligaments), which doctors may classify as grade 1 or grade 2, generally heals in 4 to 6 weeks. A severe sprain (grade 3) may take 12 to

16 weeks to fully heal. Doctors consider healing complete when the injured ankle can bear the body's weight without pain and with normal range of motion during normal activities, though very severe injuries may result in permanent limitations or laxity.

Risk Factors and Preventive Measures

Slipping, twisting, and falling are the most common risks for ankle injury. MOTOR VEHICLE ACCIDENTS, athletic activities that involve running and jumping, and recreational activities such as downhill skiing are also frequent causes of ankle injuries. People who are physically inactive or who have had multiple ankle strains may have WEAK ANKLES, a circumstance in which the ligaments supporting the ankle are soft or lax. Excessive body weight places further stress on the ankles and may cause the foot to turn inward, stretching the muscles and connective tissues in ways that limit their ability to provide stability during movement such as walking. OSTEOPOROSIS, a condition of diminished BONE DENSITY, makes the bones of the ankle vulnerable to fracture under circumstances that otherwise would not cause injury. Osteoporosis is a particular risk in women who are past MENOPAUSE and in men over age 65.

Regular weight-bearing activity such as walking helps strengthen the structures of the ankle. People who are prone to ankle injuries may choose to wrap, tape, brace, or otherwise support their ankles during activities that involve increased risk for unexpected twisting, such as running or sports. A physical therapist can teach specific exercises to strengthen weak ankles and improve FLEXIBILITY. WARM-UP exercises to stretch and loosen the ankles are important before engaging in physical activities. It is important to wear the right shoes for the activity, to give the foot and ankle proper support. Worn-out shoes, even if designed for the particular activity, increase the risk for injury.

ankylosing spondylitis A form of chronic, degenerative arthritis (INFLAMMATION of the joints) that primarily affects the spine. The inflammation permanently damages the vertebrae (bones of the spine), causing outgrowths of bony tissue that fuse vertebrae to one another such that their mobility and range of motion can become extremely limited. Ankylosing spondylitis, sometimes called Marie-Strümpell disease, is one of the AUTOIMMUNE DISORDERS related to RHEUMATOID ARTHRITIS. In most people who develop the condition, symptoms remain confined to the spine. However, in some people inflammation also involves structures of the EYE (IRITIS and UVEITIS), the HEART valves, the LUNGS, and other joints such as the shoulders and hips.

Symptoms and Diagnostic Path

Early symptoms of ankylosing spondylitis are general and include low BACK PAIN and stiffness, especially upon awakening. The PAIN often becomes intense at night, which is the primary reason any people seek medical evaluation. Over time the stiffness and pain may spread to the entire back, shoulders, and hips. As the condition progresses, additional symptoms may include loss of spine FLEXIBILITY and range of motion, constricted movement of the chest (from inflammation of the joints connecting the ribs to the spine), fatigue, and hunched or stooped posture.

The diagnostic path typically includes a comprehensive medical examination and PERSONAL HEALTH HISTORY, X-rays of the spine, and BLOOD tests to look for signs of inflammation within the body. Because symptoms are fairly general until the condition is well advanced, early diagnostic efforts look for more common causes such as OSTEOARTHRITIS.

Treatment Options and Outlook

Treatment typically combines prescription medications such as ANTI-INFLAMMATORY DRUGS (NSAIDS) and PHYSICAL THERAPY with lifestyle measures such as daily physical exercise, stretching and flexibility activities, and techniques to support upright posture. Some people experience symptom relief and delayed progression of the condition with medications used to treat rheumatoid arthritis, such as DISEASE-MODIFYING ANTIRHEUMATIC DRUGS (DMARDS). Though treatment cannot prevent the vertebrae from fusing, lifestyle measures can help retain

maximum functional capacity of the spine. Many doctors aim for a goal of shaping the fusion so the spine remains erect, which allows better mobility than when the spine fuses into a hunched posture. Ankylosing spondylitis is a lifelong condition.

Risk Factors and Preventive Measures

Ankylosing spondylitis typically begins before age 40 and is more common in men. It is also more common in people who have INFLAMMATORY BOWEL DISEASE (IBD) and in people of Native American heritage. Researchers have identified a GENE, HLA-B27, associated with ankylosing spondylitis. The HUMAN LEUKOCYTE ANTIGENS (HLAS) are proteins on the surfaces of cell membranes that identify the cells to the IMMUNE SYSTEM. HLA-B27 is one of the numerous genes that encodes for HLAs. Researchers believe this variant of the gene predisposes an individual for ankylosing spondylitis though does not inevitably result in the condition. Remaining as active as possible helps extend the spine's flexibility and range of motion.

arthrogryposis The collective term for a group of congenital disorders, also called arthrogryposis multiplex congenita, in which multiple contractures restrict JOINT function throughout the body. Joints may be partially or completely fused. Researchers believe about 30 percent of arthrogryposis develops when the FETUS is not able to move freely in the UTERUS before birth. The restricted movement causes muscles and connective tissues such as tendons and ligaments to grow abnormally around the immobile joints, fixing them in their positions. Circumstances that may restrict fetal movement include

- insufficient AMNIOTIC FLUID
- abnormalities of the uterus
- large UTERINE FIBROIDS
- twins or other multiples
- neurologic and other developmental anomalies in the fetus, such as MUSCULAR DYSTROPHY or MITOCHONDRIAL DISORDERS, that inhibit normal movement

Symptoms and Diagnostic Path

The doctor may suspect arthrogryposis when the pregnant mother reports that the movements of her unborn baby are infrequent. ULTRASOUND can detect the changes in soft tissue structure and BONE fusions at the joints before birth; the joint deformities are obvious at birth. The delivery of an infant who has arthrogryposis may be challenging when the affected joints prevent normal passage through the birth canal. The obstetrician may recommend CESAREAN SECTION to avoid injury to infant and mother. Ultrasound after birth may provide additional information about the extent to which contractures affect the infant's joints as well as help doctors determine whether there are other anomalies present.

Treatment Options and Outlook

Treatment depends on the extent of the contractures though typically combines surgery to correct joint deformities and casting with aggressive PHYSICAL THERAPY to restore as much function as possible. Surgery can relieve the abnormal tension shortened connective tissue and MUSCLE structures place on the joints, and the surgeon often can reconstruct more functional alignments to improve movement of the joint. Surgery may also restructure bone tissue, generally in multiple operations timed with growth patterns throughout childhood. Physical therapy helps strengthen the tissues and extend range of motion.

Although the deformities are permanent, they are not progressive; thus the condition does not worsen as the child grows. Aggressive treatment early in life may allow a relatively normal lifestyle in late childhood and adulthood when contractures are mild to moderate. Severe contractures tend to result in permanent disabilities that require adaptive techniques and devices for mobility.

Risk Factors and Preventive Measures

Inability of the fetus to move freely in the uterus is the primary risk factor for arthrogryposis. Pregnancies in women who have neuromuscular disorders such as MYASTHENIA GRAVIS, MULTIPLE SCLEROSIS, or MYOTONIA are at higher risk. Extended high FEVER during PREGNANCY, such as may occur with serious INFECTION, may affect the development of the fetus in ways that impair muscle, connective

tissue, and NERVE structure and function. These impairments secondarily affect joint function.

About 30 percent of arthrogryposis is hereditary, though affected parents may have such mild symptoms that they do not know they have the condition. When one or both parents have arthrogryposis, there is increased risk the infant will also have the condition. GENETIC TESTING and GENETIC COUNSELING may help such parents evaluate their risk and make FAMILY PLANNING decisions.

arthroscopy A MINIMALLY INVASIVE SURGERY procedure that allows an orthopedic surgeon to view the inside of a JOINT using a lighted, flexible endoscope adapted for this use, called an arthroscope. Arthroscopy, also called arthroscopic surgery, has both diagnostic and therapeutic applications. Inserted into the joint through a small incision, the arthroscope has a tiny camera at its tip that sends images to a monitor. The orthopedic surgeon manipulates the arthroscope and specially designed instruments to examine the joint and repair damage to CARTILAGE, LIGAMENT, TENDON, and other tissues. Arthroscopy has largely replaced OPEN SURGERY for most operations on the joints except JOINT REPLACEMENT.

Surgical Procedure

The orthopedic surgeon performs arthroscopy in a hospital operating suite or an AMBULATORY SURGERY facility. Most arthroscopies are same-day (outpatient) procedures, with the person arriving a few hours before the scheduled arthroscopy and going home a few hours after the surgeon completes the procedure. ANESTHESIA may be regional (a NERVE block that numbs the limb) or general (puts the person to sleep). The orthopedic surgeon makes two or more small incisions around the JOINT: one for the insertion of the arthroscope, one for insertion of the irrigating catheter, and others for insertion of the arthroscopic instruments. Most arthroscopic procedures take 20 to 60 minutes.

After the arthroscopic operation, the person rests in the recovery area until the anesthetic is fully worn off and the person is comfortable enough to go home. Generally the person receives mild to moderate ANALGESIC MEDICATIONS for PAIN relief, depending on the extent of discomfort he or she feels. Because the entry into the joint is minimal, many people experience little discomfort or pain after the procedure.

Risks and Complications

As with any surgical procedure, arthroscopy has a risk for excessive bleeding and INFECTION. However, these complications are uncommon. Soreness and bruising at the incision sites is common though usually mild. When the arthroscopic examination reveals more extensive damage than the orthopedic surgeon can repair arthroscopically, the operation may become an open surgery with longer recovery and rehabilitation periods.

Outlook and Lifestyle Modifications

Most people recover from arthroscopic procedures fully and without complications, returning to their regular activities within several days to two weeks, depending on the surgeon's recommendation and the type of procedure. Arthroscopic procedures generally repair injuries that have limited the person's mobility or function, so most people are much improved after their operations and may return to activities their injuries had prevented them from performing.

athletic injuries ACCIDENTAL INJURIES that occur during athletic activities or sporting events. Though a certain degree of risk is inherent in athletic events, particularly competitions, most athletic injuries occur for three main reasons. They are

- inadequate CONDITIONING or TRAINING
- insufficient WARM-UP and pre-event preparation
- inappropriate or improperly fitted clothing, shoes, equipment, or protective gear

Athletic injuries may be acute (occur suddenly) or chronic (develop over time). The most common acute injuries are SPRAINS AND STRAINS—damage to the soft tissue structures of the musculoskeletal system. Also common are fractures and open wounds (cuts and scrapes). Chronic injuries among recreational, collegiate, and professional athletes gener-

ally arise from overuse and may result in discomfort and limitations of use long after athletic participation ends. OSTEOARTHRITIS, EPICONDYLITIS, and PATELLOFEMORAL SYNDROME are the most common chronic injuries among athletes.

Training and conditioning activities that improve overall STRENGTH, FLEXIBILITY, and ENDURANCE can significantly reduce the risk for injury. Equally important is proper technique (including clothing and equipment) for the activity. It is worthwhile to attend clinics and classes for specific activities to learn methods and techniques that both improve performance and reduce the risk for injury. Most athletic injuries are preventable.

B

back pain PAIN that arises from injury to the structures of the spine. Most back pain involves the soft tissue structures—muscles, ligaments, tendons, and CARTILAGE. Back pain is very common, affecting nearly every adult at some time in his or her lifetime and is second only to HEADACHE as a reason for missing work. Though most back pain heals without residual consequences, chronic back pain (back pain that continues beyond three to six months) remains the leading cause of occupational disability.

Acute back pain develops suddenly, a consequence of traumatic injury or surgery, and improves when the underlying cause improves. The low back (lumbar spine) and the neck (cervical spine) are the most vulnerable to traumatic injury. Low back strain is a common injury often related to overuse, incorrect lifting (including lifting too much weight), and sudden twisting movements. Cervical strain often results from incorrect posture, especially prolonged sitting in the same position, or whiplash-type trauma in which the head moves suddenly and more rapidly than the body in a whipping fashion that stretches muscles and ligaments. Chronic back pain is pain that exists or continues when there is no pathologic reason and more often affects the low back.

Back PAIN with accompanying numbness or weakness in the legs may indicate damage to NERVE structures. Neck pain with FEVER or headache may indicate serious INFECTION (ENCEPHALITIS or MENINGITIS). These circumstances require immediate medical evaluation.

Symptoms and Diagnostic Path

Back pain, whether acute or chronic, may be sharp, dull, shooting, persistent, intermittent, or achy in character. The nature and location of the pain sometimes helps the doctor determine the cause. Most back pain results from soft tissue injury; unless there are neurologic symptoms, such as weakness or numbness in the legs or arms, the doctor may recommend a trial of conservative treatment before progressing to diagnostic testing. Pain that persists requires further diagnostic effort that may include X-RAY, COMPUTED TOMOGRAPHY (CT) SCAN, or MAGNETIC RESONANCE IMAGING (MRI). These imaging procedures help the doctor visualize the structure of the spine to determine whether there is deterioration or other injury that could be pressing on spinal NERVE roots and other structures of the back to produce pain.

Treatment Options and Outlook

Most acute back pain improves with conservative treatment to relieve INFLAMMATION. Such treatment may include alternating heat and cold to the area of pain, ANALGESIC MEDICATIONS for pain relief, NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) to relieve inflammation and pain, and sometimes MUSCLE RELAXANT MEDICATIONS when MUSCLE spasms are a problem. Some doctors recommend a day or two of relative inactivity to allow the back muscles to rest and relax, though some studies show HEALING occurs more rapidly in mild to moderate back pain when people continue their regular activities (except strenuous exercise or heavy lifting).

Treatment for chronic back pain depends on what underlying reasons the doctor can identify that could be accountable. Complementary methods such as ACUPUNCTURE, various types of MASSAGE THERAPY, CHIROPRACTIC manipulation, and OSTEO-

PATHIC MANIPULATIVE TREATMENT (OMT) often provide relief. YOGA and PHYSICAL THERAPY are methods for improving FLEXIBILITY and STRENGTH after the initial injury heals.

Risk Factors and Preventive Measures

Key risk factors for back pain include occupational risk (jobs that require heavy lifting, pushing, or pulling), OBESITY, physical inactivity, and cigarette smoking. Most back pain occurs as a result of injury to the back, commonly strained muscles or sprained ligaments. Regular physical exercise to maintain strength and flexibility reduces the risk for such injury and aids in weight loss efforts when excessive body weight is a factor. Proper lifting technique and good posture are also important.

Baker's cyst A fluid-filled sac, also called a popliteal cyst, that forms at the back of the knee. The cyst develops when there is a tear in the synovial capsule (the membranous structure containing the fluid that lubricates the JOINT) that allows synovial fluid to leak into the ears of least resistance, which is the popliteal fossa. The leaking fluid bulges out from the knee joint or forms a connection with a BURSA in the back of the knee. Either circumstance allows synovial fluid to collect, forming a noticeable lump behind the knee. A Baker's cyst is soft to the touch and usually painless, though a large cyst can be uncomfortable or painful with movement or pressure.

NOTHING TO DO WITH BAKING

It is a common assumption that the term Baker's cyst has something to do with being a baker, just as bricklayer's shoulder tends to afflict bricklayers and tennis elbow develops in people who frequently play tennis (both conditions are forms of BURSITIS). But Baker's cyst takes its name from the British surgeon who first identified it: William Morrant Baker (1839–1896).

When the cyst causes PAIN, the doctor may use MAGNETIC RESONANCE IMAGING (MRI) to determine whether other factors are involved. Occasionally a Baker's cyst is a symptom of a torn meniscus (CARTILAGE in the knee), in which case treatment such as surgery may be necessary. Nearly always a Baker's cyst eventually goes away without treatment.

bone The rigid tissue that gives the body structure and mobility. Bone consists of living cells contained within a mineralized structure called the bone matrix. Collagen fibers form intricate networks to which crystals of calcium phosphate, calcium carbonate, and other mineral compounds adhere, forming the dense and rigid structure familiar as bone. Despite its density and its impression as a static structure, bone is in a perpetual state of change, called remodeling. Throughout life certain processes destroy old bone and other processes construct new bone.

Bone Cells

Three types of cells make up bone tissue:

- Osteoblasts form new bone. In response to stimulation from hormones such as CALCITONIN, ESTROGENS, and TESTOSTERONE, osteoblasts draw calcium and other minerals into the bone to strengthen and solidify the bone matrix. Osteoblasts produce a collagen-based substance called osteoid. Calcium, phosphorus, magnesium, and other minerals bind with the osteoid to form mineralized bone (the bone matrix).
- Osteocytes make up the structure of existing bone. Contained within the bone matrix, osteocytes have a lifespan of 20 years or more. Osteocytes begin their lives as osteoblasts, then become enclosed in the bone's mineralized structure. The spaces they occupy within the mineralized framework are lacunae. Each lacuna has a rich BLOOD supply to nourish and support the osteocytes.
- Osteoclasts remove old bone. Osteoclasts derive from monocytes and are phagocytic; they encircle and consume cellular debris. As they consume old bone tissue, osteoclasts release its calcium into the blood circulation. PARATHYROID

HORMONE plays a key role in regulating this release. The process of bone resorption leaves vacant lacunae on the surface of the bone that subsequently fill with new bone structure.

In health, osteoblasts and osteoclasts function in relative balance so the rate of new bone formation matches the rate of old bone destruction. This process of bone remodeling is one of maintenance, not growth. Bone growth, in which the bones increase in size, occurs through ossification (conversion of CARTILAGE cells to bone cells). Imbalance may result from disease processes that alter HORMONE levels in the body or when calcium levels in the blood circulation are too low. Calcium is vital to numerous cellular activities and crucial for MUSCLE contraction and the conduction of NERVE signals; when its levels in the blood circulation are inadequate, the body accelerates bone resorption so it can withdraw calcium from the bones.

Bone Structure

Were they solid, bones would weigh more than the body could support or the muscles could move. So instead they are a combination of densities that provide a balance between STRENGTH and mass. Though all bones contain the same elements of structure, the particular combination of those elements varies according to the bone's role.

The outermost layer of bone, called compact bone or cortical bone, is made of multiple thin layers, called lamellae, that contain tightly packed osteocytes. Each lamella contains a somewhat different structure of cells, altering the density and orientation of the bone structure for maximum strength. Compact bone is heavily mineralized and very dense; tooth enamel is the only other substance in the body that is harder than compact bone. An intricate network of canals, called the Haversian systems, bring blood vessels and nerves through the lamellae to nourish and support communication among the osteocytes. Compact bone protects the inner bone structures and provides the stiffness necessary to leverage the muscles for movement.

The middle layer of bone is cancellous, or spongy, bone, also called trabecular bone, where mineralized filaments form intricate networks of walls and spaces. The spaces contain osteocytes, fluids, and other cells. The structure of cancellous bone is more elastic than that of compact bone, allowing the bones to absorb compression such as occurs with walking, running, and jumping. Cancellous bone has less than half the density of compact bone but many times more the surface area.

Some bones contain a center channel, the medullary canal, that houses BONE MARROW. In children every bone contains red bone marrow, the type of bone marrow that produces new blood cells. By adulthood only the long bones, sternum, and hip bones contain appreciable amounts of red bone marrow. Yellow bone marrow, a mix of collagen and fatty tissues, occupies the innermost layer of most other bones. Some bones do not contain any marrow.

A thin but tough membrane called the periosteum covers the surface of the bones except at the joints. It forms the attachment surface for tendons and ligaments. The periosteum contains a rich network of blood vessels and nerves that help nourish the compact bone. Osteoblasts in the periosteum are "first responders" when there is injury to the bone, rapidly forming new bone for repair. The nerves in the periosteum are largely responsible for PAIN signals when there is injury to the bone.

Types of Bones

The SKELETON contains four basic types of bones: long, short, flat, and irregular. Long bones, such as those in the arms and legs, must support the body's weight and mass. Their length and structure also allows them to function as levers to make movement possible. A thin layer of compact bone provides the rigidity the long bones require; a substantial middle layer of cancellous bone provides added bone mass for strength and stability. The intricate trabecular structure of cancellous bone makes it much stronger for supporting weight, though more vulnerable to impact. At each end of a long bone is the epiphysis, or growth plate, where ossification takes place during growth in childhood. The shaft of a long bone is its diaphysis. Lengthwise through the center of a long bone is a medullary canal that contains bone marrow.

Short bones, such as those that form phalanges (metacarpals in the fingers and metatarsals in the toes), are structurally long bones on a much

smaller scale. However, a short bone does not have a medullary canal or bone marrow. Flat bones, such as the scapulae (shoulder blades), sternum (breastbone), and pelvis (hip bones), serve as attachment surfaces for the large muscles of movement. They contain a substantial thickness of compact bone with a thin layer of cancellous bone in the center. The sternum and the pelvis also contain bone marrow. Irregular bones, such as the vertebrae (bones of the spine), carpals (bones of the wrist), and tarsals (bones of the ankle), are primarily structures of compact bone with cancellous bone centers.

Bone Health and Disease

Bones require a steady intake of dietary calcium and other minerals as well as an adequate amount of vitamin D, VITAMIN K, and various hormones to maintain themselves. Deficiencies (and less commonly, excesses) of these substances alter bone structure in ways that can affect bone function. Though a certain degree of demineralization occurs naturally as a component of the aging process, excessive calcium loss results in thin and weak bones that are particularly vulnerable to FRACTURE. Fracture is the most common health condition that affects the bones. Other health conditions involving the bones include OSTEOPOROSIS, INFECTION (OSTEOMYELITIS), and congenital musculoskeletal anomalies (BIRTH DEFECTS that affect muscle and bone structure and function).

bone cancer Cancer that occurs in the tissues of the BONE, either as primary cancer (cancer that originates in the bone) or metastatic cancer (cancer that spreads to the bone from an origin elsewhere in the body). Primary bone cancer is rare; doctors in the United States diagnose about 2,500 people with primary bone cancer each year. Its three forms are

- osteosarcoma, which arises from osteoid (the formative tissue of new bone) usually in the upper leg or upper arm in young people ages 10 to 25
- Ewing's SARCOMA, which results from a TRANSLOCATION GENE MUTATION and generally arises from the long bones (and occasionally soft tissue structures) during ADOLESCENCE
- chondrosarcoma, which develops in the cartilage of the shoulders or pelvis in adults over age 50

Osteosarcoma accounts for about a third of primary bone cancers. RADIATION THERAPY for other cancers increases the risk for osteosarcoma. Though primarily a cancer of childhood, osteosarcoma sometimes occurs in older adults. Oncologists (cancer specialists) often stage primary bone cancer only as localized (one contained site) or metastasized (spread to multiple sites).

The bone is a common site for cancer that metastasizes from other sites in the body such as the BREAST, PROSTATE GLAND, and COLON. Metastatic cancer retains the name of its original site. Multiple myeloma, a cancer of the BLOOD, also affects bone structure though is not a true bone cancer.

Symptoms and Diagnostic Path

The main symptom of bone cancer is PAIN, usually at the site of the tumor. The pain may be present for several months before becoming intense enough for the person to seek treatment, or may develop suddenly. Sometimes the first indication of bone cancer is a FRACTURE, either spontaneous (without trauma) or as a consequence of minor trauma that would not fracture healthy bone. The diagnostic path typically begins with X-rays, which can show

most bone cancers. COMPUTED TOMOGRAPHY (CT) SCAN, MAGNETIC RESONANCE IMAGING (MRI), and radioisotope bone scan can provide greater detail about the tumor to aid in its diagnosis. POSITRON EMISSION TOMOGRAPHY (PET) SCAN can detect whether or to what extent the cancer has metastasized to other sites in the body. A blood test to measure the level of alkaline phosphatase, an enzyme osteoblasts release when configuring new bone tissue, may suggest—though cannot confirm—bone cancer. Blood levels of this enzyme are normally high during periods of bone growth. Biopsy of the tumor provides the definitive diagnosis.

Treatment Options and Outlook

Treatment depends on the location and size of the tumor. Treatment options for primary bone cancers include CHEMOTHERAPY, radiation therapy, and surgery to remove the tumor. Often, radiation therapy or chemotherapy administered first can shrink the tumor so the surgeon can remove it without the need to amputate the involved limb. Oncologists often administer chemotherapy both before and after surgery. The course of chemotherapy before surgery is typically 8 to 10 weeks; chemotherapy after surgery may extend for a year. The oncologist is likely to add radiation therapy to the treatment regimen when there are metastases the surgeon cannot safely remove. Treatment for metastatic cancer of the bone depends on the type of primary cancer and the degree of METASTASIS.

The outlook after treatment depends on the extent of cancer present at the time of diagnosis. Significant surgery, such as AMPUTATION, requires intensive rehabilitation. The outlook for metastatic cancer of the bone depends on the type of primary cancer and the aggressiveness of metastatic disease.

Risk Factors and Preventive Measures

Though Ewing's sarcoma has a clear genetic connection, doctors know little about the risk factors for and causes of other forms of primary bone cancer. Radiation exposure, such as radiation therapy to treat a different cancer, increases the risk for osteosarcoma. There are no measures known to prevent bone cancer.

bone density The amount of mineral, primarily calcium, the bones contain that gives them their mass. BONE density is important to give the SKELETON enough structure to support the body. Insufficient bone density results in the bone loss conditions OSTEOPENIA and OSTEOPOROSIS. Numerous hormones participate in maintaining bone density. Among them are estrogen, TESTOSTERONE, CALCITONIN, vitamin D (in the form of calciferol), and PARATHYROID HORMONE. Though calcium is the mineral most commonly associated with bone structure and bone density, other minerals that also are important, including magnesium and phosphorus.

Bone density naturally diminishes with increasing age, beginning at about age 35, at a rate of about 2 percent per year. Because estrogen is particularly essential for maintaining bone density in women, bone density drops precipitously at MENOPAUSE when a woman's estrogen production drops to nearly nothing. Because men's bodies are larger, they inherently have greater bone mass. Testosterone contributes to this mass, as it does a man's greater MUSCLE mass. The natural decrease in bone density is usually not a health concern until a man reaches his middle to late 60s.

Disorders of Bone Density

Most health problems related to bone density arise from diminished bone mass, which presents increased risk for bone FRACTURE. Spontaneous fracture (fracture that occurs without trauma or other cause) is possible when bone density is very low. The spine and the hip are at particular risk. The most common of these conditions are osteopenia (bone loss that places the individual at increased risk for fracture) and osteoporosis (bone loss that places the individual at significant risk for fracture). Compression fractures of the spine, in which the vertebrae collapse, can endanger the SPINAL CORD; HIP FRACTURE IN OLDER ADULTS is a key cause of disability and death. Medications are available that stimulate bone growth, helping restore lost bone mass. The doctor may prescribe such medications, along with lifestyle measures such as RESISTANCE EXERCISE, to increase bone density. Excessive bone mass is far less common

though may occur in conditions such as OSTEOPETROSIS.

Bone Density Testing

A number of tests can measure bone density. Among them are

- dual energy X-RAY absorptiometry (DEXA or DXA), which uses low-DOSE X-ray to measure the bone mass in the spine and hip
- peripheral dual energy X-ray absorptiometry (pDEXA or pDXA), which uses low-dose X-ray to measure the bone mass in the wrist or heel
- single-energy X-ray absorptiometry (SXA), which uses low-dose X-ray to measure the bone mass in the wrist or heel
- quantitative ULTRASOUND, which uses sound waves to measure the bone mass in the heel, patella (kneecap), and tibia (long bone in the lower leg)
- quantitative computed tomography (QCT), which uses X-ray to measure the bone mass in the spine
- peripheral quantitative computed tomography (pQCT), which uses X-ray to measure the bone mass in the wrist

DEXA provides the most detailed information and is simple to perform. QCT and pQCT are variations of COMPUTED TOMOGRAPHY (CT) SCAN that use somewhat higher doses of X-ray and are more complex to perform but can be more reliable in people who have already had fractures of the spine or hip. Mobile clinics and even some pharmacies use peripheral methods for screening. All testing methods to measure bone density are painless, noninvasive, and take 20 minutes or less to complete.

Bone density tests report two scores:

- The T-score compares an individual's bone density to a figure that represents the bone density of a healthy adult in his or her mid-20s, the period when bone density is at its highest. The comparison is gender specific.
- The Z-score compares an individual's bone density to a figure that represents other adults of the same age. The Z-score comparison is also gender specific.

Because older adults have lower bone mass, the Z-score is less significant than the T-score for assessing the presence of osteopenia and osteoporosis. Generally the T-score and the Z-score correlate; a person who has a low T-score also has a low Z-score.

The difference between an individual's bone density score and the representative standard score is the standard deviation (SD), reported as a positive (+) or negative (–) figure. Each full SD represents about 10 percent of normal bone mass. The lower the T-score, the greater the percentage of bone loss. A T-score that is 2.5 SDs or more below the norm (–2.5) is the diagnostic marker for osteoporosis.

BONE DENSITY SCORES

Diagnostic Category	T-Score	Z-Score
healthy	–1 or higher	–1 or higher
OSTEOPENIA (increased risk for fracture)	–1 to –2.5	–1 to –2.5
OSTEOPOROSIS (significant risk for fracture)	below –2.5	below –2.5

bone spur An extension of BONE tissue, also called an osteophyte, that commonly develops near a JOINT. A bone spur has a jagged, pointed appearance. Doctors believe bone spurs develop as a means of protecting a joint exposed to excessive stress or disease process. Most bone spurs do not cause symptoms, though may be apparent as bumps in the MUSCLE or other soft tissue. Bone spurs cause PAIN when they irritate surrounding tissues such as MUSCLE and CARTILAGE. Bone spurs are especially common in the heels, hands, shoulders, and spine.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) often succeed in relieving the INFLAMMATION and pain. For bone spurs that cause substantial pain, the doctor may inject the site with cortisone and a topical anesthetic agent to reduce inflammation and relieve pain.

See also ACHILLES TENDON INJURY; REPETITIVE MOTION INJURIES.

bursa A fluid-filled sac between layers of MUSCLE that buffers the movement of muscles against each

other. A synovial membrane, which secretes a lubricating fluid (synovial fluid), lines the inside of the bursa. This is the same kind of membrane and fluid that encloses and lubricates the joints. Most people have between 130 and 160 bursae throughout their bodies, typically located near joints. Bursae are vulnerable to INFLAMMATION (BURSITIS) and fibrosis (scarring), both of which cause pain and interfere with the bursa's proper function.

For further discussion of bursae within the context of musculoskeletal structure and function, please see the overview section "The Musculoskeletal System."

See also CARTILAGE; JOINT; LIGAMENT; TENDON.

bursitis INFLAMMATION of a BURSA, a fluid-filled sac between muscles or between muscles and BONE that protects tissues from friction during movement. Bursitis is a common condition often associated with overuse of particular joints though the joints themselves are normal. Casual terminology for bursitis often relates it to the activities that precipitate it, such as tennis elbow. Accidental falls and blunt blows over bursae may also cause bursitis, particularly of the deep bursae. Bursae near the shoulder, elbow, hip, and knee are most often affected. An adult has 130 to 160 bursae throughout the body, any of which may become inflamed.

The primary symptoms of bursitis are PAIN and swelling in the area of the involved bursa. When there is also FEVER, an INFECTION may be the cause of the bursitis. Bursitis due to infection often requires surgical debridement (opening the bursa to remove damaged tissue and accumulated pus) and treatment with ANTIBIOTIC MEDICATIONS. Intermittent cold packs over the affected area during the first 48 hours of symptoms may slow inflammation and relieve pain. After 48 hours intermittent heat provides greater relief. NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) further relieve inflammation and pain.

Most bursitis improves in two to six weeks with such treatment. The doctor may inject a steroid medication, alone or in combination with a local anesthetic agent, into a bursa that is causing severe or chronic pain and restricting range of motion. Though resting the affected JOINT is helpful in the early stages when the bursitis is most uncomfortable, regular physical activity hastens HEALING and maintains full function of the joint.

C

calcium and bone health The correlation between dietary intake of calcium and the density and STRENGTH of the bones. Calcium is essential for proper BONE structure, strength, and mass. The bones contain about 99 percent of the calcium in the body. From before birth until about age 30, the body adds calcium and other minerals to bone tissue to increase bone mass and strengthen the skeletal structure. The SKELETON reaches peak bone mass and strength in the late 20s. After age 30, bone mass begins to decrease. With increasing age after 30 the body's ability to absorb dietary calcium diminishes. Cigarette smoking and long-term excessive ALCOHOL consumption accelerate the decrease. It is important for long-term bone health that peak bone mass be as high as possible. Regular weight-bearing exercise, such as walking and running, stimulates the growth of new bone tissue.

BONES: THE BODY'S CALCIUM BANK

Calcium is a vital mineral for many activities in cells throughout the body, including the conduction of NERVE signals and the contraction of MUSCLE cells. The body uses the calcium stores in the bones to meet its other needs for calcium when dietary intake does not meet those needs and calcium in the BLOOD circulation drops. CALCITONIN and PARATHYROID HORMONE are the hormones that primarily regulate calcium transport between the blood circulation and the bones.

Without adequate calcium the bones can become dangerously thin and weak, making them susceptible to FRACTURE under circumstances that otherwise would not harm the bones. The key health conditions of inadequate BONE DENSITY are OSTEOPENIA and OSTEOPOROSIS. Osteoporosis is the leading cause of HIP FRACTURE IN OLDER ADULTS, which often results in long-term disability or premature death. Though loss of bone density with aging is inevitable, lifelong measures such as adequate calcium intake and daily weight-bearing exercise can maintain bone health and prevent osteoporosis.

The body must obtain calcium through dietary sources or supplements. The amount of calcium an individual needs changes across the spectrum of age. The years of ADOLESCENCE are among the most vulnerable for inadequate calcium consumption because teens tend to drink much less milk and eat fewer dark green vegetables, the primary dietary sources of calcium in the American diet.

CALCIUM INTAKE NEEDS

Age	Daily Adequate Intake (AI) Amount of Calcium
birth to 3 years	500 milligrams (mg)
4 to 8 years	800 mg
9 to 18 years	1300 mg
19 to 50 years	1000 mg
51 years and older	1200 mg

Natural dietary sources of calcium include dairy products (milk, cheese, yogurt), dark leafy vegetables such as spinach and broccoli, and tree nuts such as almonds and pecans. Many foods sold in the United States are calcium-fortified (contain added calcium). They include orange juice, cereals, breads, SOY milk, and soy products such as tofu. Low-fat dairy products, which have lower amounts of saturated fats, are the more healthful choice and contain just as much calcium as higher fat products. Labels on packaged foods in the United States state, per serving, the food's calcium

Three forms of calcium are commonly available as dietary supplements: calcium carbonate, calcium citrate, and calcium phosphate. However, many doctors believe the form of calcium matters far less than maintaining adequate intake of calcium. Individuals have varying tolerances and responses to the different forms of calcium supplements. Many doctors recommend calcium carbonate in the form of chewable antacid tablets as the most available, easiest to take, and least expensive calcium supplement product. Because numerous factors influence how much calcium the gastrointestinal tract absorbs, health experts recommend obtaining as much calcium as possible through dietary sources with calcium supplementation to make up the difference. Total calcium consumption that exceeds 2000 milligrams (mg) a day does not provide any added benefit and may cause health problems due to excessive calcium.

The body also requires vitamin D to absorb dietary calcium. The primary sources of vitamin D are sunlight and dietary supplements. The body can synthesize (make) as much vitamin D as it needs with adequate SKIN exposure to sunlight. However, many people do not get enough sunlight. SUN PROTECTION products, necessarily applied to protect against SUNBURN block the ultraviolet rays that activate vitamin D synthesis. As well, there is not adequate ultraviolet light exposure during the winter months for people who live in the northern hemisphere—in the United States, above a line roughly drawn from San Francisco to Boston. Because of these factors, most calcium-fortified foods also contain supplemental vitamin D. Inadequate vitamin D causes softness of the bones—RICKETS in children and OSTEOMALACIA in adults—regardless of calcium intake because the body cannot absorb calcium without vitamin D.

Though insufficient calcium intake is by far the more significant health issue because of the effect it has on bones, excessive calcium consumption has potentially serious adverse effects on the body systemically. Excessive calcium can cause ARRHYTHMIA (irregularity in the HEART RATE), MUSCLE cramps, kidney stones (NEPHROLITHIASIS), and NERVE disturbances.

carpal tunnel syndrome A collection of symptoms resulting from compression of the median NERVE as it passes through the carpal tunnel, a narrow channel in the carpal bones of the wrist. The ligaments that form the carpal tunnel can become irritated and inflamed, constricting the median nerve and the tendons in the area. The median nerve supplies the inside of the hand, the thumb, and the first three fingers (the ulnar nerve supplies the outside of the hand and the little finger). Compression of the nerve affects sensation and function in the hand.

Symptoms and Diagnostic Path

Symptoms of carpal tunnel syndrome progress gradually over months to years. They may include

- tingling
- numbness
- weakness
- loss of ability to use the thumb and first two or three fingers
- PAIN that shoots from the hand up the forearm

Some people also experience perceptible swelling and tenderness to touch over the wrist. Symptoms are generally intermittent at the onset and progress to occur more frequently and have greater intensity. The diagnostic path includes tests of the hand and wrist that are able to bring on or intensify the symptoms. The doctor may order electromyogram (EMG) and nerve conduction studies for further diagnostic information.

Treatment Options and Outlook

Treatment efforts attempt to manage symptoms conservatively, with measures such as NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS), injection of a corticosteroid, and splinting. When fluid retention (edema) is a factor, diuretic medications ("water pills") may help. Some people experience

improvement in their symptoms when they take vitamin B_6 (pyridoxine) supplements. Certain YOGA postures that increase FLEXIBILITY and STRENGTH of the wrists improves symptoms for some people. Surgery, either open or laparoscopic, to cut the carpal LIGAMENT is the curative treatment for most people who have carpal tunnel syndrome. Such an OPERATION opens the carpal tunnel, relieving compression against the median nerve. Full recovery from the open procedure takes about 12 weeks and from the laparoscopic procedure about 8 weeks. A rare complication of carpal tunnel surgery is permanent weakness in the hand as a consequence of cutting the median nerve. Other possible complications, also rare, include excessive bleeding and postoperative INFECTION.

Risk Factors and Preventive Measures

Doctors believe many people who develop carpal tunnel syndrome have an inherently narrow carpal tunnel, making the passage tighter. Women, who have smaller BONE structures than men, are three times more likely to develop carpal tunnel syndrome. Carpal tunnel syndrome may also follow injury to the wrist, such as strain or FRACTURE, or accompany OSTEOARTHRITIS of the wrist. People who have DIABETES, PERIPHERAL VASCULAR DISEASE (PVD), and other conditions associated with NEUROPATHY (injury to the nerves) are particularly susceptible to compression syndromes such as carpal tunnel syndrome.

Work that subjects the wrists to continuous vibration or repetitive movement also increases the risk for carpal tunnel syndrome. The highest risk is among people who do assembly-line work, such as in manufacturing, professional sewing, meat packing, and poultry processing. Job tasks in these occupations subject the wrists to repeated flexing under pressure. Though occupations involving extensive typing, keyboarding, or data entry were long suspected as prime causes of carpal tunnel syndrome, recent studies support only a slight increase in risk. Frequent short breaks to stretch and flex the wrists during work and wearing supportive wrist braces can help prevent carpal tunnel syndrome or minimize its symptoms.

cartilage Dense connective tissue that provides the foundation for BONE in the developing fetus and covers bone ends in the joints in adults. The fetal SKELETON forms first as a translucent type of cartilage called hyaline cartilage, with conversion to bone beginning at about the fourth week of pregnancy. Calcification continues after birth. In the adult skeleton, hyaline cartilage forms the disks between the vertebrae in the back, the rings that give the TRACHEA stability, and the extensions that connect the ribs to the sternum. A type of cartilage that contains fibers of elastin that allow greater FLEXIBILITY, called elastic cartilage or yellow cartilage, gives shape to the outer ears (auricles), auditory canal (EAR canal), and end of the NOSE.

Cartilage consists of a thick, somewhat elastic base of collagen (an insoluble protein) with small clusters of cartilage cells (chondrocytes) suspended within it. Though cartilage does not have its own BLOOD or NERVE supplies, it continuously renews itself through a process called remodeling in which chondrocytes facilitate a slow turnover of collagen molecules and other substances. This remodeling provides chondrocytes with the NUTRIENTS they need to function.

Researchers believe imbalances in the remodeling process, in which the breakdown of collagen molecules exceeds rebuilding, is the basis for OSTEOARTHRITIS. Various mechanisms, notably repeated trauma such as through use of the joints and activation of CYTOKINES through the inflammatory process, contribute to this imbalance. Damage to cartilage is the foundation of osteoarthritis, HERNIATED NUCLEUS PULPOSUS, and most KNEE INJURIES.

For further discussion of cartilage within the context of musculoskeletal structure and function, please see the overview section "The Musculoskeletal System."

cervical spondylosis Narrowing of the channel between the vertebrae in the neck through which the SPINAL CORD passes. Cervical spondylosis results from chronic, degenerative OSTEOARTHRITIS in which there is extensive INFLAMMATION and damage to the CARTILAGE disks that separate and cushion the cervi-

cal vertebrae (bones of the neck). The damage is permanent and eventually restricts the movement of the neck. Pressure against the NERVE roots of the spinal cord may cause tingling or loss of sensation in the shoulders and arms. Sometimes the pressure also causes weakness of the muscles in the upper back and the arms. Cervical spondylosis is more common in people over age 60.

Symptoms of cervical spondylosis include

- stiffness in the neck
- HEADACHE
- PAIN along the back of the neck that radiates into the shoulders and upper arms
- abnormal sensation in the upper back and arms, sometimes extending to the hands and fingers

The diagnostic path includes X-RAY of the neck and upper back, which typically reveals the changes in the alignment of the vertebrae as well as the formation of bone spurs and calcifications within the disks. Additional imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN, MAGNETIC RESONANCE IMAGING (MRI), and myelogram (injection of radio-opaque dye into the spinal column) often show the degree to which the spondylosis compresses the nerve roots or, when degeneration is severe, the spinal cord itself.

Treatment options include NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) to relieve inflammation and pain. A soft cervical collar that immobilizes the neck allows the muscles of the neck to relax, helping inflammation to recede. Injections of steroid medications can often reduce inflammation that does not respond to other treatments. Heat and PHYSICAL THERAPY aid HEALING and restoration of movement. Though cervical spondylosis is a chronic and progressive condition, most people are able to obtain relieve through a combination of medical and lifestyle methods.

Charcot-Marie-Tooth (CMT) disease An inherited neuromuscular disorder in which the myelin sheath that covers and protects the PERIPHERAL NERVES deteriorates. The loss of the myelin sheath allows NERVE signals to escape from the nerves before they reach their destinations. CMT is the most common inherited neuromuscular disorder in the United States, affecting about 150,000 Americans. CMT is slowly progressive though not fatal, with symptoms typically beginning in late ADOLESCENCE or early adulthood.

There are numerous forms of CMT, each arising from MUTATION of different genes that encode the proteins that form the myelin sheath. The most common is CMT1, which occurs in three autosomal dominant variations that cause abnormal structure in the myelin sheath:

- CMT1A results when the person inherits an extra copy of the GENE on CHROMOSOME 17 that encodes peripheral myelin protein 22 (PMP-22), causing excessive production of PMP-22.
- CMT1B occurs as a result of mutations to the gene that encodes myelin protein 0 (MP-0).
- CMT1C results from mutations to genes that encode for other peripheral myelin proteins, though researchers have not yet identified the mutations.

Other forms of CMT include

- CMT2, in which there are defects in the axons of the peripheral nerves rather than in the structure of the myelin sheath
- CMT3, also called Dejerine-Sottas disease, which results from mutations to the MP-0 or PMP-22 gene and causes severe symptoms beginning in the first year of life
- CMT4, in which various gene mutations cause symptoms that begin in childhood and progress to complete loss of motor function of the lower extremities by adolescence
- CMTX, which arises from a mutation in the connexin 32 gene on the X chromosome and causes more severe symptoms in males

Occasionally CMT occurs as a spontaneous mutation, without family history of the disease, and may affect any of the genes that encode for myelin proteins.

Symptoms and Diagnostic Path

Symptoms affect primarily the legs and feet in most forms of CMT, though in some forms may

also affect the arms and hands. Though the motor symptoms of CMT are most prominent, CMT also affects sensory perceptions and can cause tingling and numbness (PARESTHESIA). Characteristic symptoms of CMT include

- apparent clumsiness or difficulty walking, running, and jumping
- progressive weakness in the legs and feet, and occasionally in the arms and hands
- atrophy (wasting) of MUSCLE mass in the affected extremities
- diminished sensory perception in the extremities, particularly of heat, cold, and PAIN
- foot drop and heel slap when walking, indications of muscle weakness in the lower leg and foot

The diagnostic path includes a comprehensive NEUROLOGIC EXAMINATION, detailed PERSONAL HEALTH HISTORY, nerve conduction studies, and electromyogram (EMG). The neurologist may also perform a nerve biopsy to examine the structure of nerve cells in the muscle tissue and GENETIC TESTING for mutations known to cause CMT. The neurologic examination typically shows diminished or absent reflexes at the elbow, knee, and ACHILLES TENDON.

Treatment Options and Outlook

CMT is a progressive, lifelong condition. Symptoms in CMT1 generally stop short of complete loss of motor function in the affected extremities. Other forms of CMT, notably CMT4 and CMTX, may result in inability to walk. PHYSICAL THERAPY and daily physical activity—STRENGTH exercise, RESISTANCE EXERCISE, and activities to improve balance and FLEXIBILITY such as YOGA—can extend unassisted mobility. Bicycling and swimming are excellent activities for AEROBIC EXERCISE as well as for strengthening and flexibility with minimal impact on the ankles, which are the most vulnerable as CMT progresses. Adaptive devices such as braces, walkers, and wheelchairs can aid mobility when motor function deteriorates to a point that cannot support independent mobility. Some people benefit from surgery to rebalance muscles and tendons, in particular to provide support for the feet. Despite the progressive nature of CMT, the condition is not fatal; and with adaptive devices and environmental modifications, most people who have CMT can enjoy productive lifestyles.

Risk Factors and Preventive Measures

CMT is nearly always an inherited condition, so the key risk factor is genetics. GENETIC COUNSELING can assist couples with FAMILY PLANNING. Early diagnosis and treatment preserves muscle strength and function to the greatest extent possible. High-top shoes and braces to support the ankle extend mobility and reduce the risk for ankle injuries such as sprains, strains, and fractures.

chondritis INFLAMMATION of CARTILAGE that may occur anywhere in the body though is most common in the cartilage of the ribs (costochondritis), on the ends of the bones (osteochondritis), and within the external EAR (auricular chondritis). Chondritis often results from trauma, such as a blow or, when the external ear is involved, after a burn injury. Bacterial INFECTION may accompany the inflammation. Polychondritis is an autoimmune disorder in which inflammation affects multiple locations of cartilage throughout the body. Some rheumatologists believe polychondritis is a form of VASCULITIS. NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) may suppress the inflammatory response. Bacterial infection requires treatment with ANTIBIOTIC MEDICATIONS. However, chondritis may respond slowly to treatment because cartilage does not have a BLOOD supply to carry medications to the site of the inflammation. Heat and rest may provide some relief.

clubfoot See TALIPES EQUINOVARUS.

congenital hip dysplasia A condition in which the head of the femur (thigh BONE) does not properly seat in the acetabulum (pelvic socket) at birth. Numerous potential causes may account for

congenital hip DYSPLASIA, also called congenital hip displacement or developmental dysplasia of the hip. The dysplasia is sometimes apparent at birth; doctors may suspect it when the delivery presentation is breech because this holds the infant's hips in a flexed position. Symptoms may include a perceptible clicking, often felt and heard, when moving the legs to activate the hip JOINT. Rarely, the leg may be obviously out of alignment with the pelvis. X-RAY can often confirm the diagnosis, though some dysplasias may not be detectable until the infant is older.

The pediatrician may choose watchful waiting for a mild dysplasia. A special brace called a Pavlik harness holds the hips in their proper position in moderate dysplasia, until the connective tissues develop the STRENGTH to hold the femur snugly within the acetabulum. Severe dysplasia or dysplasia that is undetected until the child is walking may require closed reduction, in which the orthopedic surgeon manipulates the joint into place with the child under ANESTHESIA, or open reduction, in which the orthopedic surgeon makes surgical repairs to the joint. Early and appropriate treatment is important for proper mobility and development of the leg.

See also BIRTH DEFECTS; CONGENITAL ANOMALY; SURGERY BENEFIT AND RISK ASSESSMENT.

contracture An abnormal shortening or tightening of connective tissue or MUSCLE that impedes proper movement of a JOINT, digit, or other musculoskeletal structure. Contractures typically develop when fibrous tissue (scarring), which is relatively inflexible, replaces normal connective tissue. This process may reflect autoimmune activity in the body (such as occurs in RHEUMATOID ARTHRITIS), repeated trauma (such as occurs in REPETITIVE MOTION INJURIES), or a neuromuscular disorder (such as MUSCULAR DYSTROPHY or CEREBRAL PALSY). Contractures can cause permanent deformity of joints, resulting in limited function or movement.

Common types of contracture include

- Dupuytren's contracture, in which fibrous tissue in the fascia of the hand causes the ring and sometimes little (third and fourth) fingers to draw toward the palm
- foot drop, which results from damage to the muscles and nerves of the lower leg
- wrist drop, which results from damage to the muscles and nerves of the lower arm
- Volksmann's contracture, which results from injury that restricts the flow of BLOOD to the forearm and hand

Early symptoms of contracture include difficulty straightening a joint and occasionally discomfort or PAIN with movement of the joints. Therapeutic efforts such as gentle stretching and braces may improve function, though surgery may be necessary to release fibrotic tissue.

See also ARTHROGRYPOSIS; SCAR; TALIPES EQUINOVARUS.

cramp A painful, involuntary, and often extended contraction of a MUSCLE. Cramps may occur in any muscle and often occur with overuse, such as writer's cramp and leg cramps during running. Overexertion, DEHYDRATION, and fatigue are key contributors to muscle cramps. Uterine cramps are common with MENSTRUATION. Gentle stretching and massage can relieve the contraction, allowing the muscle to relax. Heat to the area, such as with menstrual cramps, helps maintain the muscle in a relaxed state. Stretching before physical exercise helps prepare the muscles for activity. Adequate hydration helps muscles release toxic byproducts into the BLOOD circulation.

See also DYSMENORRHEA; SPASM.

crepitus A cracking, clicking, or snapping sound, also called crepitation, that occurs with movement of a JOINT. Crepitus may occur in normal, healthy joints though is often quite pronounced in degenerative joint disorders in which the surfaces of joint structures are rough or irregular and protective CARTILAGE structures have deteriorated. Crepitus is a common feature of TEMPOROMANDIBULAR DISORDERS, PATELLOFEMORAL SYNDROME, fractures due to trauma, and OSTEOARTHRITIS.

D–G

dislocations Separations of the structures within a JOINT, typically as a result of traumatic injury. The digits (fingers and toes), shoulders, and hips are particularly vulnerable to dislocation. Traumatic dislocation is very painful. Generally a doctor should reduce the dislocation (restore the bones to their correct positions) and evaluate the injury for any damage that would require additional treatment; however, people tend to "pop" dislocations back into place themselves. Such self-treatment can cause further trauma, depending on the circumstances. Splinting the joint and applying ice to the area can reduce swelling and PAIN until the doctor can realign the structures. Sometimes a dislocation reflects an abnormality of the joint that requires a doctor's assessment and treatment to prevent subsequent dislocations.

dwarfism See SKELETAL DYSPLASIA.

dystonia Extended contractions of the muscles that hold the body in unnatural postures. Dystonia may occur as a primary disorder of movement, typically a hereditary disorder, or as an undesired SIDE EFFECT of certain medications to treat PARKINSON'S DISEASE, PSYCHOSIS, SCHIZOPHRENIA, and SEIZURE DISORDERS that affect DOPAMINE binding in the BRAIN. Dopamine is a key NEUROTRANSMITTER for movement as well as for mood. Sometimes, though unfortunately not always, stopping the medication ends DRUG-related dystonia. Inherited forms of primary dystonia may be spastic (involve rigid, distorted postures) or repetitious, often rhythmic, involuntary movements such as grimaces, twitches, and jerking.

There are no treatments for primary dystonia that are certain to stop the MUSCLE contractions. Some people experience relief with high doses of anticholinergic drugs that affect acetylcholine, a neurotransmitter important to fine motor movements. When the dystonia occurs in a localized or regional part of the body, BOTULINUM THERAPY (injections of weakened botulinum toxin) sometimes can paralyze the muscles enough to significantly reduce or eliminate the dystonia. The effects of botulinum therapy are temporary, however, with repeat treatments required about every six months.

epicondylitis INFLAMMATION of the TENDON at the elbow end of the humerus (long BONE of the upper arm). Epicondylitis may be lateral or medial. Lateral epicondylitis, commonly called tennis elbow, affects the outer side of the elbow (little finger side). Bending the wrist back or applying pressure to the bony projection (the humeral epicondyle) on the outside of the elbow causes PAIN at the elbow. Painting and plastering are common occupational causes of lateral epicondylitis. Medial epicondylitis, commonly called baseball elbow or golfer's elbow, affects the inner side of the elbow (thumb side). Bending the wrist toward the palm of the hand or squeezing a ball held in the palm of the hand causes pain at the base of the elbow.

The doctor makes the diagnosis on the basis of symptoms and personal history of overuse or a blow to the elbow. Diagnostic procedures are usually not necessary. Treatment combines NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) or injections of CORTICOSTEROID MEDICATIONS, which reduce inflammation and pain, with alternating heat and cold to the area. A brace or band worn over the humeral epicondyle provides relief for some people. Epicondylitis generally goes away in

8 to 12 weeks. Recurrent epicondylitis may require surgical repair.

fascia The fibrous membrane that covers connective tissue. Deep fasciae enclose, support, and separate MUSCLE structures deep within the body. Superficial fasciae support the SKIN and connect the skin to inner layers of tissue. Fascia has high tensile STRENGTH and a sheetlike appearance. It varies in thickness, depending on its location and purpose. Fasciae throughout the body are susceptible to INFECTION, INFLAMMATION, and traumatic injury.

See also CONTRACTURE; FIBROMYALGIA NECROTIZING FASCIITIS; PLANTAR FASCIITIS.

fibromyalgia A chronic condition of PAIN felt in the muscles and connective tissues throughout the body, with accompanying fatigue and multiple trigger points (areas on the body where the slightest touch activates a severe pain response). Characteristically people experience a constant level of discomfort with pressure or contact causing overt pain in the shoulders, chest, back, hips, and knees. Many people also experience stiffness in the areas of pain, similar to the stiffness of RHEUMATOID ARTHRITIS or OSTEOARTHRITIS. However, there is no JOINT INFLAMMATION or deterioration with fibromyalgia. Fibromyalgia may persist for months to years. About 6 million Americans have fibromyalgia, the majority of whom are women. Researchers believe fibromyalgia develops through a convergence of multiple factors.

Symptoms and Diagnostic Path

The symptoms of fibromyalgia are widely variable, making diagnosis somewhat of a challenge for many people. Some people have periods of weeks to months without any symptoms, interlaced with periods of weeks to months with symptoms severe enough to prevent normal activity. Other people have a clear path of symptom onset, persistence, and improvement that spans months to years. Characteristic symptoms of fibromyalgia include

- MUSCLE pain throughout the body
- sleep disturbances such as insomnia and RESTLESS LEGS SYNDROME
- fatigue
- gastrointestinal symptoms that suggest IRRITABLE BOWEL SYNDROME (IBS), such as frequent NAUSEA and DIARRHEA
- DEPRESSION, anxiety, and mood swings
- headaches
- hypersensitivity to sensory stimulation (sight, sound, touch, taste, smell)

The diagnostic path begins with a comprehensive medical examination including general BLOOD and urine tests, a NEUROLOGIC EXAMINATION, and detailed PERSONAL HEALTH HISTORY. The doctor may conduct further tests to rule out other conditions that can cause similar symptoms, such as rheumatoid arthritis and SYSTEMIC LUPUS ERYTHEMATOSUS (SLE). However, there are no tests that can confirm the diagnosis of fibromyalgia. Doctors typically follow clinical guidelines for reaching a diagnosis of fibromyalgia that include the presence of these key signs:

- diagnostic tests rule out other possible causes for the symptoms
- point tenderness (discomfort or pain with mild pressure) at a minimum of 11 places on the body
- widespread, persistent aching or pain in the muscles and joints for at least three months

The diagnosis also considers factors researchers believe may be precipitating, such as recent INFECTION or injury, the existence of any AUTOIMMUNE DISORDERS, and family history of fibromyalgia. Symptoms generally begin between ages 30 and 50.

Treatment Options and Outlook

Treatment efforts focus on relieving symptoms to a degree that allows participation in regular activities and satisfactory QUALITY OF LIFE with the presumption that symptoms will persist indefinitely. Though the condition may eventually go away, in most people the course of fibromyalgia is unpredictable though symptoms do not worsen. Treatment is a process of finding the combination of approaches that most effectively relieves symptoms. Common treatment options include

- ANALGESIC MEDICATIONS such as acetaminophen and NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) to relieve pain
- ANTIDEPRESSANT MEDICATIONS to treat depression and to relieve pain
- MUSCLE RELAXANT MEDICATIONS
- CHIROPRACTIC, OSTEOPATHIC MANIPULATIVE TREATMENT (OMT), and MASSAGE THERAPY to relax muscles and improve range of motion and FLEXIBILITY of joints
- ACUPUNCTURE for pain relief and stress reduction
- YOGA and TAI CHI to improve flexibility, STRENGTH, and balance and to relieve stress
- MEDITATION for stress relief

Doctors seldom prescribe narcotic pain relievers, sleep medications, CORTICOSTEROID MEDICATIONS (such as prednisone), or benzodiazepine muscle relaxants (such as diazepam), because these treatments interfere with normal activities and are not proven to improve symptoms long term. As well, the side effects and potential dependency issues with these medications are greater than the short-term benefits for most people. Doctors also recommend daily physical exercise because it increases the release of endorphins and enkephalins, the body's natural pain relievers. It also stretches and strengthens the muscles and connective tissues, and promotes a sense of accomplishment and well-being.

Risk Factors and Preventive Measures

About 80 percent of people who have fibromyalgia are women, though researchers do not know why this gender correlation exists. People who have autoimmune forms of arthritis, such as rheumatoid arthritis or ANKYLOSING SPONDYLITIS, also have increased risk for fibromyalgia. Because researchers do not know what causes fibromyalgia, there are no recommended preventive measures.

fracture A break in a BONE. The most common cause of bone fracture is traumatic injury. Spontaneous fracture may occur in people who have health conditions such as OSTEOGENESIS IMPERFECTA, severe OSTEOPOROSIS, or BONE CANCER. Fractures may take various forms, including

- avulsion, in which a small chip of bone breaks away
- closed (simple), in which the bone ends remain relatively in alignment and do not penetrate through the SKIN
- comminuted, in which the bone fragments into multiple pieces
- compression, in which the bones collapse onto one another (such as vertebrae in the back)
- greenstick, which typically occur in young children whose bones are still supple and appear as a bend or curve rather than an outright break in the bone
- open (compound), in which the bone ends are significantly separated and protrude through the skin, causing an open wound
- spiral, which occur when sudden force twists the bone and the break runs in line with the bone's axis
- stress, in which hairlike cracks develop in bones subject to repetitive stress (such as the tibia, the long bone in the lower leg, with running)

Bone fractures require prompt care from a doctor. Nearly always it is necessary to immobilize the bone ends so they remain aligned and can heal back together.

Do NOT move a person who may have a fractured neck or back. Summon emergency medical aid and keep the person still, calm, and as comfortable as possible.

Symptoms and Diagnostic Path

Severe PAIN and rapid swelling after trauma are the most common symptoms of bone fracture. Most often, the person cannot bear weight or put pressure on the involved area. The limb or digit may appear distorted or a bone end may protrude through the skin. X-RAY nearly always confirms the diagnosis, though more sophisticated imaging procedures such as MAGNETIC RESONANCE IMAGING (MRI) and bone scan are occasionally necessary

to confirm stress fractures and some spiral fractures.

Treatment Options and Outlook

Treatment immobilizes the bone ends. The most common method of immobilization is a plaster or fiberglass cast, applied as a wet wrap around the fracture and usually spanning the joints above and below the break in the bone. The cast hardens as it dries, and remains in place for three to six weeks for most fractures. Other methods of external immobilization include splints and braces.

Sometimes the doctor must move the bone ends into alignment, a procedure called reduction. For most fractures that require reduction, the doctor first administers a strong sedative or ANESTHESIA, then manipulates the bones. When no incision is necessary the reduction is a closed reduction; when the doctor must open the fracture site to realign the bones the reduction is an open reduction (surgery). During an open reduction the doctor generally places pins, plates, screws, or nails to hold the bone ends in place. Fractures set via open reduction generally do not require casting and the person can return to movement as tolerated because the hardware holds the bone together.

Most fractures heal within 6 to 10 weeks. Immobilized muscles atrophy (shrink), and the person may need PHYSICAL THERAPY to restore MUSCLE STRENGTH and JOINT range of motion after the doctor removes the cast or other immobilizing device. The area of HEALING remains thicker than the rest of the bone for up to a year. Refracture at the same site is very unlikely.

Risk Factors and Preventive Measures

MOTOR VEHICLE ACCIDENTS and athletic or recreational activities that expose a person to impact or falling present the greatest risk for fractures. Older people are vulnerable to fractures with falls, primarily as a consequence of OSTEOPENIA or osteoporosis (conditions in which the bones become thin and weak). Proper protective equipment—for example seat belts, pads, braces, and helmets—can prevent many fractures and other injuries.

frozen shoulder See ADHESIVE CAPSULITIS.

gangrene The death of tissue (necrosis) resulting from deprivation of BLOOD circulation to an area of the body. Gangrene most commonly affects the digits (fingers and toes) and extremities (hands and feet). FROSTBITE, PERIPHERAL VASCULAR DISEASE (PVD), NEPHROPATHY of DIABETES, severe INFECTION (such as clostridial infections and NECROTIZING FASCIITIS), and RAYNAUD'S SYNDROME are common causes of gangrene. TESTICULAR TORSION in which a TESTICLE becomes strangulated (twisted such that its blood supply is cut off) can result in testicular gangrene. A strangulated HERNIA, which entraps a segment of bowel, can similarly result in intestinal gangrene. Gangrene can also affect internal organs that lose their blood supply, such as may occur with a major thromboembolism (blood clot in an ARTERY). Gangrene tends to progress as it consumes healthy tissue. Gangrenous tissue is characteristically black or greenish black and may have a foul odor. Because the tissue is dead, the person has no sensation of PAIN from the area though inflamed tissue at the periphery of the gangrenous tissue may cause intense pain.

Methods to improve blood circulation, such as thrombolytic medications to dissolve blood clots and vasodilator medications to dilate (widen) the arteries for increased blood flow, may restore enough circulation to allow the area to heal. Oxygen delivered under pressure in a hyperbaric chamber is sometimes successful in restoring enough oxygen to the tissues that they can begin to heal. Generally, however, the doctor must surgically remove all gangrenous tissue for HEALING to take place. Such removal may require AMPUTATION of the affected digit or limb. Often recovery is then complete, depending on the underlying cause for the gangrene. People who have diabetes, PVD, or peripheral neuropathy have increased risk for gangrene to develop in what would otherwise be minor wounds.

See also INFECTIOUS ARTHRITIS; OSTEOMYELITIS; PROSTHETIC LIMB.

gout A form of inflammatory arthritis. Gout develops when uric acid crystals form within the JOINT capsules, causing irritation and INFLAMMATION. Uric acid is a waste byproduct of the METABOLISM of

forms of protein (nucleic acids) called purines. Purines occur naturally in the body as well as in meats consumed in the diet (especially organ meats such as liver and fish such as mackerel and herring). The most common site for gout is the first (largest) joint of the big toe. Gout may also affect the metatarsal and tarsal joints in the feet as well as the ankles and knee; it less commonly involves the fingers and wrists.

Symptoms and Diagnostic Path

Gout generally begins with sudden and severe PAIN in the affected joint, usually the first joint of the big toe. The pain commonly arrives at night and wakes the person. The affected joint may be red, swollen, and warm to the touch. The pain and other symptoms typically go away within 10 days, and there can be an extended period before symptoms return. The diagnostic path includes X-rays of the affected joints and tests of the BLOOD and URINE to measure uric acid levels. Sometimes the doctor will numb the joint and use a needle and syringe to withdraw synovial fluid to examine for the presence of uric acid crystals. As gout progresses, often the uric acid crystals also form deposits, called tophi, under the SKIN.

Treatment Options and Outlook

Treatment during a gout attack focuses on relieving inflammation and pain. NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NASAIDS) or CORTICOSTEROID MEDICATIONS are generally the first line of medications to target these symptoms. Medications to reduce the risk for future gout attacks include colchicine, allopurinol, and probenecid, which slow the body's production of uric acid. These medications do not prevent gout from progressing but can extend the time between attacks as well as reduce the permanent damage the inflammation can cause.

FOODS WITH HIGH PURINE CONTENT

cod	crab	duck
ham	herring	kidneys
lentils	liver	lobster
mackerel	mushrooms	mussels
oysters	sardines	scallops
shrimp	sweetbreads	trout
turkey	veal	venison

Risk Factors and Preventive Measures

About 20 percent of people who have gout also have other family members who have gout, giving rise to suspicion of a genetic factor. Circumstances that increase the amount of uric acid in the blood circulation significantly raise the risk for gout. Such circumstances include consumption of foods high in purines, medications that affect the body's ability to excrete purines (such as diuretic medications and immunosuppressive drugs after ORGAN TRANSPLANTATION), DIABETES, HYPERLIPIDEMIA, and OBESITY. Excessive ALCOHOL consumption interferes with the ability of the KIDNEYS to filter uric acid from the blood. Though there do not appear to be effective ways to prevent gout from developing, avoiding circumstances that increase blood uric acid levels can reduce the frequency and severity of gout attacks. Men are more likely to develop gout before age 50 and women after age 50.

hernia A separation or tear in the fibers of a MUSCLE that allows the underlying tissue or structure to bulge through. Hernias may occur as a result of congenital weakness or incomplete closure of a channel in the muscle (such as an umbilical or inguinal hernia) or because of injury (unintended or surgical). The common types of hernia are

- inguinal hernia, which occurs in the inguinal canal (groin)
- femoral hernia, which occurs in the upper thigh
- umbilical hernia, which occurs at the umbilicus (belly button)
- HIATAL HERNIA, which occurs in the DIAPHRAGM and is not visually perceptible
- incisional hernia, which occurs at the site of a surgical incision, usually abdominal

Hernias present in children often heal as the child grows. Hernias in adults are often present from childhood and become problematic when some sort of strain puts pressure on them. Hernias are somewhat more common in men. When the person or doctor can push the hernia back into the muscle wall it is reducible; an incarcerated hernia is a hernia that will not recede. When the hernia traps a segment of intestine or other tissue to the extent that it cuts off the BLOOD supply, it is a strangulated hernia. Though some hernias, particularly in children, may correct themselves, most hernias require surgery to repair the defect in the muscle wall.

Symptoms and Diagnostic Path

A hernia may appear as a painless bulge or may cause discomfort, depending on its location and the extent to which it allows intestinal structure to protrude through the muscle wall. Many abdominal hernias are more prominent with coughing or bearing down. Symptoms of hiatal hernia may include DYSPEPSIA (heartburn) and difficulty swallowing. Diagnosis is primarily clinical, based on the appearance of the symptoms. The doctor may request an ULTRASOUND examination to confirm the presence of the hernia and to create a visual image to help assess the appropriate therapeutic course.

Treatment Options and Outlook

Most hernias require surgery to repair the weakness in the muscle wall. The doctor may decide to take an approach of watchful waiting when the hernia is very small, in a young child, or in a person for whom surgery is a significant risk. Nonsurgical approaches such as a truss (a supportive device that places pressure against the hernia to keep it within the abdominal wall) may relieve symptoms for the short term but cannot correct the hernia. Though some hernias may remain small and inconsequential for long periods of time they may become problematic without warning, at which point they may require immediate or urgent medical attention. An incarcerated hernia is a medical emergency that requires immediate surgery, otherwise the strangulated tissue dies and is at very high risk for GANGRENE.

Hernia repair surgery, called herniorrhaphy or hernioplasty, can be OPEN SURGERY (an OPERATION in which the surgeon makes a two- to three-inch-long incision over the site of the hernia and directly exposes the involved muscles) or MINIMALLY INVASIVE SURGERY (an operation in which the surgeon uses a laparoscope and special instruments to operate through one to three small incisions). ANESTHESIA may be regional, epidural, or

general. Variables that influence the surgeon's decision about the type of operation include the location and size of the hernia, the person's age and general health status, and whether the hernia is reducible or incarcerated.

For most hernia repairs the surgeon places a small piece of plastic mesh behind the opening in the muscle wall to help support the muscle layers. The surgeon then sutures those layers together to restore stability and STRENGTH to the muscle wall. Recovery takes about two weeks for a laparoscopic surgery and up to six weeks for an open surgery. Once repaired, hernias do not generally recur though it is common to feel twinges of discomfort and even PAIN periodically at the site up to several years after the surgery.

Risk Factors and Preventive Measures

Repeated straining, such as with bowel movements or because of chronic COUGH, can pressure a weak place in the abdominal wall. Though sudden, strenuous movement can bring out a hernia, such movement can occur with a strong SNEEZE or cough as easily as lifting too heavy a weight. Regardless of the activity that bears blame, the underlying cause of a hernia is a weakness in the muscle structure. Though exercises to improve muscle strength may prevent injuries such as strains and muscle tears, exercises cannot prevent or treat hernia. There are no known measures for preventing hernia.

herniated nucleus pulposus Damage to the structure of the CARTILAGE that cushions the vertebrae, also called a herniated, slipped, or ruptured disk. A herniated nucleus pulposus becomes increasingly common with advancing age, the result of wear and deterioration of the tough outer cartilage (called the annulus fibrosus) that allows the soft inner portion of the disk (called the nucleus pulposus) to bulge beyond its enclosure. Often there is a clear tear in the outer cartilage (a rupture). A traumatic injury, such as a motor vehicle accident, or heavy lifting may also cause a disk to herniate.

This deterioration and bulging is common enough that doctors believe in itself it does not represent a health condition that requires treatment. However, the situation becomes problematic when the herniation places pressure against the roots of the SPINAL NERVES or the SPINAL CORD, causing PAIN and weakness or numbness in the leg (typically only one leg). Though symptoms may seem to start suddenly, they reflect processes that usually have been under way for a considerable time.

Symptoms and Diagnostic Path

The main symptom of herniated disk is sharp, shooting pain in the low back and in the leg (called radiculopathy). The pain in the leg is more significant for many people, and the leg may feel weak or numb in certain areas, depending on which spinal NERVE roots the herniation compresses. Some people experience discomfort in both legs, may have difficulty walking, and may have partial or complete loss of bladder or bowel function.

Sudden loss of bladder or bowel control is a serious symptom that requires immediate evaluation from a doctor.

The diagnostic path begins with a comprehensive medical examination, including NEUROLOGIC EXAMINATION and detailed PERSONAL HEALTH HISTORY. Diagnostic imaging procedures such as X-RAY of the spine, COMPUTED TOMOGRAPHY (CT) SCAN, MAGNETIC RESONANCE IMAGING (MRI), and myelography (dye injected into the spinal column and viewed with X-ray) often reveal the location and severity of the herniation. The doctor may also request nerve conduction studies and electromyogram (EMG) to assess neuromuscular function. It is possible for diagnostic tests to be unable to pinpoint the precise cause of the symptoms, which does not necessarily rule out herniation.

Treatment Options and Outlook

Most doctors prefer, and most people respond to, conservative, nonsurgical treatment that targets relieving the pain and INFLAMMATION. Such an approach may include

- NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS)
- heat or cold to the area

- limited activity for two to three days to allow the inflammation to subside
- MUSCLE RELAXANT MEDICATIONS to relieve MUSCLE SPASM
- structured, progressive PHYSICAL THERAPY including strengthening exercises for the back and proper techniques for lifting
- gradual return to regular activities

When pain is severe or does not respond to oral medications the doctor may inject the area with a corticosteroid medication in combination with a local anesthetic. Such an injection typically provides rapid and direct relief that lasts from several weeks to several months and may be sufficient to heal the damage to the disk.

A small percentage of disk herniations continue to cause pain and interfere with normal activities after conservative treatment efforts. In such situations, the doctor may recommend LAMINECTOMY, a surgical OPERATION to remove the damaged disk. Health experts strongly encourage a second opinion consultation with another doctor who specializes in treating back conditions before agreeing to back surgery. Though successful back surgery both relieves pain and restores function, complications are high enough to have earned designation as a health condition themselves: failed back surgery syndrome (FBSS). Both orthopedic surgeons and neurosurgeons perform surgeries for conditions of the spine; it is often valuable to have opinions from each type of doctor before making a decision about back surgery.

Risk Factors and Preventive Measures

The key risk factors for herniated nucleus pulposus are age and sudden stress to the back such as heavy lifting or traumatic injury. Cigarette smoking accelerates normal processes of deterioration and reduces the flow of BLOOD to the structures of the spine. Regular physical exercise to strengthen back muscles and abdominal muscles improves support for the spine, helping maintain proper alignment of the vertebrae to reduce wear and deterioration. Proper lifting methods reduce strain on the back. Though there are no measures to prevent herniation, such measures help protect the spine from injury that exacerbates other factors. Most people recover from an episode of ACUTE PAIN with conservative treatment and are able to return to their regular activities.

hip fracture in older adults An injury, often preventable, that often results in significant disability or premature death. One in four hip fractures in adults over age 50 results in limited mobility after HEALING; one in four is fatal. Hip FRACTURE becomes a risk with increasing age for a combination of factors that include

- increasing loss of BONE and MUSCLE mass resulting in decreased STRENGTH and unsteady balance
- slowed reflexes and physical reactions
- diminished VISUAL ACUITY
- OSTEOPOROSIS (a condition of thin, weak bones due to loss of BONE DENSITY)
- health conditions such as ALZHEIMER'S DISEASE that impair judgment
- health conditions such as PARKINSON'S DISEASE that impair mobility
- medication side effects such as drowsiness, dizziness, and orthostatic HYPOTENSION (a sudden drop in BLOOD PRESSURE that occurs when rising)

Falls, two thirds of which occur in the home, account for 95 percent of hip fractures. Risks include loose rugs on the floor, uneven or slippery walking surfaces, and objects out of place that become obstacles. Though women are more likely to fracture a hip in a fall, men are more likely to die after hip fracture. Hip fracture has such a poor prognosis because recovery requires extended immobility, which has high risk for complications such as BLOOD clots and PNEUMONIA. Older adults are often reluctant to tell family members or their doctors when they fall for fear of losing independence. Efforts to reduce the risk for falls are the most effective measures for preventing hip fracture. Measures to strengthen bone and muscle, such as daily walking and light RESISTANCE EXERCISE (weightlifting), also help.

I–J

infectious arthritis INFLAMMATION of a JOINT that results from INFECTION. The infectious agent (PATHOGEN) may be BACTERIA or mycobacteria or a VIRUS, or fungus and travels to the joint through the BLOOD circulation. Infectious arthritis, also called septic arthritis, may also develop as a consequence of contamination during surgery on the joint. The doctor may withdraw fluid from the infected joint to examine its cells and determine the causative pathogen.

Immediate treatment with the appropriate ANTIBIOTIC MEDICATIONS or ANTIFUNGAL MEDICATIONS is essential to limit damage to the joint. NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) are effective for relieving inflammation, PAIN, and FEVER associated with infectious arthritis. Sometimes needle aspiration or surgery is necessary to drain accumulated pus from the joint. With prompt and appropriate treatment, most people recover from infectious arthritis with few or no complications or long-lasting residual effects.

joint An articulating structure that connects two or more BONE surfaces to allow movement. The movement may be slight or the joint fused, such as the sutures in the cranium (skull). A joint may function like a hinge, such as the knee and elbow, or like a ball and socket, such as the hip and shoulder. In the carpal (hand) and tarsal (foot) joints, the bones glide along each other. Synovial capsules enclose joints that allow extensive movement between the bone surfaces, such as the knees, hips, and shoulders. The synovial membrane produces synovial fluid, which lubricates the bone ends within the joint to reduce friction between or among the structures of the joint during movement. Joints are particularly vulnerable to injury and damage resulting from repetitious motion.

joint replacement A surgical OPERATION, also called total JOINT replacement, to remove a severely diseased or damaged joint and replace it with a prosthetic joint. OSTEOARTHRITIS and RHEUMATOID ARTHRITIS are often to blame for joint deterioration severe enough to require joint replacement. The most commonly replaced joints are hips, knees, and shoulders. Prosthetic joints are also available for fingers, elbows, and ankles. Prosthetic joints are made of a variety of materials, usually combinations of metals (such as titanium) and plastic composites (such as polyethylene) that are durable, strong, and light.

Surgical Procedure

Joint replacement requires a hospital stay of three to seven days. The surgeon performs the operation with the person under general ANESTHESIA. For hip or knee replacement, an option is epidural or

spinal anesthesia with sedation for comfort. A joint replacement operation takes about two hours, during which the surgeon makes an incision large enough to adequately expose the joint, cuts away the damaged joint structures, prepares the remaining BONE structure to receive the prosthesis, and cements or otherwise attaches the prosthesis components into place. After the surgeon finishes the operation, the person goes to the recovery unit for close nursing supervision and care until the anesthesia wears off and PAIN control is satisfactory, usually for two to four hours.

Return to activity begins almost immediately and is essential for full recovery of joint function. It is especially important for the person to begin walking right away for hip and knee replacements. The doctor will prescribe ANALGESIC MEDICATIONS for pain relief. Intensive PHYSICAL THERAPY moves the new joint through passive and active range of motion exercises. Frequent walking also reduces the risk for blood clots. The doctor may prescribe medication, support stockings, or inflatable compression cuffs.

Risks and Complications

All surgeries carry the risk for excessive bleeding during or after the operation, blood clots, and INFECTION of the surgical wound. A particular risk with joint replacement is infection that infiltrates the bone, causing more extensive damage than a repeat joint replacement could repair. Other potential complications of joint replacement include failure of the prosthesis, loosening of the insertion of the prosthesis into the bone ends, DISLOCATIONS, and loss of function due to wear over time.

Outlook and Lifestyle Modifications

A prosthetic joint has a life expectancy of 5 to 15 years, depending on the joint and the person's lifestyle. Some strenuous physical activities may no longer be possible, depending on the replaced joint. A replacement hip or knee generally cannot tolerate activities such as running and jumping, for example, though swimming and bicycling are excellent alternatives for aerobic conditioning and improving STRENGTH, ENDURANCE, and FLEXIBILITY. Most people who undergo joint replacement enjoy vastly improved QUALITY OF LIFE after HEALING is complete. Complete rehabilitation and return to normal activities may take three to six months.

K

knee injuries Sprains, strains, CARTILAGE tears, and fractures involving the structures of the knee. The knee is a hinge JOINT that allows the leg to flex (bend back) and straighten, essential actions of walking. Unique among hinge joints in the body, the knee also allows a small amount of rotation. The knee is vulnerable to both traumatic and repetition injuries. Knee injury is the leading reason for visits to orthopedic surgeons in the United States.

The knee primarily joins the femur (thigh BONE) to the tibia (shin bone) and the fibula (small long bone behind the tibia). It also contains the patella (kneecap), a small bone that provides added leverage for movement of the lower leg. A C-shaped thick pad of cartilage, the meniscus, cushions the ends of the bones from each other. Each knee contains two menisci: the medial meniscus, which wraps around the inside of tibia, and the lateral meniscus, which wraps around the outside of the tibia. Strong ligaments bind the knee from each side and the center, holding the bones in place.

The most damaging traumatic injuries to the knee are those that result from a blow or fall that rapidly stretches the ligaments and causes them to tear (ligament sprain). Sudden twisting motions in which the foot plants but the rest of the leg continues to move also expose the knee to such injury. The knee takes considerable pounding in the course of everyday activities that subject it to repeated impact (such as occurs with walking, running, and jumping). Repetition or "wear and tear" injuries of the knee include OSTEOARTHRITIS and PATELLOFEMORAL SYNDROME.

Symptoms and Diagnostic Path

PAIN and swelling are symptoms common to many kinds of knee injuries. Damage to ligaments and menisci often result in an unstable knee that feels "loose" or may not bear the person's weight. With a moderate to severe injury the person hears and feels a substantial "pop" from the knee, which is the LIGAMENT tearing. Depending on which ligament the injury damages, the knee may feel it wants to bend too far back, extend too far forward, or slip to one side or the other. A significant blow to the side of the knee can cause multiple injuries within the knee, rendering the knee useless. Hyperextension and dislocated patella present characteristic appearances that make the diagnosis obvious. A fractured patella can cause excruciating pain and complete inability to use the knee or leg.

The diagnostic path begins with a detailed accounting of the nature of the pain and description of any precipitating trauma. The doctor will thoroughly examine both knees. Diagnostic procedures may include X-RAY, especially if the doctor suspects a FRACTURE, though COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) typically yield more information about the nature and extent of soft tissue injuries such as are most common in the knee. Diagnostic ARTHROSCOPY, a MINIMALLY INVASIVE SURGERY, may be necessary to fully assess the damage and has the advantage of allowing the surgeon to immediately repair the injury.

Treatment Options and Outlook

Ice to the knee and restricting movement are the most effective immediate treatments for traumatic injury. Prompt icing can reduce INFLAMMATION and swelling to minimize the severity of the injury. Suspected patella fracture or severe sprain requires immobilization to prevent further damage. Many knee injuries heal with conservative, nonsurgical treatment approaches. The doctor may recommend a knee wrap or brace, depending on the injury. NONSTEROIDAL ANTI-INFLAMMATORY

COMMON KNEE INJURIES

Injury	Common Causes	Key Symptoms
anterior cruciate LIGAMENT (ACL) sprain	sudden twisting of the knee or blow to the front of the knee	pop or snap felt and heard swelling mild PAIN "loose" feeling to knee inability to bear weight on the leg
hyperextension	direct blow to the front of the knee	pain with hyperextension soreness after knee returns to normal extension
lateral collateral ligament (LCL) sprain	impact to the inside of the knee	pain pop or snap felt and heard knee buckles to the outside
medial collateral ligament (MCL) sprain	impact to the outside of the knee	pain pop or snap felt and heard knee buckles to the inside
meniscus tear	sudden rotation of the upper body with the foot planted	pain clicking or locking within the knee instability of the knee
patella DISLOCATION	impact to the side of the patella fall that jars the side of the patella	pain patella obviously out of position, usually to the side of the knee inability to bend the knee
patella FRACTURE	sharp blow to the patella	severe pain and swelling inability to move the knee or bear weight on the leg
patellar TENDON rupture	stumbling in an attempt to avoid a fall landing after a jump from considerable height	pain tenderness to touch at point of rupture difficulty bending or extending the lower leg displaced patella
PATELLOFEMORAL SYNDROME	long-term repetitious movement of the knees such as with running and bicycling poor conditioning	pain with bending or extending the knee
posterior cruciate ligament (PCL) sprain	impact or blow to the front of the knee	pop or snap felt and heard swelling mild pain "loose" feeling to knee inability to bear weight on the leg

STAGE SCALE: LIGAMENT SPRAIN OR TEAR

Grade	Extent of Injury or Damage	Symptoms
grade 1 or first degree	minor stretching of LIGAMENT fibers though knee remains stable	mild PAIN with pressure to the knee mild swelling
grade 2 or second degree	moderate tear of the ligament with some instability of the knee	moderate pain with pressure to the knee moderate swelling
grade 3 or third degree	complete tear of the ligament and its nerves; unstable knee	little if any pain with pressure to the knee pronounced pop felt and heard at time of injury inability to bear weight or use the knee

DRUGS (NSAIDS) relieve inflammation and pain for both traumatic and overuse injuries. Gentle stretching and exercise such as walking help keep the knee flexible and facilitate HEALING.

Mild to moderate ligament sprains often heal without surgery in four to six weeks. Severe ligament sprains and meniscal tears often require surgery to repair. Orthopedic surgeons can perform nearly all such operations arthroscopically, which allows minimal recovery time. PHYSICAL THERAPY facilitates rehabilitation after surgery and most people able to return to regular activities in about six months. Return to sports may require more time, especially for activities of high vulnerability for knee injury such as football, soccer, downhill skiing, and basketball.

Risk Factors and Preventive Measures

Contact sports (such as football) and other sports that involve running, twisting, and jumping (such as soccer, basketball, and tennis) expose the knee to direct blows with great risk for injury. Any sport that uses cleats to improve traction (such as track, soccer, and football) has increased risk for knee injury resulting from excessive torsion (twisting under pressure). Sports and athletic activities account for the majority of knee injuries in people under age 25. By midlife, repetitive trauma (such as results from running) begins to take its toll and overuse injuries become more common. Excessive body weight further stresses the knees.

Strong thigh muscles—the quadriceps in the front and the hamstrings in the back—improve stability of the knee. Weight-lifting or RESISTANCE EXERCISE can strengthen these muscles. YOGA is excellent for improving FLEXIBILITY as well as stability of the knees. Knee supports, braces, and protective pads reduce the risk of knee injury in some sports. Proper technique and adequate physical conditioning are crucial elements of injury prevention for any athletic activity. Other preventive measures include stretching and WARM-UP before and after participating in vigorous exercise or sports events.

kyphosis A deformity of the upper spine that gives the appearance of a hump in the upper back. Kyphosis may represent a CONGENITAL ANOMALY in the structure of the spine or may develop later in life as a consequence of damage to the CARTILAGE disks between the vertebrae that allow the vertebrae to slide out of position. Mild kyphosis generally does not cause symptoms and may be noticeable only with X-rays of the spine. Moderate kyphosis can cause upper BACK PAIN, resulting from distorted posture that strains the back muscles. Treatment may include PHYSICAL THERAPY or CHIROPRACTIC care to stretch the back, strengthen muscles, and improve posture. Sometimes sleeping on a very firm mattress with a low pillow allows the spine to correct itself. The doctor may prescribe a back brace for moderate kyphosis. Severe kyphosis may require surgery to realign and support the vertebrae.

L

laminectomy A surgical OPERATION to remove a segment of vertebra (BONE of the spine) to relieve pressure against the SPINAL CORD or a spinal NERVE root. Laminectomy treats neurologic symptoms arising from HERNIATED NUCLEUS PULPOSUS (herniated or slipped disk), CERVICAL SPONDYLOSIS, and SPINAL STENOSIS. When laminectomy is the appropriate therapeutic choice, it has a fairly high success rate for relieving symptoms (such as PAIN, weakness, and numbness in the leg) and allowing the person to return to regular activities. However, it is important to first consider all other therapeutic options as the rate of success for back surgery is highly variable.

Laminectomy is an OPEN SURGERY on the back performed under general ANESTHESIA. An orthopedic surgeon or a neurosurgeon may perform the operation. The surgeon makes a long incision (five to seven inches) along the spine at the site of the impingement; separates the soft tissue structures from the vertebra to expose the bone; and removes a lamina, one of the flat segments of the vertebral arch. Depending on the cause of the impingement and the overall health of the vertebrae (whether there is progressive deterioration such as is common with spinal stenosis), the surgeon may choose also to fuse the operated vertebra to an adjacent healthy vertebra for stability. Most people stay in the hospital up to three days after the operation. Recuperation and return to normal activities takes six to eight weeks.

The risks of laminectomy include excessive bleeding during surgery, postoperative INFECTION, continued symptoms after HEALING, and sensory disturbances resulting from surgical injury to the spinal nerve root. When the cause of the nerve compression was deterioration of the vertebra due to a progressive condition such as OSTEOARTHRITIS, further damage may occur to the same vertebra or other vertebrae. About 70 percent of people experience full relief from their symptoms and return to work and recreational activities without restriction.

ligament A cordlike structure of tough connective tissue that binds bones together at joints. Ligaments are vulnerable to injury from stretching, which can cause them to tear. Such a ligament injury is a sprain. Most sprains heal with conservative treatment, though some (notably complete tears) require surgery to repair them. Ligaments may also join or support organs and structures other than bone, such as the round ligaments in the pelvis that suspend the UTERUS within the abdominal cavity.

lipoma A benign (noncancerous) soft tissue tumor. Lipoma is the most common type of tumor. It arises from adipocytes—fat cells—though can develop in any kind of tissue. Lipomas are particularly common in the MUSCLE, appearing as a small painless lump. A lipoma near the surface of the SKIN feels soft and fairly well defined. Lipoma does not hurt or become cancerous and requires no treatment unless it becomes larger than five centimeters. Large lipomas may be cosmetically unacceptable or cause irritation to the surrounding tissue. The doctor may choose to biopsy or remove a lipoma that occurs in the BREAST or COLON, to be certain of the diagnosis as other kinds of breast and colon tumors may be malignant (cancerous). Lipomas have a tendency to recur after surgery to remove them.

See also ADENOMA; BREAST CANCER; COLORECTAL CANCER; SURGERY BENEFIT AND RISK ASSESSMENT.

lordosis An abnormally exaggerated inward curvature of the lumbar spine at the small of the back, giving the appearance of protruding buttocks in the back and protruding belly in the front. Lordosis may result from congenital abnormalities of the spine and often develops when a child begins to walk. CONGENITAL HIP DYSPLASIA, CEREBRAL PALSY, SPINA BIFIDA, and neuromuscular disorders in which the muscles are weak are common congenital causes for lordosis. Lordosis is also common in ACHONDROPLASIA and other forms of SKELETAL DYSPLASIA.

Lordosis does not usually cause symptoms other than its appearance. Sometimes lordosis results from habitual poor posture. X-RAY is usually sufficient to confirm the diagnosis. Treatment attempts to prevent progression of the curvature as well as to correct the existing deformity to retain spinal stability for support of the axial SKELETON. However, most lordosis in otherwise healthy children corrects itself as the child grows.

Marfan syndrome A genetic disorder arising from mutations in the *fbn1* GENE that affect the structure of connective tissues throughout the body. The *fbn1* gene encodes for fibrillin 1, a protein molecule essential for the formation of elastin. Elastin is the basis of the fibers that form the connective tissues. In Marfan syndrome the elastin is too soft, allowing connective tissues to stretch more than normal. The INHERITANCE PATTERN for Marfan syndrome is autosomal dominant, meaning one parent who has the mutated gene can pass the condition to his or her children. Marfan syndrome primarily affects the cardiovascular system, musculoskeletal system, and eyes.

Symptoms and Diagnostic Path

Marfan syndrome produces hallmark physical characteristics that include

- tall, lanky frame with extraordinarily long arms
- elongated, narrow face
- crowded TEETH
- narrow, sunken chest
- long, thin fingers

Many people who have Marfan syndrome have severe MYOPIA (nearsightedness) and abnormalities of the CORNEA. Within the body, one of the most significant effects of Marfan syndrome is on the major BLOOD vessels, notably the AORTA, and the HEART valves. Because the connective tissue within the walls of the arteries is softer than it should be, the walls of the arteries are susceptible to separation (ANEURYSM). As well, the heart valves are often larger than normal and do not close properly, allowing blood to backflow within the heart. Mitral valve prolapse is the most common manifestation of this aspect of Marfan syndrome. To compensate, the heart intensifies the STRENGTH and frequency of its contractions, which over time enlarges the heart (CARDIOMYOPATHY).

There are no definitive diagnostic tests for Marfan syndrome, and symptoms are sometimes mild enough to escape detection until midlife or later when cardiovascular problems begin to emerge. An accumulation of symptoms points to the diagnosis, particularly if there is a family history of Marfan syndrome. The doctor may conduct GENETIC TESTING for the *fbn1* gene MUTATION to confirm the diagnosis.

Treatment Options and Outlook

Treatment focuses on early detection of and therapy for potential complications, notably CARDIOVASCULAR DISEASE (CVD). Doctors advise against activities, especially competitive sports, that cause rapid and extreme changes in BLOOD PRESSURE and HEART RATE. Treatment may include medications to maintain low blood pressure and heart rate as preventive measures. Most people who have Marfan syndrome should have an ECHOCARDIOGRAM (ULTRASOUND examination of the heart) annually to screen for changes in the heart's size and valve function and the stability of the aorta. Early surgery to intervene when echocardiogram suggests a dissecting aortal aneurysm can be lifesaving.

Risk Factors and Preventive Measures

Because cardiovascular complications of Marfan syndrome can be severe or life threatening, doctors recommend GENETIC COUNSELING for people who have the disease. Marfan disease is preventable only by preventing transmission of the mutated *bfn1* gene. For the 30 percent or so of people in whom the mutation is spontaneous

(occurs without apparent family history of the condition), there are no measures of prevention.

See also GENETIC DISORDERS.

meniscectomy A surgical OPERATION to remove part or all of a damaged meniscus in the knee. Each knee has two menisci, C-shaped pads of CARTILAGE that cushion the ends of the femur (thigh BONE) and tibia (shin bone) as they come together within the knee JOINT. Meniscus tears are common ATHLETIC INJURIES and occur when there is torsion under pressure—the body above the knee twists suddenly during movement but the foot remains planted. Most of the time the orthopedic surgeon can perform a partial meniscectomy with ARTHROSCOPY (MINIMALLY INVASIVE SURGERY using a specialized endoscope), which allows rapid recovery and return to regular activities.

Cartilage, which is very dense, does not have its own BLOOD supply but rather draws necessary NUTRIENTS from surrounding tissues and fluids. Tears near the outer edge of the meniscus are more likely to heal than tears in the center of the meniscus. The surgeon may attempt to repair an outer tear though will likely need to remove the damaged segments of meniscus when the tear is interior. The goal is to remove as little of the meniscus as possible because without it the bone ends loose protection. It is equally important to remove any pieces of the meniscus that are torn or fragmented to prevent them from "jamming" the joint.

The risks of meniscectomy include excessive bleeding during surgery and postoperative INFECTION, both of which are rare. Full recovery after arthroscopic surgery takes about six weeks and after OPEN SURGERY may take up to six months. Even after HEALING, complete meniscectomy may limit some athletic activities that place significant stress on the knee, such as downhill skiing.

muscle Contractile fibers or the structures these fibers form. Muscles move the body, some under voluntary control and others reflexively. The gastrointestinal tract, genitourinary tract, and BLOOD vessels contain smooth (nonstriated) muscle, which is under involuntary control of the autonomic NERVOUS SYSTEM. The HEART contains a specialized form of muscle called myocardial, also under control of the autonomic nervous system. The bulk of the muscle tissue in the body is skeletal (striated) muscle, which responds to voluntary control through the CENTRAL NERVOUS SYSTEM.

The skeletal muscles are responsible for movement and account for about 40 percent of the body's mass. They generally appear in opposing pairs attached to BONE via tendons. When one muscle contracts, its opposing muscle relaxes. This allows smooth, balanced movement. The SKELETON provides resistance and leverage for the muscles as they contract and relax. The body contains about 650 muscles, the largest of which is the gluteus maximus (main muscle of the buttocks) and the smallest of which is the stapedius in the middle EAR (moves the stapes bone).

Movement requires interaction between neurons (NERVE cells) and muscle fibers. This interaction occurs at the neuromuscular junction, a synapse where the NEURON's axons end (terminate) and the muscle fiber begins. When conveying a nerve impulse to activate a skeletal muscle fiber, the motor neuron releases a molecule of acetylcholine, a NEUROTRANSMITTER. The acetylcholine molecule binds with an acetylcholine receptor on the muscle fiber, forming a biochemical bridge that allows the nerve impulse to travel from the neuron to the muscle fiber. The impulse creates an action potential in the muscle fiber—a cycle of activation, discharge, and recovery—that becomes a muscle contraction.

Skeletal muscles contain two types of fiber that dictate how rapidly and with what intensity they complete an action potential. Type 1 fibers, also called slow-twitch or red fibers (red because they have a high myoglobin content), have a slow and steady response. Type 1 fibers are in a constant state of partial contraction; they provide muscle tone and are essential for maintaining the body's posture. Type 2 fibers, also called fast-twitch or white fibers (white because they contain very little myoglobin), have a rapid response. Type 2 fibers are responsible for muscle STRENGTH. Most skeletal muscles contain a combination of type 1 and type 2 fibers. Exercise to extend ENDURANCE increases the percentage of type 1 fibers; exercise to improve strength increases the percentage of type 2 fibers.

muscle relaxant medications Medications that relieve MUSCLE spasms, cramps, and stiffness. Some muscle relaxants are also called antispasmodic medications. Doctors may prescribe these medications to treat acute BACK PAIN, acute sprains, severe muscle tension HEADACHE, and muscle spasticity due to conditions such as CEREBRAL PALSY, MULTIPLE SCLEROSIS, SPINAL CORD INJURY, MUSCULAR DYSTROPHY, FIBROMYALGIA, and many others. There are various types of muscle relaxant medications that work through different mechanisms, though all act on the CENTRAL NERVOUS SYSTEM rather than on the muscles directly. Because of this, most muscle relaxants also affect alertness, balance, and other neurologic functions.

As with any medication, muscle relaxants can have adverse side effects and interact with other drugs, including OVER-THE-COUNTER (OTC) DRUGS and herbal remedies. Typically muscle relaxants provide short-term relief during acute injury. Once muscle fibers begin to heal, they return to normal contraction and relaxation patterns and muscle relaxant medications are no longer necessary or helpful for recovery. Muscle relaxants in the benzodiazepine family of drugs (such as diazepam) cause significant drowsiness and can become habit forming; doctors generally prescribe them sparingly because of these risks.

muscular dystrophy The collective term for a group of GENETIC DISORDERS of the MUSCLE resulting in progressive weakness. Most types of muscular dystrophy arise from a deficiency of the protein dystrophin, which is essential for skeletal (striated) muscle cell integrity and function. Without it the skeletal muscles deteriorate and movement becomes difficult or impossible. About 50,000 Americans have muscular dystrophy. The three most common of the nine major types of muscular dystrophy are Duchenne's muscular dystrophy, facioscapulohumeral muscular dystrophy, and myotonic muscular dystrophy.

Duchenne's muscular dystrophy Duchenne's is an X-linked recessive MUTATION affecting the dystrophin GENE. As such, it nearly exclusively affects boys. Symptoms begin to appear in early childhood with characteristic postures and gait. Progression is steady, and most boys who have Duchenne's lose the ability to walk by about age 12. The skeletal muscles of the upper chest become involved in ADOLESCENCE, affecting BREATHING. Duchenne's is usually fatal before age 20.

A milder presentation of similar symptoms and pattern of progression with a later age of onset (late childhood or early adolescence) is Becker's muscular dystrophy. Though the course of the disease is ultimately fatal, most who have it live into their 30s. Treatment is primarily supportive, with PHYSICAL THERAPY to help preserve muscle STRENGTH and function. CORTICOSTEROID MEDICATIONS may improve symptoms.

Facioscapulohumeral muscular dystrophy An adult-onset type of muscular dystrophy, facioscapulohumeral muscular dystrophy affects men and women equally. Symptoms first appear as weakness in the muscles of the face and shoulder girdle (upper arms and shoulders). The shoulders often "wing" outward. Over the course of the disease, muscle weakness moves downward through the body though the lower arms are usually the last affected. Symptoms are mild enough in about half of those who have this form of muscular dystrophy to permit fairly normal function and mobility throughout life. In others, symptoms may affect swallowing and mobility.

Myotonic muscular dystrophy In myotonic muscular dystrophy the muscles lose the ability to relax after contraction, causing them to become stiff. Myotonic muscular dystrophy is the most common type of adult-onset muscular dystrophy and affects men and women equally. The cause is a mutation in the gene that encodes for myotonica protein

MAJOR TYPES OF MUSCULAR DYSTROPHY

Type of Muscular Dystrophy	Key Characteristics	Inheritance Pattern
Duchenne's	most common type affects primarily muscles of the upper arms, upper legs, and pelvic girdle first symptoms usually appear between ages 2 and 6	X-linked recessive
myotonic	affects primarily muscles of the face and neck, hands, and feet gastrointestinal, cardiac, EYE, neurologic, and endocrine involvement later in the disease first symptoms appear in adulthood	autosomal dominant
Becker's	affects primarily muscles of the upper arms, upper legs, and pelvic girdle very similar to Duchenne's with milder symptoms symptoms begin in late childhood or early ADOLESCENCE	X-linked recessive
limb-girdle	affects primarily the muscles of the pelvic girdle and shoulder girdle symptoms begin in late adolescence or early adulthood	autosomal recessive or autosomal dominant
facioscapulohumeral	affects primarily the muscles of the face, neck, and shoulders symptoms begin in late adolescence or early adulthood	autosomal dominant
congenital	affects all skeletal muscles often affects the CENTRAL NERVOUS SYSTEM, causing seizures symptoms are present at birth	autosomal recessive
oculopharyngeal	affects the muscles of the eyelids and THROAT symptoms begin in middle to late adulthood	autosomal dominant
distal	affects the forearms, hands, lower legs, and feet symptoms begin in adulthood	autosomal recessive or autosomal dominant
Emery-Dreifuss	affects primarily the shoulders, upper arms, pelvis, and lower legs symptoms typically appear first as contractures, then weakness symptoms begin in late childhood or early adolescence	X-linked recessive

kinase. Other gene mutations may also contribute. Though progression is usually slow, myotonic muscular dystrophy affects other body systems as well. Cataracts and diabetes are common.

Symptoms and Diagnostic Path

In most forms of muscular dystrophy, the primary symptoms are muscle weakness and disturbances of posture and gait (walking style). The diagnostic path begins with detailed PERSONAL HEALTH HISTORY and family health history. Because muscular dystrophies are inherited disorders, the family health history is particularly important. A comprehensive NEUROLOGIC EXAMINATION identifies the specific symptoms, which helps narrow the diagnosis. BLOOD tests may show excessive proteins that indi-

cate muscle destruction. Each type of muscular dystrophy has fairly characteristic patterns of symptoms. Muscle biopsy shows damage to the muscle cells.

Treatment Options and Outlook

Treatment for all types of muscular dystrophy is primarily supportive. Physical therapy, braces, orthotics, and mobility aids extend the ability to walk and function independently. Corticosteroid medications slow the progression of symptoms in some types of muscular dystrophy, notably Duchenne's. Though all types of muscular dystrophy are lifelong, muscular dystrophy is not necessarily fatal. Many people with milder types of the disease live normal life expectancy with relative independence.

Risk Factors and Preventive Measures

Muscular dystrophy is always inherited, so the key risk factor is family history. People who have muscular dystrophy or family history of muscular dystrophy should consider GENETIC COUNSELING to aid in FAMILY PLANNING decisions. There are no measures known to prevent muscular dystrophy, though research holds hope for GENE THERAPY that can someday correct the mutations that cause the disease.

myasthenia gravis A rare autoimmune disorder in which the IMMUNE SYSTEM produces antibodies that target acetylcholine receptors on the cell membrane surfaces of MUSCLE cells. Acetylcholine is a NEUROTRANSMITTER that carries NERVE impulses from neurons to muscle cells to initiate movement. Acetylcholine receptors are specialized molecules that bind acetylcholine molecules, a process analogous to plugging an electrical cord into an outlet. The NEURON releases acetylcholine to carry the impulse across the synapsis to the muscle cell. Binding forms a complete circuit and the nerve impulse passes from the neuron to the muscle cell.

The antibodies present in myasthenia gravis attack and destroy acetylcholine receptors, reducing the ability of acetylcholine to carry to completion the nerve impulses that direct movement. Because there are fewer acetylcholine receptors in myasthenia gravis, the acetylcholine molecule the neuron releases often dissipates before a receptor becomes available. As a result, muscle contractions are weak. Muscles that have the fewest numbers of acetylcholine receptors to begin with—the muscles of the eyelids, eyes, face, MOUTH, and THROAT—are the most dramatically affected. Muscle function worsens during activity that uses affected muscles, such as chewing or talking, and improves after rest.

Myasthenia gravis may develop at any age though is most common in women under age 40 and men over age 60. Researchers do not know what causes myasthenia gravis but suspect a dysfunction of the THYMUS, a structure of the immune system responsible for the maturation of T-cell lymphocytes, may play a significant role. The thymus, which normally has little function in adults, is abnormally active in people who have myasthenia gravis. Symptoms of myasthenia gravis relate to the muscles affected and may include difficulty focusing the eyes, slurred speech, or difficulty swallowing. Involvement of peripheral muscles may result in balance and gait dysfunctions.

Because myasthenia gravis is relatively rare, doctors typically explore more common causes for weak muscles before looking specifically for myasthenia gravis. BLOOD tests can detect the presence of the acetylcholine receptor antibodies in most people who have myasthenia gravis. Other diagnostic procedures that point to the disorder include specialized electromyogram (EMG) and tests that measure the muscle's response to acetylcholine.

Treatment includes anticholinesterase medications, which block the action of cholinesterase, an enzyme that breaks down acetylcholine, and IMMUNOSUPPRESSIVE MEDICATIONS, which interfere with the release of antibodies to slow the destruction of acetylcholine receptors. Many people experience significant improvement in their symptoms after THYMECTOMY (a surgical OPERATION to remove the thymus). Most people who have myasthenia gravis are able to enjoy relatively normal lives with appropriate treatment.

myopathy MUSCLE weakness that occurs when muscle cells do not function properly. There are

numerous forms of myopathy, many of which are congenital (present at birth) or genetic (the result of inherited GENE mutations). Some myopathies are progressive (become worse with time) and others remain stable. Metabolic disorders, HIV/AIDS, IMMUNE DISORDERS, and ADVERSE REACTION to drugs (including ALCOHOL) may cause myopathies. Treatment targets the cause of the myopathy in acquired myopathy and attempts to relieve symptoms when myopathy is congenital or genetic. Treatment approaches may include medications, PHYSICAL THERAPY, braces or other devices to support weak muscle structures and aid mobility, and MASSAGE THERAPY.

myotonia A neuromuscular circumstance in which the muscles contract properly but do not relax, causing temporary stiffness. Movement may be slow and difficult until the muscles warm up, after which they seem to function more smoothly. Myotonia may be a symptom, such as with some forms of MUSCULAR DYSTROPHY, or a congenital condition. Myotonia congenita is a rare form of myotonia that occurs as a result of GENE mutations. Some forms of myotonia are progressive though most are not. Myotonia is a disorder of the ion channels in the MUSCLE cells (channelopathy), most often the chloride, sodium, or potassium channels. The ion channels regulate the ion exchange that must occur for a cell to "fire," which in the case of muscle cells is to contract and relax.

The diagnosis of myotonia is primarily clinical, based on the doctor's observance of the person's movement and muscle function. Characteristic alterations in the electromyogram (EMG) generally can confirm the diagnosis. Treatment with antiseizure medications and drugs that affect the ion channels often improve symptoms and muscle function. Myotonia resulting from another disorder often improves when the underlying condition improves. Though myotonia is a lifelong circumstance, most people who have myotonia are able to enjoy fairly normal lifestyles with appropriate medication therapy.

neurogenic arthropathy Degeneration of a JOINT, commonly the knee, as a consequence of NEUROPATHY (impaired NERVE function) that causes loss of sensation. Injuries occur to the affected joint because there is limited perception of PAIN or sense of the joint's position relative to the body and its immediate environment (PROPRIOCEPTION). Neurogenic arthropathy sometimes called Charcot's joints, often includes unrecognized fractures that do not heal properly because the joint is in continuous motion. As a result the joint becomes deformed and dysfunctional, changes that cause only mild discomfort because of the underlying NEUROPATHY.

The diagnostic path begins with recognition of the underlying neuropathy. X-RAY can usually confirm the damage to the joint. Treatment for neurogenic arthropathy aims to preserve joint structure and function to the extent possible and may include BONE graft or surgery to stabilize the joint. Some people are good candidates for JOINT REPLACEMENT, though in progressive forms of neurogenic arthropathy the joint may continue to deteriorate around the prosthesis.

occupational therapy A therapeutic approach to teach people the skills they need for living as independently as possible with long-term injury or disability. Occupational therapy focuses on techniques and devices to make easier the activities and events of daily living, aiding with such circumstances as recovery after STROKE, developmental disability in children, and rehabilitation after serious injury or surgery. The doctor may also recommend occupational therapy for people who have neuromuscular disorders, MYOPATHY, NEUROPATHY, and CHRONIC PAIN syndromes. Occupational therapists also conduct home visits to recommend environmental adaptations to reduce the risk of falls as well as to accommodate factors such as wheelchair accessibility. In the United States occupational therapy services require a prescription from a doctor.

Osgood-Schlatter disease A disorder of the epiphysis (growth plate) of the tibia, the long BONE in the lower leg (shin bone) that typically develops in athletically active adolescents. ADOLESCENCE is the period during which growth of the long bones is very rapid. The patellar TENDON stretches across the head of the tibia to attach at the top of the tibial tubercle. Athletic activities that extensively use the quadriceps MUSCLE in the thigh, such as basketball, place considerable pressure on the tendon insertion point. In Osgood-Schlatter disease, sometimes called jumper's knee, tiny fragments of developing bone tissue pull away from the epiphysis and become embedded in the tendon. As these fragments, called avulsion fractures, mineralize they form a hard lump just below the patella (kneecap).

The main symptoms of Osgood-Schlatter disease, also called osteochondrosis, are a noticeable lump and PAIN in the area of the knee. Pain is often more intense when going up and down steps, running, and jumping. Osgood-Schlatter disease tends to affect girls at a younger age (10 to 12 years) than it affects boys (12 to 14 years). The doctor bases the diagnosis on the presentation of symptoms and the findings on X-RAY studies. The doctor may also conduct a bone scan when the X-ray findings are unclear. However, diagnosis is usually straightforward.

Osgood-Schlatter disease is self-limiting; it goes away when growth in the tibia ceases. Ice to the area and NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) to relieve INFLAMMATION and pain are generally sufficient treatment. A physical therapist or sports medicine specialist can teach the child stretching exercises for the quadriceps and for the hamstrings, in the back of the thigh, to reduce pressure against the patellar tendon.

osteoarthritis A condition of progressive degeneration of the joints. Osteoarthritis tends to develop in adults age 60 and older and to affect joints subject to excessive stress throughout life, often in occupational settings. Recreational and athletic activities may also result in osteoarthritis. The fingers, cervical spine (neck), knees, hips, and lumbar spine (low back) are most commonly affected. About 20 million Americans have osteoarthritis.

Osteoarthritis damages CARTILAGE, the thin layer of smooth connective tissue that coats the ends of bones with the joints. Cartilage is so dense that it does not have its own BLOOD supply. Instead, it relies on adjacent tissues and the synovial fluid to supply it with the NUTRIENTS it requires. Cartilage cannot regenerate or rebuild itself so damage to it

is permanent. Osteoarthritis is a leading cause of disability in the United States.

Symptoms and Diagnostic Path

Many people who have osteoarthritis sufficient to show up on X-RAY have few if any symptoms. Researchers estimate that by age 60, more than half of Americans have radiologic evidence of osteoarthritis. However, fewer than 20 percent of Americans seek medical treatment for symptoms of osteoarthritis. Stiffness and PAIN in the joints are the main symptoms of osteoarthritis. Discomfort is usually greatest in the morning when first getting out of bed and after physical activity.

The diagnostic path may include X-ray to assess the extend of damage within painful joints. But because the damage primarily affects cartilage, a soft tissue, the full extent of osteoarthritis is not likely to be apparent with X-ray. The doctor may request other diagnostic procedures to rule out conditions that have similar symptoms. However, a detailed PERSONAL HEALTH HISTORY in combination with a comprehensive medical examination is generally sufficient for the doctor to make the diagnosis.

Treatment Options and Outlook

Treatment for osteoarthritis attempts to slow the degeneration by reducing INFLAMMATION. NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) and injections of CORTICOSTEROID MEDICATIONS are very effective in accomplishing this goal. NSAIDs also relieve pain. Other treatment includes easing the stress on the joints, daily physical exercise for WEIGHT LOSS AND WEIGHT MANAGEMENT, and measures such as moist heat to affected joints. Exercises can strengthen the muscles and other structures of the joints. YOGA is excellent for improving range of motion and FLEXIBILITY.

Though there are no treatments that can cure osteoarthritis, a blend of medical therapies and lifestyle modifications can keep symptoms in check. Many people who have osteoarthritis are able to enjoy favorite activities with few if any restrictions when they follow appropriate measures to control future damage of the joints. Significant damage to the joint may require joint replacement.

Risk Factors and Preventive Measures

The primary risk for osteoarthritis is increased age. Osteoarthritis is uncommon in people under age 50. Early diagnosis allows early treatment, which helps prevent further deterioration of the involved JOINT. Because so many factors converge to establish osteoarthritis, there are no measures known to prevent it.

osteochondrosis See OSGOOD-SCHLATTER DISEASE.

osteogenesis imperfecta A genetic disorder, commonly called brittle BONE disease, in which there are defects in the ways the body produces type 1 collagen, a fibrous protein that is the foundation of bone formation. As a result the bones lack proper structure and density and are highly susceptible to FRACTURE. The defective collagen may affect other structures in the body as well, notably the LUNGS. HEARING LOSS is also common. Most osteogenesis imperfecta is inherited though may occur as the result of spontaneous MUTATION.

There are four types of osteogenesis imperfecta:

- Type 1 osteogenesis is the most common. People who have type 1 disease generally reach normal height and have few obvious skeletal deformities. Type 1 osteogenesis imperfecta typically causes more fractures during childhood than in adulthood. Hearing loss is pronounced and begins early in childhood.
- Type 2 osteogenesis imperfecta is the most rare and the most severe. It produces numerous deformities of the SKELETON and often is fatal in infancy. The abnormal collagen formation also profoundly affects the lungs, causing significant BREATHING problems.
- Type 3 osteogenesis imperfecta produces obvious skeletal deformities. Fractures before birth are common; ULTRASOUND can detect them in the FETUS. Type 3 disease also affects the lungs and muscles. Hearing loss begins in early childhood and often becomes complete by ADOLESCENCE.

- Type 4 osteogenesis imperfecta is more severe than type 1 but less severe than type 3. Fractures are most common before PUBERTY. Hearing loss begins in early childhood and is often profound.

The bones of infants who have osteogenesis imperfecta are very fragile and may fracture with the slightest contact, even that of picking up or holding the infant. Nonetheless, touch and holding are very important for proper development. The health-care team can provide suggestions to minimize the risk for fracture. Treatment for fracture is generally conservative, targeting a balance between immobilizing the fracture long enough for it to heal and allowing normal MUSCLE function as quickly as possible. Physical activity helps strengthen muscles and bone, which in turn minimizes fractures. The most numerous fractures occur during childhood when the bones are growing and thus have lower mineral content. The risk for fracture is lifelong, however, and may increase in women after MENOPAUSE when BONE DENSITY naturally declines. There are as yet no treatments to overcome the collagen deficiencies of osteogenesis imperfecta.

See also GENETIC DISORDERS; INHERITANCE PATTERN.

osteomalacia Softening of the bones that most often occurs as a result of vitamin D deficiency or abnormalities in vitamin D METABOLISM that prevent mineral crystals from accumulating in the BONE tissue. Vitamin D is essential to bone remodeling and the bone's ability to draw calcium and other minerals from the BLOOD circulation.

Osteomalacia develops when there is insufficient mineralization of the osteoid, a collagen-based substance the osteoblasts (bone-forming cells) produce. Instead of hardening into the bone matrix, the osteoid simply accumulates within the bone. Other causes of osteomalacia include chronic LIVER disease, END-STAGE RENAL DISEASE (ESRD), hypophosphatemia (insufficient phosphorus intake or metabolism), fluoride toxicity, and excessive antacid consumption.

Symptoms of osteomalacia include

- bone PAIN, especially in the hips
- numbness or tingling around the lips
- MUSCLE weakness
- pathologic bone FRACTURE (fractures that occur with minimal trauma or spontaneously)

Bone biopsy provides the conclusive diagnosis. Treatment is usually intense vitamin D supplementation until bone mineralization returns to normal. Depending on the underlying cause of the osteomalacia, some people may also need to take phosphorus supplements. Most people recover fully with appropriate treatment.

osteomyelitis An INFECTION of the BONE. Typically the infection starts elsewhere in the body and spreads through the BLOOD circulation to the bone, though may originate in the bone as a complication of surgery on the bone (such as open reduction of a FRACTURE or JOINT REPLACEMENT). Bacterial infection causes most osteomyelitis, though other pathogens such as fungi (yeast) may also be responsible. The long bones in the leg are the most common locations for osteomyelitis in children; osteomyelitis in adults tends to settle in the hip or pelvis.

Symptoms and Diagnostic Path

Symptoms of osteomyelitis include

- PAIN from the area of the infection
- swelling in the area of the infection
- FEVER
- generalized discomfort and sense of not feeling well

The diagnostic path begins with a comprehensive medical examination and PERSONAL HEALTH HISTORY to identify any recent infections, injuries, or surgeries. X-RAY may show the area of infection, though other imaging procedures such as bone scan or MAGNETIC RESONANCE IMAGING (MRI) often produce more complete information. Biopsy of the site confirms the diagnosis and can identify the responsible PATHOGEN. Blood tests such as complete

blood count (CBC) are likely to show elevated white blood cell (WBC) count and other changes in the blood when there is an infection present.

Treatment Options and Outlook

Surgical debridement (an OPERATION to clean pus and damaged tissue from the infected area) and ANTIBIOTIC MEDICATIONS administered intravenously are the first course of treatment for osteomyelitis. Once the infection is under control, the doctor may switch to oral antibiotics. The course of antibiotic treatment may extend six weeks or more, depending on how well the infection responds.

Infections in the bone are particularly hard to treat because the bone's blood circulation does not deliver antibiotic medications to the bone very effectively. The infection may cause an ABSCESS (pocket of pus) that in turn causes the death of bone tissue. When such a scenario unfolds, the osteomyelitis becomes chronic and may destroy considerable bone tissue. It may be necessary for the orthopedic surgeon to create a surgical wound over the site of the infection to clean it and irrigate the area.

Acute osteomyelitis that responds to antibiotic medication may heal without complications. Chronic osteomyelitis, particularly with abscess, may have a less favorable outcome with extended antibiotic therapy necessary for several months. Several surgical operations may be necessary to clean the infection site and prevent abscesses from forming. The surgeon may leave the wound open or insert a drain to facilitate HEALING. Long-term chronic osteomyelitis can cause permanent damage to the structure of the bone. When chronic osteomyelitis accompanies joint replacement, it may be necessary to remove the prosthesis until the infection heals. The treatment of last resort is AMPUTATION.

Risk Factors and Preventive Measures

People at particular risk for osteomyelitis are those who have DIABETES or who are on hemodialysis for END-STAGE RENAL DISEASE (ESRD). Trauma to the bone, such as open fracture or surgery, also increases the risk for infection. Prevention is not always possible, though using measures to appropriately care for wounds and respond to early symptoms such as pain can keep the infection contained enough for antibiotic therapy to be effective.

osteopenia A preclinical circumstance of reduced BONE DENSITY. Doctors generally consider osteopenia to precede OSTEOPOROSIS. Osteopenia has no symptoms and is a diagnosis the doctor arrives at as a consequence of the person's BONE density score with radiologic (X-RAY based) bone density measurement. About 34 million Americans, mostly women at or beyond MENOPAUSE and men older than age 60, have osteopenia.

Osteopenia may result from various metabolic circumstances. The World Health Organization (WHO) defines osteopenia as bone density that is no greater than 2.5 standard deviations below normal bone density (reported as a T-score between –0.1 and –2.5). Conventional diagnostic methods establish a scale of bone density relative to that of a young person of the same gender at an age when bone density is at its peak.

Many people can restore bone density through RESISTANCE EXERCISE and increased calcium consumption. Doctors generally do not treat osteopenia beyond these measures but instead closely monitor bone density. Osteopenia is a warning sign for women approaching or beyond menopause, as bone density loss accelerates when estrogen levels in the body decrease. Lifestyle factors that contribute to osteopenia include physical inactivity, cigarette smoking, and excessive ALCOHOL consumption, all of which interfere with calcium transfer and other metabolic processes related to bone remodeling.

See also CALCIUM AND BONE HEALTH; ESTROGENS; EXERCISE AND HEALTH; LIFESTYLE AND HEALTH; OSTEOPETROSIS.

osteopetrosis A rare genetic disorder in which BONE remodeling is defective. Though the body builds new bone (osteoblastic activity), it does not adequately clear away old bone (osteoclastic activity). Consequently the bones become very dense though are also very brittle and vulnerable to FRACTURE. When symptoms are present early in childhood (infantile osteopetrosis), the outcome is very poor because the excessive bone structure

crowds out the BONE MARROW. BONE MARROW TRANSPLANTATION is at present the only successful treatment for infantile osteopetrosis but itself carries significant risk.

Adult-onset osteopetrosis is present from birth but does not cause symptoms until adulthood when the abnormalities of bone structure are advanced enough to become apparent. Many adults who have osteopetrosis do not have overt symptoms and discover they have the disorder when receiving treatment for another condition for which the doctor requests an X-RAY. X-ray provides definitive diagnosis as osteopetrosis has a distinct, characteristic presentation. There are no treatments for adult-onset osteopetrosis other than efforts to reduce the risk for fracture. Adult-onset osteopetrosis increases the risk for OSTEOMYELITIS (INFECTION of the bone), which is one of the common reasons people initially seek medical care.

osteoporosis A condition of diminished BONE DENSITY (the extent of mineralization of the bones). Though some loss of mineralization is a normal process of aging, osteoporosis represents an accelerated loss that causes health problems. Osteoporosis weakens the BONE structure; increases the risk for FRACTURE; and may result in bone deformities, particularly of the spine. The spine and hip are most vulnerable to fracture. Osteoporosis typically affects women after MENOPAUSE, though may develop earlier in women who do not produce estrogen, and men age 75 and older. About 10 million Americans have osteoporosis, 80 percent of whom are women.

Osteoporosis appears to primarily affect women for two reasons: estrogen and body size. Researchers do not fully understand how estrogen protects bone health but they do know that when estrogen levels fall dramatically, as with menopause, bone demineralization accelerates. As well, women have inherently less body mass—bone mass and MUSCLE mass—than men. Some researchers theorize that bone demineralization takes longer to affect men because their larger skeletons can withstand a greater loss of calcium before becoming thin and weak.

Symptoms and Diagnostic Path

Early indications of accelerated bone loss include loss of more than ½ inch in height and development of kyphosis (hump in the middle of the back). However, these signs develop slowly and over considerable time, often several decades, which makes them less apparent. Health experts call osteoporosis a silent disease because there are few indications of its presence until it is well established. Often the first symptom of osteoporosis is an unexpected fracture. The wrist, spine, and hip are the most vulnerable sites for fracture. X-RAY shows a characteristic porous structure to the bones, demonstrating the loss of mineral content and bone mass. Bone density tests such as DEXA scan can detect demineralization before fracture occurs.

Doctors use a scale of relative percentage of bone loss to measure the severity of osteoporosis. The scale represents bone loss as a standard deviation (SD) from the accepted norm for optimal healthy bone mass. An SD value of –2.5 or greater (2.5 SDs below the norm) is diagnostic for osteoporosis. Testing facilities report this value as a T-score; the norm for comparison is the bone density of a young healthy person of the same gender. Another representation is the Z-score, which compares the person's bone density to that of the norm for others of the same age and gender. Some testing facilities report bone loss as a percentage; a –2.5 SD value represents about a 35 percent loss of bone density (bone mass is 65 percent of what it should be).

Treatment Options and Outlook

Weight-bearing and RESISTANCE EXERCISE is essential to stimulate bone remodeling activity. For established osteoporosis treatment focuses on decreasing the resorption of bone to increase bone mass. Several kinds of medications can achieve this effect. Among them are calcium and vitamin D supplements, estrogen supplements, bisphosphonates, PARATHYROID HORMONE supplement, CALCITONIN supplement, and selective estrogen receptor modulators (SERMs). Individual circumstances determine which treatment approaches are most appropriate.

Calcium and vitamin D The body's ability to absorb dietary calcium diminishes with advancing

age. As well, people tend to drink less milk and consume fewer dairy products, the primary sources of dietary calcium, as they get older. Most adults should take calcium supplements to get 1000 to 1200 milligrams of calcium daily combined with dietary calcium. Though calcium cannot restore bone structure that is already lost to osteoporosis, the bones need abundant calcium simply to maintain bone remodeling. Vitamin D is necessary for the body to absorb calcium.

Estrogen Before the 1990s doctors routinely prescribed hormone replacement therapy (HRT) for women going through and women beyond menopause. The prevailing belief was that HRT provided protection for women against CARDIOVASCULAR DISEASE (CVD) and osteoporosis. Extensive studies demonstrated that HRT provided no protection for HEART disease and in fact increased the risk for some kinds of CVD (notably STROKE) as well as some forms of cancer.

The findings regarding osteoporosis were not as definitive as expected. Estrogen does slow the loss of bone. However, its effect is most pronounced during the first three to five years after menopause and it does not stimulate production of new bone. Though doctors sometimes prescribe estrogen replacement (in combination with PROGESTERONE supplement for women who have their uteruses) for women who are at high risk for developing osteoporosis, other medications are often more effective with fewer risks.

Bisphosphonates Bisphosphonates are medications that block the activity of osteoclasts to resorb bone and calcium. Because these drugs are relatively new, doctors do not know their long-term consequences. Bisphosphonates can stop the progression of osteoporosis as well as prevent osteoporosis from developing in men and women who have high risk. However, bone loss resumes when the person stops taking the medication.

BISPHOSPHONATES TO TREAT OR PREVENT OSTEOPOROSIS

alendronate	clodronate
etidronate	ibandronate
pamidronate	risedronate

Parathyroid hormone and calcitonin Parathyroid HORMONE and calcitonin are natural hormones within the body that regulate bone remodeling. Parathyroid hormone stimulates osteoblast activity (new bone formation); calcitonin suppresses osteoclast activity. Taken as supplements, these hormones have similar actions. They are not as effective as the bisphosphonates, however.

Selective estrogen receptor modulators (SERMs) Women who are beyond menopause can take SERMs, sometimes called designer ESTROGENS, which have many estrogen-like actions in the body. As the name suggests, however, SERMs selectively target estrogen receptors so are not entirely the same as estrogen. Some SERMs, notably raloxifene, have an estrogen-like effect on bone remodeling without estrogen-like effects elsewhere in the body. SERMs stop bone loss but do not stimulate new bone tissue.

Risk Factors and Preventive Measures

Women over age 70 who are white or Asian and are thin have the greatest risk for osteoporosis. However, regardless of ethnicity women past menopause have increased risk for osteoporosis because of the loss of estrogen. Other risk factors for osteoporosis include long-term use of systemic CORTICOSTEROID MEDICATIONS (such as to treat AUTOIMMUNE DISORDERS or endocrine disorders), cigarette smoking, low calcium consumption, physical inactivity, excessive CAFFEINE consumption, and excessive ALCOHOL consumption.

COMPLICATIONS OF FRACTURE

Though fracture alone is a significant health concern, the complications of fracture can be life threatening. Fracture generates a high risk for BLOOD clots as well as for fat emboli—fragments of fatty tissue that the fracture dislodges and that make their way into the blood circulation. Blood clots and fat emboli can cause STROKE or HEART ATTACK, depending on where they lodge in the blood vessels.

Calcium and vitamin D supplementation in combination with weight-bearing or resistance exercise early in life, but particularly before demineralization becomes significant, is the most effective preventive treatment. Health experts believe nearly all osteoporosis is preventable. But as with other lifestyle-related health conditions,

prevention efforts must begin in childhood and continue through life. The most effective time to supplement calcium is when the body is building bone mass—before age 20.

Paget's disease of the bone A rare and sometimes hereditary condition in which the process of BONE remodeling sporadically accelerates. The new bone that forms to replace old bone has increased mass, enlarging the bone structure, though is weaker than normal bone. Paget's disease of the bone affects bones randomly throughout the body. Most often affected are the spine, hips, legs, and cranium (skull). Paget's disease of the bone is more common in people over age 40 and affects men and women about equally. Some researchers believe Paget's disease of the bone is genetic and other researchers believe a VIRUS activates it.

Symptoms and Diagnostic Path

It is not uncommon for someone to be unaware he or she has Paget's disease of the bone until several bone fractures occur. Other people have obvious abnormalities of the spine, bowed legs, and moderate to severe JOINT PAIN and bone pain. When there is family history of Paget's disease of the bone the doctor may look in that direction for diagnosis. When there is not, doctors tend to first explore more common causes for similar symptoms (such as OSTEOPOROSIS). The diagnostic path then becomes circuitous, and diagnosis may take quite some time.

BLOOD tests to measure the presence of an enzyme, alkaline phosphatase, suggest a disorder of bone growth when the enzyme is present. Alkaline phosphatase levels in the body rise whenever there is new bone growth activity. Though not diagnostically conclusive, elevated alkaline phosphatase further points in the direction of Paget's disease of the bone. COMPUTED TOMOGRAPHY (CT) SCAN and MAGNETIC RESONANCE IMAGING (MRI) can show the extent to which the dysfunctional remodeling affects bones throughout the body. The pattern of bone damage is characteristic.

Treatment Options and Outlook

Treatment for Paget's disease of the bone targets both bone loss and symptoms such as pain. Medications to slow bone resorption (osteoclast activity) help retain more normal bone structure. Among these medications are CALCITONIN and the bisphosphonates (alendronate, clodronate, etidronate, pamidronate, risedronate, and tiludronate). ANALGESIC MEDICATIONS and NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS), in over-the-counter or prescription products, may be necessary to relieve pain.

Risk Factors and Preventive Measures

The primary risk factor for Paget's disease of the bone is a family history, known or suspected, of the condition. Though there are no measures to prevent Paget's disease of the bone, early diagnosis offers the best opportunity to mitigate bone loss and other symptoms.

palmar fibromatosis See CONTRACTURE.

patellofemoral syndrome Pain at or around the patella (kneecap) that often is worse when walking or running downhill or going down steps. Many people also experience the same kind of pain when sitting with the knees bent for a prolonged time. Doctors believe patellofemoral syndrome results from a combination of factors that include anatomy (individual variations in the structure of the knee), biomechanics (the function

of the knee), and the kinds of activities the person conducts.

The more inactive an individual is, the more likely he or she is to develop patellofemoral syndrome. However, most doctors do not believe this condition is one of overuse. Some experts believe an imbalance of STRENGTH among the four parts of the quadriceps permits dysfunctional tracking of the patella, contributing to the syndrome. Most athletic activities that use the quadriceps, such as running and bicycling, strengthen the lateral (outer) muscles more than the medial, pulling the patella off track.

Symptoms and Diagnostic Path

The main symptom of patellofemoral syndrome is PAIN going down steps or downhill and when sitting for long periods of time with the knees bent (flexed). The characteristic and specific nature of these symptoms allow the doctor to make a straightforward clinical diagnosis. X-rays and other diagnostic imaging procedures are not necessary unless there is reason to suspect another reason for the symptoms.

Treatment Options and Outlook

Treatment often combines one of the NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) to relieve INFLAMMATION and pain with PHYSICAL THERAPY to strengthen the quadriceps, particularly the medial (inner) muscles of this group. Most people experience relief from this treatment approach within two weeks and can return to their regular activities, including most sports, in four to six weeks.

Risk Factors and Preventive Measures

Women, particularly those in their late teens and early 20s who are inactive, are more likely than men to develop patellofemoral syndrome. Researchers do not know why this is. Exercises to maintain balanced strength in the quadriceps MUSCLE appears to prevent further occurrences of symptoms. A soft knee brace that holds the patella in position may also help maintain proper tracking of the patella. Some athletic trainers advocate wrapping or taping the knee before participation in an athletic event, which accomplishes a similar purpose.

physical therapy A therapeutic approach to maintain or improve the biomechanics of the body. Physical therapy employs many modalities (types of treatments) including passive and active range of motion exercises, THERAPEUTIC MASSAGE, hydrotherapy, therapeutic ULTRASOUND, heat and cold, strengthening exercises, FLEXIBILITY exercises, and balance exercises. In the United States physical therapy requires a doctor's prescription. The doctor may prescribe physical therapy for people recovering from serious injury, surgery, or STROKE. Physical therapy also is helpful for conditions of impaired motor function such as CEREBRAL PALSY and PARKINSON'S DISEASE.

plantar fasciitis INFLAMMATION of the FASCIA along the bottom of the foot (plantar surface). Fascia is a thin, tough sheet of connective tissue that covers and connects the muscles, tendons, and other connective tissue structures throughout the body. It becomes irritated and inflamed with overuse. Plantar fasciitis develops with repeated stretching of the plantar fascia such as may occur with extensive walking or prolonged standing on a hard surface such as concrete. People whose jobs require walking on hard surfaces, such as mail carriers and police patrol officers, are particularly vulnerable to plantar fasciitis. Excessive body weight contributes to the stress the plantar fascia experiences, as do overly flat shoes, exacerbating the inflammation.

The pain of plantar fasciitis is distinctly characteristic; the doctor usually makes the diagnosis on the basis of symptoms. The PAIN begins in the heel and is most significant when returning to the feet after being off of them for a while, such as when first getting out of bed in the morning or after an extended work break. Immediate ice to the area of pain helps suppress the inflammation; NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) block the inflammatory response and relieve pain. Shoes with cushioned soles and insoles, shock-absorbing floor mats, and shoe orthotics to hold the foot in the best position for the individual are among the methods that reduce the risk for plantar fasciitis. Stretching exercises to loosen the fascia further relieve pressure. Most people recover from an

episode of plantar fasciitis within six to eight weeks. With appropriate preventive measures, many people are able to keep symptoms from returning.

polydactyly Extra fingers or toes. Polydactyly may occur spontaneously and isolated (without apparent cause) or in conjunction with GENETIC DISORDERS such as PATAU'S SYNDROME (trisomy 13). Most often the extra digit is on the little finger or little toe side of the hand or foot, respectively, and is so rudimentary as to be functionless. Nearly always the doctor recommends removing the extra digit, which may be done with banding (the doctor places a band tightly around the base of a rudimentary digit, cutting off its BLOOD supply so it slowly withers and falls off) or as a surgical AMPUTATION.

See also AUTOSOMAL TRISOMY; SYNDACTYLY.

polymyositis A chronic condition of widespread INFLAMMATION of the muscles. The inflammation causes weakness and difficulty with everyday movements including walking, reaching for objects, bathing, and dressing. Polymyositis is a type of inflammatory MYOPATHY that many researchers believe is autoimmune in its origins. Other researchers believe polymyositis and other inflammatory myopathies develop after viral INFECTION or as side effects of cholesterol-lowering therapy with statin medications. Polymyositis has alternating periods of RECURRENCE and REMISSION that tend to be lifelong. Most people are age 50 or older when they develop the condition.

Symptoms and Diagnostic Path

The severity and range of symptoms vary among individuals as well as across episodes within the same person. Symptoms of polymyositis may include

- MUSCLE weakness throughout the body though most pronounced in the shoulders, upper arms, hips, and thighs
- both sides of the body equally affected
- JOINT PAIN
- fatigue
- difficulty swallowing

The diagnostic path includes BLOOD tests to detect antibodies and elevated enzymes that indicate muscle injury within the body. Muscle biopsy may show the inflammation within the sample of muscle tissue. Sometimes MAGNETIC RESONANCE IMAGING (MRI) presents a pattern of the inflammation's presence in the body. Because there are no conclusive diagnostic tests for polymyositis, the diagnostic journey can be arduous and frustrating.

Treatment Options and Outlook

Treatment for polymyositis is a combination of CORTICOSTEROID MEDICATIONS and IMMUNOSUPPRESSIVE MEDICATIONS, which work together to mitigate the IMMUNE SYSTEM's inflammatory response. Physical therapy for passive and active range of motion exercises helps maintain optimal joint function. Daily physical activity has similar effect. Polymyositis is a lifelong condition that, when symptoms are severe, can result in permanent disability.

Risk Factors and Preventive Measures

Because researchers do not know what causes polymyositis, there are no known measures to prevent its development. Early diagnosis and treatment offer the most effective approach for minimizing the course of the disease and reducing the seriousness of its symptoms.

proprioception The body's sense of its location within its physical environment. Proprioceptors are specialized molecules on PERIPHERAL NERVES in the muscles that send a continuous barrage of NERVE impulses to the basal ganglia and other structures of the BRAIN that have roles in balance and movement. The balance functions in the vestibular structures of the inner EAR also contribute sensory information. Proprioception is essential for all voluntary movement. Proprioception diminishes in neuromuscular disorders such

as PARKINSON'S DISEASE and also with ALCOHOL intoxication. The classic field SOBRIETY test is a measure of proprioceptive loss.

prosthetic limb An artificial arm, hand, leg, or foot that provides functional replacement for an amputated or missing limb. A prosthesis represents a balance between function and presentable appearance. Prosthetic limbs available today can provide a very high level of function, allowing many people to return to nearly the same lifestyle as before the amputation.

Selection and fitting of the prosthesis can take place as soon as the AMPUTATION stump heals from the surgery. The prosthesis must attach firmly to the amputation stump, which is more difficult with high amputations (shoulder or hip). Factors that are important to consider include comfort and durability of the prosthesis. Most often it is advantageous to begin using the prosthesis as soon as possible after the amputation, to return to normal daily living.

There are numerous designs and styles of prosthetic limbs; the prosthesis is fitted to the person to meet the person's unique individual needs. Some prosthetic limb designs, particularly upper extremity, strive to appear as natural as possible. Other designs are primarily functional. Some designs are mechanical and others are electronic. Some prostheses are for specific purposes, such as athletic activities (running, hiking, bicycling, downhill skiing). Other prostheses may be more oriented toward allowing the person to return to a particular occupation or skill.

R

Reiter's syndrome An inflammatory disorder commonly associated with INFECTION by the MICROBE *Chlamydia trachomatis*. Other pathogens that cause GASTROENTERITIS or SEXUALLY TRANSMITTED DISEASES (STDS) may also be responsible. Reiter's syndrome involves three components: URETHRITIS, reactive arthritis (arthritis that develops in reaction to infection elsewhere in the body), and CONJUNCTIVITIS. People who have Reiter's syndrome often have the human leukocyte antigen (HLA) B27, which is also associated with the autoimmune arthritis ANKYLOSING SPONDYLITIS. Some people develop INFLAMMATION of the AORTA and other major arteries as a consequence of the involvement of vascular connective tissue.

Symptoms and Diagnostic Path

Any of the three components of Reiter's syndrome may appear first, though commonly the urethritis is the first to manifest symptoms. The other two components generally appear within 28 to 35 days of the first component. Symptoms typically include

- general feeling of malaise
- low-grade FEVER
- MUSCLE aches and soreness, particularly when resting
- burning, itchy eyes
- conjunctivitis or IRITIS
- inflammation of the TENDON insertion point in affected joints (a unique arthritic symptom)
- genital discharge and painless, shallow ulcers

The diagnostic path includes laboratory testing for CHLAMYDIA in urethral and genital discharges as well as any fluid the doctor aspirates (withdraws with a needle and syringe) from affected joints. X-RAY studies may show characteristic changes in the affected joints.

Treatment Options and Outlook

The mainstay of treatment for Reiter's syndrome is therapy with NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS). NSAIDs, usually prescription forms, control both inflammation and PAIN. An active bacterial infection requires treatment with the appropriate ANTIBIOTIC MEDICATIONS. Symptoms tend to last three to six months in most people; sometimes longer. In about a third of people, the arthritis component becomes chronic. Two thirds of people fully recover without residual effects.

Risk Factors and Preventive Measures

Men who develop Reiter's syndrome outnumber women about 10 to 1. Sexually transmitted chlamydia infection is the most common cause of the syndrome, so measures to reduce exposure to STDs can significantly reduce the development of Reiter's syndrome.

repetitive motion injuries Soft tissue injuries that occur as a result of overuse or performing the same motion over and over. Repetitive motion injuries, sometimes called cumulative trauma injuries, may occur as occupational injuries or ATHLETIC INJURIES. The most common repetitive motion injuries are TENDONITIS (INFLAMMATION of a TENDON) and BURSITIS (inflammation of a BURSA). These injuries may develop near any JOINT though are most common in the knees, hips, wrists, elbows, and shoulders.

Typical symptoms of repetitive motion injuries are

- PAIN and swelling
- numbness or tingling
- limited range of motion or movement

When establishing the diagnosis the doctor pays particular attention to the personal history of work, recreational, and other activities the individual performs on a regular basis. Diagnostic imaging procedures are usually not necessary. Treatment is rest from the activity that caused the symptoms in combination with NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS); heat or cold to the site; and PHYSICAL THERAPY to learn stretching exercises and techniques for lifting, standing, and sitting that support musculoskeletal health.

Poor posture, staying in one position for an extended time, and repeating the same motion without breaking from it are the key risks for repetitive motion injuries. Prevention efforts include frequent changes in posture and position and frequent, short breaks from the repetitious task. This may be as simple as switching hands to perform the task or pausing at regular intervals to stretch the muscles, stomp the feet, roll the neck and shoulders, and shake or wiggle the hands.

rhabdomyoma A benign (noncancerous) tumor that originates in MUSCLE tissue, usually skeletal muscle. Rhabdomyoma is somewhat more common in children than adults. The doctor may choose to surgically remove the rhabdomyoma to obtain a definitive diagnosis and rule out cancer. However, rhabdomyoma does not become cancerous. Rather, it may have the appearance of a cancerous tumor so the doctor removes it for biopsy and laboratory analysis. Rhabdomyoma may occur in the HEART, presenting a potentially life-threatening situation that usually requires surgery to remove the tumor.

RICE The acronym for rest, ice, compression, and elevation. RICE is the common first-line therapeutic approach for most musculoskeletal injuries such as SPRAINS AND STRAINS. Rest removes the injured part from the source of the injury. Ice slows the process of INFLAMMATION and eases PAIN. Compression, such as a wrap or brace, provides support so the muscles can relax. Elevation slows the flow of BLOOD through the part, further easing pain, reducing swelling, and enforcing rest.

See also ATHLETIC INJURIES; BURSITIS; FRACTURE; SYNOVITIS; TENDONITIS.

rotator cuff impingement syndrome A chronic overuse condition involving the rotator cuff, a group of muscles and tendons in the shoulder that stabilizes the shoulder JOINT—the glenohumeral joint where the humerus (long BONE of the upper arm) joins the upper part of the scapula (shoulder blade)—during elevation of the arm. The rotator cuff is vulnerable to strains ranging in severity from minor stretching of the tissues to significant tears. The resulting INFLAMMATION constricts, or impinges, the ability of the shoulder to move through its full range of motion. OSTEOARTHRITIS may also inflame the joint with the same consequence.

The doctor's examination includes a series of movements designed to elicit specific results that are relatively conclusive for rotator cuff impingement. However, other conditions can produce similar symptoms. COMPUTED TOMOGRAPHY (CT) SCAN, MAGNETIC RESONANCE IMAGING (MRI), or ARTHROSCOPY may be necessary to confirm the diagnosis.

Most rotator cuff impingement symptoms respond to conservative treatment that includes hot or cold to the shoulder, NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS), injection with CORTICOSTEROID MEDICATIONS, PHYSICAL THERAPY, and rest with limited exercises to maintain FLEXIBILITY and function of the joint. ADHESIVE CAPSULITIS, in which the tissues fuse together within the joint, is a major risk of immobilizing the shoulder. Though most people recover from an episode of symptoms without residual complications, rotator cuff impingement syndrome tends to be chronic, with repeated aggravation setting off new cycles of symptoms.

ruptured disk See HERNIATED NUCLEUS PULPOSUS.

S

sciatica Irritation and INFLAMMATION of the sciatic NERVE, which runs from the lumbar spine (low back) down the buttock and into the leg. Sciatica is a type of peripheral NEUROPATHY that is often a chronic condition. Injuries to the hip and pelvis may involve the sciatic nerve. However, often there is no identifiable cause for sciatica.

The main symptom of sciatica is a shooting or searing PAIN that extends through the buttock and into the leg. Sciatica usually involves only one side of the body though sometimes symptoms are bilateral (involve both sides), depending on the cause. Typically no particular incident sets off the pain; it just occurs and may be severe. Sciatica may also interfere with foot placement or walking.

The diagnostic path begins with a NEUROLOGIC EXAMINATION that focuses on the lower body. In sciatica the reflexes at the knee and heel (ACHILLES TENDON REFLEX) are often slow or absent. Diagnostic procedures such as electromyogram (EMG) and nerve conduction studies typically produce abnormal results as well. Treatment targets the cause of the sciatica when known and symptoms otherwise. Medications such as NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) can relieve inflammation and pain, though people who have severe pain may need prescription ANALGESIC MEDICATIONS for pain relief. Exercises and physical activity to strengthen muscles and improve FLEXIBILITY are helpful when the inflammation subsides. Most sciatica is a long-term, chronic condition that comes and goes. Specific movements or activities may trigger pain in some people, and in other people the pain appears without apparent provocation.

scoliosis An abnormal curvature that takes the spine to the side. The healthy spine does not curve to the side. Scoliosis is idiopathic—that is, doctors do not know what causes it. Treatment to straighten the spine in childhood is important because the curvature is likely to become more extreme in adulthood and can interfere with various functions, including BREATHING. Scoliosis screening among children in the public schools is common in the United States. Adult-onset scoliosis, though uncommon, may occur with OSTEOPOROSIS, RHEUMATOID ARTHRITIS, and other inflammatory conditions that affect the spine.

Symptoms and Diagnostic Path

The distinguishing symptom of scoliosis is an S-shaped curvature seen in the spine from behind. Subtle symptoms of scoliosis that can help detect the condition before the curvature becomes pronounced include

- shoulders or hips that are noticeably uneven in height
- the tendency to lean to one side
- the appearance of a twisted or uneven waist
- shoulder blades that protrude prominently from the upper back
- complaints of backache or shoulder discomfort

The diagnosis of scoliosis is generally clear from physical examination, though the doctor may conduct X-RAY studies of the back to confirm it.

Treatment Options and Outlook

Treatment for scoliosis includes exercises to stretch and strengthen the structures of the back and often a brace that holds the spine in a more erect

posture. A child may need to wear a scoliosis brace only at night or all the time, depending on the severity of the scoliosis. Severe scoliosis or scoliosis that persists despite treatment may require surgery, in which the surgeon realigns the vertebrae, sometimes bracing them with steel or titanium rods to maintain them in proper position. Most scoliosis, when detected early, responds very well to treatment and is gone by the time the child reaches late ADOLESCENCE.

Risk Factors and Preventive Measures

Because doctors do not know what causes most scoliosis, there are no known risk factors or preventive measures. Scoliosis often accompanies other conditions such as CEREBRAL PALSY, MUSCULAR DYSTROPHY, and SPINA BIFIDA. Health experts urge women of childbearing age to take folic acid supplements, which can prevent many NEURAL TUBE DEFECTS such as spina bifida. It also tends to run in families, leading doctors to suspect there are hereditary factors at play.

skeletal dysplasia Dysfunctional growth of the SKELETON such that the person is of significantly short stature. There are numerous forms of skeletal dysplasia, commonly and collectively called dwarfism, most of which are hereditary. Skeletal dysplasia may also occur as a result of HORMONE deficiencies during childhood. Each type of skeletal dysplasia presents characteristic symptoms. In general, skeletal dysplasias result in extremely short stature. The structures of the skeleton are nearly always disproportionate. Disorders of growth that are metabolic cause proportionate smallness. HORMONE THERAPY may increase skeletal growth when the cause is endocrine or metabolic. There are no treatments to alter the skeleton when the cause of the dysplasia is genetic.

skeleton The organization of the bones in the body. The skeleton has two primary organizational divisions: the axial skeleton and the appendicular skeleton. The axial skeleton consists of the bones that form the body's axis or perpendicular line, which include the head, rib cage, and spine. It contains 80 bones. The remaining 126 bones—arms, hands, legs, feet, shoulders, pelvis, hips—form the appendicular skeleton.

The primary functions of the skeleton are to give the body structure, support and protect the body's internal organs, and enable mobility. Within certain bones is the BONE MARROW, which produces the body's BLOOD cells. The skeleton also serves as the body's "calcium bank," storing calcium when levels in the blood circulation are adequate and pulling calcium from the bones when blood levels of calcium drop too low.

For further discussion of the skeleton within the context of the structures and functions of the musculoskeletal system, please see the overview section "The Musculoskeletal System."

sprains and strains Acute, traumatic injury to muscles, tendons, and ligaments, typically as a consequence of rapid and unexpected stretching such as may occur with a stumble, sudden twisting movement, or fall. A sprain is an injury to a LIGAMENT; ligaments connect bones to each other. A strain is an injury to a MUSCLE or TENDON; tendons extend from muscles to connect them to bones. Sprains and strains nearly always occur in or near joints. A muscle, tendon, or ligament may rupture (tear completely) under the force of a sudden stretch. Though immediate treatment—RICE (rest, ice, compression, elevation)—remains the same, a rupture may later require surgical repair.

A severe strain or sprain often is difficult to distinguish from a FRACTURE and should be treated as a fracture until medical assessment determines it is not.

Symptoms and Diagnostic Path

The main symptoms of a sprain or strain are PAIN and swelling following a sudden movement that involves a JOINT. Both are often immediate, and it may be difficult to use the limb. Grade 1 sprains and strains are painful but minor and do not necessarily require a visit to the doctor. However, it is

not possible to look at an injury and know whether there is a FRACTURE. A doctor should evaluate any injury in which

- it is difficult to bear weight or use the arm or hand
- there is numbness or tingling beyond the point of the injury (in the foot with an ankle injury, for example)
- pain is severe though the injury looks minor

Grade 2 injuries seldom require diagnostic imaging, though the doctor may request X-RAY, COMPUTED TOMOGRAPHY (CT) SCAN, OR MAGNETIC RESONANCE IMAGING (MRI) when there is doubt as to the severity of the injury because this can affect the treatment approach. Doctors assign a grade value to a sprain or strain to identify its severity, with grade 1 the least and grade 4 the most severe. ARTHROSCOPY may be necessary to accurately distinguish a grade 3 from a grade 4 injury.

Grade of Sprain/Strain	Severity of Injury
grade 1	stretching and minor tearing of fibers but structure remains intact
grade 2	partial tear of the structure and some instability of the JOINT
grade 3	significant tear of the structure and major instability of the joint
grade 4	complete tear of the structure and inability to use the joint

Treatment Options and Outlook

Grade 1 and grade 2 sprains and strains heal in two to six weeks with conservative treatment that includes continued RICE: rest, ice (or heat, after 48 hours, if heat feels better than ice), compression (elastic wrap, soft splint, tape, or brace), and elevation of the injured body part. Some grade 3 and nearly all grade 4 sprains and strains require surgery to repair the damage and reconstruct the tissues. The doctor can do this repair during diagnostic arthroscopy or with arthroscopic surgery after confirming the diagnosis through other means. Recovery after surgery may take up to six months, depending on the location and severity of the injury.

Risk Factors and Preventive Measures

Though sprains and strains are often ATHLETIC INJURIES, they can occur during everyday activities such as walking or lifting as well as in MOTOR VEHICLE ACCIDENTS. Proper technique for sports, including WARM-UP, and for lifting can prevent many soft tissue injuries. Taping or bracing vulnerable joints such as ankles, knees, and wrists provides additional support.

spasm A sudden, involuntary, and extended MUSCLE contraction. Muscle spasms generally last no longer than a few seconds and are quite painful. Spasms may involve skeletal or involuntary muscle. Muscle spasms of the pulmonary system may manifest as ASTHMA or bronchiospasms that, when severe, may interfere with BREATHING. Skeletal muscle spasms may result from overuse, extreme cold, or neuromuscular disorders. Heat, massage, and gentle stretching can relieve muscle spasms. WARM-UP before strenuous exercise and regular activities to stretch and strengthen the muscles help prevent muscle spasm.

spinal stenosis Narrowing of the vertebral channel, usually in the lower (lumbar) back, that compresses the SPINAL CORD or the spinal NERVE roots. The narrowing may develop as a consequence of osteoarthritic changes, the formation of BONE spurs, or a congenital defect in which the vertebral channel is unusually narrow to begin with. Symptoms of spinal stenosis are weakness or numbness in the legs, along with disturbances of gait (the mechanics of walking) and balance. There may also be low BACK PAIN and PAIN in the legs.

The diagnostic path typically includes comprehensive medical examination with full NEUROLOGIC EXAMINATION and diagnostic imaging procedures such as MAGNETIC RESONANCE IMAGING (MRI) or COMPUTED TOMOGRAPHY (CT) SCAN that can show dimensional views of the internal and external structures of the spine. Such views help the doctor determine the location and extent of the stenosis.

When diagnosis is early, conservative treatment such as exercises that extend the spine (bend the body forward) and medications such as NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) may reduce the causes of the stenosis enough to relieve the compression of the nerves. Heat, cold, and weight loss also help. Physical exercise that stretches and strengthens the muscles without compressing the spine, such as bicycling and swimming, improves the ability of the muscles to support the body and further relieves pressure on the spine.

When these measures do not relieve symptoms, surgery to widen the vertebral channel may be necessary to prevent permanent loss of function in the legs. Because the outcome of back surgery is less predictable than many other kinds of surgery, it is important to discuss and understand the expected benefits and potential risks of any OPERATION the doctor proposes.

syndactyly Fingers or toes that are fused together by connective tissue. Sometimes the fusion is only SKIN (simple syndactyly) and other times the fusion involves MUSCLE, ligaments, and BONE (complex syndactyly). Syndactyly is present at birth and often indicates a genetic disorder with additional symptoms. Most commonly the fusion involves the third and fourth fingers or toes, though sometimes affects multiple fingers or toes. Treatment is typically to separate the fused digits surgically to allow full use of the hand or foot.

See also GENETIC DISORDERS; LIGAMENT; POLYDACTYLY; SURGERY BENEFIT AND RISK ASSESSMENT.

synovitis INFLAMMATION of the synovial membrane that lines the JOINT capsule of joints such as the hip and knee. Synovitis is common in RHEUMATOID ARTHRITIS, GOUT, SYSTEMIC LUPUS ERYTHEMATOSUS (SLE), and INFECTION. Generally there is PAIN, often severe, and swelling due to fluid accumulation. The SKIN over the joint is often hot to the touch and red. The doctor may aspirate (withdraw with a fine needle) some fluid from within the joint to rule out INFECTION.

Most synovitis improves with NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS); severe or recurrent synovitis may require injected CORTICOSTEROID MEDICATIONS along with a local anesthetic to relieve PAIN and reduce inflammation. The extent of improvement depends on the underlying cause. Unfortunately synovitis often becomes a chronic presence with rheumatoid arthritis. DISEASE-MODIFYING ANTIRHEUMATIC DRUGS (DMARDS), which slow the progression of rheumatoid arthritis, may lessen the symptoms of synovitis as well. When BACTERIA are present in the synovial fluid, treatment requires ANTIBIOTIC MEDICATIONS.

T

talipes equinovarus A CONGENITAL ANOMALY in which an infant is born with one foot or both feet deformed into the shape of a club, hence the common term for the condition, "clubfoot." The affected foot turns in and under at the heel, such that the top of the foot appears nearly upside-down. All the bones, muscles, and other connective tissues are usually present though deformed in structure.

The anomaly forms in the last part of the first trimester of PREGNANCY when the muscles, bones, and connective tissues develop. Researchers do not know what causes talipes equinovarus though believe it is a combination of environmental factors (such as the fetus's position in the UTERUS) and genetic factors. The condition must be corrected for the child to walk; treatment is most successful when it begins shortly after birth.

The current standard of treatment is progressive casting during the first months of life, typically with the cast changed each week to move the foot slightly closer to normal position and gradually stretch the foot's soft tissue structures (the Ponseti casting method). Often the doctor must cut the ACHILLES TENDON to allow it to lengthen so the foot may completely return to its normal position. When the foot finally reaches normal position, the doctor removes the casts and replaces them with a special brace that the child wears for two months. Some children require further bracing at night for another few months. After treatment, the foot looks and functions as normal.

teeth Calcified formations that grow from the gums in the MOUTH. The teeth are necessary for cutting, tearing, and chewing the food as well as for forming the sounds of language. A person develops two sets of teeth during his or her lifetime. The first set, the primary teeth, erupts around six months of age and remains in place until six or seven years of age. Then the permanent teeth begin to push through the gum and the primary teeth fall out. There are 20 primary teeth and 32 permanent teeth by adulthood. The last 4 permanent teeth, molars in the back of the mouth called the wisdom teeth, erupt through the gumline at age 18 to 20.

When a blow to the face knocks out a tooth, retrieve the tooth and put it in a plastic bag with ice. The dentist often can put the tooth back in place and the tooth will reroot.

The outer layer of the tooth, the enamel, is the densest, hardest substance in the body. Highly mineralized, enamel cannot replace itself when damaged. At the core of the tooth is one of the softest, the pulp. The pulp encases and nourishes the NERVE. Between the enamel and the pulp is a layer of calcified tissue almost as hard as BONE, the dentin. The tooth's root extends from the jawbone. The main health condition to affect the teeth is DENTAL CARIES, or cavities. A cavity is a hole through the enamel that allows BACTERIA to enter the tooth. The bacteria eat away at the tooth's inner structure until reaching the pulp, at which point the cavity causes PAIN. A dentist can plug a cavity with a resin filler to stop the process and preserve the tooth. Other health conditions that can affect the teeth include GINGIVITIS, PERIODONTAL DISEASE and traumatic injury.

temporomandibular disorders A group of conditions in which there is INFLAMMATION and often degeneration of the temporomandibular JOINT, the large joint that connects the lower jaw (mandible) to the temporal BONE of the cranium. There are numerous possible causes for temporomandibular disorders, ranging from a CONGENITAL ANOMALY of structure (such as uneven bite) to OSTEOARTHRITIS and grinding the TEETH (bruxism).

Symptoms and Diagnostic Path

The symptoms of temporomandibular disorders include

- inability to fully open the MOUTH
- locking of the jaw when open
- clicking sounds or sensations when chewing
- PAIN in the temporomandibular joint
- chronic HEADACHE

The diagnostic path begins with a comprehensive examination of the head and mouth. Sometimes the doctor determines the cause is primarily dental, such as uneven bite, and refers the person to a dentist for evaluation and treatment. Deterioration and inflammation of the joint are medical problems the doctor can attempt to treat. X-RAY can show whether there is a misalignment of the joint structures or deterioration of the bones. There is usually no need for additional diagnostic procedures unless the doctor feels the need to rule out other causes for the symptoms.

Treatment Options and Outlook

Treatment for temporomandibular disorders may include medications such as NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) to relieve inflammation and pain, heat or cold to the joint, dental splints or other devices to realign the bite, and dental repairs, if necessary. Temporomandibular disorders tend to be chronic. Many people put up with the discomfort for a considerable time before seeking medical care, by which time joint deterioration or other problems may be serious. Treatment may take time to be effective. In rare circumstances, usually when injury or congenital anomaly causes a structural problem with the joint, surgery may be necessary.

Risk Factors and Preventive Measures

Stress is often a significant factor in the circumstances that contribute to temporomandibular disorders, particularly with bruxism and clenching of the jaw, which causes irritation of the muscles and other tissues in the joint area. Many people find their symptoms improve with a combination of direct treatment (such as NSAIDs and heat) and indirect approaches such as MEDITATION or other stress-reduction techniques. These measures can reduce MUSCLE tension.

tendon A tough, fibrous band of connective tissue that joins MUSCLE to BONE. A tendon originates in the muscle. Like muscle, tendons have a rich BLOOD and NERVE supply. At its other end the tendon inserts into the bone. Mineralization at the insertion point creates a contiguous flow of tissue from muscle to bone. The largest tendon in the body is the ACHILLES TENDON, which joins the muscles of the calf to the bone of the heel. The most common health conditions involving tendons are TENDONITIS (INFLAMMATION of a tendon) and tendon rupture (a tear in the tendon).

tendonitis INFLAMMATION of a TENDON. Tendonitis most often occurs as an overuse injury. Overuse causes the fibers of the tendon to stretch and tear, leaving microscopic injuries throughout the tendon. Occasionally calcium deposits develop in a tendon. The injury activates the IMMUNE RESPONSE, which in turn initiates the inflammatory response.

The main symptoms of tendonitis are PAIN at the tendon's insertion point on the BONE and swelling over the site. Tendonitis most commonly occurs at the wrist, elbow, shoulder, knee, ACHILLES TENDON, and heel. Within the first 24 hours, RICE (rest, ice, elevation, and compression) is the most effective therapeutic approach. NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) help relieve PAIN and inflammation. Most tendonitis improves within 72 hours and completely heals in two to three weeks with appropriate treatment.

torticollis Extended contraction of the muscles in the neck, pulling the head down and to the side. Torticollis, also called wryneck, may be present at birth or acquired. Acquired torticollis may develop after injury to the nerves or muscles of the neck though sometimes the doctor is unable to determine the cause. Often the neck muscles are stiff. In addition to the altered posture of the head and neck, other symptoms of torticollis include HEADACHE and restricted ability to move the head.

The diagnostic path includes a comprehensive NEUROLOGIC EXAMINATION to rule out other possible causes for the symptoms, particularly in adults for whom the symptoms are new. Treatment aims to relax and lengthen the neck muscles on the affected side through PHYSICAL THERAPY as well as self-performed stretching and FLEXIBILITY exercises (for adults). Rarely, surgery is necessary to release the muscles. Baclofen, an anticholinergic medication that blocks neurotransmitters essential for MUSCLE contraction, provides relief for some people. MASSAGE THERAPY and sometimes cervical traction help acquired torticollis that becomes chronic. Early treatment usually corrects congenital torticollis.

PAIN AND PAIN MANAGEMENT

PAIN is an unpleasant, subjective sensation associated with numerous health conditions and circumstances. Pain specialists are physicians who have additional education and training in the treatment and management of pain. Pain specialists may be anesthesiologists, internists, neurologists, orthopedic surgeons, psychiatrists, or physiatrists.

The entries in this section, "Pain Management," are about pain and its treatment. Entries discussing health conditions for which pain may be a symptom appear in the system section appropriate for the condition.

The Mechanisms of Pain

Pain can be a potent symptom, pointing to a significant injury or disease process within the body. Pain can also be a measure of HEALING, marking the body's progress toward wellness. And pain can be an indicator of dysfunction, persisting when there is no apparent reason for its existence. At a primal level, pain is a sensory survival mechanism. It tells the body to rapidly move to avoid its source or cause. The SPINAL CORD conveys pain signals directly to several regions of the CENTRAL NERVOUS SYSTEM, such as the thalamus, that regulate the body's REFLEX responses.

The message of pain begins with specialized molecules, called nociceptors, that line the dendrites of peripheral neurons. Dendrites are branchlike networks that extend from a NEURON to capture electrical signals and convey them to the NERVE body, which focuses them into a more organized nerve impulse. Nerve impulses travel along chains of neurons (nerve fibers) until they reach the large nerve clusters, the dorsal ganglia, that feed into the spinal cord. The dorsal ganglia further sort and focus nerve impulses, blocking many from continuing to the BRAIN but allowing passage for others. At this point the pain messages transition from the PERIPHERAL NERVOUS SYSTEM to the central NERVOUS SYSTEM.

The first structure within the brain to receive the nerve signals of pain is the thalamus. The thalamus further filters the impulses and takes rudimentary action to address certain aspects of the pain response. It initiates reflex reactions for pain signals that require it, dissipates some impulses that it interprets as meaningless, and sends the remainder on to the cerebral cortex for more sophisticated interpretation. Neuron activity in the cerebral cortex determines how the person will perceive the pain—whether the signals are indeed pain and what it will feel like (sharp, dull, stabbing) and how intense it will be (mild, moderate, severe). Pain generally results in one of two actions: removing the involved body part from the source of the pain or limiting the movement of the body part.

Traditions in Medical History

For thousands of centuries people have used natural substances to relieve pain. Willow bark contains salicylic acid, the basis of aspirin. Oil of wintergreen (*Gualtheria procumbens*) also contains salicylic acid. Opium occurs naturally in the poppy species *Papaver somniferum*. The leaves of the coca plant (*Erythroxylum coca*) contain COCAINE. Many modern analgesics contain synthetic preparations or derivations of these potent pain relievers. Some substances ancient healers turned to for pain relief had very narrow margins of safety:

mandrake, henbane, and hemlock, among others. Today's pharmacopoeia recognizes these substances as dangerous poisons that have no therapeutic applications. Other approaches to pain relief before the 20th century included ALCOHOL and the literal "bite the bullet."

The first pharmaceutical preparation for pain relief was aspirin, which came into use at the end of the 19th century. Pharmaceutical preparations of OPIATES and other pain relievers soon followed. Dozens of ANALGESIC MEDICATIONS are now available that can effectively treat and often prevent pain along the full spectrum of severity.

Breakthrough Research and Treatment Advances

Research in the 1990s provided breakthroughs in knowledge and understanding of pain mechanisms and, accordingly, for new ways to provide pain relief. Researchers know, for example, that women and men experience pain differently, raising the probability that hormones play a key role in pain perception and tolerance. There are genetic factors that come into play as well, such as the function or dysfunction of the genes that regulate the production and activity of cytochrome enzymes. The LIVER produces these enzymes, such as CYTOCHROME P450 (CYP450) ENZYMES, that are integral to how the body metabolizes numerous medications, including analgesics. Understanding pain pathways has helped doctors understand how analgesics interfere with those pathways, allowing clinicians to select the analgesics with the highest likelihood for relieving the pain.

Researchers know, too, that the body releases numerous biochemicals after injury (traumatic or surgical) that influence how nociceptors perceive stimuli. The body also releases biochemicals such as endorphins and enkephalins that act at the levels of both peripheral nociceptors and central (spinal cord and brain) neuroreceptors. Research is under way to develop medications that stimulate release of endorphins and enkephalins as well as to target other mechanisms of the pain pathway to relieve pain with lowered risk of side effects.

A

acute pain PAIN that arises suddenly and is often intense or severe in its quality. Acute pain signals injury to the body resulting from trauma, surgery, or disease process that damages tissue. Acute pain is short lived (typically less than one month) and goes away when the condition causing it improves or goes away. Doctors may use the term EUDYNIA to identify acute pain. Pain that does not go away when the underlying cause improves becomes CHRONIC PAIN, or MALDYNIA.

Chest pain may indicate heart attack or pulmonary embolism and requires emergency medical evaluation.

People often describe acute pain as sharp, stabbing, or burning. Physical signs that accompany acute pain include

- rapid BREATHING (TACHYPNEA)
- rapid HEART RATE (tachycardia)
- elevated BLOOD PRESSURE
- clammy SKIN
- dilated pupils

Severe acute pain may cause loss of CONSCIOUSNESS; severe pain requires prompt or emergency medical evaluation. Chronic and terminal health conditions may also cause episodes of acute pain.

Treatment for acute pain is two-pronged, targeting the pain as well as the underlying cause. ANALGESIC MEDICATIONS are generally effective for pain relief. There are numerous types of analgesic medications; doctors often prescribe or recommend them in combinations that target the nature and sometimes the cause of the pain. For example, the NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) block the release of PROSTAGLANDINS, biochemicals the IMMUNE RESPONSE generates that activate both the inflammatory response and NERVE transmission of pain signals. Narcotic analgesics, such as morphine and oxycodone, bind to receptors in the brain, preventing the release of neurotransmitters. As a result the pain impulse cannot be transmitted and the brain does not perceive pain.

Nonmedication methods also provide relief from acute pain. Sometimes just resting the affected area calms irritation and discomfort.

Wrapping or bracing an injured JOINT or limb provides support during activity. Ice to the affected area soothes INFLAMMATION, slowing the release of prostaglandins and other biochemicals that stimulate the pain response. Heat and therapeutic massage help tight, stiff muscles relax and improves BLOOD flow to the HEALING area. Alternating heat and ice can provide substantial relief for musculoskeletal pain.

aging, changes in pain perception that occur with The perceptions of PAIN and the responses to pain relief methods change across the spectrum of age. A long-held belief is that infants experience pain only in the most rudimentary fashion; current research shows that infants experience nearly the same range and nature of pain as do adults. They also have the capacity to remember pain experiences. Children of all ages have surprisingly sophisticated understanding of pain and pain relief. At the other end of the spectrum, for about a third of people over age 60 pain is a daily experience. But as the body ages its ability to respond to ANALGESIC MEDICATIONS and other approaches to pain relief changes. So does its ability to generate its own natural pain relievers, endorphins and enkephalins.

Pain in Infants and Children

Though an infant's NERVOUS SYSTEM continues to develop after birth, the mechanisms for nociception (stimulation of nerves to transmit pain signals to the CENTRAL NERVOUS SYSTEM) are capable of function at about 28 weeks of gestational age—12 weeks before a full-term delivery. Though infants under age 12 months cry when in pain and exhibit reflexive behaviors to avoid painful stimuli, it is difficult to determine the severity of the pain. Young children (ages 1 to 5 years) are able to assess the severity of their pain and convey this to caregivers. A common pain scale for young children is the Wong-Baker Faces Scale, which uses a series of smiling-to-frowning faces for children to describe how their pain feels. Other pain assessment scales make use of the child's physical behaviors and degree to which the child responds to comforting measures to help caregivers assess the level of pain the child is experiencing.

Because a child's body is not fully developed, it metabolizes medications differently from that of an adult's body. Analgesic medications to relieve pain thus have different therapeutic levels, durations of effectiveness, and toxic levels. Some analgesics have undergone clinical study to quantify their actions and side effects in children though many have not. Pediatric dosing for analgesics is sometimes imprecise and tends to err on the side of undertreating pain in children. Children who have significant or CHRONIC PAIN should receive care from pediatric pain specialists to ensure that they receive adequate pain relief.

Pain in the Elderly

The number of peripheral sensory receptors gradually diminishes with aging, affecting the PERIPHERAL NERVOUS SYSTEM's ability to detect pain and convey pain signals to the central nervous system. This can result in more serious injury before there is adequate stimulus to avoid the situation. An older person may experience scalding and damage to the SKIN from water that is too hot, for example, before nociceptors detect the danger. Sensory receptors, including nociceptors, are also more susceptible to dysfunction and may overrespond to stimuli, resulting in MALDYNIA.

Other changes that take place in the body affect the METABOLISM of drugs, which in many circumstances means that less of the medication is necessary to achieve the desired therapeutic effect. The body may take longer to clear the medication, meaning doses should be farther apart (such as every six hours instead of every four hours) or that the DRUG may more quickly accumulate to a level of toxicity. Changes in gastric acid production and STOMACH function make the lining of the stomach more vulnerable to damage from highly acidic products, increasing the risk of bleeding with acidic medications such as ibuprofen and aspirin. Because of this the American Geriatric Society recommends that most people over age 65 take acetaminophen as the first choice for mild to moderate pain relief.

Because older people are more likely to have health conditions that require regular medications,

the risk for ADVERSE REACTION, undesired side effects, and DRUG INTERACTION is high. Among those conditions are many that cause chronic pain, such as OSTEOARTHRITIS, SCIATICA, and gout, increasing the need for pain relief methods. It is important for the older person to receive adequate pain relief, especially from chronic pain, which sometimes means taking narcotic pain relievers. Health experts recommend methods that minimize the use of analgesic medications, such as MASSAGE THERAPY, heat and cold, ACUPUNCTURE, BIOFEEDBACK, and relaxation techniques such as MEDITATION. Regular physical exercise, such as walking, increases the body's production of endorphins and enkephalins, amino acids that function as natural pain relievers.

alternative methods for pain relief Methods for treating PAIN (typically CHRONIC PAIN) that are outside the parameters of conventional approaches such as ANALGESIC MEDICATIONS. Among the more common alternative methods for pain relief are ACUPUNCTURE, BIOFEEDBACK, HYPNOSIS, CHIROPRACTIC, MAGNET THERAPY, and MASSAGE THERAPY. Herbal and botanical products may also bring relief from pain associated with specific conditions.

Acupuncture

In 1997 the US National Institutes of Health (NIH) released a consensus statement regarding acupuncture. The statement cites these circumstances in which studies demonstrate acupuncture's effectiveness in relieving pain: after dental surgery, menstrual cramps (DYSMENORRHEA), FIBROMYALGIA, myofascial pain syndrome, OSTEOARTHRITIS, chronic low BACK PAIN, CARPAL TUNNEL SYNDROME, HEADACHE, and tennis elbow. In the Eastern tradition, acupuncture works by unblocking the pathways of chi, the energy of life. In the Western tradition, researchers postulate that acupuncture acts on nociceptors and PERIPHERAL NERVES.

Biofeedback

Biofeedback allows a person to influence the perceptions and responses of certain body functions such as those related to pain. Many health-care centers provide biofeedback training; the person then uses biofeedback techniques when needed. Biofeedback is especially effective for helping avert the onset of migraine and MUSCLE tension headaches, relaxing tense muscles that contribute to muscle SPASM and pain, and relieving stress.

Hypnosis

Hypnosis is a state of deep relaxation in which a person is especially receptive to suggestions the hypnotherapist makes. These suggestions may include visualization and relaxation techniques to apply in specific circumstances, such as when feeling tense or that pain is starting. Some people are able to practice self-hypnosis, which is particularly helpful for stress reduction with chronic pain conditions.

Chiropractic

Chiropractic manipulation of the neck and back (spine) can relieve muscle tightness, improve FLEXIBILITY, and restore function. The foundation of chiropractic is realignment of the spine to restore balance to the body. Chiropractic care requires visits to a chiropractor; the number and frequency of visits depend on the health condition. Chiropractic manipulation is particularly effective for conditions such as chronic low back pain, chronic neck pain, REPETITIVE MOTION INJURIES, and other musculoskeletal pain. The chiropractor also teaches methods to minimize injury through proper posture, movement, and stretching.

Magnet Therapy

Magnetic energy affects the flow of fluids and electrolytes (salts) through the cells of the body. Though research studies show conflicting results as to the effectiveness of static magnets (magnets or magnetic devices worn on the body), pulsed electromagnetic therapy is an effective therapeutic method physical therapists and physiatrists use. Static magnets may provide a less intense effect. People who have implanted electronic devices such as a PACEMAKER should not use static magnets or have pulsed electromagnetic therapy because these treatments may affect the device's proper functioning by altering its electromagnetic field.

Massage Therapy

Therapeutic massage relaxes stiff muscles and increases the flow of BLOOD. These effects improve flexibility and movement, and bring pain-relieving chemicals (the body's own substances or medications in the blood circulation) to the area. Massage therapy is effective for many types of pain and helps relieve the emotional stress that often accompanies conditions of chronic pain.

Herbal and Botanical Remedies

Numerous herbal and botanical remedies have pain-relieving actions. Some are effective for specific discomfort, such as DONG QUAI for dysmenorrhea (menstrual cramps) and FEVERFEW for migraine headaches. These herbs appear to block the release of PROSTAGLANDINS, substances the body produces that cause INFLAMMATION. Research studies also support the effectiveness of CHONDROITIN and GLUCOSAMINE, chemical compounds that occur naturally in the body. These compounds block the actions of enzymes that destroy connective tissue. Taken as nutritional supplements, chondroitin and glucosamine may be as effective as NSAIDs for relieving the inflammation of osteoarthritis that causes pain. Herbal and botanical products for pain relief may interact with OVER-THE-COUNTER (OTC) DRUGS and prescription medications, notably NSAIDS.

Benefits and Risks of Alternative Pain Relief Methods

Some alternative pain methods can interact or interfere with conventional therapies the doctor prescribes or recommends. It is important to discuss alternative methods with the doctor to effectively integrate them with other therapeutic approaches and to minimize the risk for complications, including worsening of the condition or interactions with other methods.

analgesic medications Drugs, products, and preparations that relieve PAIN, often called pain relievers. Some kinds of analgesic medications, such as OPIATES and other NARCOTICS, solely relieve pain by acting on neuroreceptors in the brain. Other analgesics have multiple effects, such as NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS), which also relieve INFLAMMATION and FEVER, and acetaminophen, which also relieves fever. Other kinds of medications primarily prescribed for other therapeutic uses are effective for pain relief in certain pain syndromes. Some ANTIDEPRESSANT MEDICATIONS, antiseizure medications, beta-antagonist medications (beta-blockers), and calcium channel antagonists (calcium channel blockers) can provide relief from and often can prevent NEUROGENIC PAIN (pain arising from injury to nerves) and migraine HEADACHE.

Routes of Administration

Analgesic medications are available in numerous formulations for several different ROUTES OF ADMINISTRATION. The most common route of administration for analgesics is oral—pills, tablets, capsules, and liquids taken by mouth. Some medications absorb poorly through the gastrointestinal tract so are far more effective in other forms such as transdermal patch, suppository, and injection. Topical medications applied to the SKIN may relieve MUSCLE and JOINT pain. The choice of both the analgesic medication and its route of administration affects how rapidly and how completely the medication relieves pain.

Oral The processes of digestion—how much and what kinds of food are in the STOMACH and gastrointestinal tract as well as individual variations in the digestive process—affect how rapidly oral medications enter the BLOOD circulation. Most oral analgesics begin to have an effect within 20 to 45 minutes and stay in the bloodstream at a therapeutic level for two to six hours. Some long-acting formulations are effective for 12 to 24 hours.

Transdermal patch Some products are available in transdermal patches, small adhesive patches placed on the surface of the skin, which get the medication rapidly into the blood circulation via absorption through the skin. The transdermal patch is also effective for delivering sustained-release medication (medication that slowly absorbs over a planned period of time, often 48 to 72 hours).

Topical Topical medications are also applied to the surface of the skin though are not absorbed

into the blood circulation to any significant extent. Topicals come as creams (water-based), ointments (oil-based), gels, sprays, and liquids. Topical analgesics may contain aspirin or other forms of salicylate, local anesthetic such as lidocaine (which numbs the skin's surface), hydrocortisone (an anti-inflammatory DRUG to reduce swelling at the skin's surface), and capsaicin.

Suppository Rectal suppositories package the medication in a soft, waxy capsule that, after insertion into the RECTUM, melts to release the analgesic. The rectal mucosa (mucous membrane lining of the rectum) has a rich blood supply that rapidly draws in the medication. Analgesics in suppository form are especially effective when nausea is a problem and for people who have difficulty swallowing.

Injection The more potent analgesics, notably narcotics, are poorly absorbed through the gastrointestinal tract and thus are available in injectable forms (shots). An injection may be

- intravenous (directly into a VEIN), which provides the most rapid (usually seconds) though short-term (30 minutes to 2 hours) pain relief
- intramuscular (into a muscle), which provides fast relief (within 10 minutes) that can last three to four hours
- subcutaneous (into the layer of fatty tissue beneath the skin), which provides prompt relief (within 20 to 30 minutes) but slower release of the medication into the blood circulation for analgesia that can last six to eight hours
- PATIENT-CONTROLLED ANALGESIA (PCA), in which intravenous medication flows steadily into a vein (intravenous administration) via a pump that regulates the amount of medication, either as at a preset rate or by patient demand (when the person presses the button to release more medication)
- continuous infusion of local anesthesia, which infiltrates tissue in a specific area with an anesthetic agent that relieves pain by numbing the nerves such as after a surgical OPERATION
- intrathecal analgesia, in which the pain specialist inserts a thin catheter into the space around the SPINAL CORD that delivers the analgesic in somewhat the same fashion as PCA

PCA and intrathecal analgesia offer highly effective pain control for ACUTE PAIN after surgery as well as severe pain due to chronic or terminal conditions. Continuous infusion of local anesthesia is especially effective after major surgery, reducing the amount of narcotic analgesics necessary to provide adequate pain relief. Continuous infusion of local anesthesia also allows greater comfort for coughing, deep BREATHING, and return to mobility, factors that are essential for HEALING as well as to prevent postoperative complications. Injections can cause discomfort and bleeding at the injection site.

How These Medications Work

Analgesic medications work by altering how the NERVOUS SYSTEM processes pain messages. They may

- raise the pain threshold (the point at which nociceptors perceive stimuli as painful); acetaminophen functions in this way
- block production of PROSTAGLANDINS and other biochemicals that sensitize nociceptors and activate the inflammatory response; NSAIDs function in this way
- bind with neuroreceptors in the BRAIN to alter the brain's interpretation of pain signals; opiates and other narcotics function in this way
- alter the balance of peripheral and central (brain) neurotransmitters; antidepressants and antiseizure medications function in this way
- change the ionization of cells to affect how molecules pass through them; beta blockers and calcium channel blockers function in this way

Taking analgesic medications properly is as important as the correct choice of drug when it comes to effective pain relief. Some analgesics need to be taken on a scheduled basis because they are more effective when they reach a steady THERAPEUTIC LEVEL in the blood. These medications generally provide sustained pain relief for short-term acute pain due to trauma or surgery and for long-term CHRONIC PAIN. Other analgesics are more effective when taken as needed, often indicated as "prn" in the doctor's instructions. These medications generally cover mild to moderate acute pain

and breakthrough pain with chronic conditions or during recovery from injury or surgery.

NARCOTICS AND ADDICTION

Many people, including doctors, are fearful of the potential for addiction with long-term use of NARCOTICS (OPIATES). However, numerous studies show that addiction is very rare, affecting fewer than 1 percent of people who take opiates for severe CHRONIC PAIN. Pain alters the mechanisms in the BRAIN that respond to opiates such that these mechanisms do not interpret the effect of the opiate as producing pleasure (a key factor in addiction). As well, addiction involves a combination of physical and emotional factors that typically are not present in severe pain. The unwarranted fear of addiction prevents many people from taking or receiving enough medication to relieve their pain.

Therapeutic Applications

Aspirin, acetaminophen, and over-the-counter NSAIDs are the most widely used medications in the United States. They have numerous therapeutic applications for mild to moderate relief from pain, inflammation, and fever. Doctors generally move to prescription medications when OVER-THE-COUNTER (OTC) DRUGS are not effective or when the nature of the pain is such that it exceeds their ability to provide relief (such as after surgery or significant injury). As knowledge and understanding about the mechanisms of pain grow, doctors are increasingly able to structure pain relief approaches that integrate different kinds of drugs for optimal effectiveness. The therapeutic application of many analgesics is highly individualized.

Risks and Side Effects

Risks and side effects vary according to the medication. It is possible to have an ALLERGY to any analgesic, creating the potential for HYPERSENSITIVITY REACTION. Though OVERDOSE is possible with any analgesic, it is a particular risk with aspirin, acetaminophen, and NSAIDs. People are more likely to self-medicate with these drugs and to take multiple products that contain these drugs as ingredients without recognizing the cumulative amount exceeds safety. These drugs also have a lower threshold for hepatotoxicity (damage to the LIVER) and renal toxicity (damage to the KIDNEYS), and can cause irreversible LIVER FAILURE or RENAL FAILURE even when taken at recommended dosage levels. Though many people worry about overdose with narcotics (opiates), it is far less of a risk. However, inappropriate use of narcotics has high risk for addiction. Aspirin and NSAIDs also are irritating to the gastrointestinal tract and may cause bleeding.

Medications such as beta-blockers, calcium channel blockers, and antiseizure medications have particular risks associated with these classifications of drugs. Though people taking these drugs for their primary intended purpose (cardiovascular conditions or seizure disorders, respectively) are generally well aware of these risks, people taking them for pain relief may not recognize warning signs of adverse reaction. It is important to weigh the potential benefits and risks of taking these drugs for pain relief. Analgesic medications also interact with numerous other medications, including OTC products and herbal remedies.

chronic fatigue syndrome A constellation of symptoms that exist within a framework of profound, persistent fatigue and generalized PAIN. Neither the fatigue nor other symptoms improve with rest. Chronic fatigue syndrome often debilitates those who have it and confounds the doctors trying to treat them. Researchers have as yet been unable to identify clear pathologic (disease process) reasons that account for the symptoms of chronic fatigue syndrome. Proposed causes include viral INFECTION (such as with EPSTEIN-BARR VIRUS or human herpesvirus 6), HYPERSENSITIVITY REACTION (ALLERGY), autoimmune disorder or other IMMUNE SYSTEM dysfunction, hormonal imbalance, chronic intermittent HYPOTENSION (low BLOOD PRESSURE), subclinical ANEMIA, and HYPOGLYCEMIA (low blood sugar). In many people chronic fatigue syndrome appears after a serious viral infection or after an event that causes significant stress.

Symptoms and Diagnostic Path

In many people, the initial symptoms of chronic fatigue syndrome are those of a viral infection such as INFLUENZA. But the symptoms do not go away after the typical timeline for such an infection. Because ongoing symptoms are widely variable and often without apparent physical cause, medical experts have established two basic criteria for a diagnosis of chronic fatigue syndrome. For six months or longer the person must have

- severe, chronic fatigue for six months or longer with diagnostic evaluation unable to find a medical reason for the fatigue
- four or more of the eight additional key symptoms: sore THROAT, MUSCLE pain, tender LYMPH nodes, noticeable difficulty with concentration and short-term memory; pain in numerous joints; headaches; difficulty sleeping or unrestful sleep; feeling of overwhelming exhaustion after physical exertion.

In addition to these core symptoms, most people have numerous other symptoms that may include

- ABDOMINAL PAIN
- CHEST PAIN and shortness of breath
- chronic COUGH
- NAUSEA, gastrointestinal discomfort, and DIARRHEA
- night sweats
- DEPRESSION, anxiety, or panic attacks
- jaw pain
- earaches
- "pins and needles" sensations
- dizziness

There are no diagnostic procedures that define chronic fatigue syndrome. Rather, the doctor orders certain diagnostic tests to rule out other potential causes for the symptoms. These include BLOOD tests to measure thyroid HORMONE levels, blood cell types and counts, electrolytes, globulins, and GLUCOSE levels in the blood circulation. The doctor may desire additional blood tests and urinalysis. Abnormal findings point in a different clinical direction; a diagnostic criterion for chronic fatigue syndrome is that such routine tests are normal.

Diagnostic imaging procedures such as MAGNETIC RESONANCE IMAGING (MRI) and COMPUTED TOMOGRAPHY (CT) SCAN may rule out other suspected conditions though do not help the doctor

reach a diagnosis of chronic fatigue syndrome. Because the length of time the person experiences symptoms is a crucial element of the diagnosis, the diagnostic journey is often frustrating.

Treatment Options and Outlook

Because doctors do not know what causes chronic fatigue syndrome, treatment targets symptoms and is generally a combination of approaches tailored to the individual's responses and improvements. Treatment options include

- low-dose antidepressant medications, which may relieve pain as well as improve the quality of sleep
- antianxiety medications, which may relieve symptoms of anxiety, panic attacks, abnormal skin sensations, and dizziness
- antihistamine medications, which may relieve symptoms such as runny nose and nasal congestion
- modafinil, a nonamphetamine stimulant medication doctors commonly prescribe to treat narcolepsy, which improves alertness and cognitive function in some people who have chronic fatigue syndrome
- nonsteroidal anti-inflammatory drugs (NSAIDs), which may relieve joint pain and generalized discomfort
- daily physical activity at a level that is consistent but does not trigger a worsening of fatigue or other symptoms
- alternative methods such as acupuncture, biofeedback, massage therapy, craniosacral massage, hypnosis, Reiki, and therapeutic touch
- meditation, relaxation techniques, and stress-relief methods

Treatment often but does not always relieve symptoms enough to allow participation in the normal activities of living. For many people who have chronic fatigue syndrome, the fatigue is so overwhelming that it prevents virtually any level of activity despite treatment for other symptoms. Some people experience continued symptoms that wax and wane in severity. For most people who have the disorder, chronic fatigue syndrome is a long-term condition that does eventually improve or go away. The timeline for improvement is widely variable though typically spans several years. Many communities have support groups in which people who have chronic fatigue syndrome can share their experiences and concerns.

Risk Factors and Preventive Measures

Again because doctors do not know what causes chronic fatigue syndrome, there are no specific measures to prevent it. Doctors diagnose chronic fatigue syndrome in about four times as many women as men. For the most part chronic fatigue syndrome is relatively indiscriminate, affecting people across the spectrum of age and health status.

chronic pain Pain that persists longer than three months or beyond the point of healing for the condition that causes it. Chronic pain is very common, affecting the daily lives and activities of an estimated one in six Americans—about 60 million people. The most prevalent causes of chronic pain in the United States are low back pain, arthritis, and headache.

Pain experts differ in their definitions of what constitutes chronic pain. Research in the past decade has provided new understanding about the mechanisms of functional and dysfunctional pain. Some pain specialists view all chronic pain as dysfunctional because it no longer serves the purpose of warning the body. In this view the pain itself becomes the disorder, called maldynia, and treatment targets pain relief.

Other pain specialists consider some kinds of chronic pain (that which accompanies chronic health conditions such as rheumatoid arthritis) to remain symptomatic rather than dysfunctional. The pain persists because the underlying condition that causes it persists or progresses. In this view treatment targets the underlying condition, which often includes therapies to relieve pain as well as the pathology of the condition and its other symptoms. In rheumatoid arthritis, for example, treatment attempts to slow the inflammatory process

that causes degeneration in the joints as well as to relieve the pain of the degenerative changes.

Therapeutic methods for chronic pain typically combine various approaches to find those that are most effective for the individual. The subjective nature and diverse causes of chronic pain often mean effective relief comes through a process of trial and error. Generally lifestyle measures to maintain healthy body weight and optimal range of motion, such as daily physical exercise, are important for all types of pain. Exercise increases the body's release of endorphins and enkephalins, amino acid structures that act as natural pain relievers.

complex regional pain syndrome A chronic and often progressive condition of severe PAIN. There are two types of complex regional pain syndrome: type 1 (also called reflex sympathetic dystrophy), in which there is no identifiable NERVE injury, and type 2 (also called causalgia), which follows significant injury to a nerve. Type 2 is more common though the symptoms, treatment, and course of disease are similar for both types. Researchers do not fully understand the development and progression of either type of this syndrome but believe it results from dysfunction of the sympathetic NERVOUS SYSTEM, the functional division of the nervous system that regulates BLOOD flow. Complex regional pain syndrome is typically chronic (ongoing and long term) and often progressive (symptoms worsen over time). It most often develops in people who are between the ages of 40 and 60.

Symptoms and Diagnostic Path

The symptoms of complex regional pain syndrome typically involve a limb, with the arm being more common than the leg. In addition to pain, the course of disease causes pathologic (abnormal) changes in the SKIN, MUSCLE, connective tissue, and BONE. Early symptoms include

- severe burning pain that intensifies with slight touch, even that of a breeze (a nociceptor disturbance called allodynia)
- swelling in the affected arm or leg
- increased HAIR and nail growth
- dry, thin skin that alternates between warm and cool to the touch without influence from the external environment and may become cyanotic (bluish in color) or mottled (areas of irregular color)
- altered sweating (sometimes excessive, sometimes inadequate sweat production)

Symptoms change as the syndrome unfolds. Later symptoms include

- severe burning pain affects larger area of the limb
- diminished ability to move the limb
- decreased hair and nail growth
- permanent changes in the skin's texture and color (often becomes mottled)
- changes in bone structure and BONE DENSITY that are apparent on X-RAY
- TENDON contractions and muscle SPASM
- muscle atrophy (wasting of muscle tissue)

The diagnostic path is primarily clinical because the symptoms are fairly distinctive, particularly when there is history of traumatic or surgical injury to the involved limb. STROKE or HEART

ATTACK may also be a precipitating event. The doctor may use X-ray, bone scan, nerve conduction studies, and other procedures to assess the neuromuscular function of the limb. A comprehensive NEUROLOGIC EXAMINATION can rule out other possible causes of pain or complicating factors. However, there are no conclusive diagnostic procedures for this syndrome.

Treatment Options and Outlook

The earlier treatment begins, the better the outlook. Treatment may involve a blend of approaches, including

- anti-inflammatory medications such as NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) or CORTICOSTEROID MEDICATIONS to reduce INFLAMMATION and swelling
- tricyclic ANTIDEPRESSANT MEDICATIONS and antiseizure medications, which are often effective in relieving NEUROGENIC PAIN
- TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION (TENS)
- NEURAL BLOCKADE (NERVE BLOCK) for pain that does not respond to noninvasive treatments
- RHIZOTOMY or sympathectomy (surgery to cut the nerve carrying the pain messages) for pain that does not respond to other methods of relief
- medications to prevent bone loss
- PHYSICAL THERAPY and MASSAGE THERAPY to maintain FLEXIBILITY and mobility
- heat or cold to sites of pain
- BIOFEEDBACK
- ACUPUNCTURE

Early treatment may arrest symptoms and prevent their progression. When the condition progresses, permanent damage to the limb becomes extensive and may render the limb useless. In severe cases the syndrome spreads to involve other parts of the body.

Risk Factors and Preventive Measures

Though doctors know that type 2 complex regional pain syndrome, the more common type, develops after significant trauma to the limb, they do not know what causes it to occur. Type 1 complex syndrome is even more baffling because there is no clear injury that precipitates symptoms. Accordingly, there are no measures known to prevent this disorder. However, early diagnosis and treatment can prevent the condition from progressing, limiting the extent of permanent damage that occurs.

eudynia PAIN that exists as a symptom clearly associated with an underlying health condition or circumstance and results from stimulation of nociceptors (specialized sensors on the dendrites of neurons that convey pain messages). Eudynia, also called ACUTE PAIN, is typically short lived. Such pain is a common feature of injury and numerous disease processes and is the body's signal that something is wrong. Eudynia responds well to treatment with ANALGESIC MEDICATIONS and nonmedication methods such as rest, ice, compression (if appropriate), and elevation (if appropriate)—the RICE approach. ACUPUNCTURE and NEURAL BLOCKADE (NERVE BLOCK) are other methods that provide relief for pain due to traumatic injury or surgery. Eudynia resolves as the underlying condition improves.

headache PAIN perceived as coming from the face and head. Headache is a common experience, with about 45 million adults in the United States having frequent headaches. There are numerous types of headache resulting from various causes. Among them are tension headache, migraine headache, cluster headaches, sinus headache, and rebound headache. Headache may also indicate HYPERTENSION (high BLOOD PRESSURE), TRANSIENT ISCHEMIC ATTACK (TIA), or STROKE. Headache also is common with COLDS, flu, and FEVER. Very rarely headache may signal an INFECTION such as MENINGITIS or an ANEURYSM or a tumor in the BRAIN.

The nerves in the soft tissue of the head, neck, and face transmit the pain signals familiar as headache. There are no sensory nerves in the brain or bones of the skull, even though headache pain often feels as though it comes from deep within the head. Pain associated with events within the brain, such as tumor or stroke, arises from the increase in pressure within the cranium (enclosure of the skull) these conditions cause. The pressure stimulates the network of nerves that interlace with BLOOD vessels at the base of the brain. This NERVE and blood vessel network extends into the soft tissue surrounding the skull, magnifying the perception of pain.

Sudden, severe headache or headache with stiff neck, high or prolonged FEVER, or blow to the head may signal a medical emergency that requires urgent evaluation from a doctor.

Tension Headache

Tension headaches are the most common type of headache, resulting from MUSCLE tenseness in the shoulders, neck, and head. Stress, which often causes people to unknowingly tense their muscles, is a key factor. The stress may be emotional, related to job or family issues, or the stress may be physical, arising from lack of sleep, sitting too long in one position, going without eating, or loud noise. The tightened muscles aggravate nociceptors, the sensory molecules that respond to intense stimuli, which generate nerve signals of pain. The irritated muscles may also develop some INFLAMMATION, further stimulating nociceptors. Researchers believe biochemical factors, such as altered neurotransmitter balances (which affect the function of neurons) and increased production of PROSTAGLANDINS (which influence inflammation and changes in the walls of blood vessels), may also contribute to tension headaches by affecting the sensitivity of nociceptors. Tension headaches range in severity from mild discomfort to pain severe enough to cause NAUSEA, VOMITING, and disturbances of vision. Many tension headaches go away when the stressful situation ends. Others may last for several days or become chronic (recurring).

Migraine Headache

Migraine is the most common type of vascular headache. About 28 million Americans experience chronic migraine headaches. For many people the pain of migraine is debilitating. The conventional understanding of migraine is that the pain is a reaction to extreme changes (constriction and dilation) in the blood vessels that serve the head, likely as a consequence of rapid fluctuations in neurotransmitters, prostaglandins, and other substances that affect circulation. Recent research suggests there are genetic components to the mechanisms that regulate blood vessel constriction and dilation in the head, postulating that defects in genetic encoding (the protein messengers genes

send to cells that direct their activities) cause the abnormal vessel activity. Migraines tend to run in families, which supports the premise of genetic involvement.

There are two types of migraine:

- Classic migraine begins with an aura—a sensory experience, such as seeing flashing lights or smelling a particular odor that is not actually present, that portends the arrival of the headache. Disturbances of vision, confused thinking, and tingling in parts of the body such as the hands or feet may accompany the aura. Nausea and often vomiting may come next. Within about 30 minutes the pain erupts, often beginning on one side of the head or around the EYE. The pain may stay on one side of the head or spread to the entire head. A classic migraine lasts 24 to 48 hours.
- Common migraine lacks an aura though often there are vision disturbances, confusion, nausea, and vomiting before the headache starts. The pain may start on one side of the head and spread to both sides, or start with full involvement of the entire head. A common migraine may last three or four days.

Medications are the usual approach for recurring migraines. The most effective are those that prevent the migraine from unfolding. A class of drugs called triptans offering a new approach to migraine treatment became available in the early 1990s. Triptans (such as sumatriptan and zolmitriptan) work by binding with receptors on the cells in arterial walls that selectively constrict arteries, preventing the fluctuations in dilation and constriction that result in pain. The effectiveness of the different triptan products is highly individual, so often a period of trial and error is necessary to find the right match between person and drug. Triptans also have potentially severe side effects, including HEART ATTACK resulting from constricted CORONARY ARTERIES. People who have CARDIOVASCULAR DISEASE (CVD) such as CORONARY ARTERY DISEASE (CAD) or ISCHEMIC HEART DISEASE (IHD), or who have significant risk for CVD, should not take triptans.

Migraine headaches are most common in menstruating women, raising the probability of a hormonal connection. Some women have persistent migraines until pregnancy and then never have a migraine headache again. Other women develop migraines during pregnancy or after menopause. Oral contraceptives (birth control pills), which are hormones, also influence migraine headaches, improving them in some women and worsening them in others. The hormonal connection seems obvious but its precise nature remains elusive.

Cluster Headache

Cluster headache is a less common type of vascular headache in which a migraine-style headache recurs at about the same time of day for two to four months. The pain of cluster headache affects one side of the head and is typically severe. What will become a series of headaches begins suddenly, often around one eye. The involved eye becomes red and swollen, and the same side of the NOSE often becomes congested. Each headache lasts 30 to 90 minutes and then goes completely away. A person may go several months to several years between clusters. However, severe chronic cluster headache can occur in such a regular pattern that there is very little break between the end of one cluster and the start of the next. Cluster headache is more common in men and does not appear to have a hereditary component.

Sinus Headache

Sinus headaches result from the pressure of sinus congestion. The pain typically emanates from the front of the face, is more severe upon first waking and when tipping the head downward, and includes POSTNASAL DRIP among its symptoms. Sinus congestion may result from a cold, ALLERGIC RHINITIS (seasonal allergies), or sinus infection. The doctor should evaluate sinus headache that lasts longer than three weeks or when there a thick, green or yellow discharge accompanies the headache as these symptoms may indicate a bacterial infection that requires treatment with ANTIBIOTIC MEDICATIONS.

Rebound Headache

Rebound headache is an unpleasant circumstance that develops as a consequence of long-term use of analgesic medications (more than twice a week on a fairly regular basis) to treat chronic headache. The

headache improves or goes away with the medication but then returns when the medication wears off or the person does not take the medication. Eventually the medication can no longer relieve the headache and often the headaches become more frequent and more severe.

Treatment for rebound headache requires a shift to other methods for relieving pain, such as ACUPUNCTURE or BIOFEEDBACK. The doctor may also prescribe medications to prevent headaches, such as propanolol or isometheptene, and a triptan medication to thwart a migraine at its early warning signs (such as an aura). It may take several weeks to two months for the headaches to fully recede. Stress management methods such as MEDITATION and YOGA help shift focus to controlling and healing the pain rather than on the pain itself.

KEEP A HEADACHE JOURNAL

Doctors recommend people who have frequent headaches keep a journal that describes their symptoms in detail. This helps identify patterns for how the headaches develop and what effects various pain relief measures have to relieve the pain.

Symptoms and Diagnostic Path

The symptoms of headache provide important clues about the cause and potential treatment options. The doctor will want to know the following:

- How does the pain feel? Common descriptions of headache pain include sharp, dull, throbbing, stabbing, viselike.
- How does the pain start? Some headaches start as minor discomfort and increase to a level of pain that interferes with activities. Some headaches start suddenly with moderate to severe pain.
- Where is the pain? Headache pain may be primarily on one side of the head or face, involve the entire head and face, or involve only the face or only the head. The pain may feel like it encircles the head, is deep or along the surface of the scalp, or comes from a specific location.
- How long does each headache last and how often do headaches occur?
- To what extent does the headache interfere with regular activities?
- Are there any disturbances of vision (such as flashing lights or double vision), awareness, alertness, sensory perception, ability to speak, ability to move?
- Do there seem to be any particular triggers for the headache, such as stressful situations, specific foods, certain locations or activities?
- Are there other symptoms such as fever, sinus congestion, stiff neck, nausea, vomiting?
- What methods and medications have been tried to relieve the headache? Are they unsuccessful, sometimes successful, or partially successful?

The doctor will also ask questions about any other health conditions and whether other family members have chronic headache, migraine headache, seasonal allergies, and AUTOIMMUNE DISORDERS. The doctor typically performs a general medical examination including a basic NEUROLOGIC EXAMINATION and a basic OPHTHALMIC EXAMINATION. Imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN and MAGNETIC RESONANCE IMAGING (MRI) may rule out rare causes for headache such as stroke or tumor. However, the doctor often can make the diagnosis based on the symptoms and headache history.

Treatment Options and Outlook

Most treatment approaches for chronic headache combine medications and other methods to relieve symptoms when the headache occurs and prevent headaches from recurring. Relaxation techniques such as meditation and yoga can help lessen the effect of stress. Other methods in which the person learns to recognize indications that a headache is coming on are often effective in stopping the headache from unfolding. Biofeedback and HYPNOSIS may help a person halt a headache. Numerous prescription medications are available to prevent headaches.

Heat to the back of the neck and resting in a dark, quiet room are measures that often soothe headaches that do occur. Medication is the mainstay of treatment for headache once it develops. Aspirin, acetaminophen, and NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) such as ibuprofen are

TYPES OF CHRONIC HEADACHES

Type of Headache	Characteristic Symptoms	Treatment Approaches
cluster	severe migraine-like PAIN on one side of the head or face nasal congestion on the affected side headache recurs, usually daily, for a period of weeks to months (a cluster) and then goes away for a period of time	medications and other methods to try to prevent the cluster of headaches medications and other methods to head off a headache as it is starting analgesics during the headache do not usually take effect quickly enough to be useful
migraine	aura (classic migraine) such as flashing lights or other sensory activation before the headache itself begins vision, sensory, and cognitive disturbances (classic and common migraine) moderate to severe pain often on one side of the head NAUSEA and VOMITING inability to participate in regular activities	rest in a quiet, dark room caffeine NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS): ibuprofen, naproxen beta-blockers: propanolol, atenolol calcium channel blockers: amlodipine, verapamil ergot derivatives: ergotamine, dihydroergotamine, ergotamine with CAFFEINE triptans: almotriptan, eletriptan, naratriptan, rizatriptan, sumatriptan, zolmitriptan antidepressants: amitriptyline, fluoxetine, nortriptyline, paroxetine, sertraline isometheptene NARCOTICS: injection of morphine for severe pain
rebound	headache that returns as soon as the medication taken to relieve it wears off	medications to prevent headache such as beta-blocker or isometheptene relaxation techniques and other nonmedication methods
sinus	pain along the cheek bones, around the eyes, in the jaw pain is worse upon first waking up in the morning and when tipping the head forward nasal congestion and postnasal drip	ANTIBIOTIC MEDICATIONS for INFECTION ANTIHISTAMINE MEDICATIONS for ALLERGIC RHINITIS decongestant spray or drops oral decongestant medications
tension	steady, pressure-type pain that comes on gradually often occurs during times of physical or emotional stress may go away when source of stress ends	over-the-counter analgesics: acetaminophen, aspirin, NSAIDs antidepressants: amitriptyline, fluoxetine, nortriptyline, paroxetine, sertraline relaxation and stress management methods frequent stretching and movement to change position ACUPUNCTURE MASSAGE THERAPY CHIROPRACTIC

often effective for relieving the pain of headache once it develops. Severe headache of any type may require narcotic analgesic medications to relieve the pain. The exception is cluster headache, for which preventive measures are more effective because the headache, despite the severity of its pain, generally lasts a shorter period of time than it takes for analgesic medications to achieve a therapeutic effect in the body. The herb FEVERFEW, available as an over-the-counter dietary supplement in the United States, is effective against migraines for some people.

Medication is also the mainstay of prevention for migraines and cluster headache, though prevention approaches are more effective for migraine than cluster headaches. Medications that may prevent migraines and cluster headache when taken on a regular basis include propranolol, methylsergide, amitriptyline, valproic acid, verapamil, and lithium carbonate. Triptans taken at the first indication of migraine are effective for many people in preventing the headache. Occasionally a doctor may give an injection of narcotic analgesic such as morphine. Sinus headaches may require treatment with antibiotic medications for infection or ANTIHISTAMINE MEDICATIONS for allergic rhinitis. Decongestant medications (nasal sprays, nasal drops, or oral forms) may help sinus headache of either type.

Risk Factors and Preventive Measures

Risk factors for headaches include physical and emotional stress, low blood GLUCOSE from missing meals, exposure to environmental irritants such as cigarette smoke, excessive CAFFEINE consumption, allergies or HYPERSENSITIVITY REACTION, foods that contain tyramines (such as red wine, smoked meats, and hard cheeses), and MENSTRUATION in women. Preventive measures include relaxation techniques and stress management methods, avoiding known or suspected factors that precipitate headache, and prophylactic (preventive) medication. The right combination of approaches can significantly reduce the frequency and severity of chronic headaches.

living with pain Approaches and methods for improving QUALITY OF LIFE when PAIN is part of daily living. For one in five Americans, pain is a daily experience. Nearly 60 million people in the United States have OSTEOARTHRITIS, 45 million experience frequent headaches severe enough to interfere with regular activities (28 million of them have chronic or recurrent migraine headaches), and 5 million have chronic low BACK PAIN.

Living with pain requires an integration of medical and lifestyle methods. There are many kinds of ANALGESIC MEDICATIONS, some of which provide general pain relief and others that target specific kinds of pain. Research over the past 10 years has provided significant insight into the mechanisms of pain, resulting in new classifications of drugs that intercede at different junctions along pain pathways. ROUTES OF ADMINISTRATION such as transdermal patches (SKIN patches) or long-acting oral formulations can deliver a steady rate of pain medication, smoothing out the ups and downs that accompany other dosage forms such as short-acting tablets and pills. Though most people do not want to take medications on a regular basis, medications may be necessary to slow a disease process (such as RHEUMATOID ARTHRITIS) or to alleviate enough pain to allow participation in daily activities.

Daily physical exercise, such as walking, benefits nearly every condition in which there is pain. Physical activity stimulates the body to release endorphins, enkephalins, and other biochemicals that act as natural pain relievers or otherwise influence the body's inflammatory response and pain mechanisms. Regular activity also improves MUSCLE STRENGTH and JOINT FLEXIBILITY, helps maintain healthy body weight, and relieves stress. Alternative methods such as ACUPUNCTURE and CHIROPRACTIC can provide extended pain relief (days to weeks). BIOFEEDBACK, VISUALIZATION, and MEDITATION are additional methods for coping with and managing pain.

maldynia CHRONIC PAIN that exists without apparent organic or physical cause. The defining characteristic of maldynia is that the PAIN does not activate specific pain receptors (nociceptors) or follow conventional pain pathways. Some researchers believe maldynia represents a malfunction of the BRAIN's pain interpretation processes, likely an imbalance among brain neurotransmitters. Other researchers believe maldynia represents disturbances in the body's pain sensory mechanisms, perhaps changes at the level of the NEURON that alter the sensitivity of pain signals.

Maldynia is an extraordinarily frustrating condition. Beyond the limitations on enjoying life that continual pain imposes, there are the psychologic ramifications of the perception that the pain is not real. Doctors who are unfamiliar with chronic pain syndromes may be suspicious of reported pain without apparent cause that persists despite efforts to resolve it and may dismiss the person's symptoms as "psychosomatic" or emotional in its basis. Research suggests that though emotions influence pain perception, this occurs through biochemical and physiologic pathways in the body and the CENTRAL NERVOUS SYSTEM.

Symptoms and Diagnostic Path

The primary symptom of maldynia is pain that does not go away and has no apparent cause. Doctors do not generally consider chronic health conditions for which pain is a component, such as

OSTEOARTHRITIS, to be maldynia because the pain, though persistent and long-term, results from an identifiable cause. The pain associated with maldynia may be sharp or dull, burning or aching, generalized or focused, continuous or intermittent. The one constant no matter the nature of the pain is the absence of any pathologic reason for the pain to exist.

The diagnostic path differs for each individual, generally focusing on ruling out potential causes for pain. Diagnostic procedures that rule out particular causes of pain may include imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI), electromyelogram (EMG), evoked potential studies, and NERVE conduction studies.

Treatment Options and Outlook

Treatment for maldynia ranges from nonnarcotic and narcotic ANALGESIC MEDICATIONS to nerve block injections to alternative approaches such as ACUPUNCTURE and BIOFEEDBACK. For most people with maldynia, treatment is a process of trial and error with the goal of allowing participation in desired daily activities rather than complete relief from pain. Treatment is unique to the individual and varies over time, depending on effectiveness and improvement of the pain. Daily physical activity to the extent possible releases natural pain relievers in the body called endorphins. Exercise also improves balance, MUSCLE tone, and one's overall sense of well-being.

Maldynia is a life-altering condition. It interferes with nearly every aspect of life, and often is partially to completely disabling. Maldynia can persist for years, go through cycles of improvement and worsening, or suddenly disappear. The elusive nature of its symptoms makes maldynia a difficult challenge. However, with appropriate medical guidance and a positive outlook, many people are able to achieve a reasonable QUALITY OF LIFE. It is important to find a doctor who understands and has experience treating chronic pain syndromes, and to keep the faith that improvement is possible.

Risk Factors and Preventive Measures

Researchers continue to look for the reasons for maldynia. There does appear to be a correlation between maldynia and a preceding circumstance of untreated or undertreated ACUTE PAIN. Appropriate pain relief for acute pain (EUDYNIA) may prevent maldynia from following a significant trauma such as injury or surgery. Otherwise, there are as yet no clear risk factors and consequently no known measures to prevent maldynia.

TREATMENT OPTIONS FOR MALDYNIA

Over-the-Counter Medications	Prescription Medications	Injected Medications	Mechanical Approaches	Alternative Approaches
acetaminophen	NSAIDs: diclofenac, diflunisal, etodolac, fenoprofen, flurbiprofen, meclofenamate, oxaprozin, piroxicam	TRIGGER-POINT INJECTIONS	MASSAGE THERAPY	ACUPUNCTURE
aspirin		NERVE blocks	PHYSICAL THERAPY	BIOFEEDBACK
NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS): ibuprofen, ketoprofen, naproxen		injectable narcotics	TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION (TENS)	exercise
topical analgesics	NARCOTICS: codeine, hydromorphone, levorphanol, oxycodone, oxymorphone	epidural blocks	heat/cold	hydrotherapy
topical counterirritants		epidural steroids	CHIROPRACTIC manipulation	MEDITATION
	antidepressants: selective serotonin reuptake inhibitors (SSRIs), tricyclics	intracathal injection	SPINAL CORD electrostimulation	self-hypnosis

N

neural blockade (nerve block) An injection of an analgesic medication into a NERVE to block the transmission of PAIN to the CENTRAL NERVOUS SYSTEM from a part of the body. Neural blockade is common as preventive analgesia for ACUTE PAIN following surgery or injury and sometimes effective for treatment of CHRONIC PAIN. The doctor may also use a neural blockade as a trial to determine the effectiveness of such an approach before conducting a permanent procedure such as RHIZOTOMY or NEUROLYSIS. The effects of neural blockade are temporary though generally long-lasting for most people (several weeks to several months, depending on the anesthetic agent). The doctor may inject a major nerve, such as the brachial plexus, or a spinal nerve. The most common sites for neural blockade include

- occipital and trigeminal nerves, which serve the face and head
- mandibular and maxillary nerves, which serve the jaw and lower face
- suprascapular nerve, which serves the shoulder
- brachial plexus, which serves the upper arm, neck, and side of the face
- femoral nerve, which serves the hip and femur (thigh)
- sciatic nerve, which serves the back of the leg and foot

The risk is slight for complications or adverse reactions. Bleeding and bruising at the site of the injection are fairly common and generally minor. Some people are allergic to topical anesthetics and may have a HYPERSENSITIVITY REACTION to a neural blockade. Unintended loss of sensation or movement along the nerve's pathway is also possible though uncommon.

neurolysis Destruction of part or all of a NERVE to prevent it from transmitting PAIN signals to the CENTRAL NERVOUS SYSTEM. Neurolysis generally becomes a treatment option for CHRONIC PAIN, or MALDYNIA, when other methods to control pain are unsuccessful. There are three major methods of neurolysis:

- Chemical neurolysis involves injecting a chemical into the nerve that destroys the NEURON bodies. Commonly used chemicals include phenol, ethyl ALCOHOL, and hypertonic saline.
- Surgical neurolysis involves cutting the nerve along the pain pathway that carries pain signals to the BRAIN.
- Ablative methods, primarily radiofrequency ablation (which uses heat) and cryoablation (which uses freezing), cause neurons to die.

The effects of neurolysis are permanent. Complications and risks include undesired loss of sensation, loss of movement (PARALYSIS), bleeding, incomplete pain relief, or worsened pain. The results of neurolysis vary among individuals and sometimes take several weeks to months to become fully effective. When neurolysis is successful, it ends the pain.

neurogenic pain PAIN that results from dysfunction of the nociceptors, specialized molecules on

the dendrites of neurons that detect pain and initiate transmission of pain signals to the CENTRAL NERVOUS SYSTEM. Neurogenic pain often follows an injury (traumatic or surgical) for which pain is a reasonable symptom. However, when the injury heals, the nociceptors can remain hypersensitive to stimuli, particularly touch and temperature, which they perceive as painful, and the nociceptors continue to initiate pain signals. Neurogenic pain often accompanies degenerative neurologic conditions such as MULTIPLE SCLEROSIS and pain syndromes such as trigeminal NEURALGIA and COMPLEX REGIONAL PAIN SYNDROME.

The sensation of neurogenic pain is characteristically that of a persistent tingling, burning, or "pins and needles" feeling. Some people also feel sharp stabs of pain. The diagnostic path typically includes evaluation of other potential causes for the pain in the context of any history of a musculoskeletal injury or neurologic condition. Diagnosis is often clinical (based on symptoms) after the doctor has assessed or ruled out possible conditions that could account for the symptoms.

MEDICATIONS TO TREAT NEUROGENIC PAIN

amitriptyline	baclofen
carbamazepine	dantrolene
desipramine	fluoxetine
gabapentin	paroxetine
phenytoin	sertraline
tizanidine	valproic acid

Because neurogenic pain results from NERVOUS SYSTEM dysfunction, conventional ANALGESIC MEDICATIONS such as NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) and narcotics are not especially effective for providing pain relief. LOW-DOSE tricyclic ANTIDEPRESSANT MEDICATIONS and antiseizure medications often do provide relief, apparently through their influence on BRAIN neurotransmitters. Selective serotonin reuptake inhibitor (SSRI) antidepressants are also effective in some people. These medications may cause potentially serious side effects, especially antiseizure medications. Treatment may control pain until the underlying condition improves or may be a long-term therapeutic process, depending on the cause of the dysfunction.

nociceptor A specialized molecule on the dendrite of a sensory NEURON that interprets stimuli as PAIN and activates NERVE fibers (C fibers and A-delta fibers) to send pain signals to the CENTRAL NERVOUS SYSTEM. Nociceptors activate the withdrawal REFLEX—the sudden, involuntary movement to get away from the stimulus such as jerking one's hand from a hot surface. Sensory neurons often have extensive networks of dendrites, the branchlike fibers that extend from the nerve body to draw input into the neuron. Nociceptors pepper these dendrites, serving as one of the body's most primal warning mechanisms of danger from physical harm. They respond to sensations of heat, cold, sharp, and pressure.

TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION (TENS), a pain relief method, uses mild electrical current to stimulate nociceptors. Researchers believe this either restores the neuron's normal perceptions of stimuli or overloads the neuron so that it cannot transmit pain signals. Doctors believe counterirritants such as capsaicin topical ointment work in a similar fashion. Some Western researchers believe ACUPUNCTURE's effectiveness for pain relief comes from its ability to stimulate or block nociceptor function; Western doctors often combine electrical stimulation with acupuncture to intensify this effect.

For further discussion of nociceptors, please see the overview section "Pain and Pain Management."

P

pain An unpleasant perception in response to a stimulus to the body. Multiple mechanisms contribute to the perception of pain, which follows specific and predictable pathways to the BRAIN. The brain then interprets the nature of the pain and directs the appropriate body response. Pain is one of the body's main defenses for protecting itself from harm. The pain REFLEX is the unconscious and immediate effort to remove the body part from the source of the stimulus and protect it from further damage, for example pulling the hand from contact with a sharp object and grabbing the wound (which applies pressure to stop bleeding as well as the further release of PROSTAGLANDINS and other substances that stimulate INFLAMMATION and the pain response.

Pain can take the form of many and varied characteristics: it can be sharp, dull, constant, intermittent, stabbing, throbbing, burning, localized, widespread. These characteristics help identify possible causes for the pain. The presence of health conditions such as DIABETES, PERIPHERAL VASCULAR DISEASE (PVD), MULTIPLE SCLEROSIS, and SYSTEMIC LUPUS ERYTHEMATOSUS (SLE) also provide clues as to the underlying reasons for pain.

Pain management methods target various intersections along the pain pathway. Some approaches and medications aim to reduce the production of substances (such as prostaglandins) at the site of injury, reducing the body's biochemical call to action that stimulates nociceptors. Others attempt to block NERVE signals from entering the dorsal root ganglia, and still others manipulate neurotransmitters and neuroreceptors in the brain to alter the brain's interpretation and resulting perception of pain signals that reach the thalamus and the cerebral cortex. Numerous methods are available to relieve pain, including ANALGESIC MEDICATIONS, NEURAL BLOCKADE (NERVE BLOCK), and ACUPUNCTURE.

For further discussion of pain mechanisms and pain management, please see the overview section "Pain and Pain Management."

phantom pain The sensation of PAIN that feels as though it came from an amputated limb or other body part. Researchers believe phantom pain results from continued activity, after the AMPUTATION, among neurons in the BRAIN that interpret NERVE signals. Severed nerve fibers near the site of the amputation continue to send signals even though the surgery has removed most of their nociceptors (molecules that detect stimuli as pain). The remaining portions of the nerves continue to function, and the brain interprets their incomplete messages as pain signals. The pain often feels of the same nature as pain that might have been present in the limb before the amputation.

Many people who have phantom pain also have stump pain (pain in the remaining portion of the limb). Stump pain generally results from the damage to the nerves at the site of the amputation. Doctors do not know the extent to which stump pain contributes to phantom pain.

One therapeutic approach that may prevent phantom pain is administration of CALCITONIN, a HORMONE that prevents calcium from leaving the BONE to enter the BLOOD circulation, after the OPERATION. Doctors are uncertain why calcitonin has a preventive affect in this way. Phantom pain seems to respond better to medications used to treat NEUROGENIC PAIN than to conventional ANALGESIC MEDICATIONS. Such medications include antiseizure

medications, tricyclic ANTIDEPRESSANT MEDICATIONS, and antispasmodic medications.

psychogenic pain A PAIN disorder in which the pain the person experiences has no apparent organic or physical basis. Psychogenic pain often has accompanying psychologic components such as anxiety or DEPRESSION. Recurring HEADACHE, BACK PAIN, generalized MUSCLE pain, and STOMACH pain are common presentations of psychogenic pain.

In psychogenic pain, the experience of pain is as real as if there were a clear physical cause. However, over time the nature of the pain deviates from the characteristics the doctor would expect to observe with pain of organic cause. The intensity of the pain may vary with external circumstances, for example, rather than as a result of physiologic changes that would reasonably bring about increase or decrease in pain intensity.

Psychogenic pain may be acute (come on suddenly) or chronic (persist over an extended time). Most people benefit from a combination of treatment that incorporates PSYCHOTHERAPY, nonmedication methods for pain relief, and mild ANALGESIC MEDICATIONS or other medications appropriate for the person's symptoms. Recovery depends on the ability of the person and his or her health-care team to get to the bottom of the issues presenting themselves as pain, to appropriately address and resolve them.

T

terminal pain PAIN that results from the end-stages of disease processes such as cancer, CARDIOVASCULAR DISEASE (CVD), and AIDS. Doctors consider a health condition to be terminal when the person is likely to live less than six months. Terminal pain occurs because damage to the tissues and structures of the body is extensive and widespread. The damage often directly involves nerves. The pain may have a range of characteristics, from deep and sharp to pervasive and aching or dull.

Current standards of practice in the United States call for doctors to prescribe or health-care providers to administer ANALGESIC MEDICATIONS sufficient to relieve pain and provide comfort, even to the point of sedation if that is what is necessary. Family members may worry that such sedation is tantamount to euthanasia and hastens death, but this is not the case. The sedation, when the medication has such an effect, allows the person's body to relax more deeply. The resulting sleep increases comfort. Periods of wakefulness are then more peaceful. Administration methods such as implanted catheters and PATIENT CONTROLLED ANALGESIA (PCA) pumps allow the person to regulate the degree of pain relief.

The amounts of medications, typically NARCOTICS, necessary to accomplish this are typically much higher than conventional dosaging. Doctors who are not familiar with pain treatment or terminal illness are often concerned such amounts are too high and risk an life-threatening ADVERSE REACTION such as depressed respiration (BREATHING) and HEART RATE. However, recent studies demonstrate that terminally ill people tolerate these high doses without the adverse reactions people with less severe pain might experience. The physiologic changes that occur in the body with high or persistent levels of pain appear to block the normal processes that would result in slowed breathing. Because the body continues to adjust to balance vital functions, there is no clear OVERDOSE ceiling for narcotics taken to treat severe or terminal pain. ADDICTION, with its psychologic components, is not a concern in treatment for most severe pain, including terminal pain.

Family members who are concerned that their terminally ill loved ones are not receiving adequate pain relief should discuss this with the patient's doctors and other health-care providers and request consultation with a pain specialist if concerns continue. Medications and therapies are readily available to provide relief from terminal pain.

transcutaneous electrical nerve stimulation (TENS) A small device that transmits mild electrical impulses through electrodes attached to the surface of the SKIN above areas of PAIN. The impulses alter the function of the neurons (nociceptors) responsible for transmitting pain signals to the CENTRAL NERVOUS SYSTEM. TENS is primarily a treatment for CHRONIC PAIN such as neck or low BACK PAIN and is most effective for pain that is mild to moderate in severity. The doctor may suggest applying the electrodes above trigger points or major nerves, or along dermatomes, depending on the path of the pain.

Settings that provide relief are highly individualized and often TENS requires a period of trial and error before the person finds electrode positions, impulse intensity and duration, and timing settings that work. Though it is possible to set the delivery of electrical impulses at such a level as to

be painful, there is no risk for electrical shock from TENS. It is important to keep the electrode pads covered with gel. The main SIDE EFFECT with TENS is irritation to the skin from the adhesive that holds the electrodes in place or from using the electrodes without adequate gel. People who have an implanted PACEMAKER or IMPLANTABLE CARDIOVERTER DEFIBRILLATORS (ICD) cannot use TENS because the electrical current of the TENS interferes with the pacing signals.

See ACUPUNCTURE; DERMATOME; MALDYNIA; NERVE; NEURON; NOCICEPTOR; TRIGGER-POINT INJECTION.

trigger-point injection An injection of local anesthetic into an area of MUSCLE that has tightened into a knot that constricts or pressures a NERVE, causing severe PAIN. Trigger points are highly sensitive to touch or other stimuli and may form after musculoskeletal injuries and in CHRONIC PAIN conditions such as myofascial pain syndrome and FIBROMYALGIA.

Typically a pain specialist, often an orthopedic surgeon (specialist in musculoskeletal conditions) or a neurologist (specialist in conditions that affect the NERVOUS SYSTEM), administers the trigger-point injection. Depending on the cause of the damage, the injection may combine a local anesthetic with a corticosteroid medication to directly target INFLAMMATION in the area. The injection is an office procedure that causes brief discomfort from the insertion of the needle. Complete relief from pain immediately follows as the anesthetic numbs the nerves. After the numbness wears off pain relief often lasts several months and for some people is permanent.

The main risks of trigger-point injection are discomfort at the time of injection and bruising at the site that may cause superficial (surface) tenderness for several days. Ice to the site lessens the risk for bruising and relieves its discomfort. Other specific risks depend on the injection site.

U–V

understanding pain Though there are numerous physiologic mechanisms responsible for PAIN, the actual experience of pain is subjective. Not only do people perceive similar pain differently but the intensity and nature of pain varies within an individual. Many people find it difficult to express to their doctors how much pain they are experiencing, or may not themselves fully understand the intensity of their pain. Pain thresholds—the levels at which pain becomes intolerable— vary widely.

The Subjective Nature of Pain

Despite all that doctors understand about the causes and mechanisms of pain, every person experiences pain differently. Numerous factors frame an individual's perceptions and experiences of pain. Key among them are

- fear about the cause of the pain
- knowledge (or lack of knowledge)
- about the mechanisms of pain
- expectations about treatments for pain
- the presence of other health conditions and their symptoms
- the appropriateness of treatment for any underlying condition that might be causing the pain
- the appropriateness of treatment for the pain, including ANALGESIC MEDICATIONS (pain relief medications)
- attitudes of others, including family members and health care providers, about the pain

Though specific kinds of pain, such as postoperative pain (pain during recovery from surgery) typically have certain characteristics, pain varies in intensity among individuals as well as in the same person.

Chronic Pain

CHRONIC PAIN is the most frustrating kind of pain because it is dysfunctional—that is, it exists without purpose—and often does not respond consistently to pain treatment approaches. The body's pain response is a protective mechanism intended to draw conscious attention to an injurious process within the body and to enforce restricted use of the affected area of the body to facilitate healing. Chronic pain exists beyond this design, often developing as an extension of purposeful pain (EUDYNIA) to become nonpurposeful (MALDYNIA) though sometimes arising for no apparent reason.

Chronic pain can be quite debilitating. Health experts estimate that more than 70 million Americans live with chronic pain that is intense enough to interfere with their participation in common functions and activities. Though movement such as walking often improves chronic pain regardless of its source, the effort of engaging in even modest physical activity can feel overwhelming.

Referred Pain

A person experiences referred pain at a location some distance from the source of the pain. The location is sometimes so far removed from the source of the pain that the person does not connect the pain with its cause. For example, gall stones in the GALLBLADDER (cholelithiasis) often cause pain in the upper back beneath the shoulder blade. Pain associated with HEART ATTACK may occur as referred pain to the left arm, shoulder, neck, and lower jaw.

Referred pain often adds challenge to diagnosing the underlying cause of the pain. Even doctors

first look for a direct cause for the pain. When one does not exist, diagnostic efforts extend to referred causes. Injured nerves are common sources of referred pain. Doctors do not fully understand the physiologic mechanisms of referred pain.

COMMON SOURCES OF REFERRED PAIN

Pain Felt	May Arise From
beneath the right shoulder	the gallbladder
in the shoulder or neck	the diaphragm or esophagus
between the shoulder blades	the stomach
in the groin	the kidneys
in the middle of the back	the kidneys or intestines
in the ear	the throat
in the lower back	the uterus or intestines
around the belly button	the appendix
beneath the sternum	the stomach or heart
in the sides (flanks)	the kidneys
under the left arm	the heart
back of the leg	the lower spine

When to Seek Medical Care for Pain

Many people wait until pain becomes unbearable before seeking medical evaluation and treatment, particularly when no other symptoms exist. Such reluctance may arise from a perception that one should be able "tough it out" or from fear that the pain indicates a serious health problem. Often pain is an early symptom, however, and prompt medical treatment can head off serious health consequences. A person should seek medical evaluation for pain that

- arises suddenly for no obvious reason
- occurs with an injury and does not improve in 48 hours
- worsens over time or recurs frequently
- is accompanied by symptoms such as blurred or double vision, numbness or loss of function in any part of the body, or difficulty breathing
- occurs in the chest, particularly as a pressing or heavy sensation
- is associated with bloody sputum, vomit, urine, or stools
- interferes with regular activities

Chest pain may indicate HEART ATTACK and requires urgent medical evaluation. All too many people wait to see whether the pain will go away instead of going to a hospital emergency room for evaluation. The time wasted on such waiting can be the difference between life and death or significant disability due to permanent heart damage. Though no one wants to feel silly for thinking he or she is having a heart attack and then discovering the problem is dyspepsia (heartburn) or acid reflux, doctors would much rather this were the case than for the person to delay seeking medical care and have the symptoms turn out to be a heart attack. Prompt medical intervention can often minimize or prevent damage to the heart.

Explaining Pain to the Doctor

Because pain is so subjective, it is often difficult to quantify its intensity when explaining it to the doctor. It can be helpful to present the doctor with the answers to questions such as these:

- Where does it hurt?
- How does the pain feel—is it sharp, dull, throbbing, steady, aching, sharp? It may be a combination of these sensations, or change in specific circumstances.
- How long has the pain been present? Has the pain changed in any way since it started?
- Under what circumstances is the pain present? Is it constant or intermittent? Does it get worse at night or with activity?
- What makes the pain worse?
- What makes the pain better?
- Does the pain limit participation in usual activities? If so, from what activities and in what ways?

Providing specific measures such as these help both the person who has pain and the doctor treating the pain to understand the effects the pain is having on the person's ability to function in daily life.

Appropriate Pain Relief

Analgesic medications (pain relief medications) are the most common therapeutic approach for acute and chronic pain. There are many kinds of medications that provide pain relief; the appropriate medications depend on the cause and nature

of the pain, other health conditions that are present, other medications the person is taking, and the person's overall health status. Nonmedication methods of pain relief, such as ACUPUNCTURE and therapeutic massage, may also be effective.

It is important to take pain relief medications according to the directions on the label for both prescription drugs and OVER-THE-COUNTER (OTC) DRUGS. Many medications prescribed for pain relief, particularly to treat postoperative pain or chronic pain, are most effective when taken on a schedule that maintains a THERAPEUTIC LEVEL of the drug in the blood circulation.

Just as people experience pain differently, people respond to pain medications differently. Consequently, the appropriate dose and schedule for the medication varies. As well, some medications are more effective for certain kinds of pain and not very effective for other kinds of pain. It is important to let the doctor know if the prescribed medication does not adequately relieve the pain or causes unpleasant side effects.

Many people, including doctors, worry about ADDICTION with the use of NARCOTICS. As a result, doctors may underprescribe or people may take less medication than is necessary to relieve the pain. However, narcotics remain the most effective analgesic medications for moderate to severe pain, especially pain during recovery from surgery or serious injuries and pain due to CANCER. Although many people do develop TOLERANCE to pain relief medications being taken over an extended time, numerous clinical studies have demonstrated that addiction very seldom occurs. Physicians who are pain management specialists or who frequently treat conditions in which pain is a key symptom are most familiar with current approaches to pain management.

variable pain response The fluctuations that occur in the experience of PAIN. Pain's subjective nature means its intensity often varies with circumstances not directly related to the cause of the pain. Factors such as heat, cold, moisture, significant drops or rises in the barometric pressure, prolonged sitting at a computer or riding in a car, certain activities or lack of activity, the consistency with which the person takes pain relief medication, and even the foods the person consumes all may influence pain intensity. The variability of pain, especially chronic pain, is often frustrating because the person cannot always anticipate how he or she will feel, even under given circumstances. Specific conditions may act either to ease or aggravate pain, though not necessarily with predictable consistency.

weight and pain The influence of excessive body weight on the experience of PAIN. Excessive body weight may itself be the cause of pain, particularly pain that affects the joints, or may contribute to pain due to underlying health conditions such as FIBROMYALGIA, ANKYLOSING SPONDYLITIS, PLANTAR FASCIITIS, and GOUT. OBESITY is a risk factor for numerous chronic conditions that cause pain including OSTEOARTHRITIS and chronic BACK PAIN.

Excessive Body Weight and Musculoskeletal Structures

Excessive body weight has numerous adverse effects on the musculoskeletal system because it alters the person's posture and movement. The effects are most noticeable on the joints, which may develop chronic discomfort and aching. Every 10 pounds of body weight in excess of healthy weight increases the force the knees experience during walking by about 50 pounds each time the foot strikes the ground. Weight-bearing joints below the waist (hips, knees, ankles, and feet) are particularly vulnerable to weight-related pain. Because excessive body weight strains musculoskeletal structures, it often contributes to pain symptoms related to chronic conditions such as back pain. The pressure of the excessive weight over time may also cause damage to the joints; numerous studies implicate overweight and obesity in the development or escalated progression of osteoarthritis, the most common degenerative disorder affecting the joints.

Physical Activity and Pain Relief

Regular, moderate physical activity often improves chronic pain regardless of its source. Exercise, particularly activities that extend 20 minutes or longer, causes the body to release endorphins and other substances that act like natural pain relievers in the brain. The effects of these substances lasts far longer than the exercise session.

Regular physical exercise also strengthens muscles and connective tissues and broadens flexibility. These effects increase the stability of the joints, improving joint function. Even when pain is unrelated to the joints, these effects are beneficial for most underlying health conditions for which pain is a key symptom. And regular physical activity improves cardiovascular function, notably circulation, increasing the flow of blood to all parts of the body. Increased blood flow brings oxygen and other vital substances to areas of HEALING, helping both to speed healing and to keep scar tissue from stiffening.

However, the natural tendency is to avoid activity when pain is present. A reduced level of activity may be appropriate for certain health conditions, especially for a defined period of recovery time. Extended inactivity contributes to, rather than relieves, pain. It may also give rise to other health complications such as DEEP VEIN THROMBOSIS (DVT) or PULMONARY EMBOLISM (blood clots in the veins of the legs or in the lungs), pneumonia (fluid accumulation in the lungs, and pressure sores or decubitus ulcers. Extended inactivity also tends to encourage further weight gain, even when food intake remains the same, because reduced movement means the body uses less energy.

Appropriate Physical Activity

The doctor can recommend activities and intensity levels that are appropriate for both the health condition and the person's FITNESS LEVEL. A physical therapist or qualified fitness and training expert can develop a customized program for progressive

fitness improvement as well as weight loss. Such a consultation is especially helpful for people who have been physically inactive for a long period of time or who have challenges such as FLAT FEET or WEAK ANKLES. Moving too quickly into an intense exercise program can worsen the underlying health condition or cause other injuries. The doctor may also recommend nutritional counseling for further weight loss.

Wong-Baker FACES pain rating scale A proprietary, commonly used visual tool designed for use with children to help them quantify the intensity of PAIN they are experiencing. Developed by Donna Wong, Ph.D., R.N. and Connie Baker, Ph.D., R.N., the FACES scale presents a sequence of six faces with expressions ranging from happy (no pain) to neutral (some pain) to sad (much pain). Children choose the face that best expresses how their pain feels to them.

Many hospitals and pediatricians use the FACES scale, available on a pocket-size card, because it is straightforward and even very young children are usually able to associate how they feel with one of the faces. The most effective approach is for the health care provider to explain to the child what the faces indicate in terms of pain severity (for example, smiling face being no pain and very sad face with tears being the worst pain) and then ask the child to choose the face that best expresses how he or she feels.

The FACES scale has associated numeric values (0 to 5) to aid the health care provider in interpreting the child's pain level. The scale also help clinicians to assess pain as a symptom during the diagnostic process as well as to evaluate the effectiveness of pain relief methods and medications for treatment of post-operative, traumatic, and chronic pain.

MEDICAL ADVISORY REVIEW PANEL

Kyra J. Becker, M.D., is codirector of the University of Washington Stroke Center in Seattle, Washington. She is also an associate professor of neurology and neurological surgery at the University of Washington School of Medicine. Dr. Becker provides patient care through her practice at Harborview Medical Center and is a primary investigator on several stroke-related research studies.

Dr. Becker received her bachelor of science (B.S.) degree in biology *summa cum laude* from Virginia Tech in Blacksburg, Virginia, and her doctor of medicine (M.D.) degree from Duke University School of Medicine in Durham, North Carolina. She completed her internship in internal medicine, residency in neurology, and clinical fellowship in critical care neurology all at Johns Hopkins Hospital in Baltimore, Maryland. Dr. Becker is board-certified in neurology and psychiatry with a special certification in vascular neurology.

James C. Blair, III, PA-C, is director of Madrona Hill Urgent Care Center in Port Townsend, Washington. Mr. Blair is a physician assistant certified with special recognition in primary care and surgery. He is an advanced cardiac life support (ACLS) instructor and has worked much of his career to provide emergency services in small hospitals and clinical care settings in rural communities.

Mr. Blair received his associate of science degree in nursing from Wenatchee Valley College in Wenatchee, Washington, and completed the MEDEX Northwest Physician Assistant Program at the University of Washington School of Medicine in Seattle, Washington.

Alexa Fleckenstein, M.D., writes books and conducts lectures and workshops about natural health topics. Educated in Germany and the United States, she has extensive experience in natural therapies and integrative medicine. Dr. Fleckenstein is board-certified in internal medicine.

Dr. Fleckenstein received her medical degree from Universität Hamburg, Germany. She completed her internship and residency in primary care medicine at Carney Hospital in Boston, Massachusetts, and a fellowship in ambulatory medicine at VA Brockton, Massachusetts. Her subspecialty certification in natural medicine is from Ärztekammer Hamburg (German Board).

Nancy A. Lewis, Pharm.D., is a clinical pharmacist and medical science liaison for MGI Pharma, Inc., a biopharmaceutical company specializing in oncology and acute care products. Dr. Lewis frequently conducts workshops and focused training presentations. She is an active member of the Washington-Alaska Cancer Pain Initiative.

Dr. Lewis received her bachelor of science (B.S.) in pharmacy and her doctor of pharmacy (Pharm.D.) degrees from the University of Washington in Seattle, Washington. She serves on the clinical faculty at the University of Washington in Seattle, Washington and on the adjunct faculty at Washington State University in Pullman, Washington.

Gary R. McClain, Ph.D., is a psychologist, counselor, and consultant in New York City. Dr. McClain has more than 25 years of experience as a mental health professional and in the business world. The focus of his practice is healthcare and wellness.

Dr. McClain's graduate studies were in clinical psychology and education, with a focus on adult personality development and learning. He received his doctor of philosophy (Ph.D.) from the

University of Michigan. Dr. McClain has coauthored or edited 14 books and frequently conducts workshops.

Maureen Ann Mooney, M.D., is a clinical, surgical, and cosmetic dermatologist in private practice in Puyallup, Washington, where she specializes in treating skin cancer. Dr. Mooney is trained to perform Mohs' Micrographic Surgery. Dr. Mooney is board-certified in dermatology and dermatopathology.

Dr. Mooney received her bachelor of science (B.S.) degree in biology *summa cum laude* from the University of Minnesota College of Biological Sciences in St. Paul, Minnesota, and her doctor of medicine (M.D.) degree from the University of Minnesota School of Medicine in Minneapolis, Minnesota. She completed her internship at Hennepin County Medical Center in Minneapolis, Minnesota, and her residency in dermatology at New Jersey Medical School in Newark, New Jersey. Dr. Mooney also completed fellowships in Dermatopathology at New Jersey Medical School and Mohs' Micrographic Surgery at Louisiana State University Healthcare network in New Orleans, Louisiana.

Margaret J. Neff, M.D., M.Sc., is attending physician, pulmonary and critical care medicine, at Harborview Medical Center in Seattle, Washington. Dr. Neff is a medical monitor for the Cystic Fibrosis Therapeutic Diagnostics Network, co-chair of one of the biomedical committees of the University of Washington Institutional Review Board, and a clinical investigator on several research studies. She is board-certified in internal medicine, pulmonary disease, and critical care medicine.

Dr. Neff earned her bachelor's degree in biological sciences (B.S.) and medical degree (M.D.) from Stanford University in Stanford, California, and her master of science (M.S.) degree in epidemiology from the University of Washington in Seattle, Washington. She completed her internship and residency in internal medicine and a fellowship in intensive care at Stanford University and a fellowship in pulmonary/critical care at the University of Washington. Dr. Neff is an assistant professor of medicine in the division of pulmonary and critical care medicine at the University of Washington School of Medicine, Seattle, Washington.

Maureen Pelletier, M.D., C.C.N., F.A.C.O.G., is board-certified in obstetrics and gynecology as well as in clinical nutrition. A former aviation medical examiner, Dr. Pelletier is also licensed as a medical acupuncturist and is a DAN! (Defeat Autism Now!) physician. She is in private practice in Cincinnati, Ohio, with an emphasis on integrative medicine.

Dr. Pelletier received her medical degree (M.D.) from Tufts University School of Medicine in Boston, Massachusetts, and completed her residency in obstetrics and gynecology at the University of Cincinnati. She received clinical training in mind-body medicine at the Mind-Body Institute at Harvard University and completed the integrative medicine program at the University of Arizona School of Medicine. Dr. Pelletier is a national and international lecturer.

Otelio S. Randall, M.D., F.A.C.C., is director of the preventive cardiology program, hypertension and clinical trials, and the Cardiovascular Disease Prevention and Rehabilitation Center at Howard University Hospital in Washington, D.C. Dr. Randall is widely published in peer-reviewed journals and has authored two books. He has received numerous awards during his career, including the 2004 Outstanding Faculty Research Award from Howard University School of Medicine.

Dr. Randall received his bachelor's degree (B.S.) in chemistry from Howard University and his medical degree (M.D.) from the University of Michigan Medical School in Ann Arbor, Michigan. He completed his internship at the State University of New York at Brooklyn, residencies in internal medicine at Baylor College of Medicine in Houston, Texas, and University of Michigan Hospital, and a fellowship in cardiology at the University of Michigan Hospital. Dr. Randall is designated a specialist in hypertension by the ASH specialists program in affiliation with the American Society of Hypertension (ASH).

Susan D. Reed, M.D., M.P.H., is program director for the Women's Reproductive Health Research Program at the University of Washington in Seattle, Washington. She is a clinician at Harborview

Medical Center and University of Washington Medical Center. Dr. Reed is also an affiliate investigator at the Center for Health Studies and Fred Hutchinson Cancer Research Center, and an associate professor of obstetrics and gynecology, and an adjunct professor in epidemiology at the University of Washington School of Medicine. Dr. Reed's areas of clinical and research interest are gynecologic issues for women with genetic diseases, cross-cultural medicine, and management of menopause.

Dr. Reed received her master's degree (M.S.) in human genetics from Sarah Lawrence College in Bronxville, New York, her medical degree (M.D.) from Stanford University Medical Center in Stanford, California, and her Master of Public Health (M.P.H.) degree from the University of Washington School of Public Health. Dr. Reed is a licensed genetic counselor and board-certified in obstetrics and gynecology.

Jerry Richard Shields, M.D., is an ophthalmologist in private practice in Tacoma, Washington. He sees general ophthalmology patients and performs laser correction and cataract surgery. Dr. Shields is board-certified in ophthalmology and VISIX-certified.

Dr. Shields received his bachelor of science (B.S.) degree in biology *cum laude* from Wake Forest University in Winston-Salem, North Carolina, and his medical degree (M.D.) from the Medical College of Georgia in Augusta, Georgia. He completed his internship in internal medicine and his residency in ophthalmology at the University of Washington in Seattle, Washington.

Christina M. Surawicz, M.D., is gastroenterology section chief of at Harborview Medical Center in Seattle, Washington. She is also professor of medicine and assistant dean for faculty development at the University of Washington School of Medicine in Seattle. Dr. Surawicz is widely published in peer-reviewed journals and has authored, edited, and contributed to dozens of books.

Dr. Surawicz received her undergraduate degree, a bachelor of arts (B.A.) in biology, from Barnard College in New York City and her medical degrees (M.D.), awarded with honors, from the University of Kentucky College of Medicine in Lexington, Kentucky. She completed her medical internship, medical residency, and gastroenterology fellowship at the University of Washington in Seattle. Dr. Surawicz is board-certified in internal medicine and gastroenterology.

Denise L. Wych, R.N. C.M., is a cardiac nurse case manager at Palmetto Health-Richland Heart Hospital in Columbia, South Carolina, where she integrates clinical and medical appropriateness criteria in discharge planning and resource utilization within the framework of an interdisciplinary health-care team. She has worked in medical-surgical, intensive care unit, newborn, school nursing, and home health.

Ms. Wych received her diploma in nursing from Providence School of Nursing in Sandusky, Ohio. She served 10 years as an officer in the US Navy Nurse Corps, during which she was twice awarded the Navy Achievement Medal.

FOREWORD

A big part of my role as a physician is educating my patients about their health. I take as much time as each person needs to explain prevention measures, test results, and treatment options. I encourage questions. But in the moment, sitting there in my office, most people do not yet know what to ask me. By the time questions flood their thoughts, they may be back at work or at home.

Numerous events and circumstances can challenge health, and we all need to know what actions we can take to keep ourselves healthy as well as to obtain appropriate treatment for health conditions that do affect us. Knowledge empowers all of us to make informed and appropriate decisions about health care. Certainly there is no shortage of reference material. Yet there is *so* much information available today! Even for physicians, it is challenging to keep up. How can you get to the core of what you want to know, reliably and to the level of detail you need?

The Facts On File Encyclopedia of Health and Medicine is a great resource for up-to-date health information presented in a manner that is both comprehensive and easy to understand no matter what your level of medical knowledge. The encyclopedia organizes entries by body system. The progression of body systems—and entries—throughout the encyclopedia presents topics the way you think about them.

Going beyond this basic structure, however, is another layer of organization that particularly appeals to me, which is a comprehensive structure of cross references that integrates entries across body systems. After all, your body functions in an integrated way; so, too, should a reference series that discusses your body's health. Not very much that happens with your health affects one part of your body in isolation from other body structures and functions. Your body attempts to compensate and adjust, often without your awareness, until it can no longer accommodate the injury or illness. The symptoms you bring to your doctor may reflect this compensation, for example frequent headaches that point not to brain tumor (as many people fear but is very rare) but to eye strain or muscle tension or sometimes to hypertension (high blood pressure).

In my medical practice I emphasize integrative health care, embracing the philosophy that health exists as the intricate intertwining of the body's many systems, structures, and functions. So, too, does the care of health. I received my medical degree from Tufts University School of Medicine in Boston, an institution noted for remaining at the forefront of the medical profession. I also completed clinical programs in Mind-Body Medicine at Harvard University, Integrative Medicine at the University of Arizona School of Medicine, and Medical Acupuncture at the University of California-Los Angeles (UCLA). I am a board-certified obstetrician-gynecologist, a board-certified clinical nutritionist, and a licensed acupuncturist. I see patients in my practice in Cincinnati, Ohio; I teach, I lecture, and I frequently go on television and radio to talk about health topics. In each of these areas, I encourage people to think about their health and health concerns from an integrative perspective. When you understand your health from multiple dimensions, you can better understand what to do to keep yourself as healthy as possible.

I wish you the best of health for all of a long, satisfying life. But when the time comes that you must make decisions about medical care, I want you to have the knowledge to make informed

choices that are right for you. Whether you start here and move on to more specialized resources or locate all the information you need within these four volumes, you will find *The Facts On File Encyclopedia of Health and Medicine* to be a most valuable reference resource.

HOW TO USE
THE FACTS ON FILE ENCYCLOPEDIA OF HEALTH AND MEDICINE

Welcome to *The Facts On File Encyclopedia of Health and Medicine*, a four-volume reference set. This comprehensive resource is an indispensable reference for students, allied health professionals, physicians, caregivers, lay researchers, and people seeking information about health circumstances and conditions for themselves or others. Entries present the latest health concepts and medical knowledge in a clear, concise format. Readers may easily accumulate information and build a complete medical profile on just about any health or medical topic of interest or concern.

A New Paradigm for the Health and Medical Encyclopedia

As the art and science of health and medicine continues to evolve, with complex and elegant discoveries and new techniques, medications, and treatments emerging all the time, the need has arisen for a new paradigm for the encyclopedia of health and medicine—a rethinking of the old, and increasingly outmoded, presentations. Carefully researched and compiled, *The Facts On File Encyclopedia of Health and Medicine* offers many distinguishing features that present readers and researchers with an organization as up-to-date and compelling as the breakthrough information its entries contain.

Recognizing the current emphasis on presenting a truly integrative approach to both health and disease, *The Facts On File Encyclopedia of Health and Medicine* organizes content across volumes within a distinctive format that groups related entries by body system (for example, "The Cardiovascular System") or by general health topic (for example, "Genetics and Molecular Medicine"):

- **Volume 1** presents the sensory and structural body systems that allow the body to engage with its surroundings and the external environment.
- **Volume 2** presents the cell- and fluid-based body systems that transport nutrients, remove molecular wastes, and provide protection from infection.
- **Volume 3** presents the biochemical body systems that support cellular functions.
- **Volume 4** presents topics that apply across body systems (such as "Fitness: Exercise and Health") or that address broad areas within health care (such as "Preventive Medicine").
- The appendixes provide supportive or additional reference information (such as "Appendix X: Immunization and Routine Examination Schedules").

Following Research Pathways

The Facts On File Encyclopedia of Health and Medicine's organization and structure support the reader's and researcher's ease of use. Many encyclopedia users will find all the information they desire within one volume. Others may use several or all four of the encyclopedia's volumes to arrive at a comprehensive, multifaceted, in-depth understanding of related health and medical concepts and information. Researchers efficiently look up information in *The Facts On File Encyclopedia of Health and Medicine* in several ways.

Each section's entries appear in alphabetical order (except the entries in Volume 4's "Emergency and First Aid" section, which are grouped by type of emergency). The researcher finds a desired entry by looking in the relevant volume and section. For example, the entry for **acne** is in Volume 1 in the section "The Integumentary System" and the entry for **stomach** is in Volume 3 in

the section "The Gastrointestinal System." The researcher can also consult the index at the back of the volume to locate the entry, then turn to the appropriate page in the volume.

Terms that appear in SMALL CAPS within the text of an entry are themselves entries elsewhere in *The Facts On File Encyclopedia of Health and Medicine*. Encyclopedia users can look up the entries for those terms as well, for further information of potential interest. Such SMALL CAPS cross references typically provide related content that expands upon the primary topic, sometimes leading the user in new research directions he or she might otherwise not have explored.

For example, the entry **hypertension** is in the section "The Cardiovascular System." The entry presents a comprehensive discussion of the health condition hypertension (high blood pressure), covering symptoms, diagnosis, treatment options, risk factors, and prevention efforts. Among the numerous SMALL CAPS cross references within the hypertension entry are the entries for

- **retinopathy**, an entry in the section "The Eyes" in Volume 1, which discusses damage to the eye that may result from untreated or poorly managed hypertension
- **blood pressure**, an entry in the Volume 2 section "The Cardiovascular System," which discusses the body's mechanisms for maintaining appropriate pressure within the circulatory system
- **stroke** and **heart attack**, entries in Volume 2's "The Cardiovascular System" about significant health conditions that may result from hypertension
- **kidney,** an entry in the section "The Urinary System" in Volume 3, which discusses the kidney's role in regulating the body's electrolyte balances and fluid volume to control blood pressure
- **atherosclerosis, diabetes, hyperlipidemia,** and **obesity**, entries in the sections "The Cardiovascular System" in Volume 2, "The Endocrine System" in Volume 3, and "Lifestyle Variables: Smoking and Obesity" in Volume 4, and all of which are health conditions that contribute to hypertension

Following the path of an encyclopedic entry's internal cross references, as shown above, can illuminate connections between body systems; define and apply medical terminology; reveal a broad matrix of related health conditions, issues, and concerns; and more. The SMALL CAPS cross references indicated within the text of encyclopedic entries lead encyclopedia users on wide-ranging research pathways that branch and blossom.

At the end of the entry for **hypertension** a list of cross references gathered in alphabetical order links together groups of related entries in other sections and volumes, such as **smoking cessation** in Volume 4's "Lifestyle Variables: Smoking and Obesity," to provide specific, highly relevant research strings. These *see also* cross references also appear in SMALL CAPS, identifying them at a glance. Encyclopedia users are encouraged to look here for leads on honing research with precision to a direct pathway of connected entries.

So, extensive cross-references in *The Facts On File Encyclopedia of Health and Medicine* link related topics within and across sections and volumes, in both broad and narrow research pathways. This approach encourages researchers to investigate beyond the conventional level and focus of information, providing logical direction to relevant subjects. Each cross-referenced entry correspondingly has its own set of cross references, ever widening the web of knowledge.

Using the Facts On File Encyclopedia of Health and Medicine

Each section of the encyclopedia begins with an overview that introduces the section and its key concepts, connecting information to present a comprehensive view of the relevant system of the human body or health and medical subject area. For most body systems, this overview begins with a list and drawings of the system's structures and incorporates discussion of historic, current, and future contexts.

Entries present a spectrum of information from lifestyle factors and complementary methods to the most current technologic advances and approaches, as appropriate. Text that is set apart or bold within an entry gives an important health warning, or targets salient points of interest to add layers of meaning and context. Lists and tables

collect concise presentations of related information for easy reference.

Each type of entry (mid-length and longer) incorporates consistent elements, identified by standardized subheadings:

- ***Entries for health conditions and diseases*** begin with a general discussion of the condition and its known or possible causes and then incorporate content under the subheadings "Symptoms and Diagnostic Path," "Treatment Options and Outlook," and "Risk Factors and Preventive Measures."
- ***Entries for surgery operations*** begin with a general discussion of the procedure and then incorporate content under the subheadings "Surgical Procedure," "Risks and Complications," and "Outlook and Lifestyle Modifications."
- ***Entries for medication classifications*** begin with a general discussion of the type of medication and its common uses and then incorporate content under the subheadings "How These Medications Work," "Therapeutic Applications," and "Risks and Side Effects."
- ***Entries for diagnostic procedures*** begin with a general discussion of the test or procedure and then incorporate content under the subheadings "Reasons for Doing This Test," "Preparation, Procedure, and Recovery," and "Risks and Complications."

Entries in Volume 4's section "Emergency and First Aid" are unique within the orientation of *The Facts On File Encyclopedia of Health and Medicine* in that they feature instructional rather than informational content. **These entries do *not* replace appropriate training in emergency response and first aid methods.** Rather, these entries provide brief directives that are appropriate for guiding the actions of a person with little or no first aid training who is first on the scene of an emergency.

Each volume concludes with a complete, full index for the sections and entries within the volume. Volume 4 of *The Facts On File Encyclopedia of Medicine* contains a comprehensive index for all four encyclopedia volumes that researchers can use to quickly and easily determine which volumes contain desired sections or entries.

The Facts On File Encyclopedia of Health and Medicine in Four Volumes

PREFACE TO VOLUME 2

Volume 2 of the four-volume *The Facts On File Encyclopedia of Health and Medicine* presents the body systems that nourish, cleanse, and protect the body. These are the systems of cells and fluids and the structures that transport them throughout the body. Though distinct in their functions and purposes, these systems overlap and integrate with one another in inseparable ways.

The Cardiovascular System

Volume 2 opens with "The Cardiovascular System," the structures and functions that carry blood throughout the body. An amazing pump—the heart—and miles of blood vessels—the arteries and veins—are the hallmarks of this system that mostly functions without conscious awareness save for the regular rhythm of the heartbeat.

Advances in medical technology make it possible to treat cardiovascular disease that even 30 years ago would have been fatal. Medications and devices can regulate the functions of the heart to overcome or compensate for disease and damage. Heart transplantation and mechanical heart substitutes, once the dream of surgeons but the venue of fiction, are now among the standard treatment options for some heart conditions. Many of the entries in "The Cardiovascular System" discuss these sophisticated therapeutic approaches. Yet lifestyle strongly influences cardiovascular health, which encyclopedia users will detect as a prevalent theme in this section.

The Blood and Lymph

These two fluid-based systems of the blood and the lymph have separate yet interconnected circulatory networks. The blood bridges the functions of the cardiovascular and pulmonary systems, circulating through arteries, veins, and capillaries to carry oxygen and nutrients to, and metabolic wastes from, cells throughout the body. The cells that do this work, the erythrocytes, make up about half the blood's cells and give blood its characteristic red color. The lymph network is the immune system's major highway; its cells are lymphocytes. These white blood cells lack color, giving lymph the appearance of watery milk. Lymph circulates through its own structure of lymph vessels though crosses from the lymphatic circulation to the blood circulation at two junctions, the cisterna chyli and the thoracic duct.

The Pulmonary System

The pulmonary system is the body's primary interaction with the external atmosphere. The lungs pull oxygen-bearing air deep into the body where an intricate molecular exchange takes place to load each outgoing breath with metabolic waste. The laws of physics—particularly those relating to relationships between pressure and volume, regulate the functions of the pulmonary system. The pulmonary system intimately interacts with the blood and the cardiovascular system. Without these interactions, the functions of the pulmonary system are of little value to the body. Acquired pulmonary disease often coexists with cardiovascular disease; entries in this section provide both discussion and cross-references to establish such connections.

The Immune System and Allergies

The immune system is a complex network of primarily cells and substances that circulate in the lymph and the blood and reside in the tissues. With much current research focused on HIV/AIDS and the understanding and treatment of cancer, knowledge of the immune system's functions con-

tinues to evolve at a pace not experienced since the discovery of antibiotics and vaccines. New approaches to conditions across the spectrum of health incorporate methods that use the immune system's own mechanisms to prevent and fight infection and disease.

Infectious Diseases

Infectious diseases remain a significant threat to health throughout the world. Vaccines, antibiotics, antiviral medications, and other therapies in combination with community health practices such as sanitation measures and water purity standards now can prevent or treat many infections that were fatal not so long ago. Entries in this section integrate medical treatments and lifestyle or preventive approaches, as both are essential to control the health consequences of infectious diseases.

Cancer

Cancer is a broad category of disease that can affect any body system. Current medical thinking is that cancer represents an intersection of genetic, immune, and lifestyle factors in varying mixes depending on the type of cancer. Like in the immune system, knowledge in this area is rapidly and continually changing. New treatments take advantage of new understandings. The entries in this section, "Cancer," cover topics that apply to cancer in general. Encyclopedia users will find entries for specific types of cancer in the relevant body system sections.

THE CARDIOVASCULAR SYSTEM

The cardiovascular system circulates BLOOD through the body to deliver nutrients and collect wastes from cells. Physician specialists who treat conditions of the HEART and blood vessels are cardiologists. This section, "The Cardiovascular System," presents an overview of the structures and functions of the cardiovascular system, a discussion of cardiovascular health and disorders, and entries about the health conditions that can affect the cardiovascular system.

Functions of the Cardiovascular System

The cardiovascular system circulates blood through the body to supply cells with nutrients, notably oxygen and GLUCOSE, and to remove the waste byproducts of METABOLISM. The centerpiece of this system is the heart, a muscular organ about the size and shape of a closed fist that beats 70 to 90 times a minute in a healthy adult at rest. The body's circulation is a closed, pressurized system that contains a constant blood volume of about 10 liters (2.6 gallons). An extensive network of blood vessels–which, if stretched end to end, would traverse 100,000 miles—transports that blood through the body.

Cardiovascular function defines life and death. The cardiovascular system is among the first of

the body systems to become functional. The rudimentary heart begins beating at three weeks gestational age, and by eight weeks the heart's formation is complete. Doppler ULTRASOUND, a noninvasive procedure that uses sound waves to detect motion, can detect the fetal heartbeat at 10 to 12 weeks into PREGNANCY.

PULSE and BLOOD PRESSURE—the rate and force of blood as it flows through the arteries—are among the basic vital signs health-care providers assess to determine core health status and indeed life or death. When the heart stops beating, pulse and blood pressure cease. Cells in the BRAIN and the MYOCARDIUM, deprived of oxygen, begin to die. Though myocardial cells are capable, to an extent, of regenerating, brain cells are not. Only two to three minutes without oxygen can result in permanent neurologic damage and even death.

The heart The heart lies behind the protective enclosure of the rib cage, its left side beneath the STERNUM (breastbone) and its right side extending about to the center of the right BREAST. A tough sac, the PERICARDIUM, encases the heart. A thin layer of fluid between the pericardium and the myocardium (heart MUSCLE) allows the heart to move continuously without friction in much the same way motor oil permits pistons to glide freely within an engine. A crownlike network of arteries, the CORONARY ARTERIES, encircles the outer surface of the myocardium. This network directs roughly 20 percent of the body's blood supply and 70 percent of the blood's oxygen content to the heart with each heartbeat. A thin membrane, the ENDOCARDIUM, lines the chambers of the heart. The endocardium is so smooth not even platelets, the blood's clotting cells, can stick to it.

The heart's four chambers collect and expel blood through rhythmic, synchronized contractions. The two upper chambers, the atria, receive blood into the heart. The two lower chambers, the ventricles, pump blood from the heart. One-way valves regulate the flow and volume of blood into and out of each chamber. The four chambers of the heart contract and relax in precise coordination. The walls of the heart become progressively thicker from the atria to the ventricles, reaching their greatest density and STRENGTH in the left ventricle to support its work to contract with enough force to pump blood to the most distant cells in the body. A thick inner wall, the septum, separates the heart's chambers.

A cluster of specialized NERVE cells, the SINOATRIAL (SA) NODE, generates a "pacing" electrical impulse that starts with the right atrium and builds momentum as it courses through the cells and fibers of the myocardium. Other electrical structures—the BUNDLE OF HIS, right BUNDLE BRANCH and left bundle branch, ATRIOVENTRICULAR (AV) NODE, and the Purkinje fibers—amplify and focus the electrical impulses so they reach maximum intensity when they arrive at the left ventricle. This collective effort forms the CARDIAC CYCLE, the sequential and coordinated contraction and relaxation of the atria and the ventricles.

The right atrium and right ventricle, known collectively as the right heart, handle deoxygenated blood returning from the body. Blood flows from the superior VENA CAVA (bringing blood from the upper body) and inferior vena cava (bringing blood from the lower body) into the right atrium, which pumps it through the tricuspid valve into the right ventricle. The right ventricle pumps the blood through the pulmonary valve into the pulmonary ARTERY, which carries it to the LUNGS for OXYGENATION.

The left atrium and left ventricle, known collectively as the left heart, handle oxygenated blood. The PULMONARY VEINS (right and left, from the right lung and left lung respectively) deliver oxygenated blood from the lungs to the left atrium. The left atrium pumps the blood through the mitral valve into the left ventricle. The left ventricle propels blood through the aortic valve into the AORTA, the body's largest blood vessel, and on its circulatory journey.

The blood vessels Blood vessels circulate blood throughout the body. Arteries carry blood *from* the heart. All arteries except the pulmonary artery carry oxygenated blood; the pulmonary artery carries deoxygenated blood from the heart to the lungs. Arteries have multilayered, muscular walls that pulsate in coordination with the heart's contractions. The innermost layer, the intima, functions in the same fashion as the endocardium to keep the blood from sticking to the artery's inner walls. Veins carry blood *to* the heart. All veins except the two pulmonary veins carry deoxygenated blood; the pulmonary veins transport

oxygenated blood to the heart from the lungs. Veins have thin, flexible walls with valves that allow blood to flow only in one direction.

The smallest of the blood vessels, the arterioles and the venules, have walls fractions of a millimeter in thickness and so narrow that only the smallest of blood cells, oxygen-bearing erythrocytes, can squeeze through and even they must pass single-file. These tiny vessels mesh into the CAPILLARY BEDS, the terminus for the blood's journey. Blood cells are at their busiest here, exchanging oxygen and other nutrients for carbon dioxide and other metabolic wastes.

Most blood vessels exist in mirror structures on each side of the body and occur in parallel. The femoral artery and femoral VEIN run together, for example, one set serving each upper leg. Often these vessels have similar names, such as the femorals or the popliteal artery and popliteal vein. As the coronary arteries channel oxygenated blood to the heart, the arteries that form the CIRCLE OF WILLIS at the base of the brain direct oxygen-rich blood to the brain.

The circulation Each beat of the heart propels 80 milliliters (2.5 ounces) of blood into the AORTA, the largest artery in the body. It takes about 20 seconds for that same volume of blood to complete its journey through the body's blood vessels and return to the heart. Every minute, 5 to 6 liters (0.85 to 1.5 gallons) of blood circulates through the body—the equivalent of three 2-liter bottles of soda. In the course of a day the volume of blood the heart pumps is enough to fill an Olympic-size swimming pool.

Pressure aids the heart in pushing blood through the blood vessels. A complex interaction of hormones and other chemicals regulates blood pressure. Blood in the arteries is under high pressure, helping push it to the cells that require the oxygen and nutrients it carries. The pressure within the arteries allows blood to defy the pull of gravity as it courses to the body's tissues. Because the circulation is a closed system, the pressure of the arterial flow helps send blood through the veins as well, much as the pressure of a river's water continues to create current in the small streams that branch from it. The pressure of the blood within veins is significantly lower than the pressure within arteries. Valves in the veins act as one-way gates to keep blood flowing back to the heart. Skeletal muscles encase the major veins, further supporting them. With every movement these muscles massage the veins to help move returning blood along its passage back to the heart.

Health and Disorders of the Cardiovascular System

The cardiovascular system has the capacity to maintain healthy function in adults well into the seventh decade and beyond, though for many people it does not. More than 70 million Americans are LIVING WITH CARDIOVASCULAR DISEASE; 10 million of them are disabled to an extent that they are unable to enjoy the lifestyles they desire as a result. CARDIOVASCULAR DISEASE (CVD)—a collective term for the many health conditions that affect the heart and blood vessels—causes the deaths of more than 900,000 Americans each year, making it the leading cause of death among men and women alike in the United States. Most CVD among Americans is acquired, developing through the course of life and nearly always as a consequence of lifestyle factors. Genetic factors and other health conditions, notably DIABETES, may also contribute.

FORMS OF CARDIOVASCULAR DISEASE (CVD)

ANEURYSM	ARRHYTHMIA
ATHEROSCLEROSIS	BUNDLE BRANCH BLOCK
CARDIOMYOPATHY	CONGENITAL HEART DISEASE
CORONARY ARTERY DISEASE (CAD)	DEEP VEIN THROMBOSIS (DVT)
ENDOCARDITIS	HEART FAILURE
HYPERLIPIDEMIA	HYPERTENSION (high BLOOD PRESSURE)
HYPOTENSION (low blood pressure)	INTERMITTENT CLAUDICATION
ISCHEMIC HEART DISEASE (IHD)	KAWASAKI'S DISEASE
LONG QT SYNDROME (LQTS)	MYOCARDITIS
PERICARDITIS	PERIPHERAL VASCULAR DISEASE (PVD)
PRIMARY PULMONARY HYPERTENSION	RAYNAUD'S SYNDROME
RHEUMATIC HEART DISEASE	SICK SINUS SYNDROME
STROKE	TRANSIENT ISCHEMIC ATTACK (TIA)
VALVULAR HEART DISEASE	WOLFF-PARKINSON-WHITE SYNDROME

About 30,000 infants are born with CONGENITAL HEART DISEASE—defects of the heart and blood vessels—each year. Heart defects are the most com-

mon birth defects in the United States. Some congenital heart defects are life-threatening, such as tetralogy of Fallot and transposition of the great arteries (TGA), and require extensive surgical reconstruction or HEART TRANSPLANTATION for the infant to survive. Many congenital heart anomalies are correctable with surgery or treatable with medications, allowing the child relatively normal life experiences and life expectancy. Researchers do not know the causes of many of these defects, which arise early in embryonic development.

Though some of the most exciting technological advances in modern medicine are those that improve treatment for cardiovascular conditions such as heart failure, health experts believe lifestyle measures could prevent as much as 90 percent of acquired cardiovascular disease. Cardiovascular health depends on four key lifestyle factors:

- not smoking
- nutritious eating habits
- daily physical exercise
- maintaining healthy weight

These factors maintain the cardiovascular system in optimal health. Yet despite the overwhelming evidence that these factors do in fact prevent cardiovascular disease, two thirds of the US population is overweight and three fourths do not get the minimum recommended physical exercise. Two lifestyle-related health conditions that strongly influence cardiovascular disease are diabetes and OBESITY. Type 2 diabetes, the most common form of diabetes among American adults, and obesity are closely linked. When these two conditions coexist, some form of cardiovascular disease is almost certainly present as well.

Traditions in Medical History

The heart mystified ancient physicians. Though all cultures recognized the relationship between the heart and life itself, they differed vastly in their interpretations of what that relationship was. The Egyptians held the heart to be the base of intellect and emotion in life and the measure of that life's worth upon a person's passage to the afterworld. Mesopotamian and Sumerian physicians used MEDICINAL HERBS AND BOTANICALS to treat ailments such as pounding of the pulse and heart weakness—perhaps references to conditions contemporary doctors might diagnose as PALPITATIONS and HEART FAILURE.

Ancient Chinese physicians speculated that the heart circulated all of the body's vital substances, including air, through a complex network of vessels and passageways. Within the tenets of primitive Chinese medicine the pulse spoke to the physician, its rhythms and patterns presenting the story of the body's health and illnesses. A gifted physician could interpret hundreds of details from numerous pulse points. Intricate readings of the pulse remain integral to TRADITIONAL CHINESE MEDICINE (TCM) as practiced today.

In Western medicine, Greek and Roman physicians of antiquity postulated that the LIVER produced the body's supply of blood from the food a person ate. The veins carried the blood from the liver to the other organs, which consumed it. The arteries, in this scheme, arose from the heart though carried air. The role of the heart itself was somewhat ambiguous, with some physicians believing the heart pulled air into the arteries through pores in the skin and others that it had nothing to do with any sort of circulation but instead gave rise to emotions and thoughts.

The Greek physician GALEN (130–200) both consolidated and expanded the understandings of human anatomy and physiology of his time into the principles and practices that became the foundation of Western medicine for the ensuing 1,200 years. In Galen's view, the veins delivered to the heart blood the liver made, and the arteries carried the air drawn into the body through pores in the skin. Other pores between the chambers of the heart, according to Galen, mixed the blood and the air. Each beat of the heart then propelled this mixture through the arteries to the organs of the body. Though this schematic makes little sense in the context of current knowledge, despite its fundamental inaccuracies it came fairly on target in its projections of the body's need for oxygen and the role of the cardiovascular system to deliver it. In Galen's day, the concept was the ideal blend of the many understandings and misunderstandings about the functions of the body.

FIRST DISCOVERY OF CIRCULATION

Records survive that document the accurate perception by Arabic physician Ibn al-Nafis in 1242 of the heart's chambers and of the closed circulation of the blood. The discovery did not reach other parts of the world, however, and came to light only in the 1920s when a medical scholar uncovered an-Nafis's medical writings and drawings.

Galenism defined medical knowledge and practice into the 17th century. In 1628 English physician William Harvey (1578–1657) published the document that would become the turning point of modern Western medicine: *Exercitatio Anatomica De Motu Cordis et Sanguinis in Animalisbus*, or in English, *An Anatomical Treatise on the Motion of the Heart and Blood in Animals*. Harvey deduced, correctly, that the heart pumped the same blood repeatedly in a closed circuit through the body, with the arteries carrying oxygenated, bright blood from the heart and the veins returning deoxygenated, dark blood to the heart. *De Motu Cordis* established the basis of cardiovascular structure and function that still frames understanding of the heart's mechanical operation.

Breakthrough Research and Treatment Advances

The most significant breakthrough in cardiology was the development of the CARDIOPULMONARY BYPASS machine, successfully used for the first time in the 1950s and the cornerstone of cardiovascular surgery today. Cardiopulmonary bypass makes it possible for the cardiovascular surgeon to stop the heart, yet maintain the body's blood circulation and oxygenation. Advances in surgery techniques, technology, and pharmacology in the last decade of the 20th century made reconstructive operations for congenital heart malformations, CORONARY ARTERY BYPASS GRAFT (CABG), and even HEART TRANSPLANTATION routine offerings on the slate of treatment options. Countless people can enjoy extended, productive lives as a result.

The limited supply of donor hearts for transplantation has focused much technology research on development of a feasible artificial replacement heart that could be fully contained within the chest. In 2001 cardiovascular surgeons implanted the first of the new generation of total artificial hearts in a handful of people suffering from end-stage cardiovascular disease. Other researchers looked toward assisting, rather than replacing, ailing hearts, resulting in implanted VENTRICULAR ASSIST DEVICES (VADS) that function in coordination with the native heart. Some cardiovascular surgeons see VADs as bridge devices to sustain cardiovascular function while awaiting a donor heart for transplantation, and others as an end-stage treatment for people who have complete HEART FAILURE but are not candidates for heart transplantation because of age or other health conditions. Now an approved treatment option for end-stage heart failure, the VAD can stay in place for as long as needed.

Cardiovascular surgeons continue to explore ways to incorporate microsurgery techniques in operations such as CABG, looking to reduce the trauma of entering the chest cavity to fully expose the heart. Minimally invasive endoscopic procedures already permit operations on arteries and veins, as well as for CABG when only one coronary artery needs replacement. Cardiovascular surgeons also are beginning to apply minimally invasive techniques for valve repair and other operations on the heart.

Breakthroughs in genetics show great promise for both treatment and prevention of cardiovascular conditions in the decades ahead. Researchers have identified numerous genes responsible for heart conditions such as LONG QT SYNDROME (LQTS), certain forms of CARDIOMYOPATHY, ATHEROSCLEROSIS, and some forms of heart failure. Many of these genes interact with environmental factors such as diet and level of physical activity, contributing to rather than outright causing heart disease. Researchers are exploring ways to use GENE THERAPY to inactivate destructive genetic influences and enhance genetic influences that support or improve cardiovascular function. These influences likely explain why some people get cardiovascular diseases and others do not even when their lifestyles are similar.

Researchers also continue to unravel the mysteries of metabolism, gaining increased understanding of how exercise and nutrition affect cell function and how processes such as atherosclero-

sis get started in the body. One focus of such research is on INSULIN, which has numerous roles in the body beyond regulating glucose balance. Insulin appears to be a key factor in many functions related to cardiovascular health and disease, including cholesterol metabolism and cell activity.

Cardiology in the coming decades promises to be an intriguing blend of high-tech solutions and simple lifestyle methods. With other advances in medicine eliminating many of the circumstances that have historically resulted in early death, such as INFECTION, today's generations may be the first to fully experience the capacity of the cardiovascular system to sustain life well into the eighth decade and beyond, pushing LIFE EXPECTANCY as well as QUALITY OF LIFE to new levels.

A

aerobic fitness The efficiency with which the cardiovascular system functions to meet the oxygen needs of cells throughout the body, particularly under the increased pressure of intense physical activity or exercise. The higher a person's aerobic FITNESS LEVEL, the more air the LUNGS can take in each breath, the more oxygen that enters the BLOOD, and the more blood the HEART can eject with each contraction. The outcome is that the cardiovascular system can deliver higher concentrations of oxygen to body tissues with less effort, which increases ENDURANCE. Aerobic fitness is a key measure of cardiovascular health.

ACTIVITIES THAT IMPROVE AEROBIC FITNESS

aerobic dance	basketball	bicycling
canoeing	cross-country skiing	handball
hiking	ice skating	jogging
kayaking	racquetball	roller skating
rowing	running	shooting hoops
snowshoeing	soccer	spinning
squash	stair climbing	stationary cycling
step aerobics	swimming	tennis
treadmill	volleyball	walking

Physical activities that exercise the muscles to a level that increases the HEART RATE and BREATHING rate for a sustained time of 15 minutes or longer provide an aerobic workout for the body that strengthens cardiovascular efficiency and improves aerobic fitness. Consistency is the key to aerobic fitness. Health experts recommend aerobic activity three to four times a week, ideally in sessions that are 30 to 45 minutes long. The higher a person's aerobic fitness level, the easier it is to sustain aerobic activity for longer periods of time.

aging, cardiovascular changes that occur with The most significant age-related changes in cardiovascular function occur at birth in both sexes and with MENOPAUSE in women. Though changes in METABOLISM occur with aging that affect all body systems, researchers now believe cardiovascular health does not inherently decline simply as a function of aging. DIABETES, OBESITY, lack of physical exercise, and cigarette smoking are the leading causes of acquired CARDIOVASCULAR DISEASE (CVD) among adults. The effects of these factors are cumulative; they are more likely to result in disease the longer they exist and the more of them are present. Accordingly, the risk for acquired cardiovascular disease increases with age because as people get older they tend to develop health conditions that set the stage for cardiovascular deterioration. Most researchers believe these risks are mutable (changeable) through lifestyle.

Cardiovascular Changes at Birth

The cardiovascular system is among the first body systems to develop in the EMBRYO, with the rudimentary HEART beginning to beat at three weeks gestational age. The heart fully forms, and a rudimentary circulatory network develops and functions, by eight weeks gestational age. Before birth, the FETUS draws its oxygen supply from its mother's BLOOD supply, in an exchange that takes place across a membrane in the PLACENTA (fetal

and maternal blood supplies do not mix). Accordingly, the fetal LUNGS do not function. Blood flows to and from the fetus through the umbilical arteries and veins (UMBILICAL CORD).

In the adult heart the right ventricle pumps blood through the PULMONARY ARTERIES to the LUNGS for OXYGENATION. The blood returns to the heart via the PULMONARY VEINS. Because the fetal lungs are nonfunctional, the fetal circulatory system bypasses the lungs. An opening (shunt) between the atria, the foramen ovale, allows blood to flow from the right atrium to the left atrium, which pumps it to the left ventricle. A small amount of blood goes from the right atrium to the right ventricle, which pumps it into the pulmonary ARTERY. A shunt between the aorta and the pulmonary artery, the ductus arteriosus, directs the blood into the aorta where it mixes with the blood the left ventricle pumps into the AORTA. With the first breath following birth the lungs inflate and the changes in pressure initiate a series of biochemical actions that cause these shunts to close, establishing blood circulation through the lungs. Within a few days of birth the ductus arteriosus becomes the ligamentum arteriosum, a strip of connective tissue that stabilizes the aorta and the pulmonary artery. The umbilical veins retreat to form the round ligament supporting the LIVER and the umbilical arteries to form ligaments that support the abdominal muscles.

Cardiovascular Changes at Menopause

Estrogen, the HORMONE responsible for female FERTILITY, is essential for lipid metabolism. The high estrogen levels that mark fertility seem to exert a protective action on a woman's cardiovascular system, lowering the likelihood for HYPERLIPIDEMIA and related health conditions such as ATHEROSCLEROSIS and CORONARY ARTERY DISEASE (CAD). During the 35 to 40 years of her fertility, a woman's risk for cardiovascular disease is a third to half that of a man of comparable age and health status. At MENOPAUSE estrogen levels drop significantly and a woman's risk for cardiovascular disease takes a significant jump. Some studies suggest that during the first five years following menopause, a woman's risk for HEART ATTACK is greater than that of a man who is of comparable age and health status.

Hormone replacement therapy (HRT) to restore estrogen levels after menopause became a standard medical approach in the 1950s. In the 1990s numerous studies revealed significant increases in the risks for BREAST CANCER and uterine CANCER associated with HRT as well as failed to find supportive evidence that HRT improved cardiovascular health in women after menopause, and health experts withdrew recommendations for its routine use. Current recommendations suggest women, like men, make nutritious eating choices, get daily physical exercise, maintain healthy weight, and not smoke as the key preventive measures to lower their risk for cardiovascular disease in midlife and beyond.

Lifestyle Choices to Maintain Cardiovascular Health

Current research strongly supports the role of lifestyle choices in maintaining cardiovascular health, even to the extent that many researchers believe appropriate choices beginning in early childhood could prevent as much as 90 percent of acquired cardiovascular disease. Healthy adults who are in their 70s and 80s who do not have any form of cardiovascular disease or other chronic health conditions do not have significant changes in cardiovascular function. Weight management, not smoking, nutritious food choices, and daily physical exercise are the cornerstones of lifestyle measures to preserve cardiovascular health. Many researchers believe the healthy cardiovascular system has the capacity to function efficiently well into the eighth decade of life and beyond.

aneurysm A weakened and often distended (stretched) area in the wall of an ARTERY. Though an aneurysm may develop in any artery, the most common location is the descending or abdominal AORTA. An aneurysm is potentially life-threatening. The continual pressure of the BLOOD flowing through the artery pressures the weakened area, which can cause the layers of the artery's wall to further split and separate, called a dissecting

aneurysm, or to rupture. An aneurysm that ruptures in the BRAIN causes hemorrhagic STROKE, with mild to severe consequences depending on its location and size. Fewer than 5 percent of strokes are hemorrhagic.

Aneurysms sometimes accompany congenital malformations of the blood vessels, called ARTERIOVENOUS MALFORMATIONS (AVMS), in which the arteries and veins in a particular location, usually in the brain or brainstem, form an entangled mass. Aneurysms are also common in MARFAN'S SYNDROME, a genetic disorder that affects the musculoskeletal and cardiovascular systems. Most aneurysms, however, result from atherosclerotic deposits that damage and weaken the walls of the arteries. HYPERTENSION (high BLOOD PRESSURE), when present, exacerbates the situation by exerting further pressure against the weakened area of the artery.

A ruptured aneurysm is a life-threatening emergency that requires immediate medical attention. Loss of blood can be rapid and massive.

Often an aneurysm shows no symptoms. The doctor may detect an aneurysm during a ROUTINE MEDICAL EXAMINATION or during testing or treatment for other medical conditions. Cerebral aneurysms may cause seizures, HEADACHE, or symptoms similar to stroke such as weakness on one side of the body and memory lapses or cognitive dysfunction. An abdominal or thoracic aortic aneurysm may cause PAIN (usually severe) in the area of the aneurysm. These symptoms are usually transient (come and go) though are crucial warning signs that the aneurysm is unstable. Sometimes the doctor can palpate an abdominal aneurysm, feeling its pulsations through the abdominal wall. COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) can affirm the diagnosis. Surgery to repair the aneurysm, in which the surgeon either removes the weakened segment and sutures the healthy ends of the artery together or applies a synthetic patch over the area of weakness, is the only curative treatment. When doctors detect and repair aneurysms before they rupture, they seldom cause further health problems and require no special care after HEALING. It is important to treat the condition that may have caused the aneurysm, when possible, to prevent aneurysms from developing in other locations.

angina pectoris Chest discomfort originating from the HEART, usually resulting from restricted BLOOD flow due to CORONARY ARTERY DISEASE (CAD) that occludes (blocks) one or more of the CORONARY ARTERIES. Coronary ARTERY spasm, especially that resulting from COCAINE use, may also cause angina. Some people experience a crushing pressure that radiates into the left shoulder, arm, and THROAT. Other people experience discomfort similar to DYSPEPSIA (indigestion or heartburn). Though the nature and quality of discomfort varies among individuals, for most people angina pectoris is a chronic (long-standing) condition with predictable symptoms that appear with exertion and subside with rest.

An angina pectoris attack lasts only a few minutes, with rest bringing pronounced relief. CHEST PAIN that persists longer suggests HEART ATTACK and requires immediate medical attention.

Angina pectoris does not signal HEART ATTACK, though it is a warning that atherosclerotic accumulations in the coronary arteries have narrowed the arterial lumen (channel or opening through which blood flows) by 70 percent or more. When exercise or other stress (such as stepping out into a cold wind) increases the demand on the heart to pump more blood, the stiffened and narrowed coronary arteries, which in health could expand to nearly double the volume of blood flowing through them, cannot respond. The heart MUSCLE (MYOCARDIUM) fails to receive the oxygen it needs as well as to dispose of the metabolic wastes that are accumulating within its cells.

Treatment for angina pectoris generally combines relieving symptoms and mitigating the underlying cause. Medications to treat angina pectoris cause smooth muscle tissue (such as makes up the walls of the arteries) to relax. This allows

the coronary arteries to modestly increase the flow of blood, which usually is sufficient to ease symptoms. Commonly prescribed medications include nitrates such as nitroglycerin and isosorbide, beta antagonist (blocker) medications such as atenolol and propanolol, and calcium channel antagonist (blocker) medications such as diltiazem and verapamil. Cardiologists typically recommend ASPIRIN THERAPY for people who have angina pectoris, to help prevent MYOCARDIAL INFARCTION (blood clot that blocks the flow of blood, causing heart tissue to die).

For some people, the most effective treatment is ANGIOPLASTY to repair, or CORONARY ARTERY BYPASS GRAFT (CABG) to replace, occluded coronary arteries. However, many people who have angina pectoris remain stable with medication therapy. Cardiologists disagree about the value of CABG for people whose only symptom of disease is angina pectoris, because there is growing evidence that the risks of the surgery (including rapid occlusion of the grafts) do not counterbalance the benefits.

Two forms of angina are more serious: unstable angina and variant angina. In unstable angina, also called acute coronary insufficiency or preinfarction angina, symptoms are unpredictable and do not necessarily correlate to increased demands on the heart such as physical activity may place. Many cardiologists consider unstable angina a precursor to heart attack. With unstable angina, symptoms may occur during sleep or at rest, are often intense and extended, and progressively more severe. Sublingual (under the tongue) nitroglycerin may provide relief. As the underlying heart disease progresses, however, symptoms become more difficult to control. Angioplasty or CABG is often the most viable treatment options.

In variant angina, also called Prinzmetal's angina, spasm of a coronary artery causes symptoms that tend to occur without provocation at certain times of the day. Specific changes in the ELECTROCARDIOGRAM (ECG) accompany the symptoms. Medication (nitroglycerin or calcium channel blocker) is the most effective treatment for most people who have variant angina. CABG may relieve symptoms that do not respond to medication, though typically occlusion affects only one coronary artery to cause the symptoms. Generally the risks of OPEN HEART SURGERY, such that CABG requires, outweigh the potential benefits to replace a single coronary artery. TRANSMYOCARDIAL LASER REVASCULARIZATION (TMLR), a surgical procedure less invasive than CABG that cardiologists began using in 1998, shows promise for relieving angina that does not respond to other treatment. In TMLR, the surgeon uses a laser to pierce the left ventricle with narrow channels. As the channels heal they cause new blood vessels to develop in the myocardium, improving the flow of blood to the heart muscle.

angiogram A diagnostic test to visualize BLOOD vessels. The test is an angiography; the result is an angiogram. The cardiologist or vascular specialist injects dye into the relevant blood vessels to assess the flow of blood through them, observing the flow via FLUOROSCOPY (moving X-rays). Angiography is useful for diagnosing PERIPHERAL VASCULAR DISEASE (PVD), CORONARY ARTERY DISEASE (CAD), VENOUS INSUFFICIENCY, and DEEP VEIN THROMBOSIS (DVT). The cardiologist does angiography of the HEART during CARDIAC CATHETERIZATION. The risks of angiography include bleeding or INFECTION at the injection site and reaction to the dye. With the precision and availability of noninvasive imaging technology such as COMPUTED TOMOGRAPHY (CT) SCAN and MAGNETIC RESONANCE IMAGING (MRI), doctors use noncardiac angiography (angiography of peripheral blood vessels such as in the legs) primarily when the diagnosis or extent of blockage remains uncertain or before surgery to correct blockages.

See also ANGIOPLASTY; CORONARY ARTERY BYPASS GRAFT (CABG).

angioplasty A CARDIAC CATHETERIZATION procedure to widen the opening of an ARTERY, generally as treatment for ANGINA PECTORIS, CORONARY ARTERY DISEASE (CAD), or PERIPHERAL VASCULAR DISEASE (PVD). Angioplasty is most effective when the occlusion is between 70 percent and 90 percent and affects only one or two locations within the arteries. More extensive occlusion in the coronary arteries may require CORONARY ARTERY BYPASS GRAFT (CABG) to instead redirect the blood flow through replace-

ment arteries. The cardiovascular surgeon may also use angioplasty to remedy occlusions in arteries other than those supplying the HEART, such as to treat PVD affecting the larger arteries in the legs.

Procedure

Angioplasty is almost always an AMBULATORY SURGERY (same-day) procedure, or at most requires one night in the hospital for recovery and observation following the procedure. The cardiologist uses local ANESTHETIA and general SEDATION to make the person comfortable. After numbing the location with local anesthetic the cardiologist inserts a catheter into an ARTERY near the surface of the body, typically the femoral artery in the groin, and threads it into the occluded artery. Injected dye helps the cardiologist to visualize the catheter's progress using FLUOROSCOPY (moving X-ray), which displays the images on a closed circuit monitor.

Once the catheter is in position at the occlusion, the cardiologist uses a syringe to inject a small amount of sterile solution through the catheter to inflate a tiny balloon at the catheter's tip. The balloon applies pressure against the walls of the artery, expanding the channel through which blood flows. The cardiologist may deflate the balloon, advance the catheter, and reinflate the balloon to widen a larger segment of the artery. The procedure usually compresses accumulations of ATHEROSCLEROTIC PLAQUE (atheromas) to reduce their intrusion into the arterial passageway. The cardiologist may also use the catheter to place a STENT, a tiny springlike device that maintains pressure against the arterial wall to help maintain the widened channel in the artery at the site of the compressed atheroma.

Risks and Complications

Risks during the angioplasty include HEART ATTACK or STROKE from dislodged atherosclerotic plaque (which is rare), excessive bleeding, trauma to the artery, and irritation of the heart that causes ARRHYTHMIA. The cardiac catheterization facility or hospital where the cardiologist performs the angioplasty is equipped and staffed for immediate cardiac surgery if necessary. More common complications are bleeding and PAIN at the catheter insertion site, or INFECTION following the procedure. The cardiologist may choose to administer prophylactic ANTIBIOTIC MEDICATIONS, particularly in people who are at risk for bacterial ENDOCARDITIS.

The most common complication of angioplasty is restenosis (reclosure) of the artery, either from the compressed atheroma reexpanding or from continued atherosclerotic processes that create new atheromas. About half of people who undergo angioplasty experience restenosis within two years. About a quarter have clinically significant restenosis within six months and must have a repeat angioplasty or CABG to restore blood flow to the heart. Repeat angioplasty is generally less successful, and carries a higher risk of damage to the artery. As atherosclerosis progresses, which it tends to do, other coronary arteries occlude as well.

Outlook and Lifestyle Modifications

Angioplasty is a temporary measure for most people, providing relief of symptoms for six months to two or three years. However, angioplasty does not treat the underlying disease process, which is likely to continue even with medical interventions such as lipid-lowering medications to slow its progress. Most arteries tend to reocclude. Some people are able to undergo multiple angioplasty procedures over time though others must look to different treatment options such as CABG. The most effective outcomes are those that follow the angioplasty with lifestyle changes to improve cardiovascular health such as WEIGHT LOSS AND WEIGHT MANAGEMENT, daily physical activity, and SMOKING CESSATION.

anticoagulation therapy Prophylactic (preventive) treatment with medications to reduce the risk of BLOOD clots, broadly including approaches that inhibit various stages of COAGULATION. Anticoagulation therapy is common treatment for a number of cardiovascular conditions including ATRIAL FIBRILLATION, INTERMITTENT CLAUDICATION, DEEP VEIN THROMBOSIS (DVT), PULMONARY EMBOLISM, and VALVULAR HEART DISEASE, and following MYOCARDIAL INFARCTION (HEART ATTACK) and cerebral infarction (ischemic or thromboembolic STROKE). Anticoagulant medications prevent new clots from forming

and existing clots from getting larger, though cannot dissolve clots that already exist. Medications that dissolve existing clots are called thrombolytic agents, which have different pharmacologic actions in the body.

The appropriate anticoagulation therapy depends on the reason for the therapy (health condition), the person's overall health situation, and any other medications the person needs to take. Doctors may prescribe anticoagulation therapy for noncardiovascular reasons such as after orthopedic surgery, particularly JOINT REPLACEMENT. People commonly refer to anticoagulant medications as "blood thinners," though this is a misnomer because these medications do not alter the blood's viscosity (thickness).

Antiplatelet Agents

Antiplatelet medications, also called PLATELET inhibitors, slow clot formation by inhibiting PLATELET AGGREGATION. These medications are especially effective in people who have increased risk for CORONARY ARTERY DISEASE (CAD) or thromboembolic stroke. Platelets are the cells in the blood that are first on the scene of any injury in the body. They swarm in response to even the slightest of damage, such as the irritation and INFLAMMATION atheromas cause to the walls of the arteries. When they aggregate, or clump together, they release chemical signals that activate the sequence of events resulting in clot formation. Antiplatelet medications interfere with these chemical signals.

The most commonly used antiplatelet therapy is ASPIRIN THERAPY. Aspirin inhibits PROSTAGLANDINS, chemicals that platelets require to enable them to aggregate or stick together. Aspirin delays clotting by delaying platelet aggregation, which is the first step in the coagulation process. Platelets may come together but not stick, drifting away from each other again before they initiate the clotting process. Other commonly prescribed antiplatelet medications include clopidogrel (Plavix), ticlopidine (Ticlid), dipyridamole (Persantine), and cilostazol (Pletal). These medications may have serious side effects or interact with other medications. Ticlopidine may cause a rare but life-threatening condition, thrombotic thrombocytopenic purpura (TTP), and requires frequent blood tests to monitor for its development.

Clotting Factor Inhibitors

Other medications act to interfere with the body's ability to activate blood proteins essential for clotting (CLOTTING FACTORS). The most commonly used oral medication, warfarin (Coumadin), works by blocking one of the steps in the body's process to produce VITAMIN K. Vitamin K is essential to the metabolic processes that activate clotting factors II, VII, IX, and X. The gastrointestinal tract does not absorb heparin, which is available only in injectable form (intravenous or subcutaneous). Heparin prevents the conversion of prothrombin (clotting factor II) to thrombin, a crucial and early step of coagulation. Both of these medications are NARROW THERAPEUTIC INDEX (NTI) drugs that require very close monitoring to maintain their doses within therapeutic range. Internal bleeding, especially from the gastrointestinal tract, can occur when doses are too high. Excessive bleeding from wounds, such as ACCIDENTAL INJURIES, or from routine dental procedures, such as prophylactic cleaning, is also a risk.

Low molecular weight heparin (LMWH), also only in injectable form, acts similarly to heparin though without many of heparin's undesired side effects. Several kinds of LMWH, also called fractionated heparin, are available. Each has unique characteristics and though all are LMWH drugs, they are not interchangeable. LMWH products include dalteparin (Fragmin), enoxaparin (Lovenox), and tinzaparin (Innohep). Another injectable medication, fondaparinux (Arixtra), inhibits clotting factor X. Proper site selection and injection technique are important for people who use injectable forms of anticoagulant medications.

Benefits, Risks, and Lifestyle Modifications

Anticoagulant medications, whether antiplatelet or inhibitor, are preventive for blood clots and the health problems blood clots can cause, such as stroke, HEART attack, pulmonary embolism, and DVT. The primary risk of anticoagulation therapy is excessive or prolonged bleeding, which can be serious or life-threatening in some situations. Doctors carefully monitor blood clotting times and other measures to maintain an appropriate therapeutic balance. Spontaneous nosebleed (EPISTAXIS), easy bruising, bleeding from the gums when brushing the teeth, and blood in the stool are signs

of excessive anticoagulation that require a doctor's evaluation.

When on anticoagulation therapy it is important to avoid OVER-THE-COUNTER (OTC) DRUGS such as NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) in products for PAIN relief, menstrual cramps, and cold and flu relief, and salicylates such as Pepto-Bismol. These products have mild anticoagulation effects that can cause excessive bleeding in combination with anticoagulation medications. As well, anticoagulation medications interact with numerous other medications and may have side effects, some of which can have serious health consequences.

Many people who are on anticoagulation therapy have underlying cardiovascular conditions that would benefit from lifestyle modifications as well, such as increased physical activity and SMOKING CESSATION. Regularly stretching the muscles throughout the day, especially leg muscles, and walking for 5 to 10 minutes every few hours help keep blood from pooling and clotting.

aorta The ARTERY that carries BLOOD from the HEART to the body. The largest blood vessel in the body, the aorta arises from the left ventricle. At its widest point the aorta is about one and a half inches in diameter. As the aorta leaves the heart it ascends to curve behind the right atrium. The first arteries to branch from the base of the ascending aorta are the right and left CORONARY ARTERIES that supply the heart MUSCLE (MYOCARDIUM) with blood. Branching from the arch as the aorta crests over the heart are the three arteries that carry blood to the upper body:

- the brachiocephalic artery (also called the innominate artery), which transports blood to the right arm and right side of the BRAIN, head, and face
- the left common carotid artery, which transports blood to the left side of the brain, head, and face
- the left subclavian artery, which transports blood to the left arm

The aorta then crosses over the PULMONARY ARTERIES and drops behind the heart to descend through the chest and into the abdomen, aligned along the front of the spine, branching into the iliac arteries at the top of the pelvis. Numerous arteries branch from the descending aorta along its passage from the chest to the abdomen, supplying vital organs such as the LIVER, kidneys, STOMACH, and intestines. Acquired cardiovascular conditions that can affect the aorta include ATHEROSCLEROSIS, ANEURYSM, and AORTIC STENOSIS. A number of congenital malformations also can affect the aorta, including aortic coarctation, tetralogy of Fallot, and transposition of the great arteries (TPA). Most aortic conditions require surgical repair.

For further discussion of the aorta within the context of cardiovascular structure and function, please see the overview section "The Cardiovascular System."

aortic stenosis Narrowing of the aortic valve that restricts the flow of BLOOD from the heart's left ventricle to the AORTA. Aortic stenosis may be congenital or acquired; in either, it tends to show symptoms later in life. Acquired aortic stenosis develops as a consequence of calcium and arterial plaque deposits that infiltrate the aortic valve. Untreated aortic stenosis results in left ventricular hypertrophy (enlargement of the left ventricle), diminished CARDIAC OUTPUT, and ultimately congestive HEART FAILURE.

Symptoms of aortic stenosis may include PALPITATIONS, ANGINA PECTORIS, fatigue, SYNCOPE (fainting), and unexplained inability to participate in aerobic activities. The diagnostic path typically includes ECHOCARDIOGRAM and CARDIAC CATHETERIZATION. Treatment is surgery to replace the damaged aortic valve. After valve replacement most people experience dramatic relief from symptoms and are able to return to regular activities. Sometimes medications are necessary to treat companion conditions such as HEART failure. As with other valve operations, aortic valvuloplasty or prosthesis increases the risk for blood clots to form. Most people will need to take ANTICOAGULATION THERAPY to mitigate this risk.

apolipoprotein B100 (apoB100) A protein on the surface of lipid molecules that directs the lipid's route of METABOLISM. ApoB100 occurs primarily on low-density lipoprotein (LDL) molecules, the form of cholesterol with the highest risk for CORONARY ARTERY DISEASE (CAD). The normal level of apoB100 in the blood is 40 to 125 milligrams per deciliter (mg/dL). Elevated levels suggest familial HYPERLIPIDEMIA. ApoB100 levels also rise after MYOCARDIAL INFARCTION, when there is

damage to the HEART MUSCLE. Elevated apoB100 levels convey an increased risk for ATHEROSCLEROSIS and CAD.

arrhythmia Irregularity or abnormality of the heart's contractions. Arrhythmias can result from numerous causes including electrical disturbances of the heart's pacing mechanisms, physical damage to the HEART such as might occur with HEART ATTACK, interruptions of the heart's BLOOD supply that cause myocardial HYPOXIA (oxygen depletion), severe electrolyte imbalances, and medication side effects. COCAINE use can initiate sudden and fatal arrhythmias. Because all myocardial cells have the ability to initiate electrical impulses, it is sometimes difficult for cardiologists to determine what causes an arrhythmia.

The most common kinds of arrhythmias are

- bradycardia, in which contractions are slower than normal (typically fewer than 60 beats per minute at rest in a person whose level of routine physical activity is low)
- tachycardia, in which contractions are faster than normal (typically greater than 100 beats per minute at rest in a person whose level of routine physical activity is low)
- fibrillation, in which contractions are rapid, erratic, and nonproductive
- premature or extra beats, in which contractions occur in addition to the heart's regular contractions

The seriousness of an arrhythmia depends largely on whether it is atrial or ventricular. Typically ventricular arrhythmias are more significant and potentially hazardous than atrial arrhythmias. The most common arrhythmia that requires treatment is ATRIAL FIBRILLATION, which health experts estimate affects about one in five American adults over age 60 and which accounts for about 15 percent of strokes. The most deadly arrhythmia is VENTRICULAR FIBRILLATION, which results in seriously slowing or even halting the flow of blood to the body because the ventricles cannot pump in a coordinated manner. Some arrhythmias are transient (come and go), and others cause no symptoms or effect on cardiovascular function.

VENTRICULAR FIBRILLATION is a medical emergency that can result in death within minutes without appropriate treatment (DEFIBRILLATION).

Symptoms and Diagnostic Path

Arrhythmias may cause a range of symptoms or no symptoms at all. The most common symptoms are

- PALPITATIONS, which feel like the heart is thumping or "skipping" a beat
- weakness, lightheadedness, or fainting
- shortness of breath with exertion (DYSPNEA)
- CHEST PAIN

It is not possible to know only from the symptoms what kind of arrhythmia is present. Only an ELECTROCARDIOGRAM (ECG), a test that records the heart's electrical activity, can present the information a cardiologist needs to determine the diagnosis. The cardiologist may desire further diagnostic procedures to identify any underlying causes, as the findings may influence treatment options and decisions. Arrhythmias resulting from CORONARY ARTERY DISEASE (CAD) or HEART FAILURE, for example, require different treatment than those resulting from idiopathic electrical disturbances (problems with the heart's pacing mechanisms that have no apparent cause). Occasionally the doctor detects an arrhythmia during examination for other health concerns, which requires subsequent evaluation to determine whether, as it is not causing symptoms, it is a condition that warrants treatment.

Treatment Options and Outlook

CAFFEINE and ALCOHOL consumption can cause palpitations and other minor, benign arrhythmias, as can intense stress. Making lifestyle changes to reduce or eliminate these factors typically ends the arrhythmias related to them. Arrhythmias that are not clinically significant (those that cause no symptoms or disruptions of cardiovascular function) do not require treatment, though cardiologists generally want to monitor them to make sure

they remain benign. Antiarrhythmia medications successfully treat the majority of symptomatic arrhythmias. These medications work by blocking certain aspects of the biochemical functions responsible for myocardial contractions. The cardiologist may prescribe two or more antiarrhythmia medications in combination to treat some kinds of arrhythmias. People who have heart failure, CAD, valvular disease, and other heart disorders may take antiarrhythmia medications along with other medications to treat these conditions.

Cardiologists select antiarrhythmia medications based on the characteristics of the arrhythmia, which may be simple or complex, as well as the presence of other cardiovascular conditions, any other medications the person may be taking, and factors such as age and lifestyle. After starting antiarrhythmia therapy, it is important to continue until the cardiologist makes changes in the therapeutic approach. Suddenly stopping an antiarrhythmia medication can have significant consequences including serious arrhythmias.

Antiarrhythmia medications can have serious side effects such as worsening the existing arrhythmia or causing new arrhythmias. Some medications work by causing heart block, for example, to interrupt the conduction of aberrant electrical impulses. Finding the right medication or combination of medications sometimes takes a period of trial regimens and dosages. As the condition responsible for the arrhythmia changes over time, sometimes it becomes necessary to change the medication regimen as well.

Other interventions may become necessary if medications are ineffective or generate intolerable side effects. Such interventions may include

- CARDIOVERSION, in which the cardiologist delivers (under sedation) a mild electrical shock through the chest wall to reorganize and restore to normal the heart's electrical activity
- RADIOFREQUENCY ABLATION, a cardiac catheterization procedure in which the cardiologist uses radiofrequency impulses to kill a small and carefully targeted segment of myocardial cells to prevent them from initiating or conveying electrical impulses
- implantable PACEMAKER, a small battery-operated device that emits an electrical impulse to trigger the heart's contractions

propafenone (Rythmol)	quinidine (Cardioquin)	tocainide (Tonocard)

- IMPLANTABLE CARDIOVERTER DEFIBRILLATOR (ICD), which functions both to deliver pacing impulses and shocking impulses to convert an arrhythmia that extends beyond certain parameters

Most people are able to successfully control or eliminate arrhythmias with appropriate treatment, resulting in no changes to lifestyle or quality of life.

Risk Factors and Preventive Measures

Most arrhythmias arise as a consequence of other CARDIOVASCULAR DISEASE (CVD) or are idiopathic (without identifiable cause). Some arrhythmia disorders are congenital or genetic, such as LONG QT SYNDROME (LQTS). People who have one kind of arrhythmia are prone to developing others. Prompt medical evaluation of symptoms that could signal cardiovascular disease or arrhythmias is important, as early detection and treatment may head off consequences such as CARDIAC ARREST or SUDDEN CARDIAC DEATH.

arteriosclerosis A degenerative condition of the arteries in which the walls of the arteries become stiff and rigid. Arteriosclerosis is a leading factor in age-related HYPERTENSION (high BLOOD PRESSURE). There are three forms of arteriosclerosis:

- ATHEROSCLEROSIS in which arterial plaque deposits infiltrate the inner layer of the arterial wall
- Mönckeberg's arteriosclerosis or medial calcific sclerosis, in which the medial layer of the arterial wall accumulates calcium deposits that cause the ARTERY to become rigid
- arteriolosclerosis in which the arterioles (the threadlike arteries that form the arterial portion of the CAPILLARY BEDS) lose their FLEXIBILITY and elasticity

The primary causes of arteriosclerosis include cigarette smoking (NICOTINE is highly toxic to the smooth MUSCLE fibers of the arteries), DIABETES, and hypertension. The consequences of arteriosclerosis, particularly atherosclerotic, include increased risk for HEART ATTACK, STROKE, ANEURYSM, and increased hypertension. People often use the terms atherosclerosis and arteriosclerosis interchangeably, which is not quite accurate though is correct about 90 percent of the time because atherosclerosis is the most common form of arteriosclerosis.

arteriovenous malformation (AVM) A congenital deformity in which an entanglement of arteries and veins forms. Rather than connecting into CAPILLARY BEDS that form between them, the arteries and veins in an AVM connect directly to one another. Veins lack the structure to accommodate the pressure BLOOD is under as it flows through the arteries and over time may become weakened and rupture. The resulting bleeding can be life-threatening, depending on the size and location of the AVM. Most AVMs are in the BRAIN, although an AVM can occur in other parts of the body. Though AVMs are present at birth, many do not show symptoms until later in life, even adulthood.

The symptoms of AVM vary and often are vague, making diagnosis sometimes difficult. Cerebral AVMs (AVMs in the brain) may cause HEADACHE, seizures, and STROKE-like symptoms if they apply pressure to surrounding brain tissue or if they bleed. HEMORRHAGE in the brain can cause permanent damage to the brain, resulting in PARALYSIS, cognitive loss, or death. AVMs elsewhere in the body may cause PAIN or bleeding; hemorrhagic bleeding is life-threatening. COMPUTED TOMOGRAPHY (CT) SCAN and magnetic resonance angiography, which combines MAGNETIC RESONANCE IMAGING (MRI) with dye injected into the blood vessels, are the key diagnostic procedures to detect AVM.

Treatment depends on the size and location of the AVM and may include surgery to remove the web of blood vessels, injection of a substance to block the flow of blood through the AVM (embolization), or RADIOFREQUENCY ABLATION to close off the blood vessels. Treatment often carries signif-

icant risk of uncontrolled bleeding because of the unstable nature of the AVM, and sometimes the risk of attempting treatment is greater than the risk of leaving the AVM untreated. Treatment that successfully removes or seals the AVM ends the threat of hemorrhage.

artery A flexible, muscular BLOOD vessel that carries blood from the HEART and oxygenated blood to tissues throughout the body. The wall of an artery has three layers:

- adventitia, the outermost layer, which is primarily connective tissue that gives the artery its FLEXIBILITY
- media, the middle layer, which is mostly smooth MUSCLE tissue that gives the artery the ability to contract and relax
- intima, the inner layer, which is epithelial tissue that provides a smooth surface to facilitate the flow of blood

The adventitia is more prominent in larger arteries such as the AORTA and the carotid arteries, encasing the artery in a weblike fashion without clear direction to its fibers. In smaller arteries, the media often dominates the artery's structure. The muscle fibers of the media encircle the artery, helping strengthen and stabilize the artery's walls. The delicate intima contains two structural levels, the basement or foundation membrane and the subepithelial layer, both of which run lengthwise. Each may be only a cell's thickness in small arteries, indistinguishable without magnification.

The intima's two-level structure gives the artery its ability to carry blood cells without having them stick to its inner walls. However, it also makes the artery vulnerable to ATHEROSCLEROSIS, which develops between the intima's two levels. The tiniest of the body's arteries, about the thickness of a hair, are arterioles. The body's largest artery is the aorta, which carries blood from the heart to the network of arteries that then carry the blood throughout the body.

Fibrous sheaths enclose most of the body's arteries, usually along with the companion VEIN and NERVE. These sheaths often parallel skeletal structures for protection and stability, or run deep within the body. Arteries also receive blood themselves from other arteries, which deliver oxygen and other nutrients to the layers of the artery, and contain nerves that deliver the signals to constrict or dilate. The walls of the arteries constrict and dilate in wavelike contractions that coordinate with the heartbeat to help push blood through the body. These pulsations are detectable as the PULSE at points where the artery is near the surface of the skin, such as at the wrist and the groin.

For further discussion of the artery within the context of cardiovascular structure and function, please see the overview section "The Cardiovascular System."

aspirin therapy A form of ANTICOAGULATION THERAPY to help prevent BLOOD clots from developing, which doctors prescribe as a prophylactic measure for HEART ATTACK and STROKE. Aspirin has a moderate anticoagulation effect. It interferes with PLATELET AGGREGATION, the first step in the clotting process. Aspirin blocks the body's production of PROSTAGLANDINS, chemicals the platelets need to help them aggregate (clump together). Cardiologists generally recommend aspirin therapy for:

- men between the ages of 40 and 75
- women who are beyond MENOPAUSE
- men and women under age 40 who have HYPERTENSION, DIABETES, or OBESITY
- men and women under age 40 who smoke cigarettes

People who do not have increased risk for CARDIOVASCULAR DISEASE (CVD)—are under age 40 and have no predisposing health conditions or lifestyle factors—likely do not receive enough benefit from aspirin therapy to offset the potential risks. The primary risks of aspirin therapy are gastrointestinal upset and excessive bleeding. Aspirin may cause GASTROINTESTINAL BLEEDING in people who have PEPTIC ULCER DISEASE, and extended bleeding during dental procedures and surgeries or with wounds such as lacerations. Doctors recommend a DOSE of

81 milligrams (mg) daily (one "baby" aspirin tablet) or 325mg milligrams every other day (one "regular" aspirin). Some products are available at 162mg strength, marketed specifically for aspirin therapy.

Call 911 at the first sign of HEART ATTACK. Do not wait for an aspirin to relieve the PAIN of a heart attack. An aspirin will only help to limit blood clotting during the heart attack. It will not help the pain.

Aspirin may also limit the damage of a HEART attack that is under way. Cardiologists recommend that people who experience symptoms of heart attack first call 911 for emergency medical aid and then chew an aspirin tablet. Chewing the aspirin tablet gets it into the bloodstream more quickly than swallowing. Studies show this approach releases enough of a burst of anticoagulant into the blood to help prevent fibrin and other clotting substances from adhering to the blockage in the coronary artery that is causing the symptoms. This small action can significantly reduce the amount of heart tissue that suffers oxygen deprivation and possible death during a heart attack.

atherectomy A surgical procedure, done via CARDIAC CATHETERIZATION, to remove patches of arterial plaque (ATHEROSCLEROTIC PLAQUE), called atheromas, from the inner walls of major arteries such as the CORONARY ARTERIES. The cardiologist uses either a laser to vaporize or a rotary burr on the end of the catheter to shave away the atheromas. Often the cardiologist follows the atherectomy with balloon ANGIOPLASTY and STENT placement to help keep the ARTERY open, as atheromas tend to redevelop. Risks of atherectomy include STROKE and HEART ATTACK from debris particles that break away and become lodged in the arteries of the BRAIN or the HEART.

See also ENDARTERECTOMY; SURGERY BENEFIT AND RISK ASSESSMENT.

atherosclerosis Accumulation of lipids and other materials (ATHEROSCLEROTIC PLAQUE) between the two layers of an artery's inner wall, the intima. Over time the accumulations form brittle, hard deposits called atheromas that thicken the intima and the media (the middle of the arterial wall's three layers). The usual consequence is that the ARTERY becomes stiff and less flexible, and its inner channel, the lumen, narrows. The combined effect limits the ability of the artery to dilate or constrict, increasing the pressure necessary to push BLOOD through the artery. The result is CARDIOVASCULAR DISEASE (CVD), including HYPERTENSION (high BLOOD PRESSURE), CORONARY ARTERY DISEASE (CAD), and PERIPHERAL VASCULAR DISEASE (PVD). Atherosclerosis takes decades to develop. Many researchers believe the process of atherosclerotic accumulation begins in late childhood.

Atherosclerosis will most commonly affect medium-size arteries such as the CORONARY ARTERIES that supply the HEART, the carotid arteries that supply the BRAIN, and the primary arteries that supply the legs. Atherosclerosis can also develop in the large arteries, notably the AORTA. Atherosclerosis in the aorta presents a significant risk for aortic ANEURYSM, a potentially life-threatening circumstance in which the walls of the aorta weaken and begin to separate. The most significant risk of atherosclerosis, however, is HEART ATTACK or STROKE, resulting from particles of atherosclerotic plaque that break free and become lodged in an artery. The blockage may occur at the location of the occlusion or at a distant site. Blood clots also may form at the sites of the plaque accumulations (atheromas), occluding the artery at the site or, like the plaque particles, breaking free and becoming lodged elsewhere in the body.

Symptoms and Diagnostic Path

Atherosclerosis typically does not present symptoms until it advances to a further disease state such as CAD or hypertension resulting from renal artery stenosis. A key indicator that atherosclerosis exists, however, is elevated blood lipid (cholesterol and triglycerides) levels. Cardiologists generally perceive a total blood cholesterol level of 200 as indicating that there is some degree of atherosclerotic disease present. Lowering CHOLESTEROL BLOOD LEVELS reduces the risk for further atherosclerotic deposits and can also reverse to some extent atherosclerotic disease that already exists. The diag-

nostic path typically includes CARDIAC CATHERIZATION or vascular catheterization, which allows the cardiologist to directly visualize the extent of atherosclerotic disease present. ELECTRON BEAM COMPUTED TOMOGRAPHY (EBCT) SCAN, a noninvasive imaging procedure, shows promise for identifying atherosclerosis in its early stages. EBCT detects calcium in the atherosclerotic deposits.

Treatment Options and Outlook

Treatment may target the damaged arteries, the underlying disease process, or both. Treating the damaged artery generally takes precedence as the atherosclerotic occlusions restrict and may even block the flow of blood.

Risk Factors and Preventive Measures

The primary risk factor for atherosclerosis is elevated cholesterol blood levels, which allow fatty acids to accumulate in the blood. Cigarette smoking, OBESITY, hypertension, and DIABETES further increase the risk for atherosclerosis. Cigarette smoking and hypertension alter the cells of the arterial walls in ways that reduce their FLEXIBILITY, making them more susceptible to atherosclerotic accumulations. Diabetes and obesity both alter lipid METABOLISM. Preventive measures include a diet with fewer than 10 percent of its CALORIES from saturated fats (such as meats), daily physical exercise, SMOKING CESSATION, and WEIGHT LOSS AND WEIGHT MANAGEMENT. Health experts encourage people to develop heart-healthy lifestyle habits early in life, as so much research now confirms that the cardiovascular diseases common in people who are in their 60s and beyond get their start in the teenage years or earlier.

atherosclerotic plaque Debris that collects within the inner layer of the wall of an artery, also called arterial plaque. Atherosclerotic plaque typically includes fatty acids, dead cells, platelets, and other particles such as proteins and minerals (notably calcium, which gives the plaque its stiffness). The fatty acids, such as cholesterol and triglycerides, are heavy and sticky. The flow of the BLOOD pushes them to the outer edges, up against the arterial walls. Initially the debris is a minor irritation to the inner surface of the arteries. Over time, however, the irritation creates INFLAMMATION that attracts further debris. The sticky nature of the debris in combination with the inflammation establishes a circumstance in which the debris becomes embedded within the intima, the inner layer of the arterial wall, creating deposits called atheromas and evolving into the disease state of ATHEROSCLEROSIS. Atherosclerotic plaque in the CORONARY ARTERIES becomes CORONARY ARTERY DISEASE (CAD) and in other arteries becomes PERIPHERAL VASCULAR DISEASE (PVD).

atrial fibrillation An ARRHYTHMIA in which the upper chambers of the HEART, the atria, contract rapidly and out of synchronization with each other. As a consequence, they do not pump BLOOD very effectively to the ventricles. Though most of the blood that enters the atria drains to the ventricles, some blood pools in the atria. The pooled blood establishes a very high risk for blood clots to form and a corresponding increase in the risk of STROKE or TRANSIENT ISCHEMIC ATTACK (TIA). Atrial fibrillation is the cause of one in five strokes. Atrial fibrillation is the most common arrhythmia that requires treatment, affecting about 5 percent of people over age 65.

The typical symptoms of atrial fibrillation include

- PALPITATIONS
- rapid tiring during physical activity
- generalized fatigue
- DYSPNEA (shortness of breath)
- ANGINA PECTORIS (CHEST PAIN)
- SYNCOPE (fainting)

However, many people have mild or no symptoms, with the doctor detecting atrial fibrillation during the course of examination for other health concerns.

HYPOTENSION (low BLOOD PRESSURE) and a weak, irregular, and often rapid PULSE are common signs

the doctor detects during examination. An ELECTROCARDIOGRAM (ECG) confirms the diagnosis. ECHOCARDIOGRAM may reveal the underlying cause of the arrhythmia, especially when VALVULAR HEART DISEASE is to blame. Antiarrhythmia medications such as beta blockers or calcium channel blockers restore a normal heart rhythm (normal sinus rhythm) in most people who have atrial fibrillation. These medications can have mild to significant side effects and can slow the heart too much, causing bradycardia, another arrhythmia.

For atrial fibrillation that does not respond to these medical measures, the cardiologist may suggest CARDIOVERSION, which uses electrical shock to jolt the heart back into normal rhythm, or RADIOFREQUENCY ABLATION, which destroys a small portion of heart tissue to permanently disrupt the flow of electrical impulses in the heart. Cardiologists typically prescribe ANTICOAGULATION THERAPY, usually aspirin or warfarin and sometimes both, in addition to antiarrhythmia medications for people who have atrial fibrillation, to reduce the risk for clot formation and resulting stroke.

Common causes of atrial fibrillation include HYPERTENSION (high blood pressure), CORONARY ARTERY DISEASE (CAD), congestive HEART FAILURE, PERICARDITIS, and RHEUMATIC HEART DISEASE. Atrial fibrillation may follow MYOCARDIAL INFARCTION and is also more common among people who have DIABETES or HYPERTHYROIDISM. There are no known measures for preventing atrial fibrillation beyond lifestyle behaviors to maintain overall cardiovascular health.

atrioventricular (AV) node A cluster of electrical fibers in the HEART that focuses and intensifies the electrical impulses the SINOATRIAL (SA) NODE initiates. The SA node, a cluster of specialized NERVE fibers at the top of the right atrium near the superior VENA CAVA, is the heart's natural PACEMAKER. It generates a rhythmic electrical impulse that spreads through the myocardial cells of the right atrium. The AV node, located at the base of the right atrium at its juncture with the right ventricle, gathers the impulse and amplifies it, sending it through the BUNDLE OF HIS and into the right and left bundle branches. The electrical impulse gathers STRENGTH as it travels these electrical conduits, culminating in the Purkinje fibers near the base of each ventricle. The impulse then cascades through the myocardial cells of the ventricles, bringing the cells and the ventricles to synchronized contraction. The AV node also can generate a pacing impulse when disease or damage to the heart blocks the SA node's impulse, though the AV node impulse is considerably weaker and can sustain limited cardiac function for only a short time.

For further discussion of the AV node within the context of cardiovascular structure and function, please see the overview section "The Cardiovascular System."

automated external defibrillator (AED) A portable, computerized device to shock a HEART in fibrillation (rapid, useless contractions) into a functional rhythm. AEDs debuted in the 1990s and now are available in many public locations and workplaces. Older models are the size of a small briefcase; newer models are smaller and lighter, with some designed for transport by rescuers on bicycles or on foot. Though manufacturers and emergency medical response experts recommend people obtain training in their use, the devices are simple enough for anyone to use without training. Most models use a computerized voice to provide step-by-step instructions. Once the rescuer applies the pads to the chest of the person having the HEART ATTACK, the AED automatically reads the electrical activity of the heart and determines whether there is sufficient activity for an electrical shock to be therapeutic. An electrical shock cannot help a heart that has no electrical activity. The AED is preset to deliver a precise level and length of shock. AEDs are also available for home use by people at high risk for life-threatening arrhythmias. Many emergency response courses, including the basic life support curriculum, routinely teach AED use.

blood pressure The force BLOOD exerts against the walls of the arteries as it travels through them, as a combination of resistance and the HEART's pumping effort. A sphygmomanometer is the device that measures blood pressure, reported in millimeters of mercury (mm Hg). A typical blood pressure reading reports the pressure at the peak (systole, at ventricular contraction) and trough (diastole, at ventricular filling) of the CARDIAC CYCLE. The first number in a blood pressure reading is the systolic measure and the second number is the diastolic measure. These measures are independently important as well as significant in combination. Blood pressure is among the vital signs health-care providers measure to assess general health status.

Several mechanisms within the body, including neurologic actions in the brainstem and hormonal actions initiated in the KIDNEYS, regulate blood pressure. Clusters of specialized NERVE cells in the heart and major arteries, called baroreflex sensors, continuously send biochemical signals to the regulatory mechanisms. These mechanisms are redundant—that is, they overlap one another to respond to physiologic changes such as fluid volume and oxygen demand. These mechanisms increase blood pressure by constricting arteries and arterioles, raising the resistance blood encounters as it flows through these blood vessels, and correspondingly increasing the rate and force of the heart's contractions. They decrease blood pressure through reverse actions, dilating arteries and arterioles and decreasing the heart's pumping force. Blood pressure typically increases with exercise or stress, reflecting increased METABOLISM. Higher blood pressure pushes oxygen and NUTRIENTS more rapidly into the CAPILLARY BEDS, speeding the rate at which these substances reach cells.

Blood pressure that is higher than is optimal for cardiovascular health is HYPERTENSION; blood pressure that is too low to adequately circulate blood is HYPOTENSION. Most hypotension occurs as a SIDE EFFECT of medications or neurologic conditions, although some degree of hypotension is common with cardiovascular slowing in aging. Researchers believe age-related hypotension reflects disturbances of the baroreflexes. Cardiologists may prescribe medications to constrict the arteries and intensify the heart's contractions when hypotension causes symptoms such as mental confusion or SYNCOPE (fainting).

BLOOD PRESSURE VALUES

Classification	Systolic	Diastolic
healthy	below 120 mm Hg	below 80 mm Hg
prehypertension	120–139 mm Hg	80–89 mm Hg
stage 1 hypertension	140–159 mm Hg	90–99 mm Hg
stage 2 hypertension	160 mm Hg and above	100 mm Hg and above

Hypertension poses a significant threat to cardiovascular health, raising the risk for HEART ATTACK, RENAL FAILURE, and STROKE. Researchers do not fully understand how hypertension develops, though they do know the contributing factors the development of it (salt intake, physical inactivity, OBESITY, and DIABETES) as well as how to influence blood pressure regulatory mechanisms to bring it under control in most situations. Hypertension exists when either systolic or diastolic pressure is elevated. Health conditions that contribute to hypertension include

- arteriosclerosis, atherosclerotic disease, and cigarette smoking, each of which stiffens the arteries and narrows the arterioles

- diabetes, which damages the blood vessels, particularly the smaller arteries and the arterioles
- OBESITY, which increases body mass and creates additional pressure against the blood vessels

Health experts recommend reduced salt consumption, WEIGHT LOSS AND WEIGHT MANAGEMENT, daily physical exercise, and no smoking to maintain optimal blood pressure. Many people who have hypertension also are on ASPIRIN THERAPY or ANTICOAGULATION THERAPY to reduce their risk for heart attack and stroke.

body shape and cardiovascular health Although OBESITY in general raises the risk for numerous health conditions, the distribution pattern of excess body fat correlates to the level of risk for CARDIOVASCULAR DISEASE (CVD) as well as other health conditions such as DIABETES. Numerous research studies affirm that people who carry excess body fat primarily around the waist, the "apple" or "fat tire" body shape, are three times more likely to develop cardiovascular conditions such as HYPERTENSION (high BLOOD PRESSURE), ATHEROSCLEROSIS, CORONARY ARTERY DISEASE (CAD), ISCHEMIC HEART DISEASE (IHD), and PERIPHERAL VASCULAR DISEASE (PVD).

WAIST AND HIP MEASUREMENTS

To measure the waist:

1. Breathe out.
2. Place a measuring tape (or piece of string) snugly but not cinched around the waist, between the crest of the hip bones and the navel (belly button).
3. Note the measurement (or use a ruler to measure the string).

To measure the hips:

1. Place a measuring tape (or piece of string) snugly but not cinched around the hips at their widest point.
2. Note the measurement (or use a ruler to measure the string).

Researchers believe the "apple" pattern of body fat distribution reflects a higher level of INSULIN RESISTANCE than the "pear" body shape in which the body stores excess fat in the hips, thighs, and more equitably throughout the body. This is significant because INSULIN plays a key role in LIPID METABOLISM and regulating blood levels of cholesterol and triglycerides. Excesses of these lipids (HYPERLIPIDEMIA) lead to atherosclerosis, the accumulation of deposits in the inner layer of the walls of the arteries. Atherosclerosis is the foundation of occlusive cardiovascular conditions such as CAD and PVD, and the cause of some types of hypertension (namely renal vascular hypertension).

The WAIST-TO-HIP RATIO (WHR), which is the WAIST CIRCUMFERENCE divided by the hip circumference, determines a person's body shape classification. A WHR greater than 0.9 in men or 0.8 in women defines a body shape as "apple." Maintaining a healthy weight and daily physical exercise are especially important for people who have "apple" body shapes. Exercise improves INSULIN sensitivity and helps keep blood lipid levels and blood pressure within healthy ranges. In turn, this reduces the risk for diabetes as well as cardiovascular disease.

bundle branch An organization of NERVE fibers along the heart's ventricular septum that conveys electrical impulses to the ventricles to cause them to contract, also called the BUNDLE OF HIS. The right bundle branch extends to the right ventricle and the left bundle branch to the left ventricle. The electrical impulses, which originate with the SINOATRIAL (SA) NODE, intensify as they travel along the bundle branches. The bundle branches, as the name implies, branch out into smaller and smaller fibers culminating in the Purkinje fibers, which disperse the electrical impulses to the myocardial cells throughout the ventricles.

For further discussion of the bundle branches within the context of cardiovascular structure and function, please see the overview section "The Cardiovascular System."

See also ATRIOVENTRICULAR (AV) NODE; BUNDLE BRANCH BLOCK; ELECTROCARDIOGRAM (ECG); HEART.

bundle branch block An impediment, partial or complete, that prevents electrical impulses from

traveling along the BUNDLE OF HIS or one of the bundle branches, right or left, in the HEART. The bundle branches focus and intensify the pacing signals that originate in the SINOATRIAL (SA) NODE, concentrating them enough to stimulate and synchronize the powerful contractions the ventricles need to eject BLOOD from the heart. Various factors can block this electrical pathway. Among the most common are CORONARY ARTERY DISEASE (CAD), VALVULAR HEART DISEASE, HEART FAILURE, and CARDIOMYOPATHY. These conditions result in abnormal blood supply to the myocardial cells, interfering with their normal functions. BUNDLE BRANCH block also can exist without an identifiable cause in people who have no apparent heart disease.

Bundle branch block typically shows up on an ELECTROCARDIOGRAM (ECG) though often does not cause symptoms. The heart continues to contract and pump blood normally (unless other heart disease interferes) because factors other than electrical stimulation contribute to heart function. However, the slowed, delayed, or interrupted flow of the electrical pacing impulse can cause a slow heart rate (bradycardia) or other types of ARRHYTHMIA. The location of the blockage can disrupt the synchronized contractions of the ventricles, causing one to contract before the other instead of both contracting simultaneously. Often, the bundle branch block requires only regular monitoring, not treatment. The location and extent of the block determines the approach. When the block is fairly extensive, a PACEMAKER may be necessary to regulate the heart's electrical activity. Bundle branch block that coexists with other forms of heart disease may require careful coordination of therapeutic measures to preserve overall cardiac function to the greatest extent possible.

See also SICK SINUS SYNDROME.

bundle of His The bundle of NERVE fibers that conveys the heart's electrical pacing impulse from the ATRIOVENTRICULAR (AV) NODE to the ventricles, also called the bundle branches. The short trunk portion of the bundle before it splits into the right BUNDLE BRANCH (right bundle of His) and left bundle branch (left bundle of His) is the main bundle of His. The German physician Wilhelm His (1863–1934) discovered the bundle branches in 1893. Doctors may use the terms bundle of His and bundle branch interchangeably.

For further discussion of the bundle of His within the context of cardiovascular structure and function, please see the overview section "The Cardiovascular System."

capillary beds The meshlike network of arterioles and venules, the body's tiniest BLOOD vessels, where OXYGEN–CARBON DIOXIDE EXCHANGE takes place. Arterial pressure forces blood into the capillary beds. Erythrocytes (red blood cells) carry oxygen and other NUTRIENTS to the capillary beds, where these molecules pass through to cells. Correspondingly, the cells pass metabolic waste such as CARBON DIOXIDE and lactic acid through to the blood. The arterioles and the venules intertwine in the capillary beds, becoming indistinguishable. Capillary beds are present throughout the body.

For further discussion of the capillary beds within the context of cardiovascular structure and function, please see the overview section "The Cardiovascular System."

cardiac arrest Cessation of the heart's contractions. Cardiac arrest may occur as the result of arrhythmias (irregularities in the heartbeat), MYOCARDIAL INFARCTION (clot that blocks the flow of BLOOD through the CORONARY ARTERIES to the HEART MUSCLE), HYPOXIA (such as in drowning), ELECTROCUTION, COCAINE use, or blunt trauma to the chest. Without immediate resuscitative efforts to restore heartbeat, OXYGENATION, and circulation, death occurs within minutes. About 350,000 Americans die of cardiac arrest each year.

Although cardiac arrest can follow HEART ATTACK, they are not the same event. Cardiac arrest typically occurs suddenly and with few warning indications. People at highest risk for cardiac arrest are those who have disorders of the heart's electrical system such as LONG QT SYNDROME (LQTS), SICK SINUS SYNDROME, BUNDLE BRANCH BLOCK, WOLFF-PARKINSON-WHITE SYNDROME, and ventricular arrhythmias.

More than half of cardiac arrests occur in people who do not know they have CARDIOVASCULAR DISEASE. Most cardiac arrests take place at home with no one witnessing the event. By the time someone finds the person who has had cardiac arrest, often it is too late for resuscitation to succeed. Health experts believe prompt resuscitation could save 70 to 80 percent of people who experience cardiac arrest. CARDIOPULMONARY RESUSCITATION (CPR) is most effective within four minutes of the onset of cardiac arrest. Automated external defibrillators (AEDs), small computerized devices that automatically read the heart's rhythm and can administer a jolt of electricity to shock the heart into a functional rhythm, have become more common in public locations and at workplaces. AEDs have saved numerous lives of people who have had cardiac arrests.

cardiac capacity The ability of the HEART to increase CARDIAC OUTPUT to meet the body's increased needs for oxygen during physical activity or exercise. Cardiac capacity is a combination of the heart's physical condition and the body's AEROBIC FITNESS level. Damage to the heart, such as may occur with MYOCARDIAL INFARCTION and ISCHEMIC HEART DISEASE (IHD), reduces cardiac capacity, as do conditions that weaken the heart MUSCLE such as CARDIOMYOPATHY and HEART FAILURE. Cardiac capacity also diminishes as a normal dimension of aging. Aerobic conditioning through consistent, moderate to intense, AEROBIC EXERCISE improves cardiac capacity and helps sustain cardiovascular health.

cardiac catheterization A diagnostic or therapeutic procedure in which the cardiologist inserts a long, flexible, thin tube into an ARTERY near the surface of the SKIN and threads it through the artery into the HEART or the CORONARY ARTERIES. The cardiologist uses FLUOROSCOPY (moving X-RAY) to view the progress of the catheter's insertion via closed-circuit television. During cardiac catheterization the cardiologist typically injects dye into the coronary arteries to visualize the flow of BLOOD through them (cardiac ANGIOGRAM).

Reasons for Doing This Test

Cardiac catheterization helps diagnose CORONARY ARTERY DISEASE (CAD) and the extent of coronary artery occlusion (blockage). The cardiologist also may use cardiac catheterization to diagnose damaged or dysfunctional heart valves and biopsy the endomyocardium (inner lining and MYOCARDIUM of the heart). Therapeutic applications of cardiac catheterization include ATHERECTOMY and percutaneous transluminal coronary angioplasty (PCTA), also called balloon ANGIOPLASTY. In PCTA the cardiologist inflates a tiny balloon at the catheter's tip to compress ATHEROSCLEROTIC PLAQUE that is occluding a coronary artery.

Preparation, Procedure, and Recovery

Cardiac catheterization requires little preparation beyond nothing to eat or drink for six to eight hours before the scheduled procedure. The catheterization takes place in a sterile setting. Because there is a slight risk for complications that would require immediate OPEN HEART SURGERY, the catheterization facility has full operating room and surgical team capacity. At the start of the procedure the cardiologist administers a general sedative to help the person relax, and injects a local anesthetic into the tissues around the area where the catheter will enter the artery. The cardiologist makes a tiny incision to gain entrance to the artery, and threads the catheter through the artery to the heart and coronary arteries. Typically the cardiologist videotapes the catheterization for further study or review following the procedure.

Depending on the reason for the catheterization and the cardiologist's findings, the procedure takes 45 to 90 minutes. When finished, the cardiologist withdraws the catheter, sutures the insertion incision, and places a pressure dressing over the wound. The person remains lying down for six to eight hours, in a recovery area, allowing a good clot formation to develop and also permitting the sedative to wear off. Most people are able to go home the same day, though must have a friend or relative do the driving, and can return to regular activities within a week.

Risks and Complications

The most significant, though an uncommon, risk of cardiac catheterization is HEART ATTACK or STROKE from atherosclerotic plaque the catheter dislodges. Some people may have a HYPERSENSITIVITY REACTION or allergic response to the injected dye with angiogram. Also uncommon—though possible—is that the cardiologist may discover, upon reaching the occlusion, that the atheroma (plaque formation) is unstable and may determine that immediate CORONARY ARTERY BYPASS GRAFT (CABG) will be necessary. More common complications include bleeding and discomfort at the insertion site or INFECTION after the procedure. For most people, cardiac catheterization is uneventful and provides the information the cardiologist needs to make a definitive diagnosis.

cardiac cycle The complete sequence of the heart's contractions that results in ejecting BLOOD from the HEART to the LUNGS and body. Each cardiac cycle represents two paired actions that begin when the SINOATRIAL (SA) NODE, a cluster of specialized NERVE cells located at the apex of the right atrium, emits an electrical pacing impulse. The impulse causes the right and left atria to contract simultaneously, sending blood to the respective ventricles. The right atrium sends to the right ventricle deoxygenated blood returning to the heart from the body; the left atrium sends to the left ventricle oxygenated blood returning to the heart from the lungs.

The ATRIOVENTRICULAR (AV) NODE, a second cluster of specialized nerve cells located at the base of

the right atrium, initiates the second phase of the cardiac cycle. The AV node picks up, amplifies, and focuses the electrical impulse that has passed through the atria, sending it along the BUNDLE OF HIS and the bundle branches in wavelike fashion. The impulse causes the ventricles to contract simultaneously. The right ventricle pumps blood to the lungs for OXYGENATION, and the left ventricle pumps oxygenated blood into the AORTA for the arterial network to carry through the body.

The PULSE represents a completed cardiac cycle. The heart of an adult at rest completes about 80 cardiac cycles each minute. ARRHYTHMIA, VALVULAR HEART DISEASE, CORONARY ARTERY DISEASE (CAD), ISCHEMIC HEART DISEASE (IHD), congenital defects of the heart, and damage to the heart such as occurs with HEART FAILURE or HEART ATTACK are among the conditions that can disrupt the cardiac cycle.

cardiac enzymes Proteins the HEART releases into the bloodstream when HEART ATTACK or other circumstances cause damage to the heart MUSCLE (MYOCARDIUM). BLOOD tests that measure the levels of these enzymes help doctors determine whether, and how long ago, a heart attack has taken place. All muscle tissue releases certain enzymes when injured, so the combination of enzymes present in the blood provides the most useful clues as to the source of the injury. The cardiac-specific enzymes that indicate heart attack are cardiac troponin-T and cardiac troponin-I. The levels of these enzymes in the blood rise 3 to 6 hours after damage to the heart and remain elevated for 7 to 10 days.

Nonspecific enzymes that may suggest heart attack include creatine kinase (CK), aspartate aminotransferase (AST) and lactate dehydrogenase (LDH). Elevations of these enzymes occur whenever there is significant damage to muscle tissue of any kind. To cardiologists determining whether a person has had a heart attack, it is the rise and fall of the enzyme levels that are more useful than the levels themselves at any one point in time. Creatine kinase MB (CK-MB), one of the protein components of creatine kinase, rises more rapidly and dramatically when the damage is to heart muscle, providing a strongly suggestive marker. CK-MB rises within a few hours of heart damage though returns to normal in about 24 hours. Cardiologists evaluate cardiac enzyme levels in combination with other clinical evidence such as ELECTROCARDIOGRAM (ECG) and ECHOCARDIOGRAM to confirm the diagnosis of MYOCARDIAL INFARCTION (death of heart muscle cells due to lack of oxygen).

cardiac intensive care unit (CICU) A specialized unit within a hospital that provides comprehensive medical care for people recovering from HEART ATTACK or receiving treatment for other life-threatening cardiovascular diseases. Large hospitals have separate units for medical patients (such as those who have had HEART attacks but not surgery) and surgical patients (such as those who have had CORONARY ARTERY BYPASS GRAFT (CABG), heart valve replacement, or other operations on the heart); in smaller hospitals a single specialized unit provides care for both kinds of patients. The nurses and ancillary health-care staff who work in CICUs have specialized training in using the monitoring equipment and caring for patients who have serious cardiovascular conditions. Most CICUs restrict visitors and visiting times to protect patients and allow them to receive adequate rest as well as the intensive nursing care their conditions require.

cardiac output The volume of BLOOD the HEART pumps out to the body each minute. Cardiac output is an important measure of the heart's efficiency. Many cardiovascular diseases, such as ARRHYTHMIA and HEART FAILURE, can limit cardiac output. Cardiologists measure cardiac output as the combination of HEART RATE and stroke volume (the amount of blood the left ventricle ejects into the AORTA with each contraction). There are several methods for determining stroke volume, including dye injection and thermal differential.

In a person whose cardiovascular system is healthy, cardiac output increases with increased physical activity such as exercise, in which both heart rate and the force of the heart's contractions increase. A heart with damage due to disease such as CARDIOMYOPATHY or HEART FAILURE, or as a conse-

quence of MYOCARDIAL INFARCTION, cannot increase the force of its contractions, limiting cardiac output. Severe damage can result in cardiac output that is less than the body's needs even at rest. Medications to strengthen the heart and focus the efforts of its contractions can often improve cardiac efficiency, though only mediating the underlying cause can restore adequate cardiac output.

People who have a high AEROBIC FITNESS level, such as athletes and those who regularly engage in AEROBIC EXERCISE, can significantly increase their cardiac output to send more blood to their muscles. During intense aerobic activity, 60 percent or more of the cardiac output may go to the skeletal muscles. High cardiac output is essential to get enough blood and oxygen to vital organs at the same time.

cardiac rehabilitation Planned activities, course of recovery, or structured program for improving cardiovascular health after HEART ATTACK, CORONARY ARTERY BYPASS GRAFT (CABG), HEART TRANSPLANTATION, and other major cardiovascular events or operations. Many people, after such events, need to make significant lifestyle changes. A structured cardiac rehabilitation program helps people to define their needs and goals and establish realistic steps to move progressively toward meeting them. Most people benefit from assistance with meal planning and nutrition, exercise, and SMOKING CESSATION. Structured programs also offer social interaction with other people who have similar experiences, and may include organized SUPPORT GROUPS for people to share their feelings, perceptions, and suggestions.

Many factors influence a person's ability to participate in physical activity. Many hospitals and medical centers offer physician-supervised cardiac rehabilitation programs that feature defined yet individualized activities, some of which may take place at a facility such as a rehabilitation center and others designed for the person to do at home. Some medically supervised cardiac rehabilitation programs incorporate ambulatory ELECTROCARDIOGRAM (ECG) so people can use the telephone to send their ECG readings to cardiologists who can then determine whether physical exercise is within therapeutic range and provide assurance that the HEART is functioning satisfactorily.

Programs such as those health clubs and organizations such as the YMCA offer are less comprehensive and not under a physician's direction. They primarily provide classes in aerobic and resistance exercises as well as access to facilities and equipment. A nutritional counselor separately provides dietary guidance including instruction for WEIGHT LOSS AND WEIGHT MANAGEMENT. People who have health conditions other than cardiovascular, such as DIABETES or chronic OSTEOARTHRITIS, may need additional consultations or professional guidance to accommodate all of their health needs.

Current medical practice emphasizes a return to regular activities as quickly as possible following heart attack or major heart surgery. This reduces the risk of BLOOD clots that can cause STROKE, another heart attack, or PULMONARY EMBOLISM (blood clot in the LUNG). It also expedites HEALING and counters the emotional swings, especially DEPRESSION and anxiety, that are common with serious CARDIOVASCULAR DISEASE (CVD). Research studies have conclusively demonstrated that people who engage in cardiac rehabilitation and maintain heart-healthy lifestyle changes are much less likely to experience additional cardiovascular events and may even halt or reverse cardiovascular conditions such as ATHEROSCLEROSIS and HYPERTENSION (high BLOOD PRESSURE).

BENEFITS OF CARDIAC REHABILITATION

decreased CHOLESTEROL BLOOD LEVELS	faster return to work and other activities
fewer cardiovascular symptoms	improved AEROBIC FITNESS
improved ATHEROSCLEROSIS	improved INSULIN sensitivity
improved nutritious eating habits	improved QUALITY OF LIFE
lowered BLOOD PRESSURE	reduced postoperative discomfort
reduced risk of health problems related to smoking	stress reduction

WEIGHT LOSS AND WEIGHT MANAGEMENT

Heart attack or major heart surgery is a significant trauma for an individual to experience, with both physical and emotional components. Many people are fearful about the level of physical activity their bodies, and especially hearts, can tolerate. Some people respond with reluctance to do anything and others leap into action with a fervor

that would challenge even someone in peak cardiovascular function. Neither extreme is healthy and can result in further health problems. A person who has not been physically active for years to decades often benefits from the advice and suggestions of a health expert who can help determine an appropriate entry point for returning to an active lifestyle.

Recent studies affirm that cardiac rehabilitation has therapeutic value for people who have chronic cardiovascular conditions such as congestive HEART FAILURE, improving symptoms and QUALITY OF LIFE. Many people will begin cardiac rehabilitation before leaving the hospital after treatment or surgery, starting with an exercise STRESS TEST to determine cardiopulmonary capacity, and continue in a structured way for 3 to 6 months. Under ideal circumstances the activities of rehabilitation, including EATING HABITS and nutrition, become elements of routine daily living and foster a lifestyle that supports cardiovascular health.

cardiac resynchronization therapy (CRT) A method of biventricular pacing in which an implanted device regulates and coordinates the contractions of both ventricles, typically to treat severe HEART FAILURE. SUDDEN CARDIAC DEATH as a result of ARRHYTHMIA is a significant risk in HEART failure, particularly heart failure resulting from dilated CARDIOMYOPATHY. Certain BUNDLE BRANCH BLOCK arrhythmias also benefit from CRT.

Conventional pacing therapy stimulates only the right ventricle, which in an otherwise healthy heart results in contraction of both ventricles as the electrical impulse spreads simultaneously across them. In severe heart failure, however, both ventricles are extensively damaged and do not function in synchronization. Conventional pacing therapy ends up being counterproductive by further extending the dysfunction between the two ventricles. A biventricular PACEMAKER has two leads (wires that conduct electrical impulses), one of which the cardiologist inserts in each ventricle. The pacemaker's discharge sends impulses simultaneously to each lead.

The risks of CRT are similar to those of conventional pacing therapy and include possible INFECTION or blood clots from the inserted leads. These risks are minimal, however, and CRT provides substantial benefit for people whose arrhythmias due to heart failure do not respond to other treatments.

cardiomyopathy Weakness and loss of pumping effectiveness of the HEART, usually with changes to the structure of the heart and in particular the left ventricle. Cardiomyopathy is as likely to affect people under age 40 as people over age 60 and is a leading cause of HEART FAILURE resulting in HEART TRANSPLANTATION. Genetic factors can play a role in cardiomyopathy, especially in younger people, though lifestyle factors such as nutrition and ALCOHOL consumption are also significant. Viral and bacterial infections of the heart (MYOCARDITITIS) can leave the heart MUSCLE damaged. In many situations, however, doctors do not know what causes the structural and functional changes in myocardial (heart muscle) cells that result in primary cardiomyopathy. Secondary cardiomyopathy may also develop as a consequence of other CARDIOVASCULAR DISEASE (CVD), such as ISCHEMIC HEART DISEASE (IHD) and HYPERTENSION (high BLOOD PRESSURE).

The five major types of cardiomyopathy are

- **Dilated cardiomyopathy,** in which the heart enlarges in an attempt to compensate for damage to myocardial cells that limits the heart's ability to efficiently pump BLOOD. Long-term ALCOHOL abuse accounts for the dilated cardiomyopathy in about a third of the people who develop it. Deficiency of vitamin B_1 also damages the heart. Though uncommon in the general US population, vitamin B_1 deficiency can occur with long-term, heavy alcohol consumption as well as with long-term EATING DISORDERS such as anorexia nervosa. Dilated cardiomyopathy is more common in people over age 60.
- **Hypertrophic cardiomyopathy,** in which the walls of the heart, particularly the ventricles, thicken. Some doctors may refer to this

condition as hypertrophic obstructive cardiomyopathy (HOCM) or idiopathic hypertrophic subaortic stenosis (IHSS), both of which are older terms. Hypertrophic cardiomyopathy is hereditary, the result of mutations in a number of genes that regulate proteins essential for myocardial cell contractions (notably myosin, troponin T, and alpha tropomyosin). The hypertrophy, or thickening, typically affects the left ventricle most extensively and can involve the ventricular septum to the extent that the hypertrophy creates an obstruction for the proper functioning of the aortic valve (AORTIC STENOSIS). Undiagnosed hypertrophic cardiomyopathy is a leading cause of SUDDEN CARDIAC DEATH in younger people, especially athletes.

- **Ischemic cardiomyopathy,** which develops secondary to longstanding IHD or following extensive or repeated MYOCARDIAL INFARCTION. Ischemia results from inadequate oxygen supply to the cells, some of which die. The patches of dead muscle tissue do not contract, diminishing the heart's effectiveness. Ischemic cardiomyopathy is more common in people over age 60 who have other forms of cardiovascular disease.
- **Peripartum cardiomyopathy,** which develops in a woman during late PREGNANCY or in the first few months after CHILDBIRTH. It appears an inflammatory process in the body, though doctors are uncertain what sets it off. In some situations there is a clear bacterial or viral INFECTION, but most often there is no apparent reason for the INFLAMMATION. Most women fully recover from peripartum cardiomyopathy though are at increased risk for developing it again with subsequent pregnancies.
- **Restrictive cardiomyopathy,** in which the myocardial cells accumulate deposits that cause them to lose elasticity. The loss restricts the ability of the heart to expand, reducing the ability of the ventricles to properly fill with blood. As a consequence, the heart cannot pump enough blood to meet the body's needs. Restrictive cardiomyopathy is secondary to other health conditions such as AMYLOIDOSIS, which leaves protein deposits, and HEMACHROMATOSIS, which leaves iron deposits.

Symptoms and Diagnostic Path

Cardiomyopathy often does not show symptoms until the condition is quite advanced, and then the symptoms are likely to be those of other cardiovascular conditions, such as hypertension and heart failure, especially congestive heart failure. Doctors commonly discover cardiomyopathy during chest X-RAY done for other reasons. When symptoms are present, they typically include

- shortness of breath (DYSPNEA)
- weakness and tiredness
- inability to participate in physical activities

The diagnostic path includes ELECTROCARDIOGRAM (ECG), which detects the arrhythmias typical of an overworked heart, and ECHOCARDIOGRAM, which shows the heart's enlargement and altered function. These tests can provide definitive diagnosis for most cardiomyopathy. Other diagnostic procedures the cardiologist may recommend, depending on the kind of cardiomyopathy suspected, may include COMPUTED TOMOGRAPHY (CT) SCAN, MAGNETIC RESONANCE IMAGING (MRI), transesophageal echocardiogram (TEE), angiogram, and myocardial biopsy. GENETIC TESTING to detect mutations commonly associated with hypertrophic cardiomyopathy can help detect the potential for this condition before it manifests symptoms, allowing prophylactic interventions to delay or minimize its development.

Treatment Options and Outlook

All forms of cardiomyopathy make it difficult for the heart to pump blood effectively. Though in the early stages of the condition the heart's enlargement can compensate for some of the diminished STRENGTH, eventually the compensatory measures become ineffective and even counterproductive. Treatment targets improving the heart's efficiency, usually through a combination of medications and lifestyle modifications. Medications typically include diuretics to reduce edema (fluid accumulations), antiarrhythmia medications to maintain the heart's regular rhythm, vasodilator medications to relax the blood vessels and reduce resistance for blood flow, and medications such as digoxin (inotropic medications) to strengthen the heart's pumping effectiveness. It also is crucial to

treat any coexisting or causative cardiovascular disease such as hypertension, ATHEROSCLEROSIS, and CORONARY ARTERY DISEASE (CAD). Such measures allow the majority of people who have cardiomyopathy, particularly dilative cardiomyopathy, to enjoy normal lives.

Progressive cardiomyopathy necessitates substantial lifestyle changes and is a leading cause of disability due to cardiovascular disease. Hypertrophic, ischemic, and restrictive cardiomyopathies are most likely to be progressive. The therapeutic approach is to manage symptoms to the extent possible, making lifestyle adaptations such as reduced physical activity to accommodate diminished CARDIAC CAPACITY. Heart transplantation becomes a treatment option for people under age 65 who are otherwise healthy. Cardiomyopathy accounts for about half of heart transplantations performed in the United States. In some situations an implanted ventricular assist device (VAD) can supplement the natural heart's function, allowing the heart to regain strength and recover from damage. A VAD also can serve as a "bridge" to support the heart while a person waits for a donor heart for transplantation. Sometimes other surgical approaches, such as removing a segment of diseased heart tissue to reduce the size of the ventricle, are successful in restoring the heart's functional ability.

Risk Factors and Preventive Measures

The leading risk factors for most forms of cardiomyopathy are physical inactivity and suboptimal nutrition, which are risk factors for cardiovascular disease in general, as well as excessive alcohol consumption, genetics, and other cardiovascular disease. As with any form of cardiovascular disease, controlling lifestyle factors reduces the risk for the condition. Early GENETIC TESTING can help people who have family history of hypertrophic cardiomyopathy to determine whether they are at risk for this condition and to plan appropriate therapeutic approaches to delay its development. Most people who die suddenly because of hypertrophic cardiomyopathy do not know they have the condition. Keeping chronic cardiovascular conditions such as hypertension and atherosclerosis under control reduces the risk for secondary cardiomyopathy.

cardiopulmonary bypass A procedure in which a machine takes over the oxygenation and pumping functions of the LUNGS and HEART, making OPEN HEART SURGERY possible. Cardiopulmonary bypass allows the cardiovascular surgeon to stop the heart to operate on it, using the bypass machine to circulate the BLOOD through the body. Physician and researcher John H. Gibbon Jr. developed the first cardiopulmonary bypass machine during more than two decades of research and experimentation that culminated in its use to repair a congenital malformation in an 18-year-old woman's heart in 1953. Gibbon's design remains the foundation of cardiopulmonary bypass machines in use today.

In cardiopulmonary bypass, the surgeon inserts large catheters (cannulas) into the VENA CAVA and the AORTA, then administers a chemical solution to cause the heart to stop beating (cardioplegia). The cannulas channel blood through the bypass machine, which uses a membrane oxygenator to infuse the blood with oxygen and allow carbon dioxide to diffuse. Large doses of heparin, an anticoagulant medication, keep the blood from clotting, and special filters capture air bubbles. A pump mechanism, commonly roller pumps or centrifugal force, moves the blood through the bypass machine and in circulation through the person's body. The bypass machine also cools the blood during surgery, to reduce oxygen consumption by maintaining the body's METABOLISM at a lower rate, and warms it at the conclusion of surgery to prepare for returning the body to its own cardiovascular circulation. At the conclusion of the OPERATION the surgeon withdraws the cannulas and restores the flow of blood and the heartbeat.

The primary risks of cardiopulmonary bypass are blood clots and air bubbles that can cause embolism (occlusion of a blood vessel), damage to red blood cells (HEMOLYSIS), and systemic inflammatory response (IMMUNE SYSTEM activation). There is much debate about whether microemboli that

slip through filtration can cause damage to the BRAIN and lungs. Some people experience neurologic effects such as cognitive dysfunction, memory difficulties, and mood swings in the months after cardiopulmonary bypass. Cardiopulmonary bypass also can affect lung function. However, for most people the benefit of the operation cardiopulmonary bypass makes possible outweighs the potential risk for these usually transitory side effects. Cardiovascular surgeons continue to explore new techniques that reduce or eliminate the need for cardiopulmonary bypass, including MINIMALLY INVASIVE SURGERY and off-pump procedures though these, too, carry risks.

cardiovascular disease (CVD) The collective term for the numerous health conditions of the HEART and BLOOD vessels. Cardiovascular disease (CVD) is the leading cause of death and disability in the United States and in many other developed countries. More than 70 million Americans live with CVD; 10 million of them have sufficient disability that they cannot work or participate in the activities they enjoy. CVD claims over 900,000 lives each year. The most common forms of CVD are HYPERTENSION (high BLOOD PRESSURE), ATHEROSCLEROSIS (occluded arteries), CORONARY ARTERY DISEASE (CAD), and ISCHEMIC HEART DISEASE (IHD). Health experts sometimes refer to CAD and IHD collectively as coronary heart disease (CHD).

Most CVD develops as a consequence of lifestyle factors, though age, gender, and genetic predisposition also contribute. The primary risk factors for CVD are

- cigarette smoking
- OBESITY
- physical inactivity
- DIABETES
- renal (kidney) disease
- being a man under age 50
- age over 50 for men and over 60 for women
- family history of CVD

Acquired CVD is largely preventable through lifestyle practices that incorporate nutritious eating habits, daily physical exercise, and not smoking. These practices are also preventive for health conditions that lead to CVD, such as diabetes and obesity. Other forms of CVD may be hereditary or congenital. Hereditary CVD conditions are the result of GENE mutations. CONGENITAL HEART DISEASE results from structural defects in the heart and its major vessels, such as tetralogy of Fallot, or to blood vessels elsewhere in the body, such as ARTERIOVENOUS MALFORMATION (AVM), that occur during early gestational development and are present at birth.

For further discussion of CVD please see the overview section "The Cardiovascular System."

cardioversion The application of an electrical shock through the chest wall to the HEART, administered under sedation, to alter the heart's electrical rhythm. The cardiologist performs cardioversion in a hospital setting staffed and equipped to respond to cardiovascular emergencies. There is a slight risk for HEART ATTACK or STROKE. Cardioversion is most commonly a treatment for ARRHYTHMIA such as ATRIAL FIBRILLATION, in which the heart's electrical patterns have gotten out of synchronization in some way. The effect may be permanent, long-lasting, or short term. Some people experience slight SKIN irritation at the site of the electrodes or paddles on the surface of the chest following cardioversion. Because the procedure requires a general sedative, there may also be grogginess for several hours. Most people go home within 4 to 6 hours and return to their usual activities the following day.

carotid bruit An abnormal sound characteristic of ATHEROSCLEROSIS that the cardiologist hears through a STETHOSCOPE placed over the carotid ARTERY at the base of the neck. The sound, a murmur that occurs during systole (contraction of the left ventricle), represents turbulence as BLOOD passes through areas of the carotid artery where atheromas (collections of ATHEROSCLEROTIC PLAQUE)

occlude the inner channel of the carotid artery. Carotid bruit is a diagnostic sign that indicates the presence of CAROTID STENOSIS (narrowing of the carotid artery) and increased risk for STROKE.

See also ANGIOGRAM; ENDARTERECTOMY; HEART SOUNDS; STENT.

carotid stenosis Narrowing of the carotid ARTERY in the neck due to ATHEROSCLEROSIS. Often carotid stenosis shows no symptoms until it results in a STROKE. The doctor may detect carotid stenosis during routine physical examination when listening to the carotid arteries with a STETHOSCOPE, which reveals the characteristic murmur sound, CAROTID BRUIT, that indicates the stenosis. ANTICOAGULATION THERAPY, most commonly ASPIRIN THERAPY, helps reduce the risk of clot formation at the site of the stenosis though does not prevent or reduce atherosclerotic accumulations. ENDARTERECTOMY, surgery to remove the occluding atheromas (collections of ATHEROSCLEROTIC PLAQUE) and widen the arterial passage, becomes a viable treatment option when the stenosis reaches 60 or 70 percent. ANGIOGRAM, in which the cardiologist uses dye and X-rays to examine the arteries, helps define the degree of occlusion. Stroke occurs when clot or atheroma fragments break free from the site of the stenosis and travel through the carotid artery to the BRAIN.

chest pain Discomfort that arises from the upper portion of the body. CHEST PAIN can have various causes, many of which are not cardiovascular. Discomfort originating from the HEART is characteristically oppressive in nature, though often not the crushing pressure that is the common perception. As many as 25 percent of people do not experience appreciable pain with HEART ATTACK. Gastrointestinal pain often sends people to the emergency room worried about heart attack, yet nearly a third of people who are having heart attacks delay seeking medical care because they do not believe the symptoms they are experiencing, especially chest pain, are severe enough to be heart attack. Chest pain is unreliable as an indicator of the nature or severity of a health situation.

cholesterol blood levels The amounts and forms of cholesterol that are present in the bloodstream, usually measured after 8 to 12 hours of fasting (no food) to accommodate short-term rises that could result from eating. Cholesterol is a sterol, a chemical essential for numerous metabolic functions and necessary for health. Because cholesterol cannot dissolve in the BLOOD, it binds with protein carriers called lipoproteins that suspend it in the blood. Cholesterol becomes a health problem when the amount of cholesterol in the blood cir-

culation exceeds the body's needs. The excess lipoproteins that transport the cholesterol fall out of suspension and infiltrate the inner lining of the arterial walls, forming ATHEROSCLEROTIC PLAQUE. Health factors that increase the risk of elevated lipoprotein-cholesterol blood levels include OBESITY, DIABETES, and HYPERTENSION.

The LIVER produces most of the cholesterol in the blood circulation, manufacturing this necessary chemical from saturated fats and other dietary NUTRIENTS. Dietary cholesterol is a minor factor in this process. The liver continues to manufacture cholesterol as long as it receives the ingredients, via ingested nutrients, to do so. Cells throughout the body also can synthesize cholesterol to meet their needs. The body stores some excess cholesterol, along with other fatty acids (notably triglycerides), in adipose tissue throughout the body. The body can then withdraw this cholesterol when liver synthesis slows. However, adipose tissue can hold only so much. Remaining excess cholesterol stays in the bloodstream.

The liver manufactures the lipoproteins that carry cholesterol as well as triglycerides and phospholipids (collectively called fatty acids or lipids). Different lipoproteins transport the kinds of fatty acids. Very low-density lipoprotein (VLDL) and low-density lipoprotein (LDL) transport some cholesterol and most of the triglycerides. It is the excesses of LDL cholesterol (LDL-C) and VLDL cholesterol (VLDL-C) that create increased cardiovascular health risks. These lipoprotein packages settle out of the blood easily, collecting against the inner walls of the arteries. Over time (typically decades) the lipoproteins, along with other cellular debris that gathers, infiltrates the innermost layer of the arterial wall and forms atherosclerotic plaque. This process is the foundation of ATHEROSCLEROSIS.

High-density lipoprotein (HDL) transports primarily cholesterol. It appears that HDL not only carries cholesterol from the liver but also picks up fragments of cholesterol-bearing LDL and VLDL and returns them to the liver, which disassembles them. Lowering the available lipoproteins in the body reduces the excess circulating in the bloodstream and increases the proportion of HDL cholesterol (HDL-C) to LDL-C/VLDL-C. Cells draw the cholesterol they need from the supply in circulation, helping maintain a healthy balance. Generally, the higher a person's total cholesterol, the higher his or her LDL-C levels.

When the body's nutrient intake is in balance, the liver uses up the nutrient components available to manufacture cholesterol and lipoproteins, sending into circulation the levels that the body can use. "Optimal" blood cholesterol values identify this balance, or lipid homeostasis, in which there is no increased cardiovascular risk in most people. Researchers have recently determined the LDL level to be the most significant in people who have other RISK FACTORS FOR CARDIOVASCULAR DISEASE.

Current lipid-lowering treatment recommendations emphasize LDL-C blood values; the recom-

CHOLESTEROL-LOWERING MEDICATION RECOMMENDATIONS

LDL-C Level	Risk Factor Profile	Target LDL-C Level
< 100 mg/dL	CVD + 2 or more CVD risk factors	100 mg/dL
130–160 mg/dL	CVD	100 mg/dL
160–190 mg/dL	2 or more CVD risk factors	130 mg/dL
> 190 mg/dL	no CVD or risk factors	160 mg/dL
190–219 mg/dL	male under age 35	160 mg/dL
190–219 mg/dL	female premenopause	160 mg/dL

mended LDL-C level depends on risk factors for CARDIOVASCULAR DISEASE (CVD). The higher the cardiovascular risk, the lower the recommended LDL-C level.

- Treatment may use lifestyle (diet and exercise) modification alone, which is effective for meeting LDL-C target levels for many people whose LDL-C blood values are 100–130 milligrams per deciliter (mg/dL) and who have no more than one additional CVD risk factor.
- For people who already have some form of CVD or who have two or more additional risk factors for CVD, treatment combines lifestyle with lipid-lowering medications.
- People who have very high CVD risk and very high LDL-C values may take two or more medications to bring their LDL-C blood levels to a healthier range.

Some cardiologists advocate driving LDL-C levels even lower, to 70 mg/dL, in people who have severe risk for HEART ATTACK or STROKE, such as those who have already had such a cardiovascular crisis and have numerous risk factors for cardiovascular disease. For most people, reaching the LDL-C target means a decrease of 30 to 40 percent.

circle of Willis A looped network (anastamosis) of arteries at the base of the BRAIN. Branches of the internal carotid arteries form the front of the circle and branches of the posterior cerebral arteries form the back of the circle, with smaller arteries, collectively called the communicating arteries, branching from them. The circle of Willis is a unique vascular structure in the body that provides an extended safety net of redundancy for the brain's BLOOD supply; the closest analogous configuration is that of the CORONARY ARTERIES which supply the HEART. Even if damage occurs to one or two of the circle of Willis's anastomosed arteries, blood flow to the brain continues. The base of the skull protects this arterial network. The circle of Willis, because of its complexity, varies anatomically among individuals and is a common site for congenital vascular anomalies (malformations of the blood vessels).

For further discussion of the circle of Willis within the context of cardiovascular structure and function, please see the overview section "The Cardiovascular System."

congenital heart disease HEART conditions, including structural anomalies of the heart, that are present from birth. Some forms of congenital heart disease are mild to moderate and require minimal or one-time intervention to correct. Congenital heart malformations are among the most common BIRTH DEFECTS in the United States. Though still the leading cause of infant death due to birth defects, congenital heart malformations no longer mean certain death. Beginning in the 1950s pediatric cardiology pioneers Alfred Blalock (1899–1964), Helen Taussig (1898–1986), and Vivien Thomas (1910–1985) established many of the operations and surgical techniques that remain in use today to create functional BLOOD flow through malformed hearts. Advances in CARDIOPULMONARY BYPASS and refinements in surgical techniques have made relatively normal lives possible for more than a million children with heart defects born since 1970.

Structural deformities that affect the heart's ability to circulate oxygenated blood result in inadequate oxygen reaching the body's tissues and cause CYANOSIS, a bluish tint to the lips, nail beds, mucous membranes, and SKIN. Doctors collectively refer to these conditions as cyanotic heart disease (sometimes called blue baby syndrome). These conditions are nearly always apparent within 48 hours of birth and typically require fairly immediate intervention (usually surgery). Other forms of congenital heart disease, such as LONG QT SYNDROME (LQTS) and hypertrophic CARDIOMYOPATHY, may not manifest until late childhood or adulthood.

Heart defects may occur in isolation or in combination with GENETIC DISORDERS such as DOWN SYNDROME (trisomy 21) and MARFAN SYNDROME. Heart abnormalities often occur in association with

abnormalities of the skeletal, urinary, and gastrointestinal systems, forming a collection that doctors refer to by the acronym VACTERL: vertebral, anorectal, cardiac, tracheoesophageal, renal, and limb. About 50 percent of infants born with one congenital anomaly among this grouping have at least one other. Researchers believe about 10 percent of congenital heart malformations result from GENE MUTATION or CHROMOSOME abnormalities.

Common forms of congenital heart disease The most common and most easily treatable congenital heart malformations are patent ductus arteriosus (PDA) and septal defects. The ductus arteriosus is an opening between the AORTA and the pulmonary ARTERY in the FETUS that allows fetal circulation to bypass the nonfunctioning LUNGS (the fetus draws oxygen from the mother's blood supply). At birth a sequence of events takes place, initiated with the pressure changes that occur with the infant's first breath, that cause the ductus arteriosus to close. In some infants, especially those born prematurely, the closure does not take place and the ductus arteriosus remains patent, or open. PDA allows oxygenated and deoxygenated blood to mix in the pulmonary artery, with the result that the blood the aorta sends to the body carries only partial oxygenation.

In a septal defect there is an abnormal opening in the septum, or wall, separating the heart's chambers. A septal defect allows blood to move directly between the involved chambers, which disturbs the flow of blood and can result in blood turbulence and pooling as well as reduced OXYGENATION. The most common presentation is atrial septal defect (ASD), in which the opening is between the right and left atria. The opening may be the result of incomplete closure of the foramen ovale, a natural opening between the atria in the fetus that normally closes within 48 hours of birth. ASD may also occur as a malformation of the atrial septum. A ventricular septal defect (VSD) is a malformation of the ventricular septum and results in an opening between the right and left ventricles. A VSD allows oxygenated and deoxygenated blood to mingle, reducing the oxygen content of the blood the left ventricle pumps out to the body.

Atrioventricular (AV) canal defect is a more extensive malformation of the septum in which the atrial septum, the ventricular septum, or the entire septum is missing. The heart becomes essentially a single large chamber with oxygenated and deoxygenated blood mixing freely. Blood going to the body carries insufficient oxygen, and blood going to the lungs is under much higher pressure than the lungs can accommodate. AV canal defect requires surgical repair within the first few months of the infant's life. Though AV canal defect can occur as an isolated malformation it most often occurs in conjunction with Down syndrome, affecting about 25 percent of Down syndrome infants.

Other common congenital heart defects include coarctation of the AORTA (narrowing and irregularities) and malformations of the heart valves such as AORTIC STENOSIS, bicuspid aortic valve, tricuspid atresia, and pulmonary atresia.

Grave malformations of the heart A number of heart malformations are rare, complex, and life-threatening. Their defects are severe and include alterations of the heart's structure that cannot sustain life. They require immediate surgery for survival and usually follow-up operations for further reconstruction. In some cases the only viable long-

term treatment is HEART TRANSPLANTATION. The most frequently occurring of these grave malformations are

- Tetralogy of Fallot, which is a complex of four structural anomalies: VSD, pulmonary artery and valve malformation, aortic displacement (the aorta arises between the ventricles rather than solely from the left ventricle), and hypertrophic left ventricle (thickening of the left ventricle's wall).
- Transposition of the great arteries (TGA), in which the aorta and the pulmonary artery are switched. The aorta arises from the right ventricle instead of the left, carrying the deoxygenated blood from the right ventricle out to the body. The pulmonary artery arises from the left ventricle instead of the right, taking oxygenated blood back to the lungs from the left ventricle.
- Hypoplastic (or hypotrophic) left heart syndrome (HLHS), in which the left ventricle or the entire left heart fails to develop, resulting in essentially a two-chamber heart. The aorta is usually small or deformed. Blood in the heart is a mix of oxygenated and deoxygenated, and the right ventricle pumps to both the lungs and the body.
- Persistent truncus arteriosus, which is a combination of VSD and deformities of the PULMONARY ARTERIES and aorta that disrupts the heart's ability to pump oxygenated blood to the body.
- Anomalous pulmonary venous return, in which the PULMONARY VEINS attach to the right atrium instead of the left atrium, returning oxygenated blood to the same chamber that pumps deoxygenated blood to the lungs. This malformation typically occurs in combination with ASD, so the flow of blood between the atria moves some oxygenated blood into the left atrium and subsequently the left ventricle.

Often, ULTRASOUND during PREGNANCY reveals these significant heart deformities, allowing the neonatal team to be prepared for them at the infant's birth. In many situations initial treatment includes administering PROSTAGLANDINS to maintain a patent ductus arteriosus, which allows some oxygenated blood into the body's circulation.

Congenital heart disease in adults Some forms of congenital heart disease first manifest in adulthood, such as hypertrophic cardiomyopathy and LQTS. Other forms of heart disease in adults may have congenital origins, such as the ARRHYTHMIA disorder WOLFF-PARKINSON-WHITE SYNDROME and some VALVULAR HEART DISEASE. Cardiologists believe that most situations of SUDDEN CARDIAC DEATH reflect undetected congenital heart anomalies, either structural or functional (arrhythmias). With congenital heart disease, whether undetected or previously treated, comes increased risk for ENDOCARDITIS (especially with valve malformations), arrhythmias, and clot formation leading to HEART ATTACK, STROKE, or PULMONARY EMBOLISM.

A growing number of adults had corrective surgery for congenital heart disease as infants or children. Cardiologists do not yet know the long-term effects of these operations or what precautions are necessary to protect cardiovascular health later in life. The generation born in the 1970s was the first to have these options available. As this generation comes into middle age, cardiologists will learn much about how repaired hearts accommodate the routine cardiovascular stresses of life and whether they are more susceptible to acquired forms of heart disease such as CORONARY ARTERY DISEASE (CAD) and HEART FAILURE. At present, the longest survival of infant heart transplantation is 15 years and of adolescent heart transplantation is 16 years. Rejection of the donor heart remains a significant concern, and most cardiologists expect retransplantation will become necessary for most people who receive heart transplants in infancy or childhood.

Symptoms and Diagnostic Path

The most common symptoms of congenital heart disease, notably malformations of the heart, in newborns is cyanosis and difficulty BREATHING. Congenital heart disease not immediately apparent at birth may manifest later in childhood with symptoms such as fainting with physical exertion, shortness of breath with mild activity, slowed growth, rapid heartbeat and respirations, and frequent upper respiratory infections. Young children experiencing shortness of breath often squat, which makes it easier for them to breathe.

Congenital heart disease that manifests in adulthood, such as ASD and hypertrophic cardiomyopathy, often produces symptoms such as PALPITATIONS, shortness of breath, and pulmonary or generalized EDEMA if the heart's pumping capability becomes ineffective (heart failure). The diagnostic path may include ELECTROCARDIOGRAM (ECG), ECHOCARDIOGRAM, and COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI), and CARDIAC CATHETERIZATION.

Treatment Options and Outlook

Minor congenital heart defects may require only watchful waiting. Most ASDs close within 2 years of birth and VSDs by age 7. Septal defects that persist and cause symptoms may require surgery, often via cardiac catheterization to patch the defect. Surgery is the most viable treatment option for most serious malformations of the heart. Surgery may be corrective, in which the OPERATION returns the heart to normal structure and function, or palliative, in which the operation relieves symptoms though does not restore normal structure and function. Surgery may be isolated, in which a single operation corrects the defect, or staged, in which the surgeon performs several sequential operations over a period of time. Some congenital heart malformations require surgery within days of birth, and others within months to 2 or 3 years.

When doctors detect significant congenital defects before or shortly after birth, they often administer prostaglandins to maintain a patent ductus arteriosus. Though in ordinary circumstances a PDA would be a heart defect, in the presence of congenital heart defects PDA allows continued though limited circulation of oxygenated blood to buy time until the infant is stable enough for surgery. In some circumstances the neonatal cardiologist may perform a balloon septostomy to surgically create an ASD, which further allows a mixture of oxygenated and deoxygenated blood to flow from the heart to the body.

Risk Factors and Preventive Measures

Genetic factors are emerging as the likely causes, or at least precipitating circumstances, for many forms of congenital heart disease. There are clear genetic links for conditions such as hypertrophic cardiomyopathy and LQTS, for example, as well as known correlations between specific heart malformations and genetic disorders such as Down syndrome and TURNER'S SYNDROME. As well, the VACTERL constellation of birth defects speaks to genetic underpinnings. Prevention for these kinds of heart problems remains uncertain, though future treatment is likely to include GENE THERAPY.

Some congenital heart malformations occur as the result of maternal infections such as RUBELLA (German MEASLES). Heart defects in infants are more likely to occur with mothers who have DIABETES. Numerous medications, both prescription and over-the-counter, as well as ALCOHOL consumption also cause specific kinds of birth defects. Women who are pregnant or planning to become pregnant should discuss with their doctors any routine medications they take. Many ANTISEIZURE MEDICATIONS and ANTIPSYCHOTIC MEDICATIONS are especially damaging to the developing fetus.

Despite advances in gene technology and knowledge of the body, much congenital heart disease is idiopathic—that is, doctors do not know why it occurs. Studies suggest that folic acid supplementation, which doctors already recommend to reduce the risk for NEURAL TUBE DEFECTS, also reduces the risk for malformations of the heart. Like the neurologic system, the cardiovascular system evolves early in fetal development so most malformations occur in the first weeks of pregnancy. Doctors can detect many heart abnormalities before birth, allowing parents and doctors to make appropriate treatment decisions.

coronary arteries The network of arteries that encircles the HEART to provide its BLOOD supply. The two primary coronary arteries, the right coronary ARTERY and the left coronary artery, branch from the AORTA as it arises from the left ventricle. The left coronary artery is significantly larger and supplies the left heart. It drops along the left atrium, branching at the base of the left ventricle into the left anterior descending (LAD) and circumflex arteries. The circumflex artery wraps behind the heart, further branching into smaller

arteries that trail across the left ventricle. The right coronary artery traverses the right atrium, nourishing the upper right heart. Numerous smaller arteries branch from it, the largest of which is the right marginal artery. The arterial network intertwines across the front of the heart in a network called Vieussens's ring, which is similar in structure and purpose to the CIRCLE OF WILLIS at the base of the BRAIN. The precise pattern of the coronary arteries is unique for each person, however.

The coronary arteries deliver the largest volume of blood to the heart during diastole, the trough phase of the CARDIAC CYCLE during which the ventricles fill with blood, pulling blood from the aortic root as systole draws to a close. About 60 percent of the ventricular ejection goes to the coronary arteries. During systole, the peak of the cardiac cycle during which the ventricles pump blood out, the dynamic forces of the heart's contraction cause the coronary arteries to constrict.

The extensive branching of the coronary arteries provides a fairly substantial level of redundancy for supplying the heart with blood. Even if damage or occlusion blocks one branch or several branches, other arterial branches can deliver blood to the same or nearby areas to cover the deficit. As well, the heart tends to develop collateral circulation in response to arterial damage, a self-repair feature in which new small arteries sprout to extend around the area of damage. These mechanisms can sustain adequate myocardial perfusion (distribution of blood throughout the heart MUSCLE) for a considerable time, even in the face of significant damage to the heart's circulatory structures. As occlusion of the coronary arteries progresses, the collateral circulation of Vieussens's ring extends.

The efficiency of coronary circulation is such that symptoms of oxygen deficiency (notably ANGINA PECTORIS and shortness of breath with exertion) do not become apparent until damage to the coronary arteries drops blood flow to about 30 percent of normal. At this point a cardiologist may recommend ANGIOPLASTY with STENT placement. The standard diagnostic point for the more invasive CORONARY ARTERY BYPASS GRAFT (CABG) is 90 percent or greater occlusion. The symptoms of restricted blood flow become most apparent when occlusion affects the larger branches of the coronary arteries, notably the LAD and circumflex. The primary conditions that affect the coronary arteries are ATHEROSCLEROSIS, called CORONARY ARTERY DISEASE (CAD) when it involves the coronary arteries, and coronary artery spasm, which often results from CAD though may have other causes.

For further discussion of the coronary arteries within the context of cardiovascular structure and function, please see the overview section "The Cardiovascular System."

coronary artery bypass graft (CABG) A surgical OPERATION to replace diseased CORONARY ARTERIES supplying the HEART with BLOOD. Cardiovascular surgeons began performing CABG to treat severe CORONARY ARTERY DISEASE (CAD), typically following HEART ATTACK, in the 1960s. The operation became feasible with refinements in CARDIOPULMONARY BYPASS technology and surgical technique. In the ensuing decades CABG has become one of the most frequently performed operations in the United States, with surgeons performing more than 300,000 a year. The surgeon may use CABG to replace one to five coronary arteries; three or four is most common (triple or quadruple bypass). The most frequently bypassed coronary arteries are the left anterior descending (LAD), which traverses the front of the heart; the circumflex, which wraps around the heart; and their respective branches.

Weighing the Benefits and Risks

Whether CABG is an appropriate treatment choice depends on numerous variables that include the person's age and general health status, degree and extent of occlusion in the coronary arteries, and the presence of other CARDIOVASCULAR DISEASE (CVD). Variables that strongly influence the procedure's success include lifestyle factors such as cigarette smoking, body fat and weight, physical inactivity, and dietary habits. Other health conditions that affect HEALING, such as DIABETES, are also important considerations, as are conditions affecting the LUNGS such as CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD).

Now that several million Americans have had CABG and researchers have accumulated data

spanning four decades, evidence is emerging that calls into question the ultimate effectiveness of CABG in preventing deaths due to CAD. A number of studies indicate that CABG may not extend LIFE EXPECTANCY or improve QUALITY OF LIFE to the degree cardiologists and others believe it does. Researchers continue to explore all dimensions of this debate.

Surgical Procedure

The typical CABG takes 75 to 90 minutes for the surgeon to perform. The first steps in CABG are to open the chest, initiate cardiopulmonary bypass, and stop the heart. The preferred approach for the grafts is to use the person's own blood vessels to reconstruct the occluded coronary arteries. The most viable vessels for this purpose are the right and left internal mammary arteries, which the surgeon exposes when opening the chest to perform the CABG. These arteries are ideal because they do not require additional incisions to obtain, and there is a good supply of arterial circulation to replace them. As well, the mammary arteries are about the same size as the coronary arteries, allowing them to accommodate the demands the coronary circulation will place on them. The surgeon may be able to craft two and sometimes three grafts using both internal mammary arteries. Because of its size and importance to coronary circulation, the LAD is first in line for an arterial graft. The surgeon needs about 6 inches of graft for each coronary ARTERY bypass created.

When the CABG involves more coronary arteries than the mammary arteries can accommodate, the surgeon typically harvests a segment of the saphenous VEIN from the leg, which requires an incision in the groin. Though effective enough, the saphenous vein graft is less than ideal for service as a coronary artery and is more prone to postoperative complications. Although its size makes it a sturdy vessel, the saphenous vein lacks the muscular construction of an artery and has a greater risk of collapsing or closing than does an arterial graft. As well, some people have residual edema and other complications after surgery in the leg from which the surgeon harvests the vein. An alternative practice is to instead harvest segments of arteries from elsewhere in the body for which there is relatively redundant circulation (other arteries to provide blood supply), such as the radial artery or the brachial artery in the arm. When autografts such as these are not possible, the surgeon may use a synthetic material specially treated to resist clotting. However, synthetic grafts are not as reliable as autografts.

The surgeon sutures (sews) one end of the graft into the AORTA above the occlusion and the other end into the coronary artery below the occlusion to establish the bypassed path of circulation. The surgeon does this for each occluded coronary artery. When the internal mammary artery provides the graft, the surgeon needs only to suture at the distal end because the proximal end is already in place. The diseased coronary artery segments stay in place though will no longer carry blood. When finished bypassing the occluded coronary arteries, the surgeon restores blood circulation through the heart and restarts the heart with a chemical solution or an electrical charge. After making sure the grafts are intact and not leaking, the surgeon closes the chest. Wires hold the ribs and sternum in place, while sutures and staples close the layers of MUSCLE and SKIN.

Risks and Complications

CABG entails numerous risks and complications. Though its frequency gives the perception that it is a routine operation, CABG is a significant major surgery during which the surgeon places the person on cardiopulmonary bypass, cuts through the breastbone and several ribs to expose the heart, stops the heart to reconstruct the coronary arteries, and then restarts the heart and closes the chest. Each step carries its own risks. Collectively, the major risks of CABG include

- air emboli (air bubbles that get into the bloodstream and create blockages), causing heart attack, STROKE, or PULMONARY EMBOLISM
- excessive bleeding during surgery
- bleeding when the surgeon restores circulation through the heart
- inability to restart the heart
- inability to wean from the cardiopulmonary bypass machine when surgery is done
- postbypass neurologic damage with residual consequences that may include cognitive dys-

function, memory impairment, and physical dysfunctions such as localized loss of feeling or function
- rapid restenosis (within six months) of the grafts
- collapse of venous grafts

Improved technology is making other treatment options, notably ANGIOPLASTY, increasingly viable. Some studies suggest that angioplasty with STENT placement, which is significantly less invasive and less expensive than CABG, is equally effective for multiple vessel CAD and in a good number of people lasts as long as CABG. On the other side of the debate, clinical results with all-arterial grafts for CABG show increased reliability. As well, advances in microsurgery and endoscopic surgery are making MINIMALLY INVASIVE CARDIOVASCULAR SURGERY increasingly feasible, allowing surgeons to perform minimally invasive direct coronary artery bypass (MIDCAB) procedures using multiple small incisions rather than fully opening the chest. Some surgeons are using "off-pump" procedures, in which the heart continues to function during the operation, to reduce the risk for neurologic and pulmonary side effects. Others are combining angioplasty with MIDCAB in a procedure called hybrid CABG. Researchers and surgeons continue to study these approaches and methods, comparing outcomes to determine the most appropriate options.

Outlook and Lifestyle Modifications

Most people spend three to five days in the hospital and another four to eight weeks recovering at home before making a full return to regular activities. The improvement in cardiovascular function is apparent immediately for most people. Cardiologists typically recommend cardiac rehabilitation for people who have had CABG, to help establish a structure for any necessary lifestyle modifications. The clinical standard for postoperative care now includes medications such as beta blockers and statins, drugs to stabilize HEART RATE and lower cholesterol blood levels, respectively. Statins also appear to have a stabilizing and strengthening action on the heart, with numerous clinical studies showing that people who take statins following CABG have significantly fewer complications, notably heart attack, after surgery. Cardiologists also urge people to eat nutritiously, get a minimum of 30 minutes of physical exercise each day, stop smoking, and lose weight to achieve a healthy BODY MASS INDEX (BMI). Most people experience complete and uneventful recovery from surgery and return to work and the recreational activities that interest them.

coronary artery disease (CAD) ATHEROSCLEROSIS of the CORONARY ARTERIES that reduces BLOOD flow to the HEART. About 14 million Americans have CAD, though many of them do not know it until HEART ATTACK strikes. CAD causes 1.2 million heart attacks and more than 600,000 deaths in the United States every year. Autopsy findings show that two thirds of women and nearly half of men who lose their lives to SUDDEN CARDIAC DEATH had unsuspected CAD. Although CAD is more common in people age 60 and older, it is becoming increasingly common among younger people. Genetic factors may underlie CAD in some people, though most often CAD is an acquired condition that is the direct consequence of lifestyle factors such as cigarette smoking, EATING HABITS, and physical inactivity.

HEART ATTACK is a life-threatening emergency. Call 911 immediately with symptoms or when heart attack is possible. Many people delay, wanting to be sure. Waiting can be fatal.

CAD, like generalized atherosclerosis, develops over decades. Many cardiologists believe CAD begins in childhood. The most commonly affected coronary arteries are the left anterior descending (LAD), the circumflex, and their branches. These coronary arteries provide the blood supply for most of the heart MUSCLE, including nearly all of the left ventricle. CAD may affect the right coronary ARTERY as well. Cardiologists classify CAD according to the number of occluded coronary arteries. A coronary artery can be 70 percent occluded before the restricted blood flow impairs

cardiac function, though cardiologists believe reduced OXYGENATION begins with about 50 percent occlusion. The heart's ability to develop collateral circulation, the growth of new arteries, allows CAD to worsen without overtly affecting cardiac function.

CAD develops when ATHEROSCLEROTIC PLAQUE infiltrates the arterial intima, the innermost layer of the arterial wall, and accumulates into deposits called atheromas. The atheromas cause the arterial wall to thicken, reducing its elasticity and thus its ability to contract and expand in response to blood flow needs. Atheromas also protrude into the channel of the artery, reducing the artery's interior diameter (lumen) and reducing the volume of blood the artery can transport. These factors converge to restrict blood flow to the heart, particularly with exertion (such as during physical exercise), and deprive segments of the heart of adequate oxygenation. The result is ischemia, or tissue HYPOXIA. Typically the ischemia eases with rest, as the heart's demand for oxygen diminishes.

Symptoms and Diagnostic Path

The key symptom of CAD is ANGINA PECTORIS, a pressurelike discomfort or pain originating in the central chest and often radiating up the arm into the jaw and through the shoulder area to the back. At this stage, medical or surgical interventions can head off CAD-induced heart attack. For many people, however, the first indication of CAD is heart attack, which can occur when an atherosclerotic coronary artery ruptures or a blood clot lodges in a section of a coronary artery where CAD has narrowed the passageway. The resulting blockage, or occlusion, interrupts blood flow to a portion of the heart and the heart tissue dies.

CARDIAC CATHETERIZATION and ANGIOGRAM provide definitive diagnosis. These procedures allow the cardiologist to visualize the path of blood through the coronary arteries, highlighting constricted or blocked areas. Severe CAD also causes ARRHYTHMIA (disturbance of the heart's electrical activity), which a person may experience as PALPITATIONS and that show up on ELECTROCARDIOGRAM (ECG). Exercise STRESS TEST, particularly radionuclide testing, reveals the functional limitations resulting from the CAD. ECHOCARDIOGRAM often reveals the dysfunction of the walls of the heart served by diseased coronary arteries, as well as decreased heart function if there has already been damage, and with Doppler ULTRASOUND may show restrictions in the flow of blood.

Some cardiologists use MAGNETIC RESONANCE IMAGING (MRI) to visualize the structure and function of the coronary arteries and the rest of the heart. MRI also detects new collateral circulation (angiogenesis). However, anyone who has a PACEMAKER, IMPLANTABLE CARDIOVERTER DEFIBRILLATOR (ICD), stents, ANEURYSM clips, or other internal metallic objects cannot undergo MRI. An advantage of MRI is its ability to represent dimensional cross-sections of the areas of suspected atherosclerotic accumulation. This reveals the extent to which the CAD has caused the arterial wall to thicken.

A variation of CT scan, ELECTRON BEAM COMPUTED TOMOGRAPHY (EBCT) SCAN, can detect calcification in the arterial walls. Calcification indicates long-standing accumulations of plaque that have solidified within the intima, a sign of well-established CAD that, while perhaps not causing symptoms, is significant enough to pose the risk of heart attack. Of equal, and perhaps greater, concern to cardiologists is the accumulation of soft, unstable atherosclerotic plaque, sometimes called vulnerable atheroma. These soft accumulations appear to cause continued irritation to the arterial wall, with resulting clot formation and the risk that the atherosclerotic plaques will rupture, spilling particles and debris into the blood circulation.

Treatment Options and Outlook

Although CORONARY ARTERY BYPASS GRAFT (CABG) remains the leading treatment for CAD in the United States, cardiologists are moving toward less invasive approaches. CABG is an OPEN HEART SURGERY with numerous risks and complications. A number of studies in the late 1990s and early 2000s raised questions as to whether CABG provides a clear benefit over other treatment alternatives such as ANGIOPLASTY, aggressive lipid-lowering therapy, and significant lifestyle modifications. Cardiologists now implement the latter two methods after CABG, and there is increasing evidence that they are equally effective without CABG. Angioplasty, a cardiac catheterization procedure in which a balloon at the tip of a catheter compresses

the occlusion, remains a popular intervention because it is far less invasive than CABG, requires minimal recovery time, and results in immediate improvement of coronary circulation. However, restenosis (return of the atherosclerotic narrowing) is more the norm than the exception and occurs in a fourth to a third of people within six months. Angioplasty with STENT placement (a tiny springlike device that remains at the site of the occlusion to hold pressure against the arterial wall) fares somewhat better. Treatment options and recommendations continue to evolve as new medications and technologies become available.

The most significant long-term consequence of CAD is damage following heart attack, which may or may not improve with CABG. LEFT VENTRICULAR EJECTION FRACTION (LVEF), a calculation of the percent of blood that leaves the heart with each contraction of the left ventricle, projects the extent of disability resulting from heart attack due to CAD. LVEF above 60 percent generally correlates with little loss of cardiovascular function except with extreme physical exertion. Most people with an LVEF greater than 40 percent can return to work and normal activities. LVEF that drops below 40 percent limits the heart's capacity to meet the body's oxygen needs during moderate physical exertion, and below 20 percent restricts nearly all physical activity.

MAJOR RISK FACTORS FOR CAD

age 50 or older	cigarette smoking
DIABETES	family history of young HEART ATTACK
HYPERLIPIDEMIA	HYPERTENSION
OBESITY	PERIPHERAL VASCULAR DISEASE (PVD)
physical inactivity	

Risk Factors and Preventive Measures

The most clear-cut early warning sign for the development of CAD is HYPERLIPIDEMIA (elevated cholesterol and triglycerides blood levels). Hyperlipidemia indicates dysfunction with the body's lipid synthesis and storage mechanisms, which typically results in accumulations of fatty acids along the inner arterial walls. These accumulations irritate and inflame the artery's intima, establishing the foundation for atherosclerotic plaque development. Numerous studies show that lowering blood lipid levels reduces atherosclerotic accumulations, slowing the progression of CAD. DIABETES, HYPERTENSION, and OBESITY accelerate the progression of CAD. The prevalence of CAD in young people alarms health experts, who emphasize that it is never too early to implement a heart-healthy lifestyle.

An important understanding about CAD is that it is a chronic, lifelong cardiovascular condition. Even with CABG or angioplasty, the disease process continues. Treatments aim to slow the progression but so far are not able to prevent it. Lifestyle changes are imperative for people who want to enjoy extended LIFE EXPECTANCY as well as QUALITY OF LIFE. Though the outlook for controlling CAD has never been brighter, CAD remains a major health concern. Lifestyle modifications to improve cardiovascular health, in combination with medical interventions such as ASPIRIN THERAPY and medications to regulate heart function, can significantly impede CAD's progression.

c-reactive protein A substance the body's tissues release when they become inflamed. Some health experts believe elevated levels of c-reactive protein in the BLOOD may indicate the presence of ATHEROSCLEROSIS. Though cardiologists and researchers have known for some time that inflammatory processes accompany atherosclerosis, studies in the 1990s and early 2000s began to suggest that INFLAMMATION, perhaps due to low-grade INFECTION, might be a contributing cause of atherosclerosis. Elevated blood levels of c-reactive protein in people who have had HEART ATTACKS portend significant increase in risk for subsequent HEART attacks. However, cardiologists are not certain how important elevated c-reactive protein levels are in people who do not appear to have CARDIOVASCULAR DISEASE (CVD). Chronic inflammatory conditions may also elevate c-reactive protein. Cardiologists generally recommend considering a person's level of c-reactive protein in context with other RISK FACTORS FOR CARDIOVASCULAR DISEASE, and base intervention decisions on the overall cardiovascular risk picture.

cyanosis A bluish coloration to the lips, nail beds, and SKIN that indicates inadequate oxygenation. Clinically, cyanosis exists when the oxygen saturation of arterial BLOOD drops below 85 percent. Cyanosis may result from conditions that affect the ability of the LUNGS to oxygenate the blood, such as may occur with CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD), or that affect cardiac function, such as HEART FAILURE or MYOCARDIAL INFARCTION (HEART ATTACK). Cyanosis may also result from severe ANEMIA and other blood disorders that affect the blood's ability to transport oxygen. Poisoning with mercury or silver can cause the skin to take on a bluish hue, as can certain antipsychotic medications. Doctors call this pseudocyanosis because it is not the result of the blood's oxygen levels.

DASH eating plan The acronym for "dietary approaches to stop HYPERTENSION." The DASH eating plan is the result of a pair of clinical research studies and features a diet high in fruits, vegetables, low-fat dairy products, whole grain products, and low in fats (particularly saturated fats) and sodium. Numerous studies correlate dietary habits, particularly sodium consumption, with hypertension. The DASH eating plan is appropriate for anyone to follow to maintain cardiovascular health. The plan, available through health-care providers and online from the National Heart, Lung, and Blood Institute (NHLBI) at www.nhlbi.nih.gov, features menus and extensive food choices to help people plan nutritious meals that help lower BLOOD PRESSURE. It also provides guidelines for transitioning to more heart-healthy eating and other lifestyle habits.

defibrillation A therapeutic method for delivering an electrical shock to the HEART to restore it to a functional rhythm. Defibrillation is an emergency treatment necessary to prevent death resulting from VENTRICULAR FIBRILLATION (rapid, discordant, and ineffective contractions that fail to pump BLOOD out of the heart). The body cannot survive in ventricular fibrillation for longer than a few minutes, making rapid response essential. The most common causes of ventricular fibrillation are MYOCARDIAL INFARCTION, arrhythmic cardiac disease such as LONG QT SYNDROME (LQTS), ELECTROCUTION, and drowning.

In hospital-based defibrillation, a health-care professional (usually a doctor) places paddles or electrodes on the outside of the chest. The defibrillator machine delivers the determined electrical impulse, generally producing a pronounced jolt in the person's body. The desired effect is for all electrical activity in the heart to momentarily cease, then for the heart to resume normal electrical activity to the extent possible in the context of damage that may have occurred to the heart. The doctor may choose to administer multiple charges, depending on the response and the likelihood for successful restoration of a regular HEART RATE.

In the 1990s a basic portable device, the AUTOMATED EXTERNAL DEFIBRILLATOR (AED) became available. AEDs allow virtually anyone to administer a potentially lifesaving electrical shock to someone who is experiencing ventricular fibrillation. The computerized programming of an AED reads the ELECTROCARDIOGRAM (ECG) of the person to confirm the ventricular fibrillation, then delivers a preset electrical shock. AEDs have saved countless lives.

The risks of defibrillation include electrical BURNS to the person being resuscitated and electrical shock or burns to the person administering defibrillation. Burns may occur at the contact points of the paddles or electrodes and also elsewhere on the body where there are items of metal such as jewelry or, in a hospital setting, monitoring electrodes. As well, anyone in contact with the person or with the bed the person is lying on is at risk for contact electrical shock. The success of defibrillation depends on the cause of the ventricular fibrillation, how long the heart has been in ventricular fibrillation, and the person's overall cardiovascular and general health status.

deep vein thrombosis (DVT) The formation of BLOOD clots in the veins, usually the deep or inte-

rior veins in the legs and lower pelvis. Physical inactivity is the primary cause of DVT. The veins, which are not as muscular as the arteries, rely on the skeletal MUSCLES to support them. The contraction and relaxation of skeletal muscles, such as occurs during walking and other physical activities, helps move blood through the veins. This support and massaging action is particularly important for function of the large veins in the legs, which transport significant volumes of blood toward the HEART against pressure that can reach three times the force of gravity.

During periods of extended inactivity the skeletal muscles relax the tension they otherwise would exert against the veins, allowing the flow of blood to become sluggish. When other problems with the veins exist, such as VENOUS INSUFFICIENCY (inadequate function of the valves in the veins) and VARICOSE VEINS, blood may pool. The pooling provides opportunity for the blood to begin clotting, which can cause the localized occlusion and PAIN that characterizes DVT as well as HEART ATTACK, STROKE or PULMONARY EMBOLISM (blood clot in the LUNG) if a particle of the clot breaks away and travels through the bloodstream.

Birth control pills, even low-DOSE formulations, increase the risk for deep vein thrombosis, most significantly in women who also smoke.

The most effective approach for DVT is prevention, which for many people can be as simple as walking for a few minutes every couple hours during the day, even if only around a desk or lifting the legs as if marching in place. Additional risk factors include OBESITY, DIABETES, VARICOSE VEINS, PERIPHERAL VASCULAR DISEASE (PVD), and cigarette smoking. Doctors may recommend ANTICOAGULATION THERAPY as a further preventive measure to reduce the blood's clotting ability for people who are at risk for developing DVT. Though extended airline flights present a well-popularized risk for DVT, less than one tenth of 1 percent of the 2 million Americans who develop DVT do so as a result of flying.

Once the thrombosis, or clot, develops it blocks the flow of blood, which results in a backup of fluid that seeps into the surrounding tissues (edema). The clot also irritates the walls of the VEIN, causing INFLAMMATION. Symptoms of DVT include

- redness and swelling (edema) at the site of the clot
- tenderness or PAIN at the site of the clot
- FEVER and generalized discomfort

The diagnostic path may include ULTRASOUND or VENOGRAM of the suspected occlusion, which typically provides the visualization necessary to confirm the diagnosis. Treatment typically consists of

- anticoagulation therapy to prevent the clot from enlarging or other clots from forming
- bed rest, with heat to the area to improve circulation, until the clot dissolves
- support stockings

People who have one experience with DVT face increased risk for subsequent DVTs and usually take prophylactic anticoagulation therapy to lower the risk. Lifestyle measures such as daily walking and other physical activity, SMOKING CESSATION, and weight loss if necessary are also key to preventing subsequent DVTs.

diabetes and cardiovascular disease A leading consequence of DIABETES (type 1 or type 2) is CARDIOVASCULAR DISEASE (CVD), and diabetes is a leading cause of cardiovascular disease. The extent to which diabetes and cardiovascular disease intertwine has caused some health experts to view diabetes as a form of cardiovascular disease. Among people with diagnosed diabetes, more than 95 percent have some form of cardiovascular disease, the most common being HYPERLIPIDEMIA (elevated BLOOD levels of cholesterol and triglycerides) and HYPERTENSION (high BLOOD PRESSURE).

Diabetes causes numerous changes in the body that influence or accelerate the development of cardiovascular disease. Key among them are

- dysfunctions of lipid METABOLISM that result in elevated blood levels of low-density lipoprotein

cholesterol (LDL-C) and very low density lipoprotein cholesterol (VLDL-C), and lowered blood levels of high-density lipoprotein cholesterol (HDL-C)

- altered myocardial cell structure and activity, resulting in CARDIOMYOPATHY (myocardial dysfunction)
- increased levels of fibrinogen and clotting substances that increase the blood's tendency to clot, raising the risk for STROKE and HEART ATTACK
- elevated blood GLUCOSE levels damage peripheral blood vessels and the nerves that supply them, raising the risk for PERIPHERAL VASCULAR DISEASE (PVD)
- damage to the glomerular structures of the KIDNEYS, resulting in NEPHROPATHY of diabetes and its slate of complications, key among them being hypertension

Cigarette smoking, itself a significant risk factor for cardiovascular disease, doubles the cardiovascular risk of diabetes in people who smoke and have diabetes. Increasing age is a risk factor for both diabetes and cardiovascular disease. As well, diabetes slows HEALING, increasing the risk for complications with surgical treatment options for forms of cardiovascular disease such as CORONARY ARTERY DISEASE (CAD).

Early diagnosis of INSULIN RESISTANCE with lifestyle and medication, if appropriate, to delay its progression to type 2 diabetes, improves the cardiovascular risk. Once diabetes develops, meticulous control of blood glucose levels slows many of the changes that create increased risk for cardiovascular disease. Aggressive medical interventions such as lipid-lowering medications, ASPIRIN THERAPY, and antihypertensive measures (lifestyle, medication, or both) help moderate risks related to changes in lipid, clotting, and blood pressure mechanisms.

Health experts recommend these targets for people who have diabetes to lower their risk for cardiovascular disease:

- A1c (also called HbA1c or glycohemoglobin)—6 percent or lower (indicates blood glucose levels over time)
- blood pressure—129/79 millimeters of mercury (mm Hg) or lower
- LDL-C —100 milligrams per deciliter (mg/dL) or lower
- BODY MASS INDEX (BMI)—24.9 or lower (healthy weight)
- no smoking
- 30 minutes of moderate physical exercise (such as walking) daily

With diligent control of diabetes and efforts to reduce cardiovascular disease risks, most people who have diabetes can achieve near-normal cardiovascular health for years to decades.

diet and cardiovascular health The influence of eating habits and food consumption on the health and function of the cardiovascular system. Researchers first conclusively connected diet with cardiovascular health in the 1950s when they recognized that dietary fat was a key source of cholesterol for the body. Health experts issued the first statements about this correlation in the early 1960s. Though researchers now understand much more about how the body acquires and uses NUTRIENTS, they continue to investigate the ways in which dietary factors, independent of as well as in conjunction with other lifestyle variables such as physical exercise, affect cardiovascular health. Much of this research has focused on the role of dietary cholesterol and fats, as excesses of these nutrients in the body are key RISK FACTORS FOR CARDIOVASCULAR DISEASE (notably ATHEROSCLEROSIS).

Through the years doctors have recommended various "diets" (proportions and restrictions of nutrients) to support cardiovascular health and reduce the risk for CARDIOVASCULAR DISEASE (CVD). Research has shown, however, that variety and moderation are factors most important for meeting the body's nutritional needs. The body needs carbohydrates, proteins, and fats—the core nutrients—in varying proportions according to age, activity level, and other variables. Rather than focusing on these proportions, however, health experts recommend instead shifting emphasis to the kinds of foods consumed to

- eat more vegetables, fruits, whole grain products, low-fat dairy products, lean meats (especially fish and poultry)
- eat fewer processed foods, which tend to be high in fats, carbohydrates, and sodium
- balance the number of calories consumed with the number of calories expended through physical exercise

Many people consume far more fats and carbohydrates than they realize, so returning to nutritionally balanced EATING HABITS may at first seem restrictive in the context of a "diet." Portion size is a significant factor as well. The intent of HEART-healthy eating is to supply the body with the nutrients it needs through food choices that appeal to the individual.

The body also needs a wide range of vitamins and minerals to carry out its functions and processes. Minerals such as calcium, potassium, sodium, and magnesium are additionally important for cardiovascular function. These minerals, called electrolytes because they conduct electrical current, facilitate and regulate the electrical activity in the HEART that causes it to contract. The KIDNEYS also use electrolytes to adjust the body's fluid balance, a key aspect of BLOOD PRESSURE regulation. Excessive electrolyte consumption (such as sodium, the primary ingredient of table salt) or insufficient electrolyte consumption (such as results with prolonged VOMITING and DIARRHEA) alters the body's fluid balances, which affects blood pressure and cardiac workload.

In recent years much attention has focused on nutrients that appear to inhibit or even prevent disease processes. Key among them in regard to cardiovascular health are ANTIOXIDANTS, omega fatty acids, and SOY. Antioxidants are chemicals that counter the effects of oxidation, a normal dimension of METABOLISM, in the body. Oxidation represents "spent" fuel, the remnants of energy generation. Oxidation produces molecular fragments called free radicals that randomly attach themselves to other molecules. When they do so, they create molecular structures that are not useful to the body. Researchers believe the accumulation of free radicals is a dominant factor in health conditions such as atherosclerosis and CORONARY ARTERY DISEASE (CAD). Antioxidants bind with free radicals, creating molecular structures the body can eliminate as cellular waste. Vitamins A, C, and E contain antioxidants that may slow the progress of atherosclerosis. Another ANTIOXIDANT, COENZYME Q10, also appears to have a measurable effect in slowing atherosclerotic processes.

Omega fatty acids are polyunsaturated fats—the "good" fats—that help to lower low-density lipoprotein cholesterol (LDL-C) and also help to prevent ATHEROSCLEROTIC PLAQUE from accumulating. Sources of omega fatty acids are cold-water fish such as tuna, salmon, mackerel, lake trout, herring, and sardines. Soybeans and soy-based foods such as tofu contain alpha linolenic acid (ALA), which is an omega fatty acid precursor (the body can convert it to omega fatty acid).

echocardiogram A noninvasive, diagnostic ULTRASOUND examination of the HEART that can show the heart's structure and, when combined with Doppler technology, the flow of BLOOD through the heart's chambers and the CORONARY ARTERIES. Echocardiogram is most effective for evaluating VALVULAR HEART DISEASE and structural malformations of the heart such as major congenital deformities, septal defects, and patent ductus arteriosus (PDA).

There is no preparation for a echocardiogram, which uses soundwaves to create visual images. For a transthoracic echocardiogram (TTE), the ultrasonographer places a small amount of gel on the SKIN of the chest to improve contact with the transducer, the device that sends and receives the sound signals. The ultrasonographer then moves the transducer over the surface of the skin. For a transesophageal echocardiogram (TEE), the ultrasonographer numbs the back of the THROAT and passes a narrow cable with a transducer at the tip down the throat into the ESOPHAGUS. A TEE places the transducer as close as possible to the heart, usually to obtain specific images such as to detect septal defects or certain valve malformations.

A computer converts the sound signals into two- or three-dimensional images. Typically the cardiologist does an ELECTROCARDIOGRAM (ECG) at the same time, to correlate the visual images from the echocardiogram with the heart's electrical activity. Sometimes the cardiologist will combine the echocardiogram with an injection of dye, administered intravenously, to better highlight the inner structures of the heart. Echocardiogram or TTE takes 10 to 20 minutes and there is no recovery time necessary after the procedure. People undergoing TEE generally receive sedation before the procedure begins so go to a recovery area after the TEE until fully awake from the sedative and the cardiologist is satisfied there will be no adverse effects.

CONDITIONS ECHOCARDIOGRAM CAN HELP DIAGNOSE OR MONITOR

AMYLOIDOSIS	aortic ANEURYSM
AORTIC STENOSIS	CARDIAC TAMPONADE
CARDIOMYOPATHY	congenital heart malformations
ENDOCARDITIS	HEART FAILURE
HEMACHROMATOSIS	mitral valve prolapse
MYOCARDIAL INFARCTION	MYOCARDITIS
MYXOMA	patent ductus arteriosus
PERICARDITIS	PRIMARY PULMONARY HYPERTENSION
septal defect	VALVULAR HEART DISEASE

ectopic beat An extra or additional heartbeat. Ectopic beats can be atrial, called premature atrial contractions (PACs), or ventricular, called premature ventricular contractions (PVCs). PACs are nearly always benign (do not require treatment). Though most PVCs are also benign, persistent PVCs can cause symptoms that do require treatment. CAFFEINE is a common cause of ectopic beats. ALCOHOL use, cigarette smoking, and illicit drugs also can cause or exacerbate ectopic beats.

The most common symptom of ectopic beat is PALPITATIONS, the perception of the heart jumping or skipping a beat though it actually does neither. Ectopic beats are premature—that is, they are normal contractions that occur before their normal rhythm in the CARDIAC CYCLE. The beat that follows, also a normal beat, then feels intensified. An ELECTROCARDIOGRAM (ECG) shows the heart's electri-

cal pattern, including ectopic beats. Their place in the cardiac cycle and their frequency determine whether ectopic beats are part of an ARRHYTHMIA that is potentially harmful. When this is the case, the cardiologist will conduct further diagnostic testing to determine the underlying causes and guide treatment decisions.

Though ectopic beats are really not preventable, reducing factors that contribute to irregularities in the heartbeat, such as caffeine consumption, often help significantly reduce their occurrence.

electrocardiogram (ECG) A noninvasive diagnostic procedure that converts the heart's electrical activity into patterns of signals typically recorded on paper or displayed on a screen. The ECG is the cornerstone of cardiovascular diagnosis. The normal HEART generates a consistent electrical pattern; nearly anything that goes wrong with the heart shows up on an ECG. A normal heart rhythm produces five predictable fluctuations, called waves, that doctors identify by the letters P, Q, R, S, and T. The main thrust of cardiac activity, ventricular contraction, is the QRS complex.

ECG TRACING

P wave	sinoatrial (SA) node's pacing impulse initiates the CARDIAC CYCLE
Q wave	pacing impulse arrives at the ventricular apex
R wave	main ventricular contraction
S wave	completion of ventricular contraction
T wave	heart's return to readiness for the next cardiac cycle

Reasons for Doing This Test

ECG is a common procedure to assess the function of the heart. It can be baseline, diagnostic, or monitoring. A baseline ECG is generally part of a ROUTINE MEDICAL EXAMINATION and establishes a record of the heart's activity when the heart is presumably healthy. A baseline ECG provides a standard for comparison should there be cardiovascular symptoms the cardiologist needs to evaluate. The cardiologist does a diagnostic ECG to examine the heart's electrical activity as it may correlate to symptoms the person is experiencing. The most common symptoms for which doctors conduct diagnostic ECGs are CHEST PAIN and PALPITATIONS. A monitoring ECG checks the heart's rhythm as a means of evaluating whether medications are working effectively to treat ARRHYTHMIA or to determine whether the heart's function is stable following heart surgery or a cardiac crisis such as HEART ATTACK.

Preparation, Procedure, and Recovery

It is a good idea to avoid CAFFEINE and cigarettes for an hour or so before a scheduled ECG. Doctors generally prefer for ECG to show the heart at rest and prefer people not engage in strenuous exercise within four hours of ECG. Otherwise, ECG requires no preparation and may take place in the doctor's office, at a cardiovascular testing facility, or a hospital. The person lies quietly on a gurney or procedure bed and the ECG technician places about a dozen electrodes on the chest, back, arms, and legs. Talking or moving during the ECG can produce electrical "static" from the muscles. A typical ECG takes about five minutes to complete. Though the reading is immediately available, a cardiologist must interpret it and usually it takes a day for the doctor to report the results back for a routine ECG. The person may go home after the ECG recording is finished.

Variations on the standard ECG procedure include

- Holter monitor or ambulatory ECG, which uses a small, battery-operated unit the person wears on a shoulder strap or belt to monitor the heart's electrical activity over a period of time, typically 24 hours (an ECG technician places the electrodes on the person's chest and back and connects them to the unit)
- Exercise ECG, in which the person walks at varying paces on a treadmill or rides a stationary bicycle while the ECG records the heart's changes in rhythm
- Event ECG, in which the person wears electrodes attached to a small, battery-operated unit that the person turns on during a cardiac event such as palpitations

Risks and Complications

There are no risks or complications associated with ECG. Sometimes the ECG technician must shave a small area of SKIN to allow good electrode contact. Some people who are highly sensitive to adhesive may have a slight skin reaction to the adhesive pad that holds the electrode in place. And some people quickly chill when lying on the procedure table; the ECG technician can cover the person with a warm blanket for improved comfort and to prevent shivering, which can distort the ECG reading. ECG only detects and records the electrical activity of the heart; it does not send any electrical impulses to the heart.

electrophysiology study (EPS) A diagnostic procedure in which the cardiologist inserts electrodes into the HEART to measure the heart's rhythm and response to various stimuli. The EPS is similar to CARDIAC CATHETERIZATION and provides information to help diagnose disorders of ARRHYTHMIA. The EPS takes place in a hospital or cardiac catheterization laboratory setting and is a same-day procedure for most people. Preparation consists of no food or drink the night before the procedure. The person undergoing the EPS needs a family member or friend to drive to and from the hospital.

After administering a general sedative and a local anesthetic, the cardiologist threads several catheters through an incision in the groin into the femoral vein and then through the arterial network to the heart, watching their progress via FLUOROSCOPY. Once in the heart, the leads on the tips of the catheters send back electrical impulses similar to an ELECTROCARDIOGRAM (ECG). The cardiologist may administer medications or mild electrical impulses to assess the heart's response and ability to return to a normal rhythm.

An EPS takes three to four hours to complete. After the procedure is over, the person goes to a recovery area until he or she is fully awake from the sedative and the cardiologist is satisfied there will be no adverse effects. Sometimes the cardiologist will want the person to stay overnight in the hospital for cardiovascular monitoring. Most people experience mild to moderate discomfort in the groin area where the cardiologist inserted the catheters, and occasionally this is the site for post-procedure bleeding. The EPS provides comprehensive information about the heart's electrical activity.

endarterectomy An OPERATION to surgically remove accumulations of ATHEROSCLEROTIC PLAQUE (atheromas) from the arteries. The most common site for endarterectomy is the carotid arteries, which carry BLOOD to the head and BRAIN. Endarterectomy is a major surgery done under general ANESTHESIA, typically with 24 to 48 hours of inpatient hospitalization following the OPERATION. During endarterectomy, the surgeon makes a small incision through the SKIN and into the ARTERY at the site of the atheroma, briefly stops the flow of blood through the artery and removes the atheroma, restores blood flow, and sutures the artery closed. Depending on the location and size of the atheroma the surgeon may place a shunt in the artery to allow blood to flow around the site of the atheroma during the operation. The shunt maintains blood supply to the brain and helps prevent atherosclerotic fragments from escaping into the blood flow to the brain.

Endarterectomy is a fairly high risk procedure because of the potential for dislodging fragments of the atheroma during the procedure. When this happens, there is no way to prevent the fragments from traveling up the carotid artery to the brain where they cause STROKE. About 3 percent of people who undergo endarterectomy experience stroke, ranging in severity from imperceptible symptoms to disability or death. Cardiologists recommend endarterectomy when the occlusion is 80 to 99 percent. Studies show that endarterectomy can lower the risk for stroke even when CAROTID STENOSIS does not cause symptoms, though because of the risk that the operation itself can result in stroke, some cardiologists recommend surgery only when the blockage causes symptoms.

endocarditis INFLAMMATION of the ENDOCARDIUM, the lining of the HEART. Viral or bacterial INFECTION

can cause endocarditis; either is potentially life threatening, though bacterial infection is considerably more common. Bacterial endocarditis is a particular risk for people who have certain forms of CARDIOVASCULAR DISEASE (CVD) and may follow bacterial infection in other parts of the body. Pathogenic (infection-causing) BACTERIA may also enter the BLOOD circulation during dental, diagnostic, and surgical procedures that cause bleeding. Endocarditis also occurs as a complication following valve repair or replacement surgery.

CARDIOVASCULAR CONDITIONS THAT INCREASE RISK FOR ENDOCARDITIS

cardiopulmonary shunt	cyanotic CONGENITAL HEART DISEASE
HEART TRANSPLANTATION	hypertrophic CARDIOMYOPATHY
mitral valve prolapse	previous bacterial endocarditis
prosthetic heart valves	RHEUMATIC HEART DISEASE
uncorrected congenital heart malformations	VALVULAR HEART DISEASE

Symptoms may include COUGH, shortness of breath (DYSPNEA), and CHEST PAIN. Mild to moderate FEVER, weight loss, night sweats, and JOINT pain are also common. Symptoms vary with the location and nature of the infection and are often vague, making it challenging for doctors to connect them to the heart. The diagnostic path includes blood cultures to determine the presence of bacteria and ECHOCARDIOGRAM to affirm the inflammation.

Treatment for bacterial endocarditis is intensive antibiotic therapy, administered intravenously in a hospital inpatient setting. Treatment for viral endocarditis is supportive, sometimes requiring hospitalization to administer intravenous fluids and medications to ease the heart's workload until the infection runs its course. Complications of either form include endocardial abscesses, valvular abscesses, and damage to the heart valves. With appropriate treatment most people recover, though some may have residual consequences (such as valve disease) and increased risk for subsequent infections.

endocardium The membrane that lines the inner HEART, made up of epithelial cells. The endocardium also covers the heart valves, providing a smooth surface that offers no opportunity for BLOOD cells (particularly platelets) to stick to it as they pass through the heart. The endocardium contains Purkinje fibers, specialized MUSCLE cells that convey the electrical impulses that cause the heart to contract, and collagen fibers, which give the endocardium elasticity. The endocardium is vulnerable to damage from conditions such as RHEUMATIC HEART DISEASE and VALVULAR HEART DISEASE. These conditions can cause irritation that inflames the endocardium, making it susceptible to bacterial INFECTION (ENDOCARDITIS).

For further discussion of the endocardium within the context of cardiovascular structure and function, please see the overview section "The Cardiovascular System."

enhanced external counterpulsation (EECP) A therapy for ANGINA PECTORIS that uses sequential inflation and deflation of cuffs on the legs and pelvis to assist in returning venous BLOOD to the HEART and decreasing cardiovascular resistance in the peripheral arteries. EECP reduces the heart's workload during systole, when the ventricles contract, and increases pressure in the peripheral arterial network during diastole, when the ventricles fill. The net effect is that the body's tissues, including the heart, receive more blood and thus more oxygen with less work from the heart.

Researchers arrived at the concept of EECP in the 1950s. Initial therapeutic efforts were invasive, withdrawing blood from the femoral veins and then returning it. Through the ensuing decades researchers arrived at the method of using compression cuffs around the calves, thighs, and pelvis, alternately inflating and deflating them in a sequence timed with the CARDIAC CYCLE. The cuffs inflate sequentially from the calves to the pelvis during diastole and deflate rapidly and simultaneously during systole. A computer monitors the cardiac cycle via ELECTROCARDIOGRAM (ECG) and coordinates the inflation and deflation of the cuffs accordingly. A therapeutic course involves one hour of EECP daily for 35 hours (typically five days a week for seven weeks), performed at a cardiac clinic or hospital. Most people experience relief from angina for months to 2 or 3 years.

EECP is most appropriate for people who are not receiving adequate relief from medications and would benefit from CORONARY ARTERY BYPASS GRAFT (CABG) but cannot, or choose not, to undergo the surgery. EECP is not appropriate for people who have uncontrolled HYPERTENSION or ARRHYTHMIA or who have bleeding disorders. There are no identified risks associated with EECP. Some people do find the pressure of the counterpulsations somewhat uncomfortable.

fibroelastoma A noncancerous, connective tissue tumor that arises from the ENDOCARDIUM, usually on or near a HEART valve. Also called cardiac papillary fibroelastoma, this rare tumor can become serious or life threatening when it interferes with the function of a heart valve. Fibroelastomas most commonly form on or near the aortic valve or the tricuspid valve. They may become large enough to prevent the valve's proper function or to block the flow of BLOOD through the valve. A fibroelastoma may also create turbulence in the heart, allowing blood to pool and clot. Generally fibroelestomas cause no symptoms and cardiologists may detect them incidentally during echocardiogram for other purposes. Because fibroelastomas pose such a significant risk for clotting and STROKE, cardiologists typically recommend surgery to remove them. Cardiologists do not know what causes fibroelastomas, though there is some debate whether they are congenital or acquired.

gallop A pair of extra HEART SOUNDS the cardiologist can hear with the bell of the STETHOSCOPE during diastole, so-named because they occur in rapid succession and sound like the hooves of a galloping horse. The characteristic sound is that of a deep-toned thud. A gallop often exists with tachycardia (rapid, regular HEART RATE) and generally signals ventricular dysfunction such as might follow HEART ATTACK.

heart The organ that pumps BLOOD and maintains circulation. About the size of a closed fist, the heart resides in the chest between the LUNGS, slightly offset to the left behind the protective STERNUM (breastbone). It begins beating at about 3 weeks gestational age and during a typical life time contracts about 2.5 billion times. The heart's four chambers contract in coordinated sequence to pump blood to the lungs and to the body, circulating the body's 5- to 6-liter blood supply through the network of arteries and veins of the cardiovascular system up to three times a minute. Synchronized electrical impulses orchestrate the contractions. One-way valves direct the flow of blood into, through, and out of the heart. The right heart handles deoxygenated blood; the left heart handles oxygenated blood.

The heart's blood supply comes from the CORONARY ARTERIES, which arise from the root of the AORTA and encircle the heart. The heart has a substantial oxygen appetite; the coronary arteries deliver 20 percent of the body's blood supply and 70 percent of the blood's oxygen content to the heart. The heart is a remarkably sturdy and reliable structure that can withstand significant damage and still function adequately to supply the body's needs for oxygen and other nutrients.

For further discussion of the heart within the context of cardiovascular structure and function, please see the overview section "The Cardiovascular System."

heart attack The interruption of cardiovascular function. The most common cause of HEART attack is MYOCARDIAL INFARCTION, a blockage of the CORONARY ARTERIES, usually with a BLOOD clot, that disrupts the flow of blood to the heart (MYOCARDIUM). Other causes of heart attack include ARRHYTHMIA, systemic HYPOXIA (such as may occur with drowning or carbon monoxide poisoning), and ELECTROCUTION. About 1.3 million Americans experience heart attacks each year, and 40 percent of them die as a result. Health experts believe significantly more people could survive heart attack with early treatment. Up to 60 percent of people who die from heart attack do so before ever reaching a hospital.

When symptoms suggest heart attack:

- **Call 911**
- **If the person is conscious, have him or her chew an aspirin**
- **If the person is unconscious, has no PULSE or is not BREATHING, begin CARDIOPULMONARY RESUSCITATION (CPR)**
- **Continue CPR until medical help arrives**

When the heart is not beating or cannot beat effectively, oxygen does not get to the body's tissues. Within seconds the body begins to shut down nonessential functions. The BRAIN and the heart itself are the most vulnerable to damage resulting from lack of oxygen; their cells begin to die within three minutes. Immediate CARDIOPULMONARY RESUSCITATION (CPR) can restore OXYGENATION and prevent permanent damage or death. However, the likelihood of survival diminishes by about 10 percent for each minute that passes following the heart's stoppage.

Symptoms and Diagnostic Path

Symptoms vary far more widely than most people realize. The classic symptoms of heart attack are

- intense chest pressure, often crushing
- rapid BREATHING
- profuse sweating (diaphoresis)
- PAIN that radiates from the chest up the left arm
- difficulty breathing or shortness of breath

Many people, and especially women, do not experience classic heart attack symptoms. Instead, their symptoms are more generalized. The danger is that they delay seeking treatment because they are unsure whether they are having a heart attack. Such a delay can be the difference between surviving and dying from a heart attack. Nonclassic heart attack signs include

- NAUSEA and occasionally VOMITING associated with a sense of queasiness
- persistent indigestion (DYSPEPSIA)
- unexplainable anxiety
- vague discomfort in the chest, neck, jaw, or back
- lightheadedness

Warning signs that persist for five minutes require immediate medical assessment. More people survive heart attacks than do not, and more people could survive heart attacks if they received prompt medical treatment. Cardiologists recommend chewing an aspirin tablet at the first signs of possible heart attack, which helps slow the clotting process.

The diagnostic path begins with ELECTROCARDIOGRAM (ECG), which shows the heart's electrical patterns and can usually identify the location of the disrupted function. Regardless of cause, heart attack produces arrhythmias (irregularities of the HEART RATE). Blood tests to measure electrolyte levels and certain proteins that a damaged heart MUSCLE releases also help point to the diagnosis. ECHOCARDIOGRAM can show areas of structural damage to the heart, and CARDIAC CATHETERIZATION with ANGIOGRAM can identify the precise sites of occlusions in the coronary arteries.

Treatment Options and Outlook

Treatment begins with stabilizing the heart's function, which may require various medications including antiarrhythmia medications and drugs that strengthen the heart while reducing the force of its contractions. DEFIBRILLATION may be necessary to restore a functional rhythm to the heart. When doctors can determine within three hours that the cause of the heart attack is a blood clot, they may choose to administer thrombolytic medications ("clot busters") to dissolve the clot as well as anticoagulant medications to prevent further clots. Beyond three hours, thrombolytic medications are not effective. Supportive measures include OXYGEN THERAPY to increase the amount of oxygen in the blood and intravenous fluids to maintain HYDRATION and restore electrolyte balance.

Once the heart recovers, the cardiologist may recommend interventions such as ANGIOPLASTY or CORONARY ARTERY BYPASS GRAFT (CABG) to restore adequate circulation to the heart. Other treatments typically include medications to help regulate the heartbeat and strengthen the heart, and lifestyle modifications for improved cardiovascular health. Treatment also targets any identified underlying causes of the heart attack such as HYPERTENSION (high BLOOD PRESSURE) and ATHEROSCLEROSIS. Current treatment protocols recommend nearly everyone who has a heart attack take statin medications afterward. Statins are lipid-lowering medications that can reduce CHOLESTEROL BLOOD LEVELS, notably low-density lipoprotein cholesterol (LDL-C) by 30 to 40 percent within three months. Statins also help strengthen the heart. Other medications may include beta blockers or calcium channel blockers to lower blood pressure and regulate rhythm.

Depending on the heart attack's severity (the extent of damage to the heart), a person may return to regular activities within a few weeks or require several months to recuperate. Most people benefit from a structured CARDIAC REHABILITATION program.

Risk Factors and Preventive Measures

The primary risk factors for heart attack are CORONARY ARTERY DISEASE (CAD) and hypertension. Many people are unaware that they have either one, so heart attack becomes the first recognition that these conditions exist. Regular ROUTINE MEDICAL EXAMINATION, including tests to measure cholesterol blood levels and blood pressure, help detect these conditions in their early stages, when therapeutic intervention can thwart their progression to life-threatening events such as heart attack and STROKE. Key preventive measures include daily physical exercise, nutritious eating habits, WEIGHT LOSS AND WEIGHT MANAGEMENT, SMOKING CESSATION, and management of conditions such as hypertension and DIABETES.

heart failure The inability of the HEART to adequately pump BLOOD. Heart failure may affect the right heart (pulmonary circulation), left heart (body circulation), or total heart. Heart failure, occasionally called by its antiquated name dropsy, is a consequence of longstanding CARDIOVASCULAR DISEASE (CVD) that has damaged the structure of the heart. About 5 million Americans live with heart failure.

CONDITIONS THAT CAN CAUSE HEART FAILURE

ATHEROSCLEROSIS	CARDIOMYOPATHY
certain arrhythmias	CONGENITAL HEART DISEASE
CORONARY ARTERY DISEASE (CAD)	HEART ATTACK
HYPERTENSION (high BLOOD PRESSURE)	long-term ALCOHOL abuse
PRIMARY PULMONARY HYPERTENSION	VALVULAR HEART DISEASE

Symptoms and Diagnostic Path

The key symptoms of heart failure are shortness of breath (DYSPNEA) and fluid retention (edema). Because symptoms come on gradually as the heart failure progresses, many people are unaware of them until they notice fatigue, weakness with exertion, rapid or unexplained weight gain, and frequent URINATION. Right heart failure tends to produce peripheral edema (swelling of the lower legs, ankles, and feet). Left heart failure tends to produce central edema (fluid accumulation in the LUNGS), also known as congestive heart failure. Progressive heart failure generally affects the total heart, though right or left failure may be dominant. The diagnostic path typically includes chest X-RAY, which shows fluid accumulation in the lungs and enlargement of the heart, as well as ELECTROCARDIOGRAM (ECG) to assess the heart's electrical activity. Heart failure often causes ARRHYTHMIA. ECHOCARDIOGRAM shows the heart's function and size.

Treatment Options and Outlook

Treatment targets any causative cardiovascular conditions, such as CORONARY ARTERY DISEASE (CAD) and HYPERTENSION. Surgery may correct valve dysfunctions or previously undetected congenital abnormalities such as septal defect. Medications can effectively manage heart failure for many years, allowing people to work and enjoy recreational activities. However, as heart failure progresses, it imposes greater restrictions on physical activity. People who have end-stage heart failure may benefit from a ventricular assist device (VAD), a mechanical pump implanted in the chest cavity that aids the heart in pumping blood. This allows the heart to rest and sometimes to recuperate. The VAD also can serve as a bridge to HEART TRANSPLANTATION, another treatment option for end-stage heart failure.

Risk Factors and Preventive Measures

Underlying cardiovascular conditions are the most important risk factors for heart failure, particularly those that are undiagnosed or poorly managed (notably hypertension and CAD). Lifestyle measures to prevent cardiovascular disease, such as daily physical exercise and not smoking, reduce the likelihood of heart failure as well. CARDIAC REHABILITATION following heart attack can restore heart function to the extent possible. Other preventive measures include careful management of

MEDICATIONS TO TREAT HEART FAILURE

Medication Type	Representative Medications	Effects
angiotensin II receptor inhibitors	losartan, valsartan, telmisartan	dilate arteries; lower BLOOD PRESSURE
angiotensin-converting enzyme (ACE) inhibitors	captopril, enalapril, ramipril, benazepril, monopril	dilate arteries; lower blood pressure; slow progression of HEART FAILURE
anticoagulants	warfarin, heparin, aspirin	reduce blood's tendency to clot
beta blockers	carvedilol, metoprolol, propranolol, sotalol, timolol	regulate HEART RATE
calcium channel blockers	amlodipine	dilate arteries; lower blood pressure
diuretics	hydrochlorothiazide, furosemide, bumetanide, metolazone	reduce fluid accumulations (edema)
inotropics	digoxin, digitoxin	strengthen heart MUSCLE; decrease heart's workload
vasodilators	nitroglycerin, isosorbide, hydralazine, minoxidil	relax and open blood vessels

conditions such as DIABETES and OBESITY (including WEIGHT LOSS AND WEIGHT MANAGEMENT) that can lead to cardiovascular disease.

heart murmur The sound of BLOOD flowing through an abnormal opening in the HEART. Heart murmur is a sign rather than a condition. Transient heart murmurs are common and benign, generally signaling an occasional or circumstantial incomplete valve closure, and do not require further evaluation or treatment. Transient heart murmurs may be present during FEVER, especially in children, and in pregnant women. Heart murmur sometimes occurs with noncardiovascular conditions such as ANEMIA and HYPERTHYROIDISM.

Murmurs are likely to herald cardiovascular disorders when they appear with symptoms such as shortness of breath (DYSPNEA) with exertion. Persistent heart murmurs may indicate a heart condition that requires treatment. The most common cardiac causes of murmur are

- VALVULAR HEART DISEASE, in which a valve in the heart fails to close properly and blood flows back through it
- atrial septal defect or ventricular septal defect, in which there is an opening in the septum, or heart wall, between the two atria or the two ventricles that allows blood to flow directly between the affected chambers
- AORTIC STENOSIS or pulmonary ARTERY stenosis, in which narrowing of the artery causes blood to back up

Persistent heart murmurs may also be present in GENETIC DISORDERS such as MARFAN SYNDROME or CHROMOSOMAL DISORDERS such as DOWN SYNDROME (trisomy 21). These conditions often have cardiovascular components. The diagnostic path typically includes ELECTROCARDIOGRAM (ECG) and ECHOCARDIOGRAM or COMPUTED TOMOGRAPHY (CT) SCAN and may include more invasive diagnostic procedures such as CARDIAC CATHETERIZATION. Treatment targets the underlying cause of the murmur and may include medications or an OPERATION to repair the problem.

heart rate The number of times in a minute that the HEART completes a CARDIAC CYCLE, commonly measured as the PULSE. At rest, the healthy adult heart beats between 60 and 80 times per minute. The heart rate of a person who is aerobically fit is slower because the heart is more efficient and can pump more blood with each contraction. CARDIOVASCULAR DISEASE (CVD) that reduces CARDIAC CAPACITY often results in an increased heart rate as the heart attempts to compensate for decrease in volume per beat. An unusually rapid heart rate at rest is tachycardia; an unusually slow heart rate at rest is bradycardia. Noncardiac health conditions also can affect heart rate. Heart rate may increase with HYPERTHYROIDISM and decrease with HYPOTHYROIDISM. Other factors that increase heart rate include physical activity, stress, fear, and FEVER.

An aerobically fit heart can increase its pumping volume at a lower increase in heart rate to meet the body's oxygen needs during physical activity or exercise. The heart's maximum heart rate is the upper limit of cardiac function and declines with increasing age. Health experts recommend physical activity for aerobic conditioning that puts the heart rate between 25 and 75 percent of maximum heart rate for 20 to 30 minutes. An individual's target heart rate varies according to AEROBIC FITNESS level. The most effective method for reaching and staying within the target heart rate during exercise is to use a heart monitor, which counts the heartbeats of the person wearing it.

heart sounds The sounds of the opening and closing of the heart's valves and the passage of BLOOD through them. HEART sounds are an important component of physical diagnosis for cardiovascular conditions. Doctors listen to them using a STETHOSCOPE.

The classic *lubb dupp* sounds are the normal heart sounds in a healthy adult. These are the first and second heart sounds, designated S1 and S2. S1 represents the closing of the tricuspid and mitral valves between the atria and the ventricles. S2 represents the closing of the pulmonary and aortic valves as blood leaves the right and left ventricles, respectively. Other heart sounds are abnormal in adults, occurring only with certain health (and usually heart) conditions. They include

- S3, sometimes called a pericardial knock, indicates a dilated ventricle and ventricular dysfunction such as may occur with CARDIOMYOPATHY (though S3 may be a normal heart sound in young children) or HEART FAILURE. S3 is a low-pitched, vibrational sound the doctor can hear using the bell of the stethoscope.
- S4, indicates abnormal MUSCLE tissue in the heart such as might occur with MYOCARDIAL INFARCTION or hypertrophic cardiomyopathy. S4 also may occur with ISCHEMIC HEART DISEASE (IHD) and HYPERTENSION. Like S3, S4 is a low-pitched vibration the doctor hears with the bell of the stethoscope.
- A click is a high-pitched tone following S1 that indicates improper closing of a valve such as might occur with AORTIC STENOSIS or pulmonary artery stenosis, particularly when these conditions are congenital.
- A snap is a sharp sound following S2 that is typical with mitral stenosis.
- A murmur is a whooshing or whispering sort of sound that indicates blood flowing back through an incompletely closed valve. The timing and quality of the murmur's sound help determine which valve is dysfunctional. Heart murmurs are common and often have no cardiovascular significance, though persistent murmurs may indicate VALVULAR HEART DISEASE.

The cardiologist may choose to further investigate persistent abnormal heart sounds using ELECTROCARDIOGRAM (ECG), ECHOCARDIOGRAM, and other diagnostic procedures depending on the person's symptoms and cardiovascular history.

heart transplantation The replacement of a diseased HEART with a healthy heart from a deceased donor. Heart transplantation is a therapeutic

option for severe CONGENITAL HEART DISEASE such as hypoplastic left heart syndrome (HLHS) as well as hypertrophic CARDIOMYOPATHY and end-stage HEART FAILURE. South African heart surgeon Christiaan Barnard (1922—2001) performed the first human heart transplantation in 1967, when he replaced the badly diseased heart of 53-year-old Louis Washkansky with the healthy heart of 25-year-old Denise Darvall who died in an accident. Though Washkansky lived only 18 days with the new heart, the OPERATION catapulted cardiovascular medicine into a new era. Today cardiovascular surgeons perform about 2,200 heart transplant operations a year in the United States. More than 70 percent of donor heart recipients live at least 5 years; the longest survival is 24 years.

DONOR HEART SHORTAGE

More than 4,000 people wait on the donor HEART list, yet donor hearts will be available for little over half of them. Many people who could be heart donors are not. Surgeons must place the donor heart in the recipient within four hours of the donor's death. Because many people have not made decisions in advance about organ donation, the time it takes to obtain the family's permission may make it too late to use the heart. There is no cost to the donor's family for removal of donated organs.

Heart transplant recipient criteria Though many people may become critically ill with CARDIOVASCULAR DISEASE (CVD), heart transplantation is a viable option primarily for end-stage heart failure. Health experts estimate that heart transplants could save the lives of 25,000 or more people each year who currently die as a result of heart failure, though the severe shortage of donor hearts restricts heart transplantation to people who are dying from heart failure yet are otherwise healthy—people who have both great need and great potential for survival. Conditions that may result in heart transplantation include

- end-stage heart failure for which medical therapies are ineffective, typically resulting from inoperable CORONARY ARTERY DISEASE (CAD), inoperable VALVULAR HEART DISEASE, and cardiomyopathy
- life-threatening ARRHYTHMIA that does not respond to other treatment
- inoperable congenital malformations of the heart, such as HLHS and tetralogy of Fallot, when surgical reconstruction of the heart either fails or is not likely to be successful

Though numerous clinical criteria establish the severity of cardiovascular status, typically LEFT VENTRICULAR EJECTION FRACTION (LVEF) that falls below 25 percent is the decisive factor. LVEF represents the percent of blood in a full left ventricle that the heart pumps into the body with each contraction of the left ventricle. The amount of blood that enters the body is the stroke volume. A normal LVEF is 55 percent or higher; an LVEF of 40 percent is moderately debilitating. At 25 percent, there are symptoms of cardiovascular distress (such as shortness of breath and ANGINA PECTORIS) even at rest and the person is unable to perform most physical activities.

As well, there are general eligibility criteria to ensure optimal chance for survival after transplantation. These general criteria for heart transplantation include

- expectation of one year or less survival
- age 65 or younger (though an older person who meets all other criteria may be accepted as a recipient)
- otherwise good health
- capable of and willing to comply with lifelong medical care

Various health circumstances tend to preclude consideration for heart transplantation, though they are not absolute. Called comorbid conditions, these include

- INSULIN-dependent DIABETES with NEPHROPATHY, NEUROPATHY, or RETINOPATHY (damage to KIDNEYS, nerves, or eyes)
- primary irreversible kidney disease (not related to cardiovascular disease)
- primary irreversible LIVER disease such as CIRRHOSIS (not related to cardiovascular disease)
- cancer within the previous five years (except SKIN)

- PERIPHERAL VASCULAR DISEASE (PVD) with symptoms such as INTERMITTENT CLAUDICATION
- TRANSIENT ISCHEMIC ATTACK (TIA)
- PRIMARY PULMONARY HYPERTENSION (PPH), CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD), EMPHYSEMA, or severe ASTHMA
- OBESITY

Though none of these criteria is absolute, because of the extreme limited availability of donor hearts cardiologists must be able to justify exceptions. Heart transplantation centers set their own criteria, which may be more or less stringent than the general criteria. Many heart transplantation centers are reluctant to approve individuals who are not likely to maintain the rigorous therapeutic and lifestyle regimens necessary following transplant. In infants and children, heart transplantation is an option for nonsurvivable major congenital anomalies. The shortage of donor hearts severely limits heart transplantation in infants, however.

The donor heart The United Network for Organ Sharing (UNOS) maintains donor lists for all transplant circumstances (except corneas and SKIN) in the United States. UNOS coordinates the acquisition and distribution of donor organs according to strict guidelines and policies that direct available organs to the sickest people on the waiting lists for whom criteria match. Regional transplantation centers carry out the acquisitions and distributions. People waiting for heart transplants must be available 24 hours a day and must be able to reach their transplantation centers within two hours.

The donor's BLOOD TYPE must be the same as the recipient's, and the donor and recipient need to be similar in body size and weight. The heart of a donor who is six feet, four inches tall will not fit in the chest cavity of a recipient who is five feet, three inches tall. Similarly, the heart of a small donor cannot meet the cardiovascular needs of a large recipient. Gender, race, and ethnicity do not matter. The donor's heart must be healthy, and the donor must be under age 65 and free from serious or communicable diseases. Most donor hearts come from people who lose their lives in accidents that cause irreversible, overwhelming BRAIN damage. A specialized surgical team carefully harvests the heart in the operating room, after certifying brain death though while cardiovascular function continues, and places the heart in a cold electrolyte solution to preserve it during transport to the recipient's medical center. The heart remains viable for four to six hours.

Surgical Procedure

The heart transplant operation typically takes three to five hours. The surgeon opens the chest with a large incision lengthwise over the STERNUM and cuts the sternum with a saw to open the chest. After placing the person on CARDIOPULMONARY BYPASS (mechanical oxygenation and circulation of the blood), the surgeon removes the diseased heart. There are several methods for doing this; the most common is to cut away all of the heart except the back walls of the atria to preserve the connections to their blood vessels (the superior VENA CAVA, inferior vena cava, and pulmonary VEIN). Respectively, the surgeons cut away the back of the donor heart to match and suture the donor heart into place beginning with the left atrium. The great arteries—the AORTA and the pulmonary ARTERY—are the final structures the surgeon attaches. The heart spontaneously begins to beat when the surgeon restores blood flow. The surgeon closes the sternum with wire to hold it together while it heals, and closes the outer chest tissues with sutures or staples. Most people remain in the hospital up to 10 days following surgery.

Risks and Complications

Heart transplantation entails numerous risks and complications during (operative) and following (postoperative) the surgery. Operative risks include bleeding, air embolism (air that escapes into the bloodstream from the cardiopulmonary bypass), unexpected anatomic incompatibilities (the donor heart does not "fit"), and inability to restore cardiac function. The most significant complications following heart transplantation, which also account for the greatest number of deaths, are INFECTION and rejection. Arrhythmias and other dysfunctions of the heart sometimes occur, though typically respond to medications. Occasionally the transplanted heart fails to function, a circumstance called graft failure. Immediate retransplantation is generally the only treatment.

People who have transplanted hearts are vulnerable to rapidly progressive CAD, HYPERTENSION, and arrhythmias. The transplanted heart is denervated—though it contains its own conductive NERVE network to convey electrical pacing impulses, it does not have nerves connecting it to the body's sympathetic nerve pathways. Normal NERVOUS SYSTEM mechanisms (the sympathetic nerve pathways) that typically regulate HEART RATE and cardiac workload are not functional in the transplanted heart, though in some people reinnervation occurs over time. The absence of sympathetic nerve pathways also means the person does not experience angina pectoris, a primary symptom of CAD and ISCHEMIC HEART DISEASE (IHD). This increases the risk for silent HEART ATTACK. Cardiologists closely monitor the transplanted heart for any signs of CAD, and also routinely prescribe lipid-lowering medications to help prevent CAD from developing.

Other long-term risks include an increased risk for cancer, most commonly skin and lymphatic, because of the IMMUNOSUPPRESSIVE THERAPY. Infection and rejection remain risks as well. Rejection can be acute (come on suddenly and severely) or chronic (persist in a low-grade fashion over time, or come and go). Many cardiologists believe the accelerated CAD process also results from immunosuppression rather than the conventional factors.

Outlook and Lifestyle Modifications

Most people remain hospitalized for 5 to 10 days after the transplant operation, while the new heart stabilizes and the surgical wounds start to heal. During this time doctors initiate IMMUNOSUPPRESSIVE THERAPY, ANTICOAGULATION THERAPY, and various medications to support the heart's function during early HEALING. All transplant recipients will need to take IMMUNOSUPPRESSIVE MEDICATIONS for the remainder of their lives to prevent their bodies from rejecting the donor organ.

Most heart transplant recipients will continue taking other cardiovascular medications to support cardiovascular efficiency. The transplanted heart's denervation affects its ability to adjust to changing cardiovascular needs in the body, such as with exercise. Many people require a PACEMAKER after transplantation to maintain an adequate heart rate and appropriate heart rhythm. Heart transplantation requires lifetime medical follow-up, usually annual CARDIAC CATHETERIZATION and other diagnostic procedures to assess the heart's function.

Most heart transplant recipients return to their regular work and leisure activities, including sexual activity, gradually over two to three months. The cardiologist may restrict certain kinds of strenuous physical activity depending on the heart's ability to respond to the body's increased oxygen needs. The healing process is generally quite rapid as full cardiovascular function returns the body to its normal function. CARDIAC REHABILITATION helps restore the body to a level of physical STRENGTH and AEROBIC FITNESS that further supports cardiovascular health. Moderate daily physical exercise (such as walking), nutritious eating habits, and total abstinence from smoking are essential.

heredity and heart disease The genetic variables that influence the development of CARDIOVASCULAR DISEASE (CVD). Some forms of cardiovascular disease are entirely hereditary and develop without influence of lifestyle factors. Among them are hypertrophic CARDIOMYOPATHY, LONG QT SYNDROME (LQTS), WOLFF-PARKINSON-WHITE SYNDROME, and familial HYPERLIPIDEMIA. There appear to be few interventions, medical or lifestyle, that can prevent these conditions. Early diagnosis allows for optimal medical management. Researchers suspect that undiagnosed hereditary conditions, notably ARRHYTHMIA disorders, account for up to 25 percent of SUDDEN CARDIAC DEATH in the United States.

Congenital malformations of the HEART often accompany GENETIC DISORDERS or CHROMOSOMAL DISORDERS. Septal defect is common in children who have DOWN SYNDROME (trisomy 21), for example. Most people who have MARFAN SYNDROME, a hereditary connective tissue disorder, have cardiovascular abnormalities including malformed heart valves and arterial walls that lack connective tissue, weakening them and making them vulnerable to ANEURYSM.

As well, there are correlations, though researchers do not fully understand them, among BIRTH DEFECTS involving the heart that occur in conjunction with specific birth defects affecting other body structures. About a third of infants born with ESOPHAGEAL ATRESIA (incomplete formation of the ESOPHAGUS) also have the heart malformation patent ductus arteriosus (PDA). Heart malformations are also common in children who have NEURAL TUBE DEFECTS such as SPINA BIFIDA. These correlations strongly suggest GENE mutations.

Gender and race are other hereditary factors that influence the development of cardiovascular conditions. Men, until about age 60, have three to five times the risk for CORONARY ARTERY DISEASE (CAD) and HYPERTENSION (high BLOOD PRESSURE). Men under age 60 are also more likely to have HEART ATTACK or STROKE. The risk for cardiovascular disease is exponentially higher among African Americans. Hypertension is the leading cause of stroke and kidney failure among African American men between the ages of 35 and 50.

Other forms of cardiovascular disease that tend to "run in the family" may have genetic underpinnings that manifest with interplay from certain lifestyle factors such as cigarette smoking, lack of physical exercise, and eating habits. Such cardiovascular conditions include hypertension (high blood pressure), ATHEROSCLEROSIS, CAD, and PERIPHERAL VASCULAR DISEASE (PVD). Evidence is very strong that appropriate lifestyle interventions can delay or even prevent the onset of such conditions despite any genetic predisposition.

See also CARDIOVASCULAR DISEASE PREVENTION; LIFESTYLE AND CARDIOVASCULAR HEALTH; RISK FACTORS FOR CARDIOVASCULAR DISEASE.

homocysteine An amino acid in the BLOOD that the body's METABOLISM of the essential amino acid methionine produces. (An essential amino acid is one the body cannot synthesize itself but must obtain from dietary sources.) B vitamins and folic acid are necessary to break down homocysteine. Accumulation of homocysteine in the blood circulation appears to accelerate development of ATHEROSCLEROSIS. In the mid-1990s researchers discovered a connection between elevated blood homocysteine levels and early atherosclerosis. Doctors had known since the 1960s of a rare genetic condition, homocystinuria, that caused extensive atherosclerotic disease in teens and young adults. But new research led them to correlate atherosclerosis with elevated homocysteine levels in adults who had no known genetic foundation for them.

Some researchers believe that elevated homocysteine irritates the inside walls of the arteries. The irritation causes INFLAMMATION, which opens the way for ATHEROSCLEROTIC PLAQUE to infiltrate the intima, the innermost layer of the arterial walls. People between the ages of 45 and 60 who have significant atherosclerosis or CORONARY ARTERY DISEASE (CAD) often have elevated homocysteine levels. In people who have elevated homocysteine levels, atherosclerosis may develop more rapidly and at earlier ages. However, research studies as yet have not established a cause and effect relationship between elevated homocysteine and early atherosclerosis.

A blood test can measure the homocysteine level in the blood. Most doctors view homocysteine as a risk factor for CARDIOVASCULAR DISEASE (CVD), though not one that is alone significant enough to cause cardiovascular disease. They recommend people receive the minimum daily amounts of vitamins B_6, B_{12}, and folic acid through dietary sources when possible and with supplements if necessary, as a matter of general health as well as to aid in breaking down homocysteine. People who have elevated homocysteine levels along with other RISK FACTORS FOR CARDIOVASCULAR DISEASE should do what they can to reduce their overall risks, though health experts do not advise folic acid supplementation beyond the recommended intake (400 micrograms daily for an adult) as a preventive measure for cardiovascular health. Adequate folic acid intake appears essential for numerous health reasons, and may help reduce the risks for other health conditions.

hyperlipidemia A disorder of lipid METABOLISM, also called hyperlipoproteinemia, that results in abnormally high levels of cholesterol, triglycerides, and lipoproteins in the BLOOD circulation. Hyperlipidemia is a key contributor to ATHEROSCLEROSIS, CORONARY ARTERY DISEASE (CAD), and PERIPHERAL VAS-

CULAR DISEASE (PVD). Hyperlipidemia also can cause health conditions such as PANCREATITIS. Some forms of hyperlipidemia are familial or hereditary and may manifest regardless of lifestyle. Medications can cause hyperlipidemia as well, notably oral contraceptives (birth control pills), estrogen therapy, thiazide diuretics, and corticosteroids. Hyperlipidemia may also be a sign of other health conditions such as CUSHING'S SYNDROME, DIABETES, LIVER dysfunction, and SYSTEMIC LUPUS ERYTHEMATOSUS (SLE). In most people who have hyperlipidemia, however, it appears that lifestyle factors interact with genetics.

Doctors measure lipid levels in the blood and consider them individually as well as in correlation to each other in determining the extent of cardiovascular risk they pose. There are five types, or classifications, of hyperlipidemia that have unique presentations, genetic factors, and characteristic progressions. The five types of hyperlipidemia are

- type I, a rare inherited lipid disorder sometimes called apolipoprotein C-II deficiency, in which very low density lipoprotein (VLDL) triglycerides and lipids called chylomicrons accumulate in the bloodstream
- type II, a common group of familial or acquired lipid disorders, sometimes called hypercholesterolemia, in which low-density lipoprotein (LDL) cholesterol levels in the blood are elevated, and there may be apolipoprotein B deficiency
- type III, an uncommon familial lipid disorder in which VLDL and total cholesterol are elevated, usually resulting from apolipoprotein E deficiency
- type IV, a common familial or acquired lipid disorder in which blood lipid elevations are associated with OBESITY and decline with weight loss
- type V, an uncommon lipid disorder in which triglycerides are extremely elevated, though other blood lipid levels are fairly normal, and that frequently causes pancreatitis

Most forms of hyperlipidemia can occur without evidence of familial or hereditary connections.

Symptoms and Diagnostic Path

Hyperlipidemia itself does not cause symptoms. Doctors detect hyperlipidemia through blood tests, conducted after an 8- to 12-hour fast, that measure blood lipid levels. The pretest fast is important to remove any dietary influences. Elevated blood lipid levels are diagnostic. When blood lipid levels are extremely high and other risks for CARDIOVASCULAR DISEASE (CVD) exist, the doctor may recommend further evaluation to look for CAD, PVD, and other atherosclerotic conditions.

Treatment Options and Outlook

Regardless of the cause of elevated blood lipids, the important therapeutic goal is to reduce them. For people who have mild to moderate elevations and no other cardiovascular disease risk factors (including family history of hyperlipidemia), lifestyle changes alone may be enough to bring lipid levels down to acceptable ranges. Doctors are generally willing to give this approach about two months to lower blood lipid levels. When lipid levels remain elevated despite lifestyle changes, or the person cannot make adequate lifestyle changes, health experts recommend lipid-lowering medications. Lowering blood lipids results in a significant decrease in cardiovascular risk, especially for early CAD and HEART ATTACK (before age 40).

Many doctors recommend niacin, either alone or in combination with lipid-lowering medications, to help lower blood lipid levels. Niacin

decreases the liver's production of VLDL and low-density lipoprotein (LDL), which curtails triglyceride production. Niacin can cause unpleasant facial flushing and tingling sensations in the fingers and toes, however, even at low doses.

Risk Factors and Preventive Measures

The key risk factors for hyperlipidemia are family history and lifestyle habits. Most people can lower their risk for hyperlipidemia through eating habits and exercise. Even in combination with medication, lifestyle factors are important for maintaining healthy lipid metabolism.

hypertension BLOOD PRESSURE that remains consistently elevated. Health experts estimate that 25 percent of American adults—about 75 million people—have hypertension, though about half of them do not know it. Hypertension, also called high blood pressure, is a leading cause of STROKE and KIDNEY disease, and a key factor in many heart attacks.

Stroke kills nearly 150,000 Americans each year, making it the third leading cause of death in the United States, and disables about a million others. Yet as many as 80 percent of strokes are preventable through controlling blood pressure. Early diagnosis of hypertension to prevent stroke is a goal of the U.S. preventive health initiative HEALTHY PEOPLE 2010.

Loss of feeling or movement and blurred or dimmed vision, especially on only one side of the body, and difficulty forming or understanding words, are early warning signs of STROKE that require emergency medical evaluation.

Hypertension has numerous effects on the cardiovascular system, and over time alters the function of the HEART as well as the distribution of blood throughout the body. Hypertension in combination with ATHEROSCLEROSIS, the most common form of CARDIOVASCULAR DISEASE (CVD) in the United States, can be particularly damaging or lethal. In combination with DIABETES, hypertension significantly raises the risk for kidney failure and RETINOPATHY of diabetes, in which the tiny blood vessels in the RETINA rupture, causing blindness.

Symptoms and Diagnostic Path

Hypertension has no symptoms, which is why regular blood pressure monitoring is so important. For many people, the first indication of hypertension is stroke or kidney disease, the two leading complications of hypertension. Hypertension may also trigger HEART ATTACK. Occasionally people who have severely elevated blood pressure experience headaches.

Healthy blood pressure is a systolic reading below 120 millimeters of mercury (mm Hg) and a diastolic reading below 80 mm Hg. Persistent readings above these levels for either systolic or diastolic pressure constitute hypertension. Generally the doctor takes several blood pressure readings at different times of the day over a span of time before diagnosing hypertension. A diagnosis of hypertension follows a minimum of three elevated readings. Many people are anxious or nervous when visiting the doctor, sometimes resulting in a phenomenon doctors call "white coat hypertension." An assessment of vital signs, including blood pressure, usually takes place at the start of the health-care visit; when blood pressure is elevated, the doctor may take a measurement again at the end of the visit when the person's anxiety level has dropped.

HYPERTENSION CLASSIFICATIONS

Classification	Systolic	Diastolic
Prehypertension	120–139 mm Hg	80–89 mm Hg
Stage 1 hypertension	140–159 mm Hg	90–99 mm Hg
Stage 2 hypertension	160 mm Hg and above	100 mm Hg and above

Treatment Options and Outlook

Lifestyle modification is the first and the foundational treatment approach for hypertension. Intervention at the prehypertension level can bring blood pressure under control before it becomes a health problem. Overweight or OBESITY causes or exacerbates much hypertension, so often the doctor's first recommendation is weight loss through increased physical activity and changes in eating habits that reduce overall caloric intake. Further dietary modifications often include reducing

sodium consumption, as high amounts of dietary sodium cause the body to maintain fluid. This increases blood volume and, correspondingly, blood pressure. Doctors also recommend reducing dietary fat, especially saturated fat, and cholesterol to reduce the risk for HYPERLIPIDEMIA and atherosclerosis. Atherosclerosis narrows and stiffens the arteries, increasing the resistance blood encounters, and is a significant factor in hypertension.

The mainstay of treatment for hypertension is medication. There are numerous classifications and kinds of drugs that can lower blood pressure through different actions and mechanisms. Often the doctor will combine medications in a multifaceted approach. Many of the medications used to treat hypertension also treat other cardiovascular conditions. Cardiologists often prescribe beta blockers and calcium channel blockers, for example, to treat ARRHYTHMIA, CARDIOMYOPATHY, and HEART FAILURE. Because cardiovascular disease is often a constellation of conditions, this is an effective approach for preventing further cardiovascular disease from developing.

The decision to begin medication for hypertension depends on the blood pressure elevation and other cardiovascular disease or risk factors. Doctors may choose to initiate antihypertensive medication therapy for stage 1 hypertension in people who have multiple cardiovascular risks, yet try three to six months of lifestyle modification for people who have few or no other known cardiovascular risks. Medication needs may change if other health conditions develop or cardiovascular status changes. On the positive side, lifestyle modifications in combination with medication therapy often can reduce or eliminate the need for medication in people who have stage 1 hypertension and occasionally in people who have stage 2 hypertension.

KINDS OF MEDICATIONS TO TREAT HYPERTENSION

angiotensin II receptor blockers (ARBs)	angiotensin-converting enzyme (ACE) inhibitors
beta blockers	calcium channel blockers
diuretics	vasodilators

Risk Factors and Preventive Measures

The leading risk factors for hypertension are age, cigarette smoking, dietary habits, and physical inactivity. Health conditions such as obesity, diabetes, and atherosclerosis further increase the risk for hypertension. Health experts recommend all adults over age 40 undergo annual blood pressure screening, with more frequent screening for people who have increased risk. Daily physical exercise such as walking helps control weight as well as maintain cardiovascular efficiency, reducing risk across the spectrum of cardiovascular disease.

hypotension Below-normal BLOOD PRESSURE. Hypotension is most often a SIDE EFFECT of medications, a complication of HEART ATTACK, the result of significant BLOOD loss, or a component of cardiovascular SHOCK. Factors that decrease the flow of blood through the body typically result in reduced blood pressure. Idiopathic hypotension (hypotension that exists without apparent cause) often suggests a neurologic cause that reflects damage to the brainstem or HYPOTHALAMUS. STROKE that interrupts blood flow to these parts of the BRAIN may be accountable, interfering with the body's blood pressure regulation mechanisms.

Hypotension is a frequent side effect of many MEDICATIONS TO TREAT CARDIOVASCULAR DISEASE, among them diuretics, antihypertensives (drugs to lower blood pressure), and alpha blockers (drugs to lower blood pressure or treat ARRHYTHMIA). Cardiovascular conditions that reduce CARDIAC OUTPUT (the heart's ability to pump an adequate volume of blood to meet the body's OXYGENATION needs) are common causes of hypotension. Such conditions include severe dilated CARDIOMYOPATHY, advanced HEART FAILURE, bradycardia and other arrhythmias that slow the heart, AORTIC STENOSIS, and unrecognized HEART ATTACK. Hypotension, notably postural hypotension (a sudden drop in blood pressure upon arising), may be a symptom of ADDISON'S DISEASE, an autoimmune disorder that destroys the ADRENAL GLANDS. The adrenal glands produce the key hormones that increase blood pressure, ALDOSTERONE, EPINEPHRINE, and NOREPINEPHRINE.

The most common symptoms of hypotension are lightheadedness and SYNCOPE (fainting), especially when rising from sitting or lying down. The

normal pull of gravity causes blood to temporarily pool in the large veins of the legs. Any lapse between the change of position and the signals that activate the body's blood pressure regulation mechanisms, results in an inadequate blood supply to the brain that causes loss of consciousness. Syncope following meals, called postprandial syncope, also is common, as the body draws an increased blood volume to the gastrointestinal tract to support the functions of digestion. The diagnostic path typically includes review of medications the person is taking as well as blood tests to measure levels of the adrenal hormones, blood electrolytes, and blood composition. Treatment depends on the underlying cause. When the cause is medication, changing the DOSE or switching to a different medication often remedies the hypotension. Neurologic and endocrine causes may require more extensive diagnostic evaluation and comprehensive treatment approaches.

I

implantable cardioverter defibrillator (ICD) A small, battery-operated electronic device, similar to a PACEMAKER, that monitors the heart's electrical activity for certain patterns of ARRHYTHMIA and administers a moderate electrical shock when the HEART stays in the pattern beyond the programmed length of time. One or two wires, called leads, extend from the ICD's PULSE generator to the interior of the heart, threaded through a BLOOD vessel during a procedure similar to a CARDIAC CATHETERIZATION. The cardiologist creates a small pocket in the tissues near the shoulder or in the abdomen to implant the pulse generator, a tiny computer. Once placed, the leads and the ICD are permanent. The cardiologist then programs the ICD to maintain the appropriate heart rhythm.

ICD is a treatment option for ventricular tachycardia and VENTRICULAR FIBRILLATION, arrhythmia disorders that affect the ability of the ventricles to contract to expel blood from the heart. Ventricular tachycardia, in which the ventricles contract rapidly but regularly, is exhausting for the heart and does not generate adequate CARDIAC OUTPUT to meet the body's needs. Ventricular fibrillation, in which the ventricles contract rapidly and irregularly, is life-threatening. An ICD can initiate pacing impulses when the heart's rate becomes too slow or a stronger electrical impulse to shock the heart from a harmful to a normal rhythm (CARDIOVERSION). Most people do not feel the pacing impulses though do feel a jolt with cardioversion impulses. People who have ICDs need to be cautious around electrical devices because they generate magnetic fields that can interfere with an ICD's operation and programming.

intermittent claudication PAIN in the lower legs that occurs with physical activity such as walking. Intermittent claudication is the primary symptom of PERIPHERAL VASCULAR DISEASE (PVD), which is ATHEROSCLEROSIS that affects the arteries of the legs. The atherosclerotic accumulations of PVD occlude (block) BLOOD flow through the arteries, limiting their ability to respond to the increased oxygen need of the leg muscles during exercise. The insufficient oxygen causes pain that is typically severe enough to stop the activity. Resting relieves the pain and the person can resume the activity.

People who have intermittent claudication typically develop a pattern of walking and resting that accommodates their symptoms. About 60 percent of people who have intermittent claudication have it in both legs. Cigarette smoking, DIABETES, and lack of physical exercise are the leading causes of PVD and intermittent claudication. The PVD that causes intermittent claudication most often affects the popliteal ARTERY, which branches from the femoral artery and drops behind the knee to supply the lower leg with blood.

The most effective treatment is consistent exercise such as walking. Doctors recommend a progressive approach that begins with walking until pain forces rest, several times every day, and trying to extend the time by a few minutes every week. The regular physical activity conditions the leg muscles, improving the efficiency with which they use oxygen and decreasing oxygen demand. Most people who have PVD and intermittent claudication also take medications to decrease the blood's clotting tendencies, such as ASPIRIN THERAPY or anticoagulation medications such as clopidogrel (Plavix) or warfarin (Coumadin). These methods cannot eliminate intermittent claudication though they can reduce its severity.

intra-aortic balloon pump (IABP) counterpulsation A method to relieve strain on the HEART when there is significant damage to the heart such as after a major HEART ATTACK, in end-stage HEART FAILURE while awaiting HEART TRANSPLANTATION, or in cardiovascular SHOCK. Such circumstances result in the heart being unable to pump enough BLOOD to meet the body's needs. IABP counterpulsation helps pull blood through the AORTA, assisting the left ventricle's pumping efforts.

The cardiologist inserts the IABP on the tip of a catheter during a CARDIAC CATHETERIZATION, threading it through a small incision in a major peripheral ARTERY near the surface of the SKIN, such as the femoral artery in the groin or the brachial artery in the upper arm. The IABP rests in the root of the aorta, its inflated balloon cuff holding it firmly in place. An inner ringlike balloon forms the inside channel of the IABP, inflating and deflating in synchronization with the CARDIAC CYCLE. The channel narrows as the IABP inflates during diastole (filling of the ventricles) and widens as the AIBP deflates during systole (contraction of the ventricles). The effect is to pull blood into the aorta at the same time the left ventricle pumps blood out, easing the amount of pressure necessary to move the blood. A computer closely monitors the heart's electrical patterns to precisely time the inflation and deflation of the IABP's inner balloon.

ischemic heart disease (IHD) The consequential condition that results when CORONARY ARTERY DISEASE (CAD) and other conditions that affect the heart's blood supply deprive the HEART of oxygen over an extended period of time. Ischemia is the medical term for a temporary interruption of BLOOD flow; in ischemic heart disease (IHD), the interruptions are temporary but recurrent. Cardiac ischemia occurs when the CORONARY ARTERIES are unable to provide the heart with enough blood to meet its oxygen needs. Coronary artery spasm, which often occurs with moderate to advanced CAD, also can generate ischemic episodes.

Ischemia often results in a specific kind of discomfort or PAIN, ANGINA PECTORIS. However, many people who have IHD have what doctors call silent ischemia that causes no symptoms until HEART ATTACK, and sometimes not even then. Silent heart attack can further contribute to the IHD when parts of the heart MUSCLE are no longer functional. IHD may alternately improve and worsen according to the person's activity level, as the heart's oxygen needs increase with activity.

The diagnostic path seeks to identify the underlying condition of the symptoms, which is usually CAD though sometimes ARRHYTHMIA disorders are to blame. Treatment targets the causative condition, and may include ANGIOPLASTY or CORONARY ARTERY BYPASS GRAFT (CABG) as well as medications to regulate the heart's rate and workload. Ischemic heart disease generally improves with these measures.

Kawasaki disease An acute condition affecting children that can weaken the CORONARY ARTERIES and other cardiovascular structures, resulting in HEART ATTACK, ANEURYSM, or permanent damage. Kawasaki disease, also called mucocutaneous LYMPH NODE syndrome, comes on suddenly with RASH, FEVER, CONJUNCTIVITIS, and swollen lymph nodes (LYMPHADENOPATHY). The characteristic symptom that raises suspicion the condition is more than a typical viral INFECTION is the bright red color of the lips and mucous membranes in the MOUTH. After about five days the palms of the hands and soles of the feet also become bright red. The child appears, and is, very ill. The acute phase of the disease runs about three weeks. The diagnostic path is primarily clinical; there are no definitive tests for Kawasaki disease.

Treatment during the acute phase includes efforts to keep the child comfortable as well as administering high-DOSE aspirin. Aspirin, not usually given to children who have fevers because of the risk for REYE'S SYNDROME, is the treatment of choice for Kawasaki disease because it not only reduces FEVER but also reduces cardiovascular INFLAMMATION and has antiplatelet action that helps prevent blood clots from forming. These effects lower the likelihood of cardiovascular damage or crisis. Intravenous IMMUNOGLOBULIN, which delivers generalized antibodies that aid the body's IMMUNE RESPONSE, given early in the course of the disease seems to mitigate symptoms in some children.

Sometimes cardiovascular symptoms manifest during the disease's acute phase, though typically it is months to years later that problems become apparent. Doctors recommend cardiovascular assessment, including ELECTROCARDIOGRAM (ECG) and ECHOCARDIOGRAM, for children at the time of diagnosis. Detected cardiovascular changes require regular followup, with treatment as necessary. The most serious long-term consequences of Kawasaki disease are aneurysms of the coronary arteries that cause heart attack. In some children, inflammation attacks the heart valves, resulting in VALVULAR HEART DISEASE that requires ongoing medical attention and sometimes heart valve replacement in adulthood.

Doctors believe an infectious agent, such as a VIRUS, likely causes Kawasaki disease though as yet researchers have been unable to isolate it. Though occasionally there appear to be clusters of Kawasaki disease, the condition does not appear to be contagious through contact among family members and close contacts. Children under five years of age are most likely to develop Kawasaki disease. Children who have had Kawasaki disease rarely get it again.

L

left ventricular ejection fraction (LVEF) The percent of BLOOD a full left ventricle pumps into the AORTA with each CARDIAC CYCLE. LVEF provides an assessment of cardiovascular limitations resulting from damage to the HEART such as by MYOCARDIAL INFARCTION or HEART FAILURE. Normal LVEF is 55 percent; LVEF below 35 percent indicates severe heart failure. Because it is not possible to directly measure the volume of blood the left ventricle pumps, cardiologists use indirect methods to calculate the LVEF. Among these methods are ECHOCARDIOGRAM with Doppler ULTRASOUND, radionuclide scans, and MAGNETIC RESONANCE IMAGING (MRI), all of which allow the cardiologist to mathematically determine the volume of the ventricle and visualize the flow of blood through the heart. LVEF is one method to monitor the progression of a degenerative cardiovascular condition such as heart failure as a criterion for HEART TRANSPLANTATION.

lifestyle and cardiovascular health The variables of daily living and the effects they have on the health of the HEART and BLOOD vessels. Health experts estimate that lifestyle modifications alone could eliminate 90 percent or more of acquired CARDIOVASCULAR DISEASE (CVD). Given that 60 million Americans currently have at least one form of cardiovascular disease, the potential impact of such a reduction on LIFE EXPECTANCY as well as QUALITY OF LIFE is overwhelming. The three lifestyle factors that most significantly influence cardiovascular health are cigarette smoking, dietary habits, and physical activity.

Cigarette Smoking

NICOTINE, the active ingredient in cigarette smoke, is a potent vasoconstrictor and cardiovascular stimulant. Before a smoker finishes the first inhalation from a cigarette, nicotine is already surging through the bloodstream. It causes blood vessels throughout the body to stiffen and narrow, raising BLOOD PRESSURE. It raises the HEART RATE, further increasing blood pressure as well as the heart's workload. Simultaneously, other substances in cigarette smoke interfere with the OXYGEN–CARBON DIOXIDE EXCHANGE in the LUNGS, reducing the amount of oxygen the blood carries into the blood circulation. As smoking continues over time, nicotine causes physical changes in the cells of the ARTERY walls, reducing their ability to contract and relax. Blood pressure elevation may become permanent (HYPERTENSION), and the arteries are more susceptible to ATHEROSCLEROTIC PLAQUE. With SMOKING CESSATION much of the arterial function returns. Hypertension may improve though ATHEROSCLEROSIS, including CORONARY ARTERY DISEASE (CAD) and PERIPHERAL VASCULAR DISEASE (PVD), remains.

Dietary Habits

The foods and the quantities of them that a person eats significantly influence blood levels of cholesterol and triglycerides. A diet high in fruits, vegetables, and whole grain products provides a rich source of vitamins, antioxidants, and fiber that help regulate these lipids. This is important because elevated blood lipids (HYPERLIPIDEMIA) form the basis of atherosclerosis and the conditions that result, notably hypertension, CAD, and PVD. These nutrients also help the body tissues, including those of the cardiovascular system, to function efficiently. Nutritious eating further helps regulate the body's GLUCOSE–INSULIN balance, important from a cardiovascular perspective because insulin plays a key role in the kinds and amounts of cho-

lesterol and lipoproteins the LIVER manufactures. Insulin is also a key player in type 2 DIABETES, which is another risk factor for cardiovascular disease. Eating too much of any kind of food, however, results in increased body weight. OBESITY is another risk factor for numerous forms of CVD, notably hypertension and atherosclerosis. For many people a weight loss of 10 pounds can decrease systolic blood pressure by 10 millimeters of mercury (mm Hg) and lower CHOLESTEROL BLOOD LEVELS by 5 to 10 percent.

Physical Exercise

Daily physical activity is emerging as perhaps the single-most important lifestyle factor in regard to cardiovascular health and perhaps health overall. Exercise affects cellular METABOLISM in numerous ways. Cardiovascularly, exercise improves the efficiency with which cells use oxygen, lowering demand on the heart. AEROBIC EXERCISE increases LUNG CAPACITY, putting more oxygen into the blood with each breath. Exercise also increases insulin sensitivity, improving cholesterol ratios as well as glucose efficiency. Walking aids the lower extremities in moving blood back to the heart, with the skeletal muscles massaging and supporting the veins that must work against gravity to accomplish this task.

Lifestyle Modifications

Health experts agree that while the greatest cardiovascular benefits come from lifelong lifestyle habits that support cardiovascular health, it is never too late to make changes that improve cardiovascular status. Even when cardiovascular disease exists, doing lifestyle modifications such as nutritious EATING HABITS, daily physical exercise, WEIGHT LOSS AND WEIGHT MANAGEMENT, and SMOKING CESSATION can mitigate symptoms and allow a more acceptable quality of life.

living with cardiovascular disease More than 70 million Americans—nearly 35 percent of the U.S. population—live with some form of diagnosed CARDIOVASCULAR DISEASE (CVD). Many of them continue in the jobs and leisure activities they have always enjoyed, due in large part to advances in technology, surgery, and drugs that allow early diagnosis, prompt intervention, and successful treatment. Others—about 10 million—find their lives entirely changed by permanent disability. STROKE alone disables nearly a million Americans each year. Some people see their cardiovascular conditions as opportunities to improve their health and QUALITY OF LIFE, and some people see them as limitations. Living with CVD has physical and emotional dimensions that reach into nearly every aspect of life, from work and career to relationship and family.

Physical Dimensions

About 10 million Americans live with some degree of permanent disability as a result of CVD that limits their abilities to work and participate in activities they enjoy. One in three people who has a stroke experiences residual complications ranging from memory and cognitive disturbances to PARALYSIS. Half of people who have heart attacks experience compromised cardiovascular function, some of which is short term and improves over time, and some of which is long term and does not get much better with time. These changes may require adaptive accommodations in the home and the workplace. CARDIAC REHABILITATION programs help people recover to the best level possible, teaching new methods for managing lifestyle tasks and establishing individual recovery goals and the steps to reach them.

Emotional Dimensions

People who experience heart attack and other cardiovascular crises find themselves confronting their own mortality in ways that can be disconcerting and frightening. Some people experience renewed appreciation for life and its daily details. Some people turn to faith, either in gratitude or in anger. Some people flail about emotionally, suddenly unsure of life's purpose. Family members may not understand or may themselves find the close call a frightening experience. Feelings and emotions are as much a part of managing cardiovascular conditions as are medications and operations. Medical centers and hospitals that provide

cardiovascular care typically sponsor support groups where people can share their worries and fears.

Outlook

In the course of 40 years—the span of a generation—cardiovascular disease shifted from harbinger of restricted living and early death to a plethora of treatment options. For many people, living with cardiovascular disease is little different from living without cardiovascular disease. Operations, medications, and lifestyle interventions can mitigate many forms of cardiovascular disease. With the intensified focus on preventive measures and interventions, the generation born at the turn of the 21st century could be the first that does not have the experience of living with cardiovascular disease.

long QT syndrome (LQTS) An ARRHYTHMIA disorder in which an electrical conduction defect in the HEART results in delayed repolarization of myocardial cells. Repolarization is the process by which myocardial cells restore themselves to receive another electrical impulse. With LQTS, the myocardial cells hold a positive charge much longer than normal, preventing the heart from recharging for the next CARDIAC CYCLE. Most LQTS is hereditary, and researchers have isolated a number of GENE mutations that affect the heart's ion channels (conductive pathways), usually potassium channels though sometimes sodium channels. The condition can also develop as a consequence of STROKE or as a medication SIDE EFFECT, notably with antiarrhythmia and ANTIDEPRESSANT MEDICATIONS though numerous drugs affect the QT interval.

The points Q and T on the ELECTROCARDIOGRAM (ECG) identify polarization or discharge of electrical activity (the Q wave) and repolarization (the T wave). Doctors call the amount of time it takes for this phase to complete the QT interval. The longer the QT interval, the greater the risk for a dangerous arrhythmia called TORSADE DE POINTES, a form of highly unstable ventricular tachycardia (rapid though regular contractions of the ventricles, typically exceeding 100 contractions a minute). Torsade de pointes can quickly lead to VENTRICULAR FIBRILLATION, in which the ventricular contractions are rapid, irregular, and nonfunctional. Ventricular fibrillation quickly becomes life-threatening and may require emergency DEFIBRILLATION. LQTS is a common cause of SUDDEN CARDIAC DEATH in young people who are apparently healthy.

Symptoms and Diagnostic Path

Often, people who have LQTS do not have symptoms, and doctors detect the condition during ECG done for other reasons. The most common symptom that does occur is unexplained syncope (fainting), especially with intense exercise or emotional response (such as anger or fear). ECG generally provides the diagnosis, though the cardiologist may do an exercise STRESS TEST to evaluate the heart's electrical response with increased physical activity.

Treatment Options and Outlook

The standard medical treatment for LQTS is a beta blocker medication, which helps slow and stabilize the HEART RATE. The beta blockers most commonly prescribed for LQTS are propanolol (Inderal), metoprolol (Lopressor or Toprol), nadolol (Corgard), and atenolol (Tenormin). Beta blockers control LQTS in about 70 percent of people who have the condition. When medications fail to prevent arrhythmias, the next level of treatment is an IMPLANTABLE CARDIOVERTER DEFIBRILLATOR (ICD), an electronic device similar to a PACEMAKER. The ICD monitors the heart's rhythm and can deliver an electrical shock to return the heart to a normal rhythm should dangerous arrhythmias occur.

Because a prolonged QT interval is most likely to occur during intense physical exercise that puts high demand on the heart LQTS may require lifestyle modifications, especially for people who participate in competitive sports. Most people are able to enjoy recreational athletic and physical activities, however.

Risk Factors and Preventive Measures

Gene mutations establish the foundation for LQTS, probably even in secondary LQTS (LQTS

that results as a side effect of medication or other events). Family history of LQTS or sudden cardiac death is an important diagnostic clue. When LQTS is secondary, removing the cause often ends the conductive irregularities. There are no known preventive measures for primary LQTS. Treatment often controls symptoms and prevents life-threatening arrhythmia.

medications to treat cardiovascular disease Drugs that alter the function of the HEART or the BLOOD vessels. Plants provided the earliest forms of DRUG therapy for heart problems. Healers in ancient Egypt and Greece brewed teas of foxglove leaves, the source of digitalis, to slow a rapid heartbeat and strengthen a weakened heart. By the 17th century physicians were using a relatively standardized formulation of powdered foxglove to treat congestive HEART FAILURE. Foxglove leaves remain the source from which laboratories extract digitalis to manufacture digoxin and digitoxin, the digitalis-based medications that remain in use today. Quinidine, a medication to treat ARRHYTHMIA (irregular heartbeat), derives from the bark of the South American *Cinchona ledgeriana* tree (also the original source of the antimalarial drug quinine). Scientists isolated quinidine as an extract to treat ATRIAL FIBRILLATION in 1918. *Rauwolfia serpentina* was a staple in the PHARMACOPOEIA of healers in ancient India, who used its dried roots to lower BLOOD PRESSURE. The antihypertensive medication reserpine, which debuted in the 1950s, contains *Rauwolfia* alkaloid extracts. Today medications are the mainstay of treatment for most forms of CARDIOVASCULAR DISEASE (CVD), though most are synthetic formulations that come from the laboratory.

Cardiovascular disease often involves multiple, interrelated components. HYPERTENSION (high blood pressure) often arises from underlying ATHEROSCLEROSIS, the most common cardiovascular disease. CORONARY ARTERY DISEASE (CAD), a manifestation of atherosclerosis that affects the CORONARY ARTERIES supplying the heart, may generate arrhythmias and ANGINA PECTORIS. Heart failure typically features numerous symptoms arising from a constellation of cardiovascular dysfunctions. The recent direction of research has correspondingly produced medications that treat the constellation, not just a single symptom. A calcium channel blocker, a classification of medication that debuted in the 1990s, dilates peripheral arteries, and slows the HEART RATE; these actions lower blood pressure, regulate the heart's rhythm, and strengthen the heart's pumping action. Combining medications often produces more effective results. For example, the cardiologist may also prescribe a diuretic to extract additional fluid from the body, which lowers blood volume and thus blood pressure, which in turn relieves the heart's workload to reduce heart failure. The combination of the diuretic and the calcium channel blocker may restore nearly normal cardiovascular function.

People respond differently to cardiovascular drugs, even when they have the same diagnoses. It may take a trial and error period to find the right medication or combination of medications for each individual. Cardiovascular medications may interact or interfere with each other, with medications for other health conditions, with herbal preparations, and with certain foods. For example, grapefruit (whole fruit or juice) interferes with the actions of calcium channel blockers, statin lipid-lowering medications, digoxin, potassium channel blockers, and warfarin. The herb GOLDENSEAL, taken to enhance immune function, elevates blood pressure and interacts with antihypertensive medications. Dark green leafy vegetables contain VITAMIN K, which increases clotting and interferes with anticoagulant medications.

Most medications to treat cardiovascular conditions have the potential for side effects, some of which may be life-threatening. Sodium channel and potassium channel blockers, digoxin, warfarin, and heparin all are NARROW THERAPEUTIC INDEX (NTI) drugs, for which the margin between

helpful and harmful is exceedingly thin. These drugs have the potential to create life-threatening arrhythmias. Other cardiovascular medications may cause symptoms such as COUGH, HEADACHE, ERECTILE DYSFUNCTION, tiredness, CONSTIPATION, dizziness, flushing, and edema (swelling, particularly of the ankles and wrists). It is important for people to know what side effects are possible with they medications they are taking and to notify the doctor if any of them occur. Though some side effects are common to all of the drugs within a classification, sometimes switching to a different medication within the same classification eliminates the troublesome side effect.

ACE Inhibitors

Angiotensin-converting enzyme (ACE) inhibitors block the action of angiotensin-converting enzyme (ACE). Angiotensin II is a potent vasoconstrictor that raises blood pressure. Blocking the conversion of its precursor, angiotensin I (angiotensinogen), prevents these events and lowers blood pressure. ACE inhibitors also have a mild to moderate diuretic effect, further lowering blood pressure by reducing blood volume.

Pregnant women should not take ACE inhibitors during the second and third trimesters of PREGNANCY, as these drugs may cause harm or death to the fetus.

Doctors prescribe ACE inhibitors as first-line treatment, usually in combination with diuretics, to treat hypertension and heart failure and to reduce the risk of subsequent heart attacks after an initial heart attack. Some ACE inhibitor products combine an ACE inhibitor with a diuretic.

COMMON ACE INHIBITORS

benazepril (Lotensin)	captopril (Capoten)
enalapril (Vasotec)	fosinopril (Monopril)
lisinopril (Prinivil, Zestril)	moexipril (Univasc)
perindopril (Aceon)	quinapril (Accupril
ramipril (Aceon (Altace)	trandolapril (Mavik)

Among the common side effects are HEADACHE, gastrointestinal upset, dizziness, SKIN RASH or skin sensitivity to sunlight, and fatigue. ACE inhibitors have a propensity to cause a dry, nonproductive cough; though annoying, the cough is benign and typically goes away within two months of stopping the medication.

Adenosine

Adenosine is an intravenously administered medication that momentarily interrupts the flow of the heart's electrical pacing signals, creating an "electrical short" of sorts that very briefly stops the heart. It is a treatment for PAROXYSMAL ATRIAL TACHYCARDIA (PAT), also called paroxysmal supraventricular tachycardia (PSVT), that converts the heart to normal sinus rhythm. Sometimes cardiologists refer to this treatment as chemical or pharmaceutical CARDIOVERSION. Adenosine is available in the United States as the brand name product Adenocard. The effects of adenosine last only one to two minutes. Side effects may include headache, lightheadedness, NAUSEA, and shortness of breath (DYSPNEA). Adenosine also may trigger angina pectoris in people who have CAD.

Alpha Blockers

Alpha blockers, also called alpha adrenergic antagonist medications, block alpha receptors in the cells from binding with EPINEPHRINE (also called adrenaline). These drugs were among the first generation of antihypertensive medications, though beta blockers and other antihypertensives have generally replaced them. Alpha blockers relax smooth MUSCLE, including that in the walls of the arteries to produce arterial dilation. This reduces the resistance for the flow of blood, lowering blood pressure. The most common cardiovascular use of alpha blockers is to treat hypertension that arises from PHEOCHROMOCYTOMA. This endocrine tumor secretes the hormones epinephrine and NOREPINEPHRINE, causing extreme spikes in blood pressure.

Alpha blockers are not a first-line treatment approach for general hypertension because their effects are widely systemic and because their long-term use increases the risk for heart failure. Alpha blockers affect other sites of smooth muscle tissue throughout the body, such as in the gastrointestinal tract, acting to slow peristalsis, and in the genitourinary system, causing URINARY INCONTINENCE and ERECTILE DYSFUNCTION. Other side effects may include dizziness and SYNCOPE (fainting). Some alpha blockers also block beta receptors.

COMMON ALPHA BLOCKERS

clonidine (Catapres)	doxazosin (Cardura)
guanabenz (Wytensin)	guanfacine (Tenex)
labetalol (Normodyne)	methyldopa (Aldomet)
phenoxybenzamine (Dibenzyline)	prazosin (Minipress)
terazosin (Hytrin)	

Angiotensin II Receptor Blockers (ARBs)

Angiotensin II receptor blockers, also called angiotensin II receptor antagonists or ARBs, prevent the enzyme angiotensin II from binding with cells the walls of the arteries. Angiotensin II is a powerful endogenous vasoconstrictor (substance the body makes to narrow the blood vessels) that raises blood pressure. Preventing its actions relaxes and dilates the arteries, reducing the resistance blood encounters flowing through them and lowering blood pressure.

Pregnant women should not take angiotensin II receptor blockers (ARBs) during the second and third trimesters of PREGNANCY, as these drugs may cause harm or death to the fetus.

ARBs may be the first-line choice to treat hypertension, depending on the person's overall health profile and other medications. ARBs do not cause the cough and other side effects that can be troublesome with ACE inhibitors, though they do put more strain on the kidneys. The most common side effect with ARBs is headache, especially with losartan. Other side effects, though uncommon, may include anxiety, fatigue, and gastrointestinal upset.

COMMON ANGIOTENSIN II RECEPTOR BLOCKERS

candesartan (Atacand)	eprosartan (Teveten)
irbesartan (Avapro)	losartan (Cozaar)
olmesartan medoxomil (Benicar)	tasosartan (Verdia)
telmisartan (Micardis)	valsartan (Diovan)

Anticoagulants

People commonly refer to anticoagulant drugs as "blood thinners" though this is somewhat of a misnomer. The first stage of clotting, which anticoagulants delay, is a thickening of the blood as CLOTTING FACTORS begin causing cells to stick together. Anticoagulants prevent the body from processing vitamin K, which interferes with the blood's ability to activate clotting factors. Heparin, low molecular weight heparin (LMWH), and fondaparinux are injectable anticoagulants that are relatively short-acting though have cumulative effects when administered for extended periods of time. Surgeons use anticoagulants to completely suppress the blood's clotting ability during operations that require CARDIOPULMONARY BYPASS. Warfarin (Coumadin) is currently the only oral anticoagulant available, though research continues to search for alternatives. Anticoagulants are NTI drugs that require continual monitoring to maintain therapeutic levels.

Women who are pregnant or planning to become pregnant should not take warfarin, as it can cause birth defects (highest risk during first trimester).

Doctors prescribe anticoagulant medications to prevent blood clots from forming, typically to prevent DEEP VEIN THROMBOSIS (DVT) and PULMONARY EMBOLISM in PERIPHERAL VASCULAR DISEASE (PVD) with INTERMITTENT CLAUDICATION, and to prevent heart attack and stroke. Anticoagulants cannot dissolve clots that already exist (though thrombolytic agents can). The most significant side effect is excessive bleeding. Anticoagulants can interact with numerous medications. Foods high in vitamin K (such as dark green leafy vegetables) may increase the blood's clotting capability.

COMMON ANTICOAGULANTS

heparin	fondaparinux (Arixtra)
warfarin (Coumadin)	
LMWHs:	
ardeparin (Normiflo)	dalteparin (Fragmin)
enoxaparin (Lovenox)	nadroparin (Fraxiparine)
reviparin (Clivarine)	tinzaparin (Innohep)

Antiplatelet Agents

Antiplatelet agents also interfere with the blood's ability to clot by blocking platelets, the cells that initiate clotting, from aggregating or sticking together. PLATELET AGGREGATION sets in motion the sequence of chemical interactions that activate clotting factors; blocking PLATELET aggregation

delays the start of the clotting process. Antiplatelet agents often are part of an ANTICOAGULATION THERAPY regimen, in combination with anticoagulant medications.

The most commonly used antiplatelet agent is low-dose aspirin, which health experts recommend for people who have increased risk for cardiovascular disease or who have already had heart attack or ischemic stroke. Like anticoagulants, antiplatelet agents require close monitoring to maintain therapeutic levels. Three antiplatelet agents are injectable only—abciximab (Rheopro), eptifibatide (Integrilin), and tirofiban (Aggrastat)—which doctors use during ANGIOPLASTY and sometimes other CARDIAC CATHETERIZATION procedures. The oral antiplatelet agent cilostazol (Pletal) also acts to dilate the blood vessels, so doctors often prescribe it to treat intermittent claudication.

Doctors typically prescribe antiplatelet agents to prevent clots from forming in people who have PVD, CAD, valvular heart disease, prosthetic heart valves, PACEMAKER or IMPLANTABLE CARDIOVERTER DEFIBRILLATOR (ICD), or who have had heart attack, stroke, or certain kinds of heart surgery. The most significant side effect of antiplatelet agents is excessive bleeding. Over-the-counter NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) such as ibuprofen, and the herbal product ginkgo biloba, also have mild antiplatelet activity; it is important to check with the doctor or pharmacist before taking them with prescribed antiplatelet agents.

COMMON ANTIPLATELET AGENTS

abciximab (Rheopro)	cilostazol (Pletal)
clopidogrel (Plavix)	dipyridamole (Persantine)
eptifibatide (Integrilin)	sulfinpyrazone (Anturane)
ticlopidine (Ticlid)	tirofiban (Aggrastat)

Beta Blockers

Beta blockers, also called beta adrenergic antagonist medications or class II antiarrhythmics, block beta receptors in the cells from binding with epinephrine. Beta receptors are specific to the arteries and MYOCARDIUM, so the actions of beta blockers are selective and specific to these sites. In the heart, beta blockers slow the conduction of electrical impulses, which slows the heart rate and reduces the amount of blood the heart pumps (CARDIAC OUTPUT). These effects result in lowered blood pressure and also reduced cardiac workload, which relieves angina pectoris. In the arteries, beta blockers cause smooth muscle tissue to relax, which dilates the arteries to decrease the resistance blood encounters to lower blood pressure. Most beta blocker medications thus do not have the systemic or generalized effects of alpha blockers, though a few of the beta blockers (notably propanolol and sotalol) also have some alpha antagonist activity as well and may have mild systemic effects.

There are two kinds of beta receptors, beta 1 and beta 2. Muscle cells in the myocardium and NERVE cells that regulate heart rate contain primarily beta 1 receptors. Peripheral arteries and arterioles contain primarily beta 2 receptors. Different beta blocker drugs target either beta 1 or beta 2 receptors. The smooth muscle cells in the airways also contain beta 2 receptors, so beta blockers that affect beta 2 receptors in the blood vessels also affect the airways. Medications to treat ASTHMA may interact with beta blockers taken to treat cardiovascular conditions. Beta blockers prescribed for other conditions such as asthma, BENIGN PROSTATIC HYPERTROPHY (BPH), migraine headaches, GLAUCOMA, and essential tremor may also affect cardiovascular function.

Do not suddenly stop taking a beta blocker, as doing so may cause intensified ANGINA PECTORIS and increased risk for HEART ATTACK.

Beta blockers are the "workhorse" drugs in cardiology, treating a broad spectrum of cardiovascular conditions. Doctors prescribe beta blockers to treat hypertension, heart failure (especially congestive heart failure), atrial fibrillation, mild to moderate ventricular tachycardia, CARDIOMYOPATHY, angina pectoris, and to improve survival following heart attack. The most common side effects are fatigue and sleepiness, which generally improve with taking the medication over time. Beta blockers may cause erectile dysfunction in men and diminished sexual response in women. CAFFEINE and antihistamines (such as in cold and allergy products) intensify, and ALCOHOL diminishes, the effects of beta blockers. Beta blockers may interfere with the actions of oral ANTIDIABETES MEDICATIONS.

COMMON BETA BLOCKERS

acebutolol (Sectral)	atenolol (Tenormin)
betaxolol (Kerlone)	bisoprolol (Zebeta)
carteolol (Cartrol)	esmolol (Brevibloc)
metoprolol (Lopressor, Toprol)	nadolol (Corgard)
penbutolol (Levatol)	pindolol (Visken)
propranolol (Inderal)	timolol (Blocadren)

Calcium Channel Blockers

Calcium channel blockers, also called calcium channel antagonists, limit the amount of calcium that enters contractile cells. Two of the commonly prescribed calcium channel blockers act nearly exclusively on the heart (myocardial cells), diltiazem and verapamil. Cardiologists prescribe these drugs, also identified as class IV antiarrhythmics, to treat atrial fibrillation, PAT, hypertrophic cardiomyopathy, and angina pectoris. The other calcium channel blockers, sometimes called dihydropyridine calcium channel blockers, act primarily on the peripheral arteries, causing them to relax and dilate. This lowers resistance for blood flow and reduces blood pressure. Cardiologists prescribe these calcium channel blockers to treat hypertension, angina pectoris without arrhythmia, and RAYNAUD'S SYNDROME. Doctors use nimodipine following stroke to reduce the risk of arterial spasm and resulting HEMORRHAGE, as it affects primarily the arteries in the BRAIN.

Women who are pregnant or planning to become pregnant should not take calcium channel blockers, as these drugs can cause serious birth defects and STILLBIRTH.

COMMON CALCIUM CHANNEL BLOCKERS

amlodipine (Norvasc, Lotrel)	diltiazem (Cardizem, Cartia, Dilacor, Diltia, Tiazac)
felodipine (plendil)	nicardipine (Cardene)
isradipine (DynaCirx)	nimodipine (Nimotop)
nifedipine (Adalat, Procardia)	nisoldipine (Sular)
verapamil (Calan, Covera, Isoptin, Verelan)	

Side effects that may occur when taking calcium channel blockers include headache, gastrointestinal upset, fatigue, and peripheral edema. Most side effects retreat after a few weeks of taking the medication. Grapefruit and grapefruit juice interfere with most calcium channel blockers, preventing them from working properly.

Diuretics

People commonly refer to diuretic medications as "water pills" because they draw extra fluid from the body, increasing urination. The purpose is to reduce the volume of blood, which lowers blood pressure. Diuretics also help prevent edema (fluid accumulations in body tissues) such as may occur with heart failure. Doctors often prescribe diuretics in combination with other medications. There are four classifications of diuretic medications, defined by the drug's mechanism of action: ALDOSTERONE blockers, loop diuretics, potassium-sparing diuretics, and thiazides.

Aldosterone blockers Aldosterone blockers act by restricting adrenal gland production of the HORMONE aldosterone, which increases the amount of sodium the KIDNEYS withdraw from the blood. They affect the RENIN-angiotensin-aldosterone (RAA) hormonal system, one of the body's primary blood pressure regulatory systems. Though aldosterone blockers prevent the kidneys from reabsorbing sodium, they decrease the loss of potassium so they are also designated as "potassium-sparing." However, new understanding emerged in the early 2000s about other effects aldosterone has on the heart, particularly following heart attack and in heart failure and with respect to the RAA hormonal system, that have caused doctors to view aldosterone blockers as a separate category of diuretic.

The two aldosterone blockers available in the United States are eplerenone (Inspra) and spironolactone (Aldactone).

Loop diuretics Loop diuretics act on a site within the glomerular structure of the kidney called the loop of Henle, which regulates sodium reabsorption. Loop diuretics cause the kidneys to pass more sodium, and consequentially more water, into the urine, and are the most potent of the diuretic drugs. As the loop of Henle also plays a role in potassium regulation, loop diuretics also decrease potassium reabsorption and can result in potassium depletion. Doctors may also prescribe potassium supplementation to offset this effect. The most common side effect of loop diuretics is

headache. Loop diuretics also can damage the structures of the inner EAR, resulting in temporary or permanent HEARING LOSS.

COMMON LOOP DIURETICS

bumetanide (Bumex)	ethacrynic acid (Edecrin)
furosemide (Lasix, Myrosemide)	torsemide (Demadex)

Potassium-sparing diuretics These drugs prevent the kidneys from withholding sodium, the electrolyte most responsible for fluid retention, though allow the kidneys to pull potassium from the blood. They are the least potent of the diuretic drugs, acting on other sites in the glomeruli that regulate specifically sodium reabsorption. The two potassium-sparing diuretics available in the United States are amiloride (Midamor) and triamterene (Dyrenium). The aldosterone blockers eplerenone and spironolactone are also potassium sparing.

Thiazide diuretics The thiazide diuretics are the first line of therapy for hypertension and heart failure, often in combination with other cardiovascular medications. Their actions are more moderate than those of the loop diuretics, creating less of a risk for potassium depletion though such risk still exists. There are numerous thiazide diuretics, only some of which doctors prescribe for cardiovascular conditions. Because thiazides are so commonly used with other medications, there are also numerous formulations that incorporate a thiazide with another cardiovascular drug.

COMMON THIAZIDE DIURETICS

chlorothiazide (Diuril, Diurigen)
chlorthalidone (Hygroton, Thalitone)
hydrochlorothiazide (Ezide, Esidrix, HCTZ, Hydro-Chlor, Hydro-D, HydroDIURIL, Microzide, Oretic)
hydroflumethiazide (Diucardin, Saluron)
methyclothiazide (Aquatensen, Enduron)
metolazone (Diulo, Mykrox, Zaroxolyn)
polythiazide (Renese)
quinethazone (Hydromox)
trichlormethiazide (Metahydrin, Naqua, Trichlorex)

Inotropics

Inotropic drugs draw more calcium into myocardial cells, intensifying their contractility (the force with which they contract) and increasing the heart's effectiveness while decreasing the effort required. Inotropic drugs administered intravenously during cardiovascular emergency include dopamine, dobutamine, and milrinone; these drugs give the heart a "jolt" to help it pull out of CARDIAC ARREST. Digoxin (short-acting) and digitoxin (long-acting), forms of digitalis, are the inotropic medications for chronic or extended oral therapy. Though once the cornerstone of therapy for heart failure (notably congestive heart failure), digoxin has a very narrow therapeutic index, making toxicity a worrisome concern. Digoxin interacts with numerous other medications including those that more effectively treat heart failure, and the heart becomes dependent on it.

Digoxin also acts to slow the number of electrical impulses that cross the ATRIOVENTRICULAR (AV) NODE, slowing and regulating the contractions of the myocardial cells. Cardiologists may prescribe digoxin to treat atrial fibrillation. The most common brand name digoxin product in the United States is Lanoxin.

Lipid-Lowering

Lipid-lowering medications reduce blood levels of cholesterol and triglycerides, lowering the risk for atherosclerosis and its related conditions CAD and PVD. There are four classifications of lipid-lowering medications, each with a different mechanism of action: BILE acid sequestrants, fibrates, statins, and selective cholesterol absorption inhibitors. As well, niacin acts to block cholesterol and lipoprotein synthesis in the LIVER.

Bile acid sequestrants The bile acid sequestrants were the first cholesterol-lowering medications to become available. They work by binding with bile in the gastrointestinal tract, preventing the body from reabsorbing cholesterol the bile contains. Bile acid sequestrants can reduce low-density lipoprotein cholesterol (LDL-C) by about 20 percent and total cholesterol by 5 to 10 percent. These medications come as powders to mix with juices or foods such as applesauce, and commonly cause gastrointestinal distress. Bile acid sequestrants interact with numerous medications, including beta blockers, diuretics, and the anticoagulant warfarin.

COMMON BILE ACID SEQUESTRANTS

cholestyramine (Questran, Prevalite)	colesevelam (WelChol)
	colestipol (Colestid)

Fibrates The fibrates work by blocking the liver's production of LDL and VLDL (very low-density lipoprotein), the carriers for triglycerides. However, fibrates do not lower LDL-C or VLDL-C in the blood. Rather, they primarily reduce triglycerides though also raise high-density lipoprotein cholesterol (HDL-C), the "good" cholesterol. The most common side effect of fibrates is gastrointestinal distress, which usually disappears after taking the medication for a few weeks.

COMMON FIBRATES

clofibrate (Atromid-S)	fenofibrate (Tricor)
gemfibrozil (Lopid)	

Statins Statins—or 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors—are the most commonly prescribed lipid-lowering medications. They work by blocking the action of HMG-CoA reductase, an enzyme necessary for the liver to synthesize cholesterol. Statins can lower blood LDL cholesterol by as much as 35 percent in just three to six weeks, making them very effective at quickly lowering the risk for atherosclerosis-related cardiovascular events. Statins reduce the risk for the progression of CAD, which could improve heart function after heart attack and are part of the standard medication regimen after heart attack and HEART TRANSPLANTATION. Common side effects of statins include gastrointestinal distress, fatigue, headache, and sleep disturbances.

COMMON STATINS

atorvastatin (Lipitor)	fluvastatin (Lescol)
lovastatin (Mevacor)	pravastatin (Pravachol)
simvastatin (Zocor)	

Selective cholesterol absorption inhibitors The selective cholesterol absorption inhibitors block the gastrointestinal tract from absorbing dietary cholesterol, limiting the cholesterol that enters the bloodstream. Ezetimibe (Zetia) is currently the only drug in this classification that is available in the United States. Doctors often prescribe ezetimibe in combination with statin medications for the most effective lipid-lowering effect.

Potassium Channel Blockers

Potassium channel blockers, also called potassium channel antagonists or class III antiarrhythmics, limit the amount of potassium, a key electrolyte (chemical that can carry an electrical impulse), that can enter myocardial cells. This limitation restricts the flow and pattern of electrical impulses through the heart in very specific ways. Cardiologists prescribe potassium channel blockers to treat atrial fibrillation that does not respond to other medications and to treat atrial tachycardia. These drugs interact with numerous medications, including those prescribed to treat cardiovascular conditions (notably digoxin and warfarin) and to treat other health conditions such as DIABETES. Amiodarone increases sensitivity to ultraviolet light, which can result in severe SUNBURN even through clothing. Potassium channel blockers have numerous serious side effects including life-threatening or fatal arrhythmias and TORSADE DE POINTES, a highly unstable form of ventricular tachycardia.

COMMON POTASSIUM CHANNEL BLOCKERS

amiodarone (Cordarone)	dofetilide (Tikosyn)
ibutilide (Corvert)	

Sodium Channel Blockers

Sodium channel blockers, also called sodium channel antagonists or class I antiarrhythmics, limit the amount of sodium that enters myocardial cells. This limitation restricts the flow and pattern of electrical impulses through the heart in very specific ways that differ from the actions of potassium channel blockers. Because sodium is critical for myocardial contraction, restricting it requires a delicate therapeutic balance. Cardiologists reserve sodium channel blockers to treat potentially life-threatening ventricular tachycardia that does not respond to other treatment. The risks and complications of these medications are numerous and serious; they can cause fatal arrhythmias.

COMMON SODIUM CHANNEL BLOCKERS

disopyramide (Norpace)	flecainide (Tambocor)
mexiletine (Mexitil)	moricizine (Ethmozine)
procainamide (Pronestyl)	propafenone (Rythmol)
quinidine (Cardioquin, Quinidex)	

Thrombolytic Agents

Thrombolytic agents, commonly called "clot busters," dissolve blood clots that have already formed. Given early enough, they can prevent the

clot from forming, essentially halting heart attack or stroke before the event can cause any damage. However, doctors must administer them within three to four hours of clot formation. After four hours the clot has hardened and thrombolytic agents cannot dissolve them.

Thrombolytic agents are substances, either natural extracts or recombinant forms, that convert plasminogen in the blood to plasmin, an enzyme that dissolves fibrin. Fibrin is the substance in the blood that forms the webbing of the clot structure to snare platelets and other substances in the blood that become the clot. Early in the COAGULATION process fibrin is a semisolid, stringlike substance similar to the strands of a spiderweb. As the coagulation process continues, however, the fibrin strands and the cellular matter they have captured harden into the solid structure of a blood clot. Once the fibrin hardens, plasmin has no effect on it.

The most frequently used thrombolytic agents are tissue plasminogen activators (tPAs). One of the original thrombolytic agents, streptokinase, derives from the streptococcus bacterium and causes the body to develop antibodies against it. Because of this, doctors cannot administer streptokinase if the person has received streptokinase within 12 months. However, it takes about five days for the body to produce antibodies, allowing multiple administrations within five days of the initial dose. The tPAs do not seem to have this limitation, although it is possible for the body to develop antibodies against them as well.

Doctors administer thrombolytic agents intravenously to treat heart attack, stroke, deep vein thrombosis, and pulmonary embolism. The effect is rapid and short acting. Excessive and severe bleeding is a significant risk, particularly when stroke is hemorrhagic rather than ischemic. Doctors make every effort to determine the nature of a stroke before administering thrombolytic agents, though sometimes bleeding occurs even with ischemic stroke. As well, these agents may disturb the integrity of clots that have formed within the previous 10 days, such as from surgery.

COMMON THROMBOLYTIC AGENTS

alteplase (Activase)	anistreplase (Eminase)
reteplase (Retavase)	streptokinase (Streptase, Kabinase)
tenecteplase (TNKase)	urokinase (Abbokinase)

Vasoconstrictors

Vasoconstrictors cause the blood vessels to constrict, or tighten, to raise blood pressure. Doctors administer vasoconstrictors to treat cardiovascular SHOCK and HYPOTENSION. Many bronchodilating medications prescribed to treat asthma also have peripheral vasoconstriction action, and may raise blood pressure at the same time they open the airways. One of the most commonly used vasoconstrictors is pseudoephedrine, found in cold, flu, and some allergy medications. Caffeine and NICOTINE are also vasoconstrictors. Though doctors do not prescribe these products for cardiovascular use, they have the effect of raising blood pressure as well as increasing heart rate. The most commonly used vasoconstrictor for cardiovascular purposes is midodrine (ProAmatine).

Vasodilators

Many medications to treat hypertension are vasodilators, drugs that cause the blood vessels to relax so more blood can flow through them with less resistance. These medications may lower blood pressure or relieve angina pectoris. Among the general vasodilators cardiologists might prescribe to treat hypertension are hydralazine and minoxidil. Both drugs regulate the calcium that enters the smooth muscle cells of the ARTERY walls, slowing their contractility and causing the arteries to relax (dilate). Minoxidil is an NTI drug that requires close monitoring because, although it is a potent peripheral vasodilator, it also increases heart rate and has other cardiovascular actions that require additional medications to moderate.

Nitrate vasodilators are especially effective at relaxing the coronary arteries to relieve angina pectoris, which is one of the leading reasons doctors prescribe them. Nitrates also dilate the peripheral veins, which decreases the heart's workload. Nitrates come in sublingual tablets placed under the tongue at the onset of anginal symptoms, regular and long-acting oral medications, transdermal (skin) patches, and topical ointments. Because the body acquires a tolerance to nitrates, dosing schedules are particularly important. Other commonly prescribed medications that have vasodilating actions include certain of the beta blockers, calcium channel blockers, ACE inhibitors, and ARBs.

COMMON VASODILATORS

hydralazine (Apresoline)
mecamylamine (Inversine)
minoxidil (Loniten)

Nitrates

isosorbide dinitrate (Isordil, Sorbitrate)
isosorbide mononitrate (Imdur, ISMO, Monoket)
nitroglycerin (Nitro-Dur, Nitrolingual, Nitrostat)

microinfarction Tiny arterial occlusions that briefly block the flow of BLOOD to the BRAIN, causing transient ischemic attacks (TIAs), or to the HEART. What microinfarction lacks in initial effect it makes up through frequency. Microinfarction may also affect other key organs such as the KIDNEYS and LIVER. Conditions that can result in microinfarction include severe ATHEROSCLEROSIS, PERIPHERAL VASCULAR DISEASE (PVD), CORONARY ARTERY DISEASE (CAD), INTERMITTENT CLAUDICATION, and DEEP VEIN THROMBOSIS (DVT). Microinfarction also may

minimally invasive cardiac surgery Surgical methods that combine ENDOSCOPY and CARDIAC CATHETERIZATION to repair damaged HEART valves or clear obstructive ATHEROSCLEROTIC PLAQUE. Some methods involve making several small incisions in the chest and between the ribs to gain access to the heart. Others involve inserting microscopic tools, via cardiac catheterization, into the heart. There remain questions as to whether minimally invasive cardiac surgery is of greater or lesser risk than OPEN HEART SURGERY.

Though significantly less traumatic, minimally invasive cardiac surgery restricts the surgeon's ability to see the condition of the heart. Minimally invasive cardiac surgery done "off-pump" (without CARDIOPULMONARY BYPASS), further challenges the surgeon's ability to operate on a moving target. Countering these concerns are the reduced trauma to the chest because the STERNUM (breastbone) can remain intact, as well as avoiding the risks of cardiopulmonary bypass. Recovery is much more rapid and significantly less painful than with traditional open heart surgery. However, the surgeon cannot reach the back of the heart using minimally invasive procedures, limiting the value of these methods for treating CORONARY ARTERY DISEASE (CAD) that involves the posterior CORONARY ARTERIES.

myocardial infarction Death of HEART tissue. The most common cause of myocardial infarction is occlusion of the CORONARY ARTERIES such as occurs as a consequence of CORONARY ARTERY DISEASE (CAD) or less frequently of coronary ARTERY spasm. Myocardial infarction is the clinical term doctors use for HEART ATTACK. The MYOCARDIUM has very high oxygen needs, as oxygen is the only energy source for myocardial cells (unlike most other cells in the body, except the BRAIN, that also use GLUCOSE for energy). Myocardial tissue does not have significant ability to regenerate.

Myocardial tissue that dies not only can no longer contract to aid in the heart's function but

also cannot conduct electrical impulses to reach undamaged tissue. Myocardial infarction results in "dead" areas of the heart MUSCLE that cannot participate in the CARDIAC CYCLE, which often results in ARRHYTHMIA as well as ineffective pumping ability. The cellular structure of these areas changes, initially becoming soft and subsequently becoming fibrous (scarlike). New arteries are often able to develop, through a process called angiogenesis, to carry BLOOD around infarcted areas of the heart. This helps the rest of the heart remain functional. However, large infarctions may overcome the heart, resulting in heart attack or CARDIAC ARREST.

ELECTROCARDIOGRAM (ECG) and ECHOCARDIOGRAM are the diagnostic procedures that typically identify myocardial infarction. Treatment includes eliminating the cause of the infarction, such as coronary artery occlusion, and stabilizing the heart's function to the best extent possible with medications. Because CAD is nearly always the culprit, ANGIOPLASTY or CORONARY ARTERY BYPASS GRAFT (CABG) are nearly always among the treatment options.

myocardial perfusion imaging A radionuclide procedure that allows cardiologists to observe the flow of BLOOD from the CORONARY ARTERIES into the tissues of the MYOCARDIUM (HEART MUSCLE). The test usually involves a resting and an exercise component, to provide a comprehensive picture of how much blood the heart receives to assess the extent to which CORONARY ARTERY DISEASE (CAD) is reducing cardiac function. The procedure takes about an hour and requires little preparation (namely, abstaining from STIMULANTS such as CAFFEINE and NICOTINE for 48 hours before the procedure).

The cardiologist administers a small amount of a radioactive substance, called a radionuclide or radioisotope (most commonly thallium), into a VEIN in the back of the hand or in the arm. The radionuclide is mixed in a solution, usually GLUCOSE, that the blood carries to the cells. The radionuclide rides along as a "tag" on the glucose molecules, accompanying them into the cells. The radionuclide rapidly disintegrates, releasing a pattern of electromagnetic energy called gamma-rays. A special device called a gamma camera detects the gamma rays, and presents them as images. The concentrations of energy tell cardiologists where myocardial blood flow is strong and where it is restricted, helping identify areas of ischemia (oxygen-deprived tissue).

When actual physical exercise is not feasible, the cardiologist may use a DRUG (often dipyridamole) to chemically simulate the effects of exercise on the heart. People who have ANGINA PECTORIS or significant CAD may feel temporary discomfort during this simulation. There are no side effects from myocardial perfusion imaging. The radionuclides cardiologists use emit minimal radioactivity and are gone from the body within a few hours.

myocarditis INFLAMMATION of the HEART MUSCLE, often as a consequence of viral INFECTION that originates elsewhere in the body (such as a cold). Viruses known to cause myocarditis include MEASLES, RUBELLA, coxsackie, and CYTOMEGALOVIRUS (CMV). Myocarditis also may be bacterial, or the consequence of cardiotoxic exposure (such as to radiation or carbon monoxide). The autoimmune processes of systemic inflammatory disorders such as SYSTEMIC LUPUS ERYTHEMATOSUS (SLE), SARCOIDOSIS, and RHEUMATOID ARTHRITIS also can involve the myocardium. A rare and severe form of myocarditis is giant cell myocarditis, an autoimmune disorder that specifically attacks the heart.

Myocarditis may have few symptoms until there is significant damage to the heart (commonly in the form of CARDIOMYOPATHY and ARRHYTHMIA), and often is life-threatening. Symptoms of early or chronic myocarditis may mimic those of INFLUENZA or of HEART ATTACK. Diagnosis is by myocardial biopsy performed via CARDIAC CATHETERIZATION, which reveals the infiltration of lymphatic cells and other characteristic changes in the myocardium that identify an inflammatory process. Chronic or advanced myocarditis may

have FIBROSIS (scar tissue). Treatment targets relieving arrhythmias and HEART FAILURE, and may include IMMUNOSUPPRESSIVE THERAPY. HEART TRANSPLANTATION may become an option for end-stage heart failure.

myocardium The MUSCLE tissue that forms the walls of the HEART. Myocardial cells are unique in their structure, blending muscle and NERVE structures so they can both contract and conduct electrical impulses. Myocardial cells thus can contract independent of external stimulation. The myocardial fibers of the atria have a different configuration from those of the ventricles. The CORONARY ARTERIES provide an extensive network to supply blood to the myocardium, which requires about 70 percent of the blood's oxygen. With increasing age, fibrous and fatty tissue tends to infiltrate the myocardium, somewhat reducing its effectiveness.

CONDITIONS THAT CAN AFFECT THE MYOCARDIUM

CARDIOMYOPATHY	CONGENITAL ANOMALY
ISCHEMIC HEART DISEASE	MICROINFARCTION
MYOCARDIAL INFARCTION	MYOCARDITIS

CORONARY ARTERY DISEASE (CAD) is the most significant threat to the myocardium, as occlusions in the coronary arteries deprive the myocardium of blood and thus oxygen. When the consequence is MYOCARDIAL INFARCTION, CARDIAC ARREST can result.

For further discussion of the myocardium within the context of cardiovascular structure and function, please see the overview section "The Cardiovascular System."

myxoma A nonmalignant tumor that grows in the HEART, nearly always in one of the atria and most commonly in the left atrium. Myxoma arises from the ENDOCARDIUM and may be either firm or soft in consistency. The tumor can block the flow of BLOOD through the atrium, interfere with the function of the heart valves, or break apart to send fragments into the blood circulation that cause embolism (sudden blockage of an ARTERY) elsewhere in the body. Soft myxomas are more likely to fragment; firm myxomas are more likely to be occlusive. As a myxoma grows it causes increasing turbulence in the blood as it flows through the chamber, presenting a significant risk for the formation of blood clots. ECHOCARDIOGRAM generally provides definitive diagnosis. Treatment is OPEN HEART SURGERY to remove the tumor. Once removed, the tumor results in no residual consequences. Myxoma is most common in people between the ages of 30 years and 60 years.

obesity and cardiovascular disease OBESITY, a condition in which excess body weight is 20 percent or more above healthy weight as a result of excessive body fat, emerged in the 1990s as an independent risk factor for CARDIOVASCULAR DISEASE (CVD). This means that without any other additional RISK FACTORS FOR CARDIOVASCULAR DISEASE, obesity makes CVD more likely. However, the relationship between obesity and CVD is complex. Other health conditions associated with obesity also increase the risk for numerous types of cardiovascular disease. Prominent among them are HYPERTENSION (high BLOOD PRESSURE), INSULIN RESISTANCE, HYPERLIPIDEMIA, and DIABETES. Some health experts believe obesity is as significant a risk factor for cardiovascular disease as cigarette smoking.

Doctors define obesity as a BODY MASS INDEX (BMI) of 30 kilograms per meter squared (kg/m^2) or higher. This corresponds to about 20 percent above healthy weight. BMI correlates body weight with health risk. At a BMI of 30, a person is likely to have at least one health condition associated with obesity. As BMI rises, so do the associated health conditions and the risk for cardiovascular disease. When BMI reaches 40, it is unusual for there *not* to be some form of cardiovascular disease present.

Obesity affects cardiovascular function mechanically and metabolically. Excessive body fat pressures the BLOOD vessels, causing the heart to work harder to pump blood through them. As well, there is more surface area that the cardiovascular

BMI AND CARDIOVASCULAR DISEASE RISK

BMI (kg/m2)	Cardiovascular Risk	Conditions
18.5–24.9: healthy	not affected	none
25–29.9: overweight	increased	HYPERLIPIDEMIA; HYPERTENSION manageable through lifestyle
30–34.9: OBESITY	high	hyperlipidemia; hypertension; ATHEROSCLEROSIS manageable through lifestyle and medication
35–39.9: severe obesity	very high	hyperlipidemia; hypertension; atherosclerosis; mild to moderate CORONARY ARTERY DISEASE (CAD); DIABETES (type 2); OBSTRUCTIVE sleep apnea management requires multiple medications
40+: morbid obesity	extremely high	hyperlipidemia; hypertension; atherosclerosis; moderate to severe CAD; symptomatic HEART FAILURE; diabetes; obstructive sleep apnea multiple medications necessary though may not entirely manage cardiovascular conditions

system must perfuse with blood. Excessive body fat may compress the neck, causing OBSTRUCTIVE SLEEP APNEA (episodes during sleep in which the person stops BREATHING). Obstructive sleep apnea prevents adequate air flow to the LUNGS, reducing oxygenation of the blood and causing ischemic episodes in which the heart does not receive enough oxygen, which results in ARRHYTHMIA. Excessive body fat may also compress the heart itself, further increasing the forces against which it must work to pump blood. All of these factors conspire to raise blood pressure and increase HEART RATE in an attempt to help the heart, which, if allowed to progress unchecked, are likely to result in HEART FAILURE.

Metabolically, obesity triggers INSULIN dysfunction. Because insulin plays a key role in cholesterol synthesis in the LIVER, hyperlipidemia is likely. Hyperlipidemia contributes to CORONARY ARTERY DISEASE (CAD) and PERIPHERAL VASCULAR DISEASE (PVD). A more significant health concern is the evolution from insulin resistance to diabetes. Diabetes increases cardiovascular disease risk substantially, as it is itself an independent risk factor for, as well as a leading cause of, cardiovascular disease.

When obesity declines even modestly, cardiovascular risk drops and cardiovascular health improves. As little as a 10-pound weight loss can drop systolic blood pressure by 10 millimeters of mercury (mm Hg). With sustained weight loss, many cardiovascular symptoms retreat and risk continues to fall.

omega fatty acids and cardiovascular health Omega fatty acids are dietary substances that increase high-density lipoprotein cholesterol (HDL-C) and decrease low-density lipoprotein cholesterol (LDL-C). Omega fatty acids also reduce the likelihood of ARRHYTHMIA and may help lower BLOOD PRESSURE. The omega fatty acids that appear most beneficial are eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Researchers do not know how omega fatty acids affect cardiovascular health though believe they reduce INFLAMMATION and the blood's clotting tendencies. These effects slow ATHEROSCLEROTIC PLAQUE accumulation and infiltration into the arterial intima, the innermost layer of the arterial wall.

The most abundant dietary sources of omega fatty acids are cold-water fish such as mackerel, tuna, and salmon. Health experts recommend eating at least two servings a week of these fish, which contain high levels of EPA and DHA, or taking supplements that provide 1 to 1.5 grams of EPA and DHA. People who have high levels of triglycerides may need to take higher doses. However, doses higher than 3 grams may cause excessive bleeding. Flaxseed and flaxseed oil, canola oil, soybeans and soybean foods such as tofu, and walnuts are good dietary sources of alpha-linolenic acid (LNA), from which the body can metabolize omega fatty acids.

An unresolved concern remains that of mercury contamination in cold-water fish. Mercury poisoning is particularly harmful to a developing FETUS and raises the risk for certain kinds of CANCER in adults. The US Environmental Protection Agency (EPA) routinely samples and reports mercury levels in different species of fish and issues advisories for those that exceed established safety levels. People who are concerned about mercury contamination can obtain omega fatty acids through dietary supplements, which appear equally effective.

open heart surgery Any OPERATION in which the surgeon opens the chest to expose the HEART. Open heart surgery is the most common method for CORONARY ARTERY BYPASS GRAFT (CABG), valvuloplasty and heart valve replacement, reconstructive operations to correct congenital heart malformations, and HEART TRANSPLANTATION. In the United States, surgeons perform about 750,000 open heart surgery operations each year, about 600,000 of which are CABG. Open heart surgery requires general ANESTHESIA and a hospital stay of 3 to 10 days, depending on the operation. Though most open heart operations also employ CARDIOPULMONARY BYPASS, in which a machine takes over the role of oxygenating and pumping the BLOOD so the

surgeon can operate on a still heart, there is a growing trend toward "off pump" operations that do not use cardiopulmonary bypass.

Surgical Procedure

For open heart surgery, the surgeon makes a long incision lengthwise along the top of the sternum (breastbone) through the SKIN and tissues beneath, and then makes a similar saw-cut through the sternum to enter the chest cavity. Special retractors spread the sternum and hold the incision open. To reach the heart, the surgeon must open the PERICARDIUM, the protective membranous sac that surrounds the heart. Often the surgeon leaves the pericardium open after the operation on the heart, to shorten surgery time and reduce the risk for postoperative complications.

For operations using cardiopulmonary bypass, the surgeon attaches the heart's major vessels to large tubes called cannulas, then clamps the heart vessels closed. The blood reroutes through the bypass machine. The surgeon can then bathe the heart in a cold concentrated potassium solution, which causes the heart to stop beating (cardioplegia). After completing the operation the surgeon reverses the process to restore circulation through the heart, closes the sternum with sturdy wire sutures and the skin with nylon sutures or staples. The SCAR that remains after the surgical wound heals remains fairly prominent for two to three years, after which it fades to a thin line.

When the operation is "off pump," the surgical team lowers the person's body temperature to slow body functions including heart contractions. The surgeon operates on the moving heart, which requires precise technique and timing. Inadvertent damage to the heart is a significant risk.

Risks and Complications

Many of the risks of open heart surgery are the same regardless of the operation. Key among them are

- excessive bleeding due to anticoagulants
- air embolism during cardiopulmonary bypass, which can cause STROKE
- difficulty restoring the heart to normal rhythm
- failure of the surgical procedure
- surgeon error
- unexpected anatomic anomalies

General complications that can occur after surgery include

- bleeding at the operative site or at the surface surgical wound
- INFECTION, either affecting the heart or the surgical wound
- blood clots, which may cause PULMONARY EMBOLISM, HEART ATTACK, or stroke
- ARRHYTHMIA
- HYPERTENSION and HEART FAILURE

Surgeons and the health-care team are alert for complications that can arise. Most people stay for 12 to 48 hours in a specialized cardiac surgery intensive care unit, where staff monitor cardiopulmonary function continuously. Many potential postoperative complications become less likely by 48 hours from surgery, though many people stay in the hospital for up to 10 days until the surgeon is confident that HEALING is well under way.

Outlook and Lifestyle Modifications

The outlook following open heart surgery depends to great extent on the reason the surgery was necessary. Many people return to normal activities after they recover from their operations, though may require frequent follow-up visits or medications. This is especially true for heart transplant recipients. The likelihood of complications diminishes as time passes and healing becomes complete.

Most people need to make some lifestyle changes after open heart surgery, typically in eating and exercise habits. Cardiologists recommend a diet that is nutritiously balanced and daily exercise such as walking. CARDIAC REHABILITATION programs help people get started with such changes, providing customized plans to accommodate the person's starting point as well as recovery goals.

Ornish program An intensive lifestyle-oriented method for reducing the risk for CORONARY ARTERY

DISEASE (CAD) and HEART ATTACK. Named for Dean Ornish, the American physician who developed the approach, the Ornish program features a strict vegetarian diet very low in fat along with daily YOGA, walking, MEDITATION, and participation in SUPPORT GROUPS. In the early 2000s in the United States, Medicare approved the Ornish program as an alternative treatment approach for CAD and rehabilitation following heart attack. The program arises from 25 years of clinical research supporting the effectiveness of restrictive diet to halt and sometimes reverse CAD. Numerous cardiovascular rehabilitation centers around the country offer the Ornish program. It is important to maintain the lifestyle changes after completing the structured program.

P

pacemaker A small, implanted electronic device that emits electrical impulses to maintain a regular HEART RATE. The most frequent use of a pacemaker is to treat bradycardia, an ARRHYTHMIA in which the HEART rate is persistently below 60 beats per minute. A pacemaker may also be an effective treatment for obstructive CARDIOMYOPATHY, in which thickening of the heart wall interferes with the ability of the myocardial cells to convey electrical impulses.

Implanting the Pacemaker

The cardiologist implants the pacemaker during a brief procedure, with local anesthetic and a mild sedative to make the person comfortable. A standard pacemaker has two components: the pacing lead and the computerized control unit. The pacing lead extends through a BLOOD vessel into the heart, where the cardiologist positions it against the wall of the heart, usually the right ventricle or the right atrium. Some pacemakers may have two pacing leads, with one going into the right atrium and the other to the right ventricle.

The cardiologist then makes a small incision just below the collarbone to create a pocket that holds the control unit, and connects the pacing lead to the control unit. The cardiologist then programs the control unit to deliver an electrical impulse, a very mild electrical shock, when the heart rate falls below a specific threshold. Most pacemakers are set to respond "on demand," which means they emit pacing impulses only when the heart fails to generate them itself. The incision over the pacemaker control unit heals in about two or three weeks, leaving a barely noticeable protrusion.

Living with a Pacemaker

Some people notice when the pacemaker releases an electrical impulse, though most people are not aware. The "on demand" feature of current pacemakers allows the heart to accelerate its rhythm during physical exercise, sexual activity, and other situations in which the heart would naturally beat faster. Certain medical and dental equipment, such as MAGNETIC RESONANCE IMAGING (MRI), machines that deliver RADIATION THERAPY, and some dental drills also can interfere with pacemakers. Though earlier models of pacemakers were sensitive to electromagnetic interference from household appliances and other electronic devices, this is no longer the case. Only high-power devices such as welding equipment or power tools emit enough electromagnetic energy to disrupt a pacemaker. There is some question about the potential of interference from cellular and portable telephones. To be safe, cardiologists recommend keeping the phone at least six inches from, and holding it to the ear opposite, the pacemaker's control unit. Pacemakers run on lithium batteries and can function for about seven years before they need to be replaced.

palpitations Perception that the HEART is racing, pounding, or skipping beats. Palpitations are may represent signs of underlying cardiovascular conditions such as ARRHYTHMIA though frequently signal high stress, anxiety, or excessive consumption of STIMULANTS such as CAFFEINE or NICOTINE (via cigarette smoking). When palpitations do suggest arrhythmia, they tend to occur along with other symptoms such as weakness and SYNCOPE (fainting). Awareness of the heartbeat is common during or immediately following strenuous exercise,

when the heart feels as if it were pounding, and right before falling asleep at night.

SUBSTANCES THAT CAN CAUSE PALPITATIONS	
albuterol	ALCOHOL
CAFFEINE	COCAINE
levothyroxine	ma huang
NICOTINE (tobacco)	pseudoephedrine
theophylline	

The most common presentation of palpitations is the premature beat, which can be atrial or ventricular and feels like a skipped beat though it is not. Because the premature beat is early, there is a slight pause before the regular beat which makes the regular beat feel enhanced. Such palpitations are nearly always the result of stimulants (including cold and flu preparations) or anxiety, and go away either when the stopping the stimulant or removing the cause of stress.

Palpitations require a doctor's evaluation when they occur

- frequently or for sustained periods of time
- with syncope or lightheadedness
- with chest discomfort
- with shortness of breath (DYSPNEA)
- in people who have diagnosed forms of CARDIOVASCULAR DISEASE (CVD) such as HYPERTENSION, CORONARY ARTERY DISEASE (CAD), and arrhythmia disorders

The arrhythmia disorders most likely to include palpitations among their symptoms are ATRIAL FIBRILLATION and PAROXYSMAL ATRIAL TACHYCARDIA (PAT), also called paroxysmal supraventricular tachycardia (PSVT). These disorders typically cause periods of rapid heartbeat. Though disconcerting, these arrhythmias are rarely dangerous. HYPERTHYROIDISM may also cause palpitations, which go away with treatment for the hyperthyroidism.

An ELECTROCARDIOGRAM (ECG) provides the necessary information to determine whether palpitations indicate an arrhythmia or other heart problem. A Holter monitor (24-hour recording of the heart's electrical activity) and an exercise STRESS TEST help identify arrhythmias and conduction disorders that are intermittent or brought on by physical exertion. Unless there is a significant underlying arrhythmia disorder, there is no need to treat palpitations. MEDITATION, relaxation techniques, and eliminating substances that can have a stimulant effect on the heart often reduce or end the palpitations.

paroxysmal atrial tachycardia (PAT) An ARRHYTHMIA disorder, also called paroxysmal supraventricular tachycardia (PSVT), in which the atria have episodes of rapid, regular contractions. "Paroxysmal" means the symptoms start and stop abruptly, without apparent cause. During a PAT episode, the HEART RATE may reach 140 beats per minute. The atrial contractions of PAT originate in the atrium above the ATRIOVENTRICULAR (AV) NODE rather than in the SINOATRIAL (SA) NODE that usually initiates the heart's electrical pacing impulses.

The normal path for pacing impulses is from the SA node through the atria to the AV node. Many people who have PAT have more than one conduction pathway at the AV node. Errant electrical impulses from myocardial cells in the atrium can activate the alternate pathway, called an accessory pathway, triggering atrial contractions. These are called reentrant atrial tachycardias; PAT is one variation. An episode of PAT may last a few minutes or several days. The longer the episode lasts, the more likely it is to produce symptoms.

The primary symptoms of PAT are PALPITATIONS and lightheadedness, dizziness, or SYNCOPE (fainting). Some people experience CHEST PAIN, fatigue, and shortness of breath during an episode of PAT, though feel fine otherwise. Diagnosis is by ELECTROCARDIOGRAM (ECG), which may require Holter monitor to capture episodes as they occur. Treatment may include medications that can disrupt the accessory AV pathway, such as adenosine or calcium channel blockers. RADIOFREQUENCY ABLATION, which destroys a small portion of the conductive pathway to prevent electrical impulses from traveling it, is often a viable treatment option for people with recurrent PAT and usually puts a permanent end to the episodes.

pericarditis INFLAMMATION of the PERICARDIUM, the membranous sac that surrounds and protects the HEART. Pericarditis can be acute (comes on suddenly) or chronic (intermittent symptoms over a period of time), the result of an INFECTION or an autoimmune disorder such as RHEUMATOID ARTHRITIS. Infections are usually viral, with the coxsackie VIRUS and echovirus the most common culprits, though viral pericarditis may follow INFLUENZA or accompany AIDS. Bacterial pericarditis is less common and may occur after bacterial infection elsewhere in the body (such as STREP THROAT) or as a complication of an OPEN HEART SURGERY. Pericarditis may also develop after HEART ATTACK as an inflammatory response, typically with symptoms that begin within five days of the heart attack. Chronic pericarditis generally results from inflammatory processes not related to infection. Certain cancers, notably LEUKEMIA and KAPOSI'S SARCOMA, can involve the pericardium, causing ongoing or intermittent symptoms.

Any CHEST PAIN that persists longer than five minutes, especially pain that radiates into the arm and back, requires emergency medical evaluation to rule out HEART ATTACK.

The primary symptoms of pericarditis are PAIN from the chest, usually that radiates to the back or into the upper arm and shoulder, COUGH, and shortness of breath. Pain is usually sharp, worse with BREATHING in or lying down and relieved when sitting or standing upright. These symptoms are initially difficult to distinguish from heart attack, and typically result in emergency medical evaluation to determine whether heart attack is taking place. Many people have FEVER with acute pericarditis, and upon AUSCULTATION (listening to the chest with a STETHOSCOPE) the doctor can hear a characteristic sound called a friction rub. The pain of pericarditis comes from the pericardium, not the heart, a result of the pericardium rubbing against the heart or the LUNGS and chest cavity.

A potentially life-threatening complication of pericarditis is the rapid accumulation of fluid in the pericardial space, a filmy envelope in the pericardium's inner layer that normally contains a small amount of fluid to lubricate the beating heart. The fibrous outer pericardium does not have much ability to stretch to accommodate increased fluid, so the fluid instead pushes inward against the heart. The pressure restricts the heart's ability to contract to fill with BLOOD, resulting in a dangerous condition called cardiac tamponade. BLOOD PRESSURE and HEART RATE drop perilously in cardiac tamponade, and the compression can cause the heart to stop beating entirely. Some increase in fluid usually occurs with pericarditis, as that is part of the body's protective response to inflammation. When gradual and limited, such fluid increase does not usually affect the heart's function as the pericardium can slowly expand in response.

The diagnostic path includes ELECTROCARDIOGRAM (ECG), which reveals any arrhythmias or strain on the heart, and ECHOCARDIOGRAM to visualize the heart and its related structures. Echocardiogram usually shows the inflammation and any fluid accumulation, and helps distinguish pericarditis from other conditions such as heart attack or restrictive HEART FAILURE. Additional imaging procedures may include COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI). Treatment may include NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) to relieve inflammation and pain, or CORTICOSTEROID MEDICATIONS if the inflammation is severe. Pericardiocentesis, in which the doctor uses a long needle and syringe to withdraw fluid from the pericardium, is necessary when fluid accumulation pressures the heart. Pericardiocentesis can determine whether the pericarditis is bacterial, in which case the doctor administers ANTIBIOTIC MEDICATIONS as well.

Most people who do not have underlying CARDIOVASCULAR DISEASE (CVD) or other significant systemic conditions make full and complete recovery within two or three weeks. Pericarditis can complicate cardiovascular disease. Systemic AUTOIMMUNE DISORDERS or inflammatory conditions may result in chronic pericarditis that may require ongoing anti-inflammatory therapy, usually with NSAIDs.

pericardium A tough, two-layer membranous sac that encloses the HEART. The pericardium's fibrous outer layer, called the fibrous pericardium, protects the heart from contact with the chest wall and other structures in the chest, including the LUNGS and the sternum. The pericardium wraps completely around the heart, extending around the bases of the great vessels (AORTA, superior and inferior VENA CAVA, pulmonary ARTERY, pulmonary VEIN) as they arise from the heart. Two ligaments attach the top of the pericardium to the back of the sternum. Other ligaments loosely connect the bottom of the pericardium to the DIAPHRAGM. These structures anchor the heart in its place in the chest.

The inner layer of the pericardium is a filmy envelope. Its two surfaces are the parietal pericardium, which contacts the fibrous pericardium, and the epicardium, which covers the MYOCARDIUM somewhat like a wet tissue. Inside the envelope is a watery fluid that lubricates the heart. The inner pericardium forms a nearly frictionless containment field for the beating heart. The pericardium is vulnerable to INFLAMMATION and INFECTION (PERICARDITIS).

For further discussion of the pericardium within the context of cardiovascular structure and function, please see the overview section "The Cardiovascular System."

peripheral vascular disease (PVD) ATHEROSCLEROSIS that affects the peripheral arteries, notably those in the legs. ATHEROSCLEROTIC PLAQUE infiltrates the inner wall of the arteries, the intima. This causes the intima to thicken and stiffen, restricting the FLEXIBILITY of the ARTERY as well as narrowing the passage for BLOOD (arterial lumen). PVD can affect the largest to the smallest of the peripheral arteries and is the cause of INTERMITTENT CLAUDICATION as well as often an underlying factor in ERECTILE DYSFUNCTION. NEUROPATHY of DIABETES can severely exacerbate PVD, resulting in restricted circulation and limb ischemia (oxygen deprivation) that can cause tissue death (GANGRENE). PVD due to diabetes is a leading cause of limb amputation. PVD also may contribute to HYPERTENSION (high BLOOD PRESSURE).

Symptoms and Diagnostic Path

PVD often has firmly established itself by the time symptoms manifest. Intermittent claudication—PAIN with walking—is the primary symptom of PVD affecting the lower extremities. Leg or foot pain at rest, with coolness and pallor or CYANOSIS of the limb, suggests embolism (clot or atherosclerotic fragment blocking the flow of blood). Other symptoms may include lack of sensation (PARESTHESIA) or inability to move the limb (PARALYSIS), and wounds that do not heal. In severe PVD there is sometimes a mottled appearance to the SKIN. The doctor may be unable to feel a PULSE in the leg or foot, depending on the level of the occlusion or embolism. The diagnostic path often includes Doppler ULTRASOUND examination, and sometimes MAGNETIC RESONANCE IMAGING (MRI), of the legs.

Treatment Options and Outlook

The primary thrust of treatment when symptoms are present is ANTICOAGULATION THERAPY, which may include intravenous heparin when the doctor suspects an embolism. For symptoms such as intermittent claudication or rest ischemia, the treatment is typically the oral anticoagulant warfarin or antiplatelet agents such as cilostazol to reduce the risk for clot formation. A program of progressive walking improves blood flow in the legs as well as strengthens the leg muscles so they can provide additional support for the blood vessels. Weight loss reduces pressure on the arteries. The treatment regimen often includes lipid-lowering medications in conjunction with lifestyle modifications to lower blood lipid levels, which are usually elevated in PVD. Lifestyle changes include daily physical exercise such as walking, nutritious EATING HABITS, and SMOKING CESSATION. When symptoms fail to improve with these therapeutic measures, the doctor may consider ATHERECTOMY, an OPERATION to remove segments of atherosclerotic plaque from the arterial walls. Many people who have intermittent claudication benefit from wearing support stockings, which are tight against the legs to help support the blood vessels.

PVD is a progressive condition closely linked with CORONARY ARTERY DISEASE (CAD). Therapeutic

approaches, which must include lifestyle modifications to be successful, often can slow its progress.

Risk Factors and Preventive Measures

The risk factors for PVD include smoking, other atherosclerotic disease processes such as CAD, diabetes, and HYPERLIPIDEMIA. Controlling or eliminating these factors reduces the risk for PVD. Once PVD shows symptoms, then the most effective approach is aggressive management to prevent the condition from worsening.

physical exercise and cardiovascular health The influence of regular physical activity on the structures and functions of the cardiovascular system. Regular AEROBIC EXERCISE has numerous effects on the cardiovascular system, improving the heart's pumping efficiency as well as the circulation's oxygen transport to the tissues of the body. It also improves the efficiency with which cells throughout the body, and notably those of skeletal MUSCLE, use oxygen. This decreases demand on the HEART, generally slowing the HEART RATE and decreasing BLOOD PRESSURE. As well, physical activity increases INSULIN sensitivity, which helps the body maintain a healthy BLOOD lipid balance to reduce the risk for HYPERLIPIDEMIA.

PHYSICAL EXERCISE RECOMMENDATIONS

- 30 to 45 minutes of moderate physical activity five to seven days a week
- 20 to 45 minutes of vigorous physical exercise three to four days a week

Health experts consider physical inactivity to be the prime lifestyle factor contributing to most acquired CARDIOVASCULAR DISEASE (CVD). Though recommendations call for 30 minutes of moderate physical exercise daily and 30 to 45 minutes of vigorous aerobic exercise three to four times a week, fewer than 20 percent of American adults are physically active at these levels and about 20 percent get no physical exercise at all. Health experts attribute at least 250,000 of deaths from cardiovascular disease to physical inactivity. Yet the level of physical activity that could prevent these deaths is minimal, only 30 minutes a day of moderately brisk walking (a pace of 3 to 4 miles per hour).

Small amounts of moderately intense physical activity that accumulate to the recommended exercise times are equally effective as contiguous blocks of exercise time, an important finding to emerge from recent research into the relationship between physical activity and cardiovascular health. Meeting the recommended minimum activity levels could prevent as much as 40 percent of cardiovascular disease. Ideal activities for cardiovascular health include walking, bicycling, running, and swimming.

premature ventricular contraction (PVC) An early heartbeat that causes the sensation of a skipped beat. Most often PVCs are harmless. They may occur spontaneously, without apparent cause, and are most noticeable at rest or following strenuous exercise. CAFFEINE, pseudoephedrine (a vasoconstrictor and stimulant common in cold and allergy products), NICOTINE (tobacco), and anxiety (stress) may also cause PVCs. PVCs require a doctor's evaluation when they occur

- frequently
- repeatedly over a period of time rather than in isolation
- with CHEST PAIN or discomfort
- with lightheadedness, dizziness, or SYNCOPE (fainting)

A doctor also should evaluate PVCs in anyone who has diagnosed CARDIOVASCULAR DISEASE (CVD), particularly an ARRHYTHMIA disorder. Occasionally PVCs can trigger a more serious arrhythmia such as ventricular tachycardia. An ELECTROCARDIOGRAM (ECG) can identify PVCs. Because PVCs tend to be intermittent, the doctor may use a Holter monitor ECG, which records the heart's electrical activity over a period of 24 hours.

Unless PVCs indicate a serious underlying arrhythmia, cardiologists usually do not treat them. Often, eliminating potential causes such as caffeine can put an end to the PVCs. The cardiologist may

prescribe a beta blocker for persistent PVCs, after ruling out other cardiovascular conditions.

pulmonary arteries The large BLOOD vessels that carry blood from the HEART to the LUNGS. The main pulmonary ARTERY arises from the right ventricle and immediately branches into the right and left pulmonary arteries. The pulmonary arteries are the only arteries in the body that transport deoxygenated blood. Like other arteries, however, the pulmonary arteries have sturdy, muscular walls that rhythmically contract in synchronization with the heartbeat. The pulmonary valve regulates the flow of blood from the right ventricle into the pulmonary artery.

For further discussion of the pulmonary arteries within the context of cardiovascular structure and function please see the overview section "The Cardiovascular System."

See also AORTA; VALVULAR HEART DISEASE.

pulmonary hypertension Elevated BLOOD PRESSURE in the PULMONARY ARTERIES and the arteries within the LUNGS. Pulmonary HYPERTENSION develops when the arteries in the lungs become stiff and narrowed, increasing the resistance BLOOD encounters in trying to flow through them. The condition typically starts in the smallest of arteries, the arterioles, and progressively involves larger arteries until pressure within the pulmonary arteries from the HEART also rises. Elevated pressure within the pulmonary arteries increases the force the right ventricle must exert to pump blood from the heart to the lungs. Though early in the course of the condition the right ventricle can compensate by enlarging, eventually the increased workload can lead to right HEART FAILURE.

Doctors classify pulmonary hypertension, also called pulmonary arterial hypertension (PAH), as either secondary or primary. Secondary pulmonary hypertension develops as a complication of other health conditions, notably connective tissue disorders and chronic health conditions such as CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD) and PULMONARY EMBOLISM. Because it follows other health conditions that become more likely with advancing age, secondary pulmonary hypertension tends to occur more frequently in people over age 60.

CONDITIONS THAT CAN CAUSE PULMONARY HYPERTENSION

AIDS	CARDIOMYOPATHY
chronic hemolytic ANEMIA	CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD)
COCAINE use	HEART FAILURE
OBSTRUCTIVE SLEEP APNEA	PULMONARY EMBOLISM
PULMONARY FIBROSIS	RHEUMATIC HEART DISEASE
scleroderma	SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)
VALVULAR HEART DISEASE	

Primary pulmonary hypertension (PPH) exists independently of other health conditions and is far less common than secondary pulmonary hypertension. Most often doctors do not know what causes PPH, though they believe in many people the condition is congenital (present at birth). Though systemic hypertension—what people think of as high blood pressure—may damage blood vessels throughout the body as well as damage the heart, pulmonary hypertension and systemic hypertension are different conditions. PPH can affect people of any age though is more common among people under age 50.

Symptoms and Diagnostic Path

The earliest symptom of pulmonary hypertension is shortness of breath (DYSPNEA), typically with exertion. As the condition progresses, symptoms may include fatigue, SYNCOPE (fainting), chest pressure or PAIN, peripheral edema (swelling of the lower legs, feet, wrists, and hands), ASCITES (fluid retention in the abdominal cavity), and PULMONARY EDEMA (fluid accumulation in the alveoli, or air sacs, in the lungs). Symptoms of advanced disease often include shortness of breath at rest, CYANOSIS (bluish hue to the SKIN and lips), and ARRHYTHMIA (abnormal HEART RATE).

The diagnostic path begins with ELECTROCARDIOGRAM (ECG), which reveals right ventricular hypertrophy (enlargement), and ECHOCARDIOGRAM, which shows the heart's changed structure and function. The right ventricle typically enlarges and its walls thicken as the pulmonary hypertension begins to cause symptoms. Other diagnostic procedures may include MAGNETIC RESONANCE IMAGING (MRI) for additional visualization of the heart, PULMONARY FUNC-

TION TESTS to assess LUNG CAPACITY and the ability of the lungs to exchange oxygen and carbon dioxide, and CARDIAC CATHETERIZATION to measure the pressure within the pulmonary arteries.

Treatment Options and Outlook

Doctors may prescribe medications such as vasodilators and calcium channel blockers to help relax the arteries in the lungs and lower resistance to the flow of blood, anticoagulant medications to lower the risk for blood clots, and diuretics ("water pills") to reduce edema. Research suggests that many people who have pulmonary hypertension have elevated levels of endothelin, an amino acid compound (peptide) naturally present in the walls of the arteries that causes them to constrict. Whether this elevation is a consequence or cause of pulmonary hypertension remains unclear, though its recognition has resulted in the development of medications called endothelin receptor antagonists. These medications relieve the symptoms of pulmonary hypertension by relaxing the walls of the arteries in the lungs. Oxygen therapy can improve the amount of oxygen that enters the blood circulation.

Treatment targets the underlying cause, to the extent possible, when pulmonary hypertension is secondary, as well as aims to lower pulmonary blood pressure. However, any damage that occurs to the heart is generally irreversible. PPH is progressive and as yet there is no curative treatment. Early diagnosis and medications can slow PPH's progression and improve QUALITY OF LIFE. Lifestyle modifications, such as WEIGHT LOSS AND WEIGHT MANAGEMENT, SMOKING CESSATION, and regular physical activity within the capacity the person's cardiovascular function allows, help keep the cardiovascular system functioning as efficiently as possible. LUNG TRANSPLANTATION may be a treatment option for younger people when PPH is the only significant health condition. People who also have severe heart failure may benefit from a combined heart–lung transplantation. These are complex operations, however, and donor organs are extremely limited.

Risk Factors and Preventive Measures

The risk factors for secondary pulmonary hypertension are the conditions that may cause it. Early diagnosis and appropriate treatment for these conditions helps prevent pulmonary hypertension from developing. Because doctors do not know what causes PPH, they cannot identify clear risk factors.

pulmonary veins The large blood vessels that bring blood to the left side of the HEART from the LUNGS. The main pulmonary veins arise from the lungs and branch immediately into the right pulmonary vein and the left pulmonary vein. The right pulmonary vein carries blood from the right lung and the left pulmonary vein carries blood from the left lung. The pulmonary veins are the only veins in the body that transport oxygenated blood.

For further discussion of the pulmonary veins within the context of cardiovascular structure and function, please see the overview section "The Cardiovascular System."

pulse The pattern of contractions in the arteries as BLOOD passes through them, typically synchronized with the contractions of the HEART. Where an ARTERY is close to the surface, it is possible to feel the pulse by applying pressure with two fingers (but not the thumb, which has its own perceptible pulse).

PULSE POINTS

Artery	Body Location
abdominal aorta	solar plexus area of the abdomen
brachial	inside of the upper arm
carotid	each side of the neck, below the jaw
femoral	groin
pedal	top of the foot
popliteal	behind the knee
radial	wrist, below the base of the thumb
temporal	side of the forehead
tibial	inside of the lower leg, behind the inner ankle
ulnar	wrist, at the base of the hand on the opposite side from the thumb

ARRHYTHMIAS in which the heart contracts but does not eject blood with the contraction, such as with some tachycardias, may result in a disparity between the pulse and the heart rate. The nature of the pulse aids in diagnosis:

- An ***alternating pulse*** has a regular rhythm though some beats are strong and others are weak. It may suggest left HEART FAILURE.
- A ***bigeminal pulse*** is a pattern of two beats, a strong beat then a weak beat with a long pause after. It suggests PREMATURE VENTRICULAR CONTRACTIONS (PVCS).
- A ***bounding pulse*** may be rapid and forceful. It may indicate HYPERTENSION, FEVER, ANEMIA, or RENAL FAILURE. A bounding pulse also may occur following intense physical exercise, in which case it is normal.
- A ***rapid pulse,*** also called an accelerated pulse, indicates tachycardia (heart rate of 100 beats per minute or faster). It may suggest an arrhythmia, cardiovascular SHOCK, fever, HYPERTHYROIDISM, or CORONARY ARTERY DISEASE (CAD). A rapid pulse also may occur normally following intense physical exercise.
- A ***trigeminal pulse*** is a pattern of two equally strong beats then a third weak beat with a long pause after. It may suggest CARDIOMYOPATHY.
- A ***water-hammer pulse*** is a pattern in which there is a rapid surge of blood at the pulse point followed by a complete collapse of the artery. It suggests aortic regurgitation, a condition in which the aortic valve fails to close after the left ventricle pumps blood into the aorta, allowing blood to flow back into the heart.

The characteristics of the pulse change with fitness level and age. People who exercise regularly and people who are over age 70 tend to have slower pulse rates than people who are sedentary or young. The average resting pulse for an adult is 60 to 100 beats per minute. Children typically have more rapid pulse rates. The pulse rate also temporarily increases with fever, PAIN, and anxiety.

radiofrequency ablation A therapeutic procedure to treat ARRHYTHMIA disorders such as WOLFF-PARKINSON-WHITE SYNDROME or PAROXYSMAL ATRIAL TACHYCARDIA (PAT). Radiofrequency ablation uses high-frequency energy, similar to microwave energy, to destroy abnormal electrical pathways in the HEART. The cardiologist performs radiofrequency ablation via CARDIAC CATHETERIZATION, threading a catheter through a blood vessel and into the heart. Electrodes on the tip of the catheter function somewhat as an ELECTROCARDIOGRAM (ECG), sending information about the heart's electrical activity via the catheter back to a monitor. When the catheter reaches the area of dysfunctional electrical activity, the cardiologist sends a burst of high-frequency energy through the electrodes. The energy destroys the area of myocardial tissue responsible for the dysfunction, closing the abnormal electrical pathway. The heart's regular electrical pathways then become the route for the heart's electrical pacing impulses. Radiofrequency ablation permanently ends the arrhythmia about 90 percent of the time.

Raynaud's syndrome A condition in which the smallest arteries, the arterioles, in the hands and the feet spasm in response to cold. The spasm interrupts the flow of BLOOD to the fingers and toes, depriving them of oxygen. Raynaud's syndrome may be idiopathic (without identifiable cause) or secondary to other health conditions (notably connective tissue disorders). Raynaud's syndrome may also develop as a SIDE EFFECT of certain medications such as vasoconstrictors (drugs that cause the blood vessels to constrict). Cigarette smoking is often a precipitating factor and worsens symptoms. Some doctors use the terms *Raynaud's disease* to identify idiopathic Raynaud's and *Raynaud's phenomenon* to identify secondary Raynaud's.

POSSIBLE CAUSES OF RAYNAUD'S SYNDROME

cigarette smoking	dermatomyositis
electrical shock	ergot medications
FROSTBITE or HYPOTHERMIA	long-term exposure to vibration
PERIPHERAL VASCULAR DISEASE (PVD)	REPETITIVE MOTION INJURIES
RHEUMATOID ARTHRITIS	SCLERODERMA
SPINAL CORD INJURY	
SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)	

The doctor generally makes the diagnosis on the basis of the pattern of symptoms, which is distinctive and consistent. The pattern includes three phases most easily identified according to the color of the fingers or toes:

1. Cold causes the arterioles to spasm, depriving the fingers or toes of oxygen. The fingers or toes turn white.
2. The veins and capillaries dilate, flooding the tissues with deoxygenated blood. The fingers or toes turn blue (CYANOSIS) and typically feel numb.
3. With warmth the arterioles will relax, which restores the flow of circulation and floods the fingers or toes with oxygenated blood. The fingers or toes turn deep red, and may throb and feel hot.

The most effective treatment for Raynaud's syndrome is keeping the fingers and toes warm to prevent the arterioles from spasming. When an attack occurs, warming the fingers or toes gener-

ally restores normal circulation and ends the symptoms. Stress and anxiety may sometimes initiate the symptoms. Relaxation methods such as MEDITATION are helpful when this is the case. BIOFEEDBACK is effective for some people, and regular physical exercise helps maintain circulation. When Raynaud's syndrome fails to respond to preventive and lifestyle measures, doctors may prescribe medications such as beta blockers, calcium channel blockers, or topical nitroglycerin to relax the arterioles. Treating any underlying conditions helps mitigate the symptoms of Raynaud's syndrome.

risk factors for cardiovascular disease The circumstances that make a person more or less likely to develop conditions affecting the HEART and cardiovascular system. A risk factor may be fixed, or immutable, such as age, ethnicity, or gender. Other risk factors are variable, or mutable. These are the risk factors that an individual can influence, such as dietary habits and physical activity. Doctors also use the terms *alterable* and *nonalterable*, respectively. Other health conditions may also become risk factors for CARDIOVASCULAR DISEASE (CVD), notably DIABETES. Certain cardiovascular conditions, such as HYPERTENSION (high BLOOD PRESSURE) and ATHEROSCLEROSIS, are risk factors for other cardiovascular conditions such as STROKE and HEART ATTACK.

CARDIOVASCULAR DISEASE RISK FACTORS

Fixed	Variable
male	cigarette smoking
age 60 and older	OBESITY
genetic predisposition	physical inactivity
African American heritage	HYPERLIPIDEMIA (elevated blood lipid levels)
Native American heritage	HYPERTENSION (high BLOOD PRESSURE)
female postmenopause	DIABETES

More than 90 percent of cardiovascular disease among Americans develops over decades, the consequence of interactions between genetic predisposition and lifestyle. Health experts believe lifestyle choices can prevent nearly all of such acquired cardiovascular disease, even when there are genetic influences. The HUMAN GENOME PROJECT, the mapping of the human genome, has broadened scientific understanding of genes and of how they influence health and disease. Researchers are better able to assess and even manipulate the interplay between certain genetic factors and lifestyle factors. One area of ongoing genetic research is ethnicity. Though the rate of CVD is significantly higher among people of certain ethnic heritages, the reasons remain unclear.

Though individuals cannot alter genetic predisposition for health conditions, they can often mitigate, through lifestyle, the ways in which such predispositions play out in their lives. A person who has a family history of early-onset atherosclerosis, for example, may mitigate the effects of this genetic predisposition through daily moderate exercise (aerobic and STRENGTH) and dietary habits that limit fat consumption to less than 10 percent of daily calories and increased fiber consumption, as well as through maintaining healthy body weight. Other preventive measures may include frequent blood lipid level screening (every 6 to 12 months) and lipid-lowering medications for lipid levels that remain elevated despite lifestyle efforts to keep them low. These lifestyle efforts can minimize, and often prevent, cardiovascular disease.

An important dimension to risk factors for CVD is the interplay that exists among them. Physical inactivity is a key element in the development and progression of HYPERLIPIDEMIA, type 2 DIABETES, OBESITY, and hypertension. Hyperlipidemia lays the foundation for atherosclerosis, which progresses to CORONARY ARTERY DISEASE (CAD). CAD causes ISCHEMIC HEART DISEASE (IHD) and is the leading cause of heart attack. Hypertension, alone though especially in combination with atherosclerosis (CAD or PVD), is the leading cause of stroke.

Congenital heart conditions, even those repaired in early childhood, may predispose people to other forms of cardiovascular disease later in life. Adults under age 30 are the first generation for whom surgical correction of congenital heart defects was a viable treatment option. Doctors do not yet know the extent to which these anomalies may affect future cardiovascular risk.

Many health experts question whether the risk of age is more a reflection of cumulative variable risks than itself an independent risk factor. Targeting individual risk factors early in life, before substantial cardiovascular disease develops, is the most effective preventive measure. Once a cardiovascular condition begins, preventive efforts shift focus to slow the progression of disease.

rheumatic heart disease Damage to the valves of the HEART as a consequence of rheumatic FEVER, which develops as a complication of untreated or undertreated STREP THROAT. Streptococcal BACTERIA attack the heart valves, most commonly the mitral and aortic valves, which can leave them scarred and deformed. Rheumatic fever and rheumatic heart disease are now uncommon as ANTIBOTIC MEDICATIONS so successfully treat strep infections involving the THROAT. In the 1950s rheumatic heart disease was the leading cardiovascular cause of disability and death among American adults. Today, rheumatic heart disease is much less of a threat though still affects about 2 million Americans each year, about 3,500 of whom die as a result.

Signs of CARDIOVASCULAR DISEASE (CVD) that suggest rheumatic heart disease may include clinically significant HEART MURMUR and other indications of valvular insufficiency. Doctors may suspect rheumatic heart disease as the cause when there is a recent history of sore throat or strep throat in combination with symptoms that suggest autoimmune or inflammatory disease, such as inflamed joints, and of cardiac insufficiency, such as DYSPNEA (shortness of breath). The diagnostic path typically includes ELECTROCARDIOGRAM (ECG) to evaluate any arrhythmias, which are common in VALVULAR HEART DISEASE. ECHOCARDIOGRAM or MAGNETIC RESONANCE IMAGING (MRI) allows the cardiologist to visualize and assess the heart's valves, structure, and function.

Treatment for rheumatic heart disease may involve medications to treat secondary cardiovascular conditions such as arrhythmias and HEART FAILURE, and surgical repair or replacement of damaged valves. People who have rheumatic heart disease are vulnerable to subsequent infections and require ANTIBIOTIC PROPHYLAXIS before invasive diagnostic and therapeutic procedures, and with infections such as PHARYNGITIS, to prevent ENDOCARDITIS.

S

sexual activity and cardiovascular disease HEART ATTACK, STROKE, major HEART surgery such as CORONARY ARTERY BYPASS GRAFT (CABG) or HEART TRANSPLANTATION, or the diagnosis of a cardiovascular condition such as HYPERTENSION (high BLOOD PRESSURE) or CORONARY ARTERY DISEASE (CAD) often causes worry and fear that sexual activity may harm the heart. Such concerns are common though generally have no medical basis. Sexual intercourse requires about the same level of cardiovascular response from the body as walking up three flights of stairs. Following a cardiovascular event, most people may resume sexual activity when they regain interest.

These preparations may make the return to sexual activity more enjoyable:

- Plan sexual activity for when both partners are well rested, relaxed, and have no time constraints.
- Plan sexual activity to take place two to three hours after eating a meal, to allow digestion to take place. Digestion diverts more of the body's blood supply to the gastrointestinal tract.
- Choose a location that is comfortable and free from distractions such as the telephone or interruptions.
- Choose less strenuous positions and have extra pillows available for added support.
- Be patient and focus on the intimacy of being together.

People who have had OPEN HEART SURGERY or who have residual complications resulting from stroke may feel unsure of their physical attractiveness. Open, honest communication between partners can help put these concerns in perspective and allow each partner to express his or her feelings.

sick sinus syndrome A collective term for ARRHYTHMIA disorders that arise from dysfunction of the SINOATRIAL (SA) NODE and the electrical conduction network within the HEART. The SA node may stop functioning, or there may be a disruption in the pathway for the electrical impulses the SA node generates. Generally sick sinus syndrome results in bradycardia (slow HEART RATE). Key symptoms include fatigue and SYNCOPE (fainting). Sick sinus syndrome may also be present without symptoms, in which case it does not usually require treatment. ELECTROCARDIOGRAM (ECG) reveals the abnormal electrical pacing impulses and provides the diagnosis. Treatment is nearly always an implantable PACEMAKER to maintain an adequate heart rate.

sinoatrial (SA) node A small cluster of specialized NERVE and MUSCLE fibers located in the upper wall of the heart's right atrium. The SA node initiates the electrical pacing impulse that causes the HEART to contract. In the healthy heart the electrical impulse spreads in an orderly and synchronized pattern through the two atria, causing them to contract. The ATRIOVENTRICULAR (AV) NODE, a second small cluster of specialized nerve and muscle fibers located in the wall of the heart between the atria and the ventricles, picks up the impulse, amplifies it, and sends it through the ventricles to cause them to contract.

For further discussion of the SA node within the context of cardiovascular structure and function please see the overview section "The Cardiovascular System."

smoking and cardiovascular disease CARDIOVASCULAR DISEASE (CVD) is the most frequent and significant consequence of cigarette smoking, with smoking accounting for one in six deaths due to CVD. Smoking significantly increases the risk for HYPERTENSION (high BLOOD PRESSURE), ATHEROSCLEROSIS, and CORONARY ARTERY DISEASE (CAD). The combination of cigarette smoking and using oral contraceptives (birth control pills) presents a particular risk of BLOOD clot formation in women, especially women over age 35. This raises the risk for STROKE and HEART ATTACK such that many doctors will not prescribe oral contraceptives for women who smoke. Smoking is also a key factor in numerous pulmonary diseases, affecting the cardiovascular system's ability to circulate oxygen-rich blood.

The US Surgeon General offered the first conclusive evidence of the correlations between smoking and cardiovascular disease in the landmark 1964 report, *Smoking and Health: Report of the Advisory Committee to the Surgeon General of the Public Health Service*. Researchers have since continued to accumulate knowledge and understanding of the mechanisms through which smoking affects cardiovascular health. Cigarette smoke contains more than 2,000 identifiable chemicals, dozens of which are carcinogenic (CANCER-causing) or have other deleterious actions on health. Two in particular, NICOTINE and carbon monoxide, are highly toxic to the cardiovascular system.

Nicotine and Cardiovascular Function

NICOTINE is a CENTRAL NERVOUS SYSTEM stimulant that acts on nerves throughout the body. In the cardiovascular system, nicotine stimulates the nerves that regulate smooth MUSCLE tissue, causing smooth muscle cells to contract. This constricts blood vessels, notably arteries, reducing the channel for blood flow. Nicotine further stimulates the baroreflex sensors (clusters of NERVE cells in the major arteries and the heart that sense the flow and pressure of blood). These actions result in increased blood pressure, HEART RATE, and cardiac workload. Nicotine further acts as an irritant within the arteries, causing INFLAMMATION of the inner layer of the arterial wall. Researchers believe such inflammation may be the foundation for atherosclerosis.

Carbon Monoxide and Cardiovascular Function

Carbon monoxide is a poison. It has a greater affinity than oxygen for HEMOGLOBIN and binds with hemoglobin, blocking hemoglobin from carrying oxygen. This reduces the amount of oxygen that enters the bloodstream from the LUNGS. By the end of a cigarette, a smoker can have concentrations of carbon monoxide as high as 7 percent; 10 percent is the level at which symptoms of carbon monoxide poisoning begin to become apparent. Carbon monoxide in the bloodstream deprives cells in the BRAIN and heart, which rely on oxygen for fuel.

Environmental Smoke Exposure

Cigarette smoke also raises the risk for health problems, including cardiovascular disease, among people who are themselves nonsmokers though live or work in a smoking environment. Children are at particular risk. Numerous studies show the children of smokers have more EAR infections, sinus infections, and upper respiratory infections than children who live in smoke-free environments. Long-term exposure to ENVIRONMENTAL CIGARETTE SMOKE, called passive smoking, has the same health consequences as active smoking.

Smoking Cessation

The health risks of cigarette smoking diminish within 30 to 40 minutes of the last puff. With sustained SMOKING CESSATION, the risk for cardiovascular disease gradually diminishes over 5 to 10 years, finally reaching a level consistent with the risks for a nonsmoker. Any damage that has already occurred to the cardiovascular system is permanent, however.

soy and cardiovascular health Soy protein appears to help lower cholesterol blood levels, particularly low-density lipoprotein cholesterol (LDL-C). The American Health Association recommends replacing animal protein with soy protein as part of a balanced, low-fat diet. People who consume 25 to 50 grams of soy protein daily can lower their LDL-C levels by as much as 8 percent. In combination with other cholesterol-lowering approaches such as increased daily exercise, soy in the diet contributes to a heart-healthy lifestyle. Soy protein contains isoflavones—notably genistein, daidzein, and glycetein—that help to reduce the formation of ATHEROSCLEROTIC PLAQUE, thus lowering the risk for ATHEROSCLEROSIS and related conditions such as CORONARY ARTERY DISEASE (CAD). Soy protein is also high in fiber, helping absorb dietary cholesterol and fats in the intestinal tract to reduce the amount that enters the blood circulation.

DIETARY SOURCES OF SOY PROTEIN

soy cheese	soy flour
soybeans (boiled or roasted)	soy milk
textured vegetable protein (TVP) products	tofu

stent A tiny, springlike device inserted into an ARTERY to help maintain the artery's patency after ANGIOPLASTY (a CARDIAC CATHETERIZATION procedure to clear or compress ATHEROSCLEROTIC PLAQUE from the inner walls of an artery). The stent holds pressure against the artery's inner wall, maintaining compression of the plaque as well as making it difficult for the artery to constrict. Cardiologists use stents primarily in the CORONARY ARTERIES though may also use them in carotid ENDARTERECTOMY and peripheral artery angioplasty. An anticoagulant medication coats some stents, called DRUG-emitting, to discourage clot formation. Stents can extend the effectiveness of angioplasty by months to a year or more. Angioplasty with stent placement can delay the need for CORONARY ARTERY BYPASS GRAFT (CABG) or provide an acceptable alternative for people with less severe occlusions. Most stents require replacement every three to five years.

stethoscope An instrument the doctor uses to listen to sounds within the body. The cardiologist uses a stethoscope to listen to the function of the valves in the HEART, to the HEART RATE, to the flow of BLOOD through the chambers of the heart, and for abnormal sounds, such as a pericardial rub or a HEART MURMUR, that can indicate cardiovascular disorders. The French physician René Laënnec (1781–1821) invented the stethoscope and introduced the first practical model, a simple tube with a flare at one end and a small opening that served as an earpiece at the other end, in 1816. The instrument evolved over the next 100 years into the familiar style in use today, a flexible "Y" of tubing with dual earpieces and a combination bell and diaphragm with a lever to switch between them. The bell picks up low-pitched tones and the diaphragm picks up high-pitched tones.

stress test A diagnostic procedure to evaluate the cardiovascular system's ability to meet the body's increased oxygen needs during physical exercise. The most common procedure is the exercise stress test, in which the person walks on a treadmill or rides a stationary bicycle at an escalating pace. A continuous ELECTROCARDIOGRAM (ECG) monitors the heart's response. Variations of the stress test include the ECHOCARDIOGRAM stress test, in which the cardiologist uses ULTRASOUND to visualize the heart's functions during exercise, and the pharmacological stress test, in which the cardiologist administers a DRUG such as dipyridamole that causes a cardiovascular response that simulates the effects of exercise. A stress test helps determine the extent of cardiovascular impairment present as a result of conditions such as CORONARY ARTERY DISEASE (CAD) and HEART FAILURE. A stress test does not require preparation or recovery, and takes 20 to 40 minutes to complete. There is a very slight risk that a stress test may trigger a HEART ATTACK, to which the facility and its staff are prepared to respond if necessary.

stroke An interruption of BLOOD flow and oxygen supply to the BRAIN, sometimes called a brain attack. Stroke strikes about 700,000 Americans each year. For two thirds of them the stroke is a second or subsequent stroke. About 85 percent of strokes are ischemic; they result from blockage of an arterial pathway in the brain. The remaining 15 percent are hemorrhagic; they result from bleeding into the brain, typically from a blood vessel that ruptures. About 90 percent of people survive a first ischemic stroke, though a third of them experience permanent disability of varying severity as a consequence of the damage to the brain. The risk for death rises with each subsequent stroke. Hemorrhagic strokes are more likely to be fatal, claiming the lives of nearly half of those who have them. In 2000, about 2.4 million Americans were stroke survivors.

HYPERTENSION (high BLOOD PRESSURE) is the leading cause of stroke. Unfortunately, hypertension has no symptoms and many people do not know they have it until they suffer stroke or HEART ATTACK. Chronically elevated blood pressure stresses blood vessels, causing them to stiffen and thicken to help protect against the constant pounding of blood. This response (ARTERIOSCLEROSIS) makes the arteries vulnerable to INFLAMMATION and accumulations of debris (ATHEROSCLEROTIC PLAQUE), resulting in ATHEROSCLEROSIS. The high pressure of blood rushing through the arteries causes tiny fragments of the plaque to break free. The fragments float through the blood circulation until they lodge in a blood vessel, blocking the further flow of blood. When this occlusion happens in the heart, it causes a MYOCARDIAL INFARCTION or heart attack. In the brain, the occlusion causes stroke.

Health experts recommend annual BLOOD PRESSURE checks for all people age 50 and older, and for younger people who have risk factors for CARDIOVASCULAR DISEASE (CVD).

Brain cells require a constant supply of oxygen to meet their energy needs. Deprivation of oxygen for as little as 30 seconds causes them to begin shutting down. Lack of oxygen for two to three minutes causes brain cells to begin dying. After five minutes, enough brain cells can die to cause permanent loss of function in the affected area. This loss may involve cognitive function, memory, speech and language processing, and physical movement. The brain's correlation to the body is ipsilateral. Damage to the right brain may result in weakness or paralysis on the left side of the body; damage to the left brain may affect the right side of the body.

Time is crucial. Treatment for ischemic stroke that begins within four hours can incorporate drugs to dissolve the blocking blood clot, minimizing or preventing damage to the brain.

Symptoms and Diagnostic Path

Symptoms of stroke may be subtle or pronounced. The main symptoms of stroke include

- numbness or tingling on one side of the face or body
- difficulty speaking (including slurred speech) or swallowing
- drooping of facial features on one side
- weakness or PARALYSIS on one side of the body
- loss of vision or change in vision, particularly in only one EYE

It is important to seek medical attention without delay at the first indication that a stroke may be occurring. Early treatment with THROMBOLYTIC THERAPY can dissolve developing blood clots, mitigating or preventing the stroke. The diagnostic path typically includes COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) to visualize the location and extent of the stroke, and to determine whether the stroke is ischemic or hemorrhagic. ELECTROENCEPHALOGRAM (EEG), which measures the brain's electrical activity, and a comprehensive NEUROLOGIC EXAMINATION can help assess the extent of damage the stroke has caused.

Treatment Options and Outlook

Immediate treatment focuses on minimizing damage to the brain. Optimally, early intervention permits thrombolytic therapy, which must begin within four hours of the stroke's onset. Treatment

beyond this window of opportunity typically includes ANTICOAGULATION THERAPY for ischemic stroke to prevent further clots from forming and supportive measures to maintain cardiovascular stability. Most people who experience strokes have hypertension, so subsequent treatment includes measures to bring blood pressure under control through medications and lifestyle changes.

People who receive thrombolytic therapy often have no residual effects from their strokes and can return to their regular activities within a few weeks. People who experience permanent disability as a result of stroke may require inpatient or outpatient rehabilitation. The level of recovery depends on the extent of damage. Many people with serious disabilities are able to learn methods for adapting to their limitations, allowing them to return to some activities and perhaps independent living. About 70 percent of people who experience strokes are able to return to functional independence and often many of their regular activities, within three to six months.

Risk Factors and Preventive Measures

The key risk factors for stroke are hypertension and atherosclerosis. Cardiovascular conditions involving clot formation present a high risk for stroke. These include DEEP VEIN THROMBOSIS (DVT), ATRIAL FIBRILLATION, CAROTID STENOSIS, and VALVULAR HEART DISEASE. DIABETES also raises the risk for stroke. Other risk factors are those for all forms of CARDIOVASCULAR DISEASE (CVD): smoking, physical inactivity, and diet high in saturated fats and excessive calories. Stroke also becomes more likely with advancing age.

The most effective preventive measure is maintaining a healthy blood pressure. All adults over age 50 should have annual blood pressure checks, with more frequent checks when blood pressure is elevated or risk factors for hypertension are present. Efforts to maintain good cardiovascular health, such as daily physical exercise and WEIGHT LOSS AND WEIGHT MANAGEMENT, help lower the risk for subsequent stroke as well as for other forms of cardiovascular disease.

sudden cardiac death Unexpected, fatal CARDIAC ARREST (cessation of cardiac activity). Typically there are no warning signs of impending cardiovascular crisis. Electrical dysfunction is the most frequent cause of sudden cardiac death. In young people, ARRHYTHMIA disorders such as LONG QT SYNDROME (LQTS) or WOLFF-PARKINSON-WHITE SYNDROME, or hereditary HEART conditions such as hypertrophic CARDIOMYOPATHY, are often to blame. Some health experts believe ELECTROCARDIOGRAM (ECG) should be a part of the athletic physical examination, as intense physical exertion can trigger electrical dysfunctions that result in death.

In people age 50 and older sudden cardiac death typically results from arrhythmia disorders, MYOCARDIAL INFARCTION, ISCHEMIC HEART DISEASE (IHD) that is a consequence of CORONARY ARTERY DISEASE (CAD), and HEART FAILURE. Most people who experience sudden cardiac death were unaware they had CARDIOVASCULAR DISEASE (CVD) or had been undergoing successful treatment to manage a particular cardiovascular condition such as HYPERTENSION. Because the event that causes cardiovascular collapse is generally catastrophic, resuscitative efforts tend to be unsuccessful.

syncope The temporary loss of CONSCIOUSNESS and posture, commonly called fainting. Syncope is common and can arise from numerous causes ranging from standing too long, which allows BLOOD to pool in the legs, to ARRHYTHMIA and TRANSIENT ISCHEMIC ATTACK (TIA), which interrupt the flow of blood to the BRAIN. About 10 percent of syncope episodes are the result of cardiovascular events such as arrhythmias, MYOCARDIAL INFARCTION, MICROINFARCTION, HYPOTENSION, and TIA.

Any episode of syncope in a person who has a history of HEART ATTACK, STROKE, ARRHYTHMIA, or other known CARDIOVASCULAR DISEASE (CVD) requires immediate medical evaluation.

Other causes of syncope include neurologic events (such as vasovagal response), medication side effects, heat, DEHYDRATION, fear, FEVER, and PREGNANCY. Most people regain consciousness within a few seconds to three minutes. Syncope may be an isolated event or a symptom of underlying health concerns. A doctor should evaluate recurrent episodes of syncope. Such an evaluation typically includes a NEUROLOGIC EXAMINATION and an ELECTROCARDIOGRAM (ECG).

T

tachycardia See ARRHYTHMIA.

tamponade, cardiac A life-threatening compression of the HEART that prevents it from expanding to fill with BLOOD. Cardiac tamponade is most often a complication of PERICARDITIS and develops when fluid rapidly accumulates within the layers of the PERCARDIUM. The pericardium's fibrous outer layer does not readily expand, which forces the fluid to press inward against the heart. Without immediate action to drain the fluid, the heart will stop beating. ELECTROCARDIOGRAM (ECG) demonstrates the characteristic patterns of electrical changes in the heart's rhythm that strongly indicate cardiac tamponade. COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) can confirm the diagnosis. Generally the doctor can aspirate (withdraw) the fluid using a needle and syringe (pericardiocentesis), which relieves the pressure and allows the heart to resume normal function. Surgery to create an opening in the pericardium may be necessary to manage cardiac tamponade that occurs with chronic pericarditis. Penetrating trauma that causes bleeding into the pericardium may also cause cardiac tamponade.

See also MYOCARDIAL INFARCTION.

thrombolytic therapy Emergency treatment with medications to dissolve BLOOD clots that are in the process of forming. When initiated promptly, thrombolytic therapy can avert MYOCARDIAL INFARCTION or ischemic (nonhemorrhagic) STROKE, mitigating damage to the HEART or BRAIN respectively. Doctors also may use thrombolytic therapy to treat blood clots that form elsewhere in the body, such as in the leg (DEEP VEIN THROMBOSIS [DVT]) or the LUNGS (PULMONARY EMBOLISM).

Thrombolytic agents act by converting plasminogen, an inactive protein in the blood circulation, to plasmin, an active protein that breaks down the key proteins that form blood clots (fibrinogen and fibrin). These agents can only act before the clot fully forms and hardens, which establishes a therapeutic window of about four hours from the onset of clot formation. Early diagnosis is therefore essential.

COMMON THROMBOLYTIC AGENTS

alteplase (aPA)	anisoylated purified streptokinase activator complex (APSAC)
anistreplase	streptokinase
tissue plasminogen activator (tPA)	urokinase

The oldest of the thrombolytic agents is streptokinase, which doctors began using in the 1940s. Streptokinase and anistreplase derive from streptococcal BACTERIA. When administered, these agents initiate ANTIBODY production. The antibodies become active after five days and remain active for about six months. During that timeframe, doctors cannot re-administer streptokinase or anistreplase. Some people also have adverse responses to these agents, especially streptokinase. Laboratories manufacture most of the newer thrombolytic agents using recombinant technology, which nearly eliminates these immune responses.

The most significant risk of thrombolytic therapy is uncontrolled bleeding (HEMORRHAGE). For this reason, it is crucial for doctors to determine whether a stroke is ischemic (caused by a clot) or hemorrhagic (caused by bleeding) before administering a thrombolytic agent. For venous clots, such as with deep vein thrombosis, the doctor may directly inject the agent into the clot. For arterial

clots, such as with myocardial infarction or stroke, the doctor injects the agent into a vein for distribution throughout the circulation. Thrombolytic agents remain active in the bloodstream for 15 to 90 minutes, depending on the agent. With prompt initiation of thrombolytic therapy, the agent dissolves the clot and the person experiences little or no adverse effects as a consequence of the thrombolytic event.

torsade de pointes A life-threatening ventricular tachycardia (rapid contractions of the ventricles) that is the most serious complication of the ARRHYTHMIA disorder LONG QT SYNDROME (LQTS). Torsade de pointes is a distinctive pattern of QRS complex electrical activity, QRS being the points on the ELECTROCARDIOGRAM (ECG) that identify ventricular contraction.

The term "torsade de pointes" means "twisting around the points." In ballet, the term's origination, the term identifies a movement in which multiple steps rotate the dancer around an imaginary axis. On the ECG, the QRS complex appears to twist around the electrical baseline with a continuously changing point of origin, reminiscent of the ballet movement. The pattern represents a progressive change in myocardial cell polarity (abnormal shifts in the cell's electrical charge), a marked dysfunction of the heart's electrical pacing and conduction mechanisms. Unless interrupted, torsades de pointes results in SUDDEN CARDIAC DEATH.

The ECG provides definitive diagnosis. Torsade de pointes may stop spontaneously or may require emergency medical intervention such as DEFIBRILLATION (electrical shock to restore normal rhythm) or a temporary PACEMAKER. Numerous medications can cause acquired LQTS and consequently torsade de pointes, including the commonly prescribed antibiotic erythromycin, ANTIPSYCHOTIC MEDICATIONS such as the phenothiazines, and most drugs that affect the heart's function such as those to treat arrhythmias, HEART FAILURE, and HYPERTENSION (high BLOOD PRESSURE). COCAINE also can cause torsade de pointes. Stopping the causative DRUG typically ends the torsade de pointes.

transient ischemic attack (TIA) A brief, episodic interruption of the flow of BLOOD to the BRAIN, often called a mini-STROKE. The most common cause of a TIA is a fragment of ATHEROSCLEROTIC PLAQUE or a BLOOD clot that breaks free and travels through the blood circulation until it lodges in an ARTERY or arteriole. TIAs also can be hemorrhagic, the result of small ruptures in the tiny arteries in the brain, often a consequence of untreated HYPERTENSION (high BLOOD PRESSURE) and CAROTID STENOSIS (narrowing and occlusion of the carotid artery in the neck). ATRIAL FIBRILLATION and VALVULAR HEART DISEASE are other common sources of clots.

Symptoms of TIA are brief and temporary and may include

- episodes of SYNCOPE (loss of CONSCIOUSNESS) or "freezing," in which the person appears conscious and alert but does not respond
- episodes of tingling or numbness affecting the face or parts of the body such as the fingers or hand, typically only on one side of the body
- temporary inability to use the arm or leg, or both, on one side of the body
- lapses in cognitive function or memory

TIAs are more common in people over age 70. Doctors generally consider them to be warning signs of impending stroke. Early diagnosis and therapeutic intervention can help avert full-fledged stroke. The diagnostic path typically includes imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI). Treatment may include ANTICOAGULATION THERAPY to reduce the blood's tendency to clot as well as medications to treat arrhythmias (notably atrial fibrillation), hypertension, and HYPERLIPIDEMIA (elevated blood lipid levels), if these conditions are present. The cardiologist may recommend carotid ENDARTERECTOMY when carotid stenosis is a causative factor.

transmyocardial laser revascularization (TMLR) A treatment for ANGINA PECTORIS and ISCHEMIC HEART DISEASE (IHD) in which the cardiovascular surgeon

uses a laser to create several dozen tiny channels through the wall of the heart's left ventricle to improve the flow of BLOOD and oxygen to the MYOCARDIUM (heart MUSCLE). The surgeon makes a small "window" incision through the ribs to gain access to the myocardium, and the HEART continues to beat during the surgery. The channels allow blood to flow directly from the ventricle's chamber to the muscle tissue. Researchers do not know why TMLR relieves angina pectoris, though believe it allows oxygen to directly enter myocardial cells and also encourages new blood vessels to grow (collateral circulation). Cardiologists generally use TMLR only when other treatments for angina have failed or are not feasible. Most people stay in the hospital for three to seven days following surgery and are able to return to their regular activities, including work, in four to eight weeks.

triglycerides blood level The amount of the fatty acid group, triglycerides, that is present in the BLOOD circulation. Most of the body's fats are in the chemical form of triglycerides, which provide the body with energy. The cells draw triglycerides from the blood to meet their immediate energy needs. The body acquires triglycerides from dietary sources as well as manufactures them. During digestion the gastrointestinal tract extracts triglycerides from dietary saturated fats such as are abundant in meats. When the level of triglycerides in the blood meets or exceeds the body's needs, the LIVER converts excess CALORIES that derive from any dietary source into triglycerides. The body stores excess triglycerides in fat cells, drawing from these stored energy supplies when demand, such as increased physical activity, exceeds the triglycerides available in the blood circulation.

In general, blood triglyceride levels rise when CHOLESTEROL BLOOD LEVELS, and particularly low-density lipoprotein cholesterol (LDL-C), are elevated. Blood triglyceride levels also tend to be elevated in OBESITY and DIABETES. The role elevated blood triglyceride levels play in CARDIOVASCULAR DISEASE (CVD) remains unclear. The National Cholesterol Education Program (NCEP), a consensus group of health experts, has established healthy and unhealthy levels of triglycerides in the blood based on correlations between elevated levels and cardiovascular conditions such as ATHEROSCLEROSIS, CORONARY ARTERY DISEASE, (CAD), and PERIPHERAL VASCULAR DISEASE (PVD), as people who have these conditions typically have elevated blood triglycerides as well.

Doctors recommend lifestyle modifications such as reducing dietary saturated fat and ALCOHOL consumption, increased daily exercise, and WEIGHT LOSS AND WEIGHT MANAGEMENT when triglyceride levels are slightly elevated (marginal) and often prescribe lipid-lowering medications when triglyceride levels are high or very high. Some people have elevated triglyceride blood levels and healthy cholesterol blood levels. For them, doctors recommend vigilance to maintain healthy cholesterol blood levels and annual monitoring, along with lifestyle habits that support overall cardiovascular health.

TRIGLYCERIDE BLOOD LEVELS (MILLIGRAMS PER DECILITER)

less than 150 mg/dL	healthy
150 to 199 mg/dL	marginal
200 to 499 mg/dL	high
500 mg/dL or higher	very high

V–W

valvular heart disease The collective term for the malformations and disorders that can affect the valves of the HEART. Valvular heart disease may affect any of the heart's four valves: mitral, pulmonary, aortic, and tricuspid. The most common forms of valvular heart disease are

- stenosis, in which the valve does not open completely
- regurgitation, also called incompetence or insufficiency, in which the valve does not close completely
- prolapse, affecting primarily the mitral valve, in which the valve leaflets are irregularly shaped such that they bulge when they close

POSSIBLE CAUSES OF VALVULAR HEART DISEASE

ANKYLOSING SPONDYLITIS	atrial septal defect (ASD)
bicuspid aortic valve	calcification
CONGENITAL ANOMALY	CORONARY ARTERY DISEASE (CAD)
ENDOCARDITIS	GRAVES'S DISEASE
HEART ATTACK	hypertrophic CARDIOMYOPATHY
MARFAN SYNDROME	MUSCULAR DYSTROPHY
PULMONARY HYPERTENSION	RHEUMATIC HEART DISEASE
RHEUMATOID ARTHRITIS	SICKLE CELL DISEASE
SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)	ventricular septal defect (VSD)

Until the 1950s, valvular heart disease was the leading cardiovascular cause of death, and RHEUMATIC HEART DISEASE, a complication of streptococcal INFECTION such as STREP THROAT, was the most frequent cause of valvular heart disease. As ANTIBIOTIC MEDICATIONS became the standard of treatment for strep throat and other infections, rheumatic heart disease and correspondingly valvular heart disease declined dramatically. Though rheumatic heart disease still accounts for about half of valvular heart disease, other causes include congenital malformations and degenerative effects that accompany aging.

Symptoms and Diagnostic Path

Many people who have valvular heart disease do not have symptoms until damage to the heart becomes significant, progressing to HEART FAILURE, CARDIOMYOPATHY, and ARRHYTHMIA. When symptoms are present, they may include

- tiredness or fatigue
- shortness of breath, especially with exertion
- periods of lightheadedness
- chest tightness or discomfort
- PALPITATIONS

Often, the underlying valve malformation (congenital or acquired) exists for years to decades before affecting the valve's function to the extent of causing symptoms. Sometimes the doctor detects valvular heart disease before symptoms are present, commonly by hearing a HEART MURMUR during a ROUTINE MEDICAL EXAMINATION. Though many heart murmurs are occasional and innocent (not indicating any disease), certain valve disorders produce distinctive murmurs. Other procedures likely along the diagnostic path include ELECTROCARDIOGRAM (ECG), ECHOCARDIOGRAM, and COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI). Depending on the person's general cardiovascular status, the cardiologist may also recommend CARDIAC CATHETERIZATION.

Treatment Options and Outlook

Medications can control much valvular heart disease. Those commonly prescribed include antico-

agulants to reduce the risk for blood clots and beta blockers or calcium channel blockers to lower BLOOD PRESSURE and slow the HEART RATE. When heart failure or cardiomyopathy is also present, the cardiologist may prescribe digoxin to strengthen the heart's contractions and diuretic medications to reduce or prevent excessive fluid accumulation in the body tissues. Lifestyle efforts, such as nutritious EATING HABITS and daily physical exercise, are important to improve overall cardiovascular status. SMOKING CESSATION and weight loss, if appropriate, are essential to reduce the risk for further CARDIOVASCULAR DISEASE (CVD).

Surgery becomes a treatment option when medical efforts are unsuccessful or valve damage is significant. Surgical options include repair (valvuloplasty) or replacement (prosthetic valve).

Valvuloplasty Balloon valvuloplasty is a procedure to treat stenosis in which the cardiologist uses cardiac catheterization to thread a catheter with a tiny balloon on the tip through a blood vessel and into the heart. When the catheter tip is in position in the valve's opening, the cardiologist inflates the balloon to gently expand the opening. Operative valvuloplasty involves OPEN HEART SURGERY to gain access to the diseased valve. The surgeon may use various methods to repair the valve, depending on the valve and the nature of the damage.

Valve replacement The surgeon may replace a damaged valve that is beyond repair. Prosthetic heart valves fall into two general categories, tissue and mechanical. Tissue valves come from human cadaver donors or animal tissues. Animal valves are typically porcine (pig) or bovine (cow) and are sterilized and processed before use. The advantage to tissue valves is that they function in the same manner as the native valve. The disadvantage is that they wear out. Mechanical valves are made of materials such as stainless steel and high-tech plastics. Their main advantage is that they are completely inert and last a very long time. After receiving a prosthetic heart valve the person must take ANTICOAGULATION THERAPY for life and take prophylactic antibiotics before invasive dental, surgical, or diagnostic procedures. Prosthetic valves, whether tissue or mechanical, are prone to collecting blood clots. A valve replacement OPERATION is also open heart surgery.

Risk Factors and Preventive Measures

Adults who are over the age of 40 may have had rheumatic FEVER or rheumatic heart disease as children and may be vulnerable to valvular heart disease as a result. Most people under the age of 40 receive antibiotic medications as the standard course of treatment for strep throat, which has greatly reduced the spread of the infection to the heart. Despite these advances, however, nearly 20,000 Americans a year die from valvular heart disease. It remains essential to receive prompt and appropriate treatment for strep infections as well as for early indications of valvular heart disease. People who know or believe they had rheumatic fever in childhood should make sure their doctors are aware of this when having routine medical examinations or receiving treatment for other cardiovascular conditions.

varicose veins Distended and distorted veins, typically occurring in the legs. Varicose veins indicate dysfunctional venous valves, which allow BLOOD to backflow or to pool in the VEIN when standing or sitting (VENOUS INSUFFICIENCY). There appears to be a GENETIC PREDISPOSITION for varicose veins, in that they seem to run in families. Varicose veins become more common with increasing age, as the blood vessels lose elasticity and other health conditions become contributing factors. Women are more likely than men to develop varicose veins, though men and women who spend a lot of time standing are at increased risk for varicose veins.

Varicose veins appear enlarged and twisted beneath the skin's surface, most noticeably on the lower legs. For many people, varicose veins are more of a cosmetic than a health concern. Some people experience leg cramps, soreness, and itching. Severe varicose veins result in extensive blood pooling that can cause changes in SKIN color or skin ulcers (venous stasis ulcers) to develop. Most varicose veins respond to conservative treatment such as frequent elevation to relieve the pressure gravity exerts on blood flow. Regular walking

tones and strengthens the muscles of the legs, which then can help to support the veins. The rhythmic movement of the leg muscles during walking also helps push blood through the veins.

Treatment for severe varicose veins may include sclerotherapy, in which the doctor injects a chemical into the varicose vein that causes the vein to SCAR and close. Blood reroutes to other veins, and the varicose vein gradually shrinks and fades to become barely noticeable. LASER SURGERY is effective on smaller varicose veins. For large varicose veins that generate significant PAIN or are causing skin ulcers, the doctor may surgically remove the affected veins in a procedure commonly called vein stripping.

The main complication of varicose veins is DEEP VEIN THROMBOSIS (DVT), in which blood clots form in the pooled or slow-moving blood. The clots cause localized pain and swelling, and if they break free can lodge in the LUNGS, causing PULMONARY EMBOLISM, or in the BRAIN, causing STROKE. Preventive measures include frequent walking, wearing low-heeled shoes (which exercise the muscles in the lower leg), shifting the weight from leg to leg and rocking slightly back and forth when standing is necessary, and resting with the legs elevated.

vein A blood vessel that carries BLOOD to the HEART. All veins except the PULMONARY VEINS carry deoxygenated blood; the pulmonary veins return oxygenated blood to the heart from the LUNGS. Because veins lack the muscular structure and contractile capability of arteries, they have valves that keep blood moving only in one direction, toward the heart. The body's largest veins are the superior VENA CAVA and the inferior vena cava, which empty blood into the heart's right atrium.

For further discussion of the veins within the context of cardiovascular structure and function please see the overview section "The Cardiovascular System."

See also ARTERY.

vena cava The body's largest veins, which return deoxygenated BLOOD to the HEART. The superior vena cava brings blood from the upper body and enters the top of the right atrium. The inferior vena cava brings blood from the lower body and enters the bottom of the right atrium. A valve at the juncture of the inferior vena cava and the right atrium, called the eustachian valve, prevents gravity from pulling blood back into the inferior vena cava.

For further discussion of the superior vena cava and the inferior vena cava within the context of cardiovascular structure and function please see the overview section "The Cardiovascular System."

See also AORTA; PULMONARY ARTERIES; PULMONARY VEINS.

venous insufficiency A chronic condition in which the veins cannot adequately return BLOOD to the HEART, usually as a consequence of defective valves that allow blood to leak back and pool in the veins. Some people do not have valves in their veins, a circumstance that is a CONGENITAL ANOMALY. Venous insufficiency primarily affects the veins in the legs, especially the lower legs, and may accompany or contribute to VARICOSE VEINS. Symptoms include edema and characteristic changes in SKIN color and texture (lipodermatosclerosis). Many people who have venous insufficiency experience discomfort, such as burning or itching, and cramping in the lower legs, and may have frequent skin ulcers that are slow to heal. The diagnostic path may include Doppler ULTRASOUND or VENOGRAM to evaluate the flow of blood through the veins.

Treatment is conservative and supportive to the extent possible, including compression stockings to help support the veins and intensify the action of the leg muscles with walking. Frequent walking massages the veins, helping move blood upward toward the heart. Resting with the legs elevated above the level of the heart counters the effect of gravity on returning blood flow. Surgery may become necessary when skin ulcers fail to heal with treatment, or PAIN becomes intense. Surgical options include VEIN ligation (commonly called vein stripping) and vein grafts to reroute blood around severely damaged veins.

See also DEEP VEIN THROMBOSIS (DVT).

venogram A diagnostic procedure to evaluate the flow of blood in the veins, usually in the legs.

The cardiologist may use venogram to diagnose VARICOSE VEINS, VENOUS INSUFFICIENCY, or DEEP VEIN THROMBOSIS (DVT). For venogram, the radiologist injects a small amount of contrast dye into the affected VEIN network and then takes X-rays or fluoroscopy images as the dye moves with the blood through the veins. The venogram shows any structural abnormalities and occlusions. Venogram requires no preparation or recovery. Some people experience a minor burning sensation with injection of the contrast dye. People who are allergic to iodine may have an allergic reaction to the dye.

ventricular assist devices (VADs) Implanted mechanical pumps that aid the native HEART, taking over some of the workload of the ventricles. Several types of VADs are available, each with somewhat different features and functions. A VAD may assist the right or left ventricle, and in some cases both ventricles, as a bridge device while awaiting a donor heart for HEART TRANSPLANTATION or as a permanent device to treat end-stage HEART FAILURE, a therapeutic application sometimes called destination therapy. The VAD sometimes allows the heart to recover sufficiently that the VAD becomes unnecessary and the surgeon can remove it. The OPEN HEART SURGERY to implant the VAD takes between three and eight hours, depending on the person's cardiovascular status and the type of VAD the surgeon is implanting.

Though VADs offer hope of extended survival and improved QUALITY OF LIFE for many people whose heart failure would otherwise be fatal, living with an implanted device requires conscientious and consistent attentiveness. Recipients must take anticoagulant medications and may require other medications, depending on their underlying CARDIOVASCULAR DISEASE (CVD). Ongoing risks include INFECTION, mechanical failure of the VAD, damage to blood cells, bleeding at the implant site, clot formation resulting in STROKE or PULMONARY EMBOLISM, and worsening of cardiovascular status that may require additional therapeutic intervention including surgery. Because the VAD became an approved treatment in the United States only in 2004, doctors do not yet know the long-term benefits and risks of VAD implantation.

ventricular fibrillation Rapid, irregular, ineffective contractions of the heart's ventricles. Ventricular fibrillation quickly becomes fatal without treatment. The HEART cannot pump blood to the LUNGS or to the body when it is in ventricular fibrillation.

Ventricular fibrillation is a life-threatening event that requires emergency medical treatment.

The ELECTROCARDIOGRAM (ECG) provides a definitive diagnosis. Treatment may consist of DEFIBRILLATION (an electrical shock to the heart) or of medications to restore normal rhythm. Ventricular fibrillation typically follows a cardiac crisis such as HEART ATTACK, and despite its lethal potential presents an opportunity for successful resuscitation because the heart still has electrical activity. Ventricular fibrillation may also exist as the deterioration of an ARRHYTHMIA disorder such as ventricular tachycardia (rapid, regular contractions of the ventricles) or WOLFF-PARKINSON-WHITE SYNDROME.

See also ATRIAL FIBRILLATION; CARDIOPULMONARY RESUSCITATION (CPR); PREMATURE VENTRICULAR CONTRACTION (PVC).

Wolff-Parkinson-White syndrome An inherited ARRHYTHMIA disorder in which an extra conduction pathway, called an accessory pathway, exists between the heart's atria and ventricles. The accessory pathway allows the heart's electrical pacing impulse to bypass the normal conductive route, reaching the ventricles before the atria have completed their contraction cycle. While many people who have Wolff-Parkinson-White syndrome never experience any symptoms, some people have episodes of ventricular tachycardia, in which the ventricles contract regularly though very rapidly. Ventricular tachycardia is not very effective in moving BLOOD to the LUNGS and especially through body, resulting in feelings of lightheadedness or episodes of SYNCOPE (brief loss of CONSCIOUSNESS) as the blood supply to the BRAIN becomes diminished.

The ELECTROCARDIOGRAM (ECG) provides the diagnosis, showing the accessory conductive pathway. People who do not have symptoms do not need treatment though should receive regular follow-up evaluation from a cardiologist. When symptoms are present, treatment is necessary and may take the form of medication to regulate the heart's rhythm or RADIOFREQUENCY ABLATION to destroy the extra pathway. Wolff-Parkinson-White syndrome tends to show symptoms in early to middle adulthood. Undetected and untreated Wolff-Parkinson-White syndrome may result in SUDDEN CARDIAC DEATH. With appropriate treatment, most people who have the condition no longer experience symptoms.

Functions of the Blood and Lymph

The BLOOD and the LYMPH are the body's vital fluids, sharing responsibility for nourishment, cleansing, IMMUNE RESPONSE, and fluid balance. The blood primarily nourishes the cells, and the lymph cleanses and drains the tissues. The lymph derives from as well as returns to the blood. Though the blood and the lymph are unique fluids that circulate through separate networks, they share some structures that allow leukocytes, notably lymphocytes and granulocytes, to move freely between the blood and the lymph.

The rhythm of life: the blood The adult human body contains about five liters (just under six quarts) of blood that the HEART propels on a continuous circuit through the arteries and veins. Contained within the arteries and veins of the pressurized cardiovascular system, the total blood volume circulates from the heart, through the body, and back to the heart in about a minute. During strenuous activity the blood can pound through six full circuits in a minute, hammering oxygen and GLUCOSE to the cells to fuel their increased energy output.

Though fluid the blood is a living tissue, a mix of cells (45 percent of the blood's composition) suspended in a watery matrix of PLASMA (55 percent of the blood's composition). Plasma, which is about 90 percent water, also carries numerous substances dissolved in it including electrolytes, glucose (sugar), hormones, NUTRIENTS, and proteins such as CLOTTING FACTORS and ALBUMIN. A single drop of blood contains roughly:

- 500 million erythrocytes
- 33.5 million platelets
- 830,500 leukocytes

Blood cell production: the bone marrow The red BONE MARROW, located in cavities within the bones called medullary canals, produces 99 percent of the adult body's blood cells and all of its erythrocytes. This spongy, somewhat gelatinous substance has two structures, the vascular compartments through which blood circulates and the extravascular compartments that contain the BLOOD STEM CELLS. The red bone marrow is extraordinarily active tissue, releasing into circulation 2 to 3 billion erythrocytes, 2 to 3 billion platelets, up to 100 billion granulocytes, and several hundred million monocytes every 24 hours. The BONE

marrow also warehouses minerals it requires for cell synthesis and the bones need for STRENGTH and growth, such as calcium. As well, the bone marrow stores B-cell lymphocytes and plasma cells, leukocytes integral to the body's IMMUNE RESPONSE.

Oxygen transport: erythrocytes The erythrocytes, also called red blood cells (RBCs), pick up oxygen molecules in the LUNGS and carry them to the cells. After delivering the oxygen, the erythrocytes then retrieve carbon dioxide molecules, the waste byproducts of cellular METABOLISM, and cart them back to the lungs for elimination from the body through respiration. This OXYGEN–CARBON DIOXIDE EXCHANGE is the foundation of the body's survival. No cells in the body can survive longer than 10 to 15 minutes (three to five minutes for BRAIN and heart cells) without oxygen.

Erythrocytes acquire their capacity to carry oxygen from the pigmented protein HEMOGLOBIN, which is high in iron. The pigment also gives erythrocytes their red color. The iron hemoglobin contains allows the hemoglobin to bind with the oxygen molecules. A healthy, normal erythrocyte contains about 300 million molecules of hemoglobin; each molecule of hemoglobin can bind with four molecules of oxygen. Iron enters the body from dietary sources. Iron deficiency is the most common cause of ANEMIA, a condition in which the blood cannot meet the body's oxygenation needs.

Erythrocytes are concave on both sides, giving them the FLEXIBILITY to nearly fold in half to squeeze through the narrowest of the body's blood vessels, the arterioles, venules, and capillaries. As well, erythrocytes lack nuclei, the "command" structures common to cells that contain deoxyribonucleic acid (DNA). DNA gives the cell its replication instructions; without it a cell cannot reproduce. The absence of a nucleus further aids the erythrocyte's flexibility, however, which is most important for delivering oxygen deep within the body's tissues.

Because erythrocytes cannot proliferate, the red bone marrow churns out a steady supply of new ones, releasing them into the circulation at a rate of 2 to 3 million per second. Erythrocytes enter the bloodstream in a slightly immature stage, called reticulocytes. They reach full maturity after about 24 hours in circulation and live in the bloodstream for 110 to 120 days, after which the SPLEEN filters them from the blood and breaks them down (hemolyzes) into their component structures. The LIVER further metabolizes the components of hemolyzed erythrocytes, recycling their ingredients for use in synthesizing new erythrocytes as well as to manufacture BILE and other biochemical substances. Macrophages within the liver, migratory monocytes called Kupffer cells, then consume whatever remains of the erythrocytic waste.

Stop the bleeding: platelets The smallest cell elements in the blood, platelets, are encased in protein coatings that become adhesive (sticky) when chemical messengers released at the site of bleeding enter the bloodstream. The chemicals activate PLATELET AGGREGATION, in which platelets swarm to the site of bleeding and stick to each other as well as to the collagen fibers at the site to form a hemostatic plug. This activation also enables platelets to change shape, elongating or contracting as necessary to bridge the gaps among the collagen fibers to form a weblike structure that ensnares other cells and substances. As the coagulation cascade unfolds the plug expands and hardens, eventually forming the clot that halts the bleeding. On the surface of the SKIN, this clot is a scab. Within a blood vessel, it is a thrombus.

Platelets arise from the largest cells in the red bone marrow, megakaryocytes, and actually are fragments of megakaryocytic cytoplasm rather than independent cells. They are irregularly shaped and loosely defined, a structure ideally suited to their purpose. Platelets also lack nuclei and live in the circulation for about 10 days. Roughly a third of the body's total platelet volume resides in the spleen, which releases them into the circulating blood in response to bleeding.

Defend and protect: leukocytes The leukocytes, also called white blood cells (WBCs), are the foundation of the body's IMMUNE RESPONSE. They take one of three forms: LYMPHOCYTE, MONOCYTE, or GRANULOCYTE. Each has specialized functions within the immune response. Lymphocytes attack invading pathogens, and monocytes and granulocytes consume the remains of the pathogenic invaders. Lymphocytes circulate primarily in the lymph. Monocytes circulate in the blood for about 24 hours after the bone marrow releases them and

then migrate into the tissues where they establish themselves as fixed defenders called macrophages. Granulocytes circulate in the blood and in the lymph and also take up residence in the lymph structures and the general body tissues. The three subtypes of granulocytes—basophils, eosinophils, and neutrophils—have specified roles in the body's inflammatory response and are responsible for hypersensitivity reactions and allergies. The bone marrow primarily manufactures leukocytes, with assistance from the lymph tissues and spleen when necessary to meet the body's INFECTION control needs.

Flow with the body: the lymph In contrast to the force of the blood's circulation, the lymph channels through the body at a gentle flow of about 100 milliliters per hour. Gravity and the body's movements (MUSCLE contractions) massage lymph through the lymph vessels that roughly parallel the arteries and veins. The lymph vessels are thin-walled, originating with cul-de-sac structures arising in the epithelial spaces, the lymphatic capillaries, that join increasingly larger channels that carry lymph into the central body and ultimately into the circulating blood.

Slightly more watery than blood (92 percent), lymph carries a suspension of primarily lymphocytes and monocytes as well as dissolved proteins and other substances. Clear and only slightly more viscous than water, lymph drains from the spaces between cells into the lymphatic capillaries, microscopic channels comprised of a single thickness of cells overlapped like backward shingles. This construction encourages fluid to seep under the cells and into the lymph capillaries. The lymph capillaries collect the droplets of lymph, pooling them into microscopic trickles that eventually merge with larger lymphatic vessels—the CISTERNA CHYLI, THORACIC DUCT, and RIGHT LYMPHATIC DUCT—that carry the lymph toward the subclavian veins where it rejoins the bloodstream.

The lymph carries leukocytes, proteins, antibodies, and other materials directly to the cells. While erythrocytes in the blood can carry oxygen molecules into the CAPILLARY BEDS, the capillaries eventually become too narrow even for the flexible erythrocytes to make further passage. So the erythrocytes off-load their oxygen molecules into the lymph, which floats them through the capillary walls and into the interstitial spaces (the space between the cells of the tissues). Lymph flows through the interstitial spaces, bathing the cells, which then withdraw the nutrients, including oxygen and glucose, that they require. Cells also discharge their metabolic wastes into the lymph.

Critical passengers in the lymph are the leukocytes, predominantly neutrophils and lymphocytes. These protective cells vigilantly patrol the interstitial spaces on the alert for invading pathogens. When they detect pathogenic invaders leukocytes secrete chemicals, called CYTOKINES, into the lymph that initiate or activate specific immune responses. Some of these responses recruit additional lymphocytes and granulocytes (notably neutrophils) into circulation both in the lymph and in the blood. As agents of immune response, granulocytes and lymphocytes have the ability to migrate between the blood and the tissues, bolstering the body's defenses as needed.

The lymph also transports pathogens, such as viruses and bacteria, to the lymph nodes where masses of lymphocytes, macrophages (tissue-bound monocytes), and granulocytes wait to dispose of them. The lymph nodes often swell when they are busy fighting infections (LYMPHADENOPATHY) and may themselves become infected (LYMPHADENITIS). The lymph also offers a route of transport for cancer cells that leave the original tumor site. The lymph network can unfortunately carry cancer cells that enter its flow to any location within the body, facilitating METASTASIS (spread of the cancer).

Teaching the concept of self: the thymus The thymus, a loose structure of lymph tissue behind the sternum (breastbone) in the center of the chest, functions somewhat as a prep school for immature T-cells. In the thymus, T-cells learn to distinguish between "self" and "nonself," a fundamental concept of immune function that prevents the IMMUNE SYSTEM from attacking cells that belong to the body. The thymus releases those that learn the lesson, and they migrate into the lymph tissues where they can reside for many years. T-cells that fail to recognize self and nonself do not gain release, and they die without leaving the thymus. In AUTOIMMUNE DISORDERS such as MYASTHENIA GRAVIS and SYSTEMIC LUPUS ERYTHEMATOSUS (SLE), it

appears the education of T-cells somehow goes awry, and the thymus releases those that identify certain self cells as nonself. These misguided T cells attack the mistaken self cells as though they were nonself, causing an autoimmune (self-attack) response.

The thymus is most active in childhood, reaching its peak function and size in early ADOLESCENCE. By early adulthood the thymus shrinks to a mere fibrous shadow of its most proliferative self. In the 1940s doctors erroneously drew a correlation between the normally large thymus of childhood and what subsequently became known as SUDDEN INFANT DEATH SYNDROME (SIDS), resulting in "therapeutic" irradiation of the thymus to reduce its size. Unfortunately, this permanently crippled the immune system, an often fatal consequence in a time when antibiotic therapy was in its infancy. Though even today researchers do not fully understand the role of the thymus in adulthood, they know it secretes a number of hormones that appear to have functions related to immune response. THYMECTOMY (surgery to remove the thymus) remains a therapeutic option in very limited circumstances, such as in adults who have myasthenia gravis.

Health and Disorders of the Blood

The blood often is the first location within the body where health conditions manifest, and as well is itself vulnerable to disorders that affect its ability to function. Even conditions that do not directly affect the blood's function show up in the blood, such as DIABETES (elevated blood glucose levels) and ATHEROSCLEROSIS (elevated blood lipids). Diagnostic blood tests, notably the complete blood count (CBC), are part of most clinical evaluations. The numbers, types, and cytologic details of the blood cells provide crucial clues to doctors investigating broad-ranging symptoms such as fatigue, chronic infection, or allergies.

Anemia, an inability of the blood to meet the body's oxygenation needs that affects about 3.5 million people in the United States, results from numerous and varied health circumstances and conditions. SICKLE CELL DISEASE and THALASSEMIA are GENETIC DISORDERS that result in defective erythrocytes. LEUKEMIA, lymphoma, and MULTIPLE MYELOMA are cancers that involve the blood cells and the structures that make them. Inherited deficiencies alter specific aspects of the blood's composition and function, such as HEMOPHILIA, a deficiency of clotting factors that results in excessive bleeding. In many situations treating the underlying health condition eliminates its effect on the blood, such as with many types of anemia. In other cases, such as leukemia, treatment targets the blood or blood-producing organs and structures.

Traditions in Medical History

Though ancient healers understood the importance of blood to health and to life itself, they did not understand the mechanisms of its circulation or production. Doctors did not know these details of physiology until the 17th and 18th centuries, respectively. The great GALEN (129–199), father of Western medicine, pronounced that the liver was the source of the body's blood, constantly producing this vital fluid much as a natural spring produced water, with an equal mix of regularity and mystery. Though centuries later researchers would discover the fragment of truth in this view—the liver does indeed produce the cells of the blood early in fetal development—its fallacy nurtured peculiar medical practices throughout much of modern history. Among the most persistent was that of bloodletting, which remained a mainstay of clinical practice into the 20th century as a treatment for nearly any condition that did not respond to other therapeutic methods. Modern doctors know, of course, that bloodletting drains the body of the cells it needs most to fight infection.

MODERN THERAPEUTIC BLOODLETTING

As was the case with Galen's views on the source of BLOOD, there is also a fragment of validity in the practice of bloodletting. Contemporary physicians use modern variations of this ancient practice to treat several conditions. Therapeutic PHLEBOTOMY withdraws blood to treat HEMOCHROMATOSIS, in which the blood contains too much iron. Therapeutic HEMAPHERESIS selectively extracts components of the blood and returns the remainder to the individual, such as to treat SICKLE CELL DISEASE.

In 1628 British physician William Harvey (1578–1657) refuted Galen's pronouncement with his published evidence of the blood's circulation through a closed network of arteries and veins, establishing the recognition of the blood as a finite composition within the body. Within 20 years physicians began experimenting with BLOOD TRANSFUSION, though what was to become a lifesaving mainstay of medical treatment did not become practical until the early 1900s. Karl Landsteiner (1868–1943), an Austrian-American immunologist, was the first researcher to identify the polysaccharides on the surface of erythrocytes (red blood cells) that were to become known as blood types. The discovery at last explained why one person's blood could harm another person and made possible the therapeutic use of drawing blood from one person for transfusion into another person. Landsteiner won the 1930 Nobel Prize in medicine or physiology for his work, and by the 1950s blood transfusions were standard therapy for a wide range of health conditions.

Transfused blood became a notorious vehicle of death in the early 1980s with the eruption of HIV/AIDS in Western populations. Though scientists had long known of blood's ability to transmit infections such as MALARIA and HEPATITIS, this new VIRUS became a particularly lethal threat for people who relied on chronic blood transfusions to treat health conditions such as hemophilia and sickle cell anemia. It also raised ethical dilemmas in situations of massive trauma in which the only treatment was equally massive transfusions of blood. Thousands of people acquired HIV/AIDS from blood and blood products until reliable screening procedures and testing for the presence of HIV in donor blood became available in the late 1990s.

Breakthrough Research and Treatment Advances

Among the most significant breakthroughs in treatment advances are therapies for cancers of the blood, bone marrow, and lymphatic tissues. Complex CHEMOTHERAPY regimens, bone marrow transplantation, and peripheral blood stem cell (PBSC) transplantation can turn some leukemias from fatal to long-term REMISSION or cure. About 80 percent of children under age 14 who undergo treatment for acute lymphatic leukemia (ALL), for example, experience complete and apparently permanent remission such that doctors are willing to call them cured.

Much current research centers on blood stem cells, with scientists searching for ways to encourage these pluripotent cells to differentiate into cells of types other than blood cells. Peripheral blood stem cells share many of the characteristics of their omnipotent counterparts, embryonic STEM CELLS, including the ability to either replicate themselves or differentiate into specific cell types, and are easy to collect via extraction from BLOOD DONATION or HEMAPHERESIS. Though these efforts have so far met with limited success, they have resulted in new understanding of the complexities that underlie cell differentiation and proliferation in both health and disease.

A

aging, changes in the blood and lymph that occur with The BLOOD undergoes a number of normal changes across the span of the lifetime. Blood cells have life spans ranging from a few hours to decades. The blood continually renews itself, producing millions of erythrocytes and thousands of leukocytes every hour. Blood cell production accelerates to meet unique health needs, such as PREGNANCY or INFECTION.

The LIVER is the first organ in the developing fetus to produce blood cells, primarily erythrocytes, with supplemental production from the SPLEEN and the THYMUS. At about five gestational months the BONE MARROW has developed enough to begin taking over blood cell production and by birth is the primary structure for HEMATOPOIESIS. Through childhood (until about age 16), nearly all the bone marrow is red bone marrow that actively produces blood cells. As the body matures yellow bone marrow, a fibrous structure of connective tissue and fat, gradually replaces the red bone marrow. By adulthood only about 60 percent of the bone marrow is red. This level remains fairly constant until around age 70, when some red bone marrow, primarily in the long bones, again transitions to yellow marrow.

The bone marrow slows ERYTHROCYTE (red blood cell) production in advanced age, putting fewer erythrocytes into the blood's circulation. The reduced erythrocyte volume correspondingly decreases the amount of available HEMOGLOBIN in the blood, which diminishes the amount of oxygen the blood can carry to the cells with each heartbeat. This reduction commonly results in decreased AEROBIC CAPACITY, showing lessened ENDURANCE and longer recovery times with strenuous physical activity, and may cause ANEMIA. The spleen's efficiency at removing old and defective erythrocytes from the circulation declines, an accommodation that is somewhat a double-edged sword. While this slowed hemolytic action allows more erythrocytes to remain in the blood to improve the blood's capacity to carry oxygen, a greater number of those erythrocytes are less effective in this role.

The LYMPH structures and functions also change with age. The lymphatic system becomes active at about age two months when the child's IMMUNE SYSTEM begins to replace the protection from the mother's IMMUNITY. Most of the lymphocytes the lymph tissues produce swarm to the THYMUS, where they will come to maturity. The thymus contains nearly the lifetime complement of immature T-cell lymphocytes (called thymocytes in immaturity) by about age 16, at which point the thymus reaches its peak size and level of function. As the T-cells reach maturity they leave the thymus and migrate to other lymph structures throughout the body where they reside until the immune system needs them. As T-cell maturation winds down the activity of the thymus decreases and the thymus begins to shrink, diminishing by early adulthood to a few clusters of lymph tissue. After adulthood, the body can make only limited additional T-cells. Health conditions that affect T-cells, such as HIV/AIDS, that destroys them can deplete the body's supply of these vital protective cells, depriving the body of its front line immune defense.

With age lymphocyte production also decreases, resulting in fewer circulating lymphocytes and a corresponding reduced resistance to infection. Later in life the spleen diminishes in size, ultimately retreating to about half its size in early adulthood. Its functional capacity decreases as well, resulting in the spleen becoming less efficient at filtering

aged erythrocytes from circulation. The spleen also becomes less effective in fighting infection, reducing the body's resistance.

Other changes in the body that occur with advancing age affect the ability of the LYMPH VESSELS to collect fluid from the tissues and transport it back to the bloodstream. Diminished MUSCLE tone and reduced movement slow the flow of fluids into and through the lymph vessels. Other health conditions such as congestive HEART FAILURE and kidney disease affect the body's ability to move fluids through the blood vessels, creating a backlog. By about age 70, however, the body begins to decrease the total amount of water its tissues retain. This results in less water in the blood and a lower blood volume, somewhat lowering the BLOOD PRESSURE though increasing the risk for blood clots (thrombosis).

albumin The most abundant protein in PLASMA. Albumin transports various molecules through the BLOOD and helps sustain the blood's oncotic pressure, keeping fluid from seeping into the tissues. Albumin molecules are larger than the molecules it transports, allowing those substances, such as electrolytes and hormones, to pass through the walls of the blood vessels while the albumin molecules remain within the blood vessels. Albumin is among the numerous plasma proteins the LIVER produces. Albumin is also available as a blood product for transfusion. Blood banks obtain it by separating it, using a cell separator, from donated whole blood or plasma.

The blood of a healthy adult contains 3.5 to 5.0 grams per deciliter (g/dL) of albumin, which makes up about 2 percent of the blood's total volume. A low serum albumin level (hypoalbuminemia, decreased concentration of albumin in the blood) often indicates liver disease such as CIRRHOSIS or kidney disease such as GLOMERULONEPHRITIS. Hypoalbuminemia also occurs with serious BURNS. An elevated albumin level (hyperalbuminemia, increased concentration of albumin in the blood) occurs less commonly and often signals extended DEHYDRATION or DIABETES INSIPIDUS, a disorder of the ADRENAL GLANDS.

anemia A reduced ability of the BLOOD to meet the body's oxygenation needs arising from either a diminished volume of erythrocytes (red blood cells) in the blood or from reduced HEMOGLOBIN content in the erythrocytes. Though the common perception of anemia is that it is itself a health condition, doctors consider anemia an indication of other health conditions. Diagnosis and treatment target those underlying conditions. Anemia affects about 3.5 million people in the United States. Anemia can affect people of any age though is most common among menstruating women and during PREGNANCY.

Causes of Anemia

Anemia may be acute (come on suddenly) or chronic (continue over an extended time). Anemia may also result from medication interactions or ADVERSE REACTIONS, CHEMOTHERAPY, RADIATION THERAPY, and numerous health conditions. In general, anemia results from three circumstances, individually or in combination:

- excessive blood loss drains erythrocytes from the body
- the SPLEEN destroys (hemolyzes) too many erythrocytes
- the BONE MARROW produces too few defective erythrocytes

Blood loss Blood loss, either in large quantity suddenly or through chronic bleeding, has a twofold consequence on the blood's ability to carry oxygen. First, the bleeding reduces the number of erythrocytes in the blood, making fewer erythrocytes and thus less hemoglobin available. Second, old erythrocytes, which the spleen culls from the circulation to dismantle and recycle, are a key source of ingredients such as iron and hemoglobin for the production of new erythrocytes. Traumatic hemorrhage, GASTROINTESTINAL BLEEDING, and heavy menstrual bleeding are among the causes of anemia related to blood loss.

Erythrocyte destruction or deformity One of the spleen's roles is to filter erythrocytes from the blood that are old or defective, a normal process called HEMOLYSIS that maintains an appropriate balance of erythrocytes in the blood. The spleen may inappropriately sequester and destroy healthy erythrocytes, sometimes without apparent reason. SICKLE CELL DISEASE is a complex genetic disorder that results in malformed erythrocytes, causing anemia among other symptoms. In THALASSEMIA, another genetic disorder, erythrocytes are normal but hemoglobin is defective.

Inadequate erythropoiesis Nutritional deficiencies and renal failure are the leading causes of diminished erythropoiesis. The bone marrow requires vitamin B_{12}, iron, and folic acid to manufacture erythrocytes. Pernicious anemia results when the STOMACH fails to produce intrinsic factor, a substance necessary to absorb vitamin B_{12} from ingested foods. When these vital NUTRIENTS are lacking, the bone marrow cannot generate new erythrocytes. Iron deficiency anemia is the most common type of anemia in the United States.

Kidney disease and RENAL FAILURE also affect erythropoiesis because the KIDNEYS secrete ERYTHROPOIETIN (EPO), the HORMONE that stimulates the bone marrow to produce erythrocytes. Bone marrow disorders such as myelofibrosis and MULTIPLE MYELOMA also disturb HEMATOPOIESIS. Aplastic anemia is a life-threatening type of anemia that results when the bone marrow completely shuts down blood cell production.

COMMON CAUSES OF ANEMIA

adverse DRUG reactions	CHEMOTHERAPY
chronic HEPATITIS	CIRRHOSIS
DYSMENORRHEA	environmental toxins

Symptoms and Diagnostic Path

Many people do not have symptoms of anemia but instead find out they have anemia through blood tests conducted for other reasons, such as during ROUTINE MEDICAL EXAMINATION or screening for BLOOD DONATION. When symptoms are present, they are generally the same regardless of the underlying cause and commonly include

- tiredness and fatigue
- breathlessness, especially with physical exercise
- HEADACHE
- chronically cold or tingling hands and feet
- PALPITATIONS or ARRHYTHMIA (irregular or rapid heartbeat)
- irritability
- paleness of the SKIN, nail beds, and gums

Hemolytic anemia may also cause JAUNDICE. Severe anemia can be debilitating, preventing an individual from participating even in everyday activities. Such severe anemias generally result from serious underlying health circumstances. Diagnostic blood tests including complete blood count (CBC), hemoglobin, and hematocrit often provide the initial diagnosis. Further tests might include bone marrow biopsy to determine whether the bone marrow is adequately producing erythrocytes or whether the erythrocytes are normal. The doctor may choose to perform other diagnostic procedures, depending on the findings. Whether or not the anemia causes symptoms, it is important to find its cause.

Treatment Options and Outlook

Most types of anemia are curable or treatable. Treatment targets the underlying cause of the anemia. Supplemental iron, vitamin B_{12}, and folic acid can improve many types of anemia. Pernicious anemia requires lifetime injections of vitamin B_{12}. Aplastic anemia or anemia due to chronic health conditions may require BLOOD TRANSFUSION or BONE MARROW TRANSPLANTATION. Doctors may treat chronic anemia or transient anemia due to cancer treatment with EPO supplementation. Anemia resulting from GENETIC DISORDERS such as sickle cell disease or thalassemia requires ongoing treatment. Successful treatment of the

underlying cause nearly always eliminates the anemia. Most anemias are curable or treatable.

Risk Factors and Preventive Measures

A number of factors can create risk for developing anemia. People who are at greatest risk for anemia are those who

- consume a diet low in iron, folic acid, and vitamin B_{12}, nutrients the bone marrow requires to manufacture erythrocytes
- have gastrointestinal conditions that interfere with nutrient absorption, notably INFLAMMATORY BOWEL DISEASE (IBD), MALABSORPTION disorders, and CELIAC DISEASE
- menstruate or are pregnant
- have chronic health conditions that strain the body's resources, such as AUTOIMMUNE DISORDERS or INFECTION (for example, HEPATITIS or HIV/AIDS)
- have blood disorders; LEUKEMIA, LYMPHOMA, or multiple myeloma; or who are undergoing CHEMOTHERAPY or RADIATION THERAPY for other types of CANCER

People at risk for anemia should have their blood tested regularly and any time they develop symptoms of anemia. Though it is not always possible to prevent anemia, early treatment can minimize the adverse effects of anemia on overall health as well as intervene in the underlying condition at an early stage.

blood The cell-filled fluid that carries vital chemicals and NUTRIENTS via the cardiovascular system to tissues and cells throughout the body. The HEART pumps the blood, sending it under pressure through a closed network of arteries and veins. The blood provides volume within the cardiovascular system, establishing both BLOOD PRESSURE and osmotic pressure (the pressure that keeps fluid within the blood vessels). The blood carries oxygen and nourishment to and collects metabolic wastes from the cells. The blood also serves as the body's primary IMMUNE RESPONSE mechanism, transporting antibodies and specialized cells that defend the body from INFECTION as well as aid in HEALING wounds. The blood's basic composition is about 55 percent PLASMA (liquid) and 45 percent cells. The adult human body contains about five liters, or five and a half quarts, of blood accounting for 8 percent of total body weight.

Plasma

Plasma is 90 percent water. It contains a mix of proteins, electrolytes, hormones, antibodies, minerals, GLUCOSE, and other dissolved substances, forming a solution in which the blood's cells float. The constant churning and movement of the blood as the heart pumps it through the blood vessels keeps the cells and the plasma well mixed. However, in a collected blood sample the cells quickly settle to the bottom, leaving the plasma at the top. The primary proteins in plasma are ALBUMIN, IMMUNOGLOBULIN, and CLOTTING FACTORS. Plasma has a higher concentration of electrolytes (salts) than fluid in the tissues, giving the blood a higher osmotic pressure that draws fluid into the blood rather than allows it to seep from the blood in the CAPILLARY BEDS. Plasma is also essential for COAGULATION (clotting) as it carries both clotting factors and the enzymes that activate them.

Blood Cells

The blood contains three kinds of cells:

- erythrocytes, or red blood cells, which carry oxygen from the LUNGS to every other cell in the body
- leukocytes, or white blood cells, which fight infection and take one of three forms: MONOCYTE, LYMPHOCYTE, or GRANULOCYTE
- platelets, also called thrombocytes, which cause blood to coagulate (clot)

Erythrocytes make up nearly the entire volume of blood cells, while leukocytes and platelets combined make up less than 1 percent. The red BONE MARROW synthesizes (produces) the vast majority of blood cells, a process called HEMATOPOIESIS. Other structures, such as the SPLEEN, can produce limited numbers of blood cells when the body is in crisis. The LIVER and the spleen cleanse damaged, old, and deteriorating blood cells from the blood. The liver breaks erythrocytes into their chemical components, which the body then recycles to synthesize new erythrocytes in the bone marrow.

For further discussion of the blood within the context of blood and lymph structure and function please see the overview section "The Blood and Lymph."

blood donation The procedure of withdrawing BLOOD to prepare and use for BLOOD TRANSFUSION. Volunteer donors provide all human blood and

blood products used for transfusions. According to the American Association of Blood Banks, 8 million Americans donate 15 million units of blood each year. Because blood banks separate the majority of donated blood into component blood products, one unit of donated whole blood can meet multiple needs.

The body replaces lost fluid volume (PLASMA) within 24 hours of donation, and erythrocytes (red blood cells) and other blood cells in six to eight weeks. A healthy adult may donate one unit of whole blood every eight weeks. There is no cost for donating blood, and there is very minimal risk. A person cannot contract HEPATITIS, HIV/AIDS, or other infectious diseases through the process of donating blood.

Donor Requirements

In the United States, individual states and blood banks establish regulations and procedures to determine donor eligibility. In general, a prospective donor must

- be 17 years of age or older
- pass a preliminary health screening that identifies potential health risks for the donor or for recipients of the donor's blood
- weigh 100 pounds or more

Health screening questions aim to reveal behaviors or practices that carry a risk for INFECTION with diseases such as hepatitis and HIV/AIDS. Such behaviors include intravenous DRUG use and sex with multiple partners. In 1998, US blood banks also began screening prospective donors for possible exposure to variant Creutzfeldt-Jakob disease (VCJD), the human illness resulting from bovine spongiform encephalopathy ("mad cow" disease). Numerous health conditions may preclude an individual from donating blood; blood banks refer to these exclusions as deferrals.

The Blood Donation Procedure

The total blood donation process takes about 45 minutes to an hour, about 20 minutes of which is the actual blood withdrawal (called PHLEBOTOMY). Once the prospective donor clears the health screening, he or she sits in a reclining chair to be comfortable for the donation process. The technician cleanses the inner arm at the elbow with an antiseptic and puts a tourniquet briefly around the upper arm to cause the veins to engorge. The technician then inserts a sterile needle, connected to collection tubing and bag, into one of the veins and releases the tourniquet.

The technician may ask the person to periodically squeeze an object to help move blood through the VEIN during collection. After blood fills the collection bag (one unit), the technician withdraws the needle and places pressure over the puncture site for several minutes to suppress any bleeding, then applies a bandage that should stay in place for two to four hours. The person moves to a resting area, usually to have a drink of juice or water and a snack, then may leave when he or she feels comfortable. The risks associated with donating blood are very minor and may include bleeding, bruising, or discomfort at the needle insertion site.

Donor Blood Distribution and Use

Most donated blood goes to centralized blood banks for distribution to hospitals, which administer it to anyone who needs it. Two exceptions are

- autologous donation (BLOOD AUTODONATION), in which an individual donates blood for his or her own transfusion such as for a planned major surgery
- directed donation, in which an individual asks that others donate blood on his or her behalf and specified use, such as following a major trauma or unanticipated major surgery

Blood banks generally cannot use blood not used for self-transfusion (autologous donation) or not administered to the intended recipient (directed donation) for general transfusions and must instead throw it away. Some blood banks screen and process autologous donations differently from general donations, making autologous donations unacceptable for general use. Other blood banks handle autologous and general donations the same and have procedures for donors to authorize, at the time of donation, other use of their blood under such circumstances to avoid unnecessary waste of such a valuable resource. Though blood banks screen and process directed

donations the same as general donations, many health experts are concerned that donors may not be forthcoming during the health screening process, raising the risk for the blood to carry pathogens. The tests blood banks run on each unit of donated blood may not detect the presence of certain infections, making accurate health screening essential.

blood stem cells The parent cells from which all BLOOD cells arise. Blood stem cells are pluripotent or undifferentiated, which means they have the ability to become any of the three types of blood cells (erythrocytes, leukocytes, or platelets). Intricate biochemical interactions determine how the blood stem cell will differentiate (become a specific type of blood cell). Blood stem cells reside primarily in the BONE MARROW and the LYMPH tissues though some circulate in the blood.

Blood stem cell transplantation, with harvesting through BONE MARROW DONATION and peripheral blood stem cell (PBSC) donation, has become a cornerstone of treatment for cancers involving the bone marrow and blood, notably leukemias and lymphomas. Researchers are exploring ways to use blood stem cells in other ways. Unlike embryonic stem cells, which are omnipotent (can differentiate into any kind of cell), blood stem cells have limited capability to differentiate only into the various types of blood cells. However, the abundance and ease of collection of blood stem cells, which can be extracted from the blood, gives researchers hope that they may discover methods to manipulate blood stem cell differentiation to give rise to other kinds of cells.

blood transfusion A therapeutic procedure to administer BLOOD or blood products. Blood transfusions may be autologous (self-donated), when the timing of the need for blood permits planning, or allogeneic (volunteer donor). The transfusion of blood or blood products takes place intravenously, through a sterile needle inserted into a VEIN. Receiving a transfusion may take 10 to 20 minutes, depending on the blood product, condition of the recipient's veins, and the urgency with which the person needs the blood product. Frozen blood products are thawed, and most blood products are brought to body temperature, before administration.

BLOOD RECLAMATION DURING SURGERY

Many hospitals use BLOOD reclamation, also called blood collection, procedures to collect, cleanse, and return to the person during the OPERATION blood lost during a major surgery such as orthopedic, transplant, or OPEN HEART SURGERY. This practice reduces the need for blood transfusions.

Blood Type Compatibility

Though physicians attempted blood transfusions as early as the 17th century, many hazards and failures accompanied the procedure until researchers discovered blood types in the early 1900s. The techniques to allow consistent detection of BLOOD TYPE, called type and cross-match, finally became available in the 1950s. Doctors then were able to routinely match the blood type and rhesus (Rh) factor of donors to recipients and blood transfusions became a standard element of medical care. Transfusion of whole blood and cell-containing blood products such as red blood cells (erythrocytes) requires blood type compatibility between donor and recipient; transfusion of other blood products such as PLASMA, ALBUMIN, and CLOTTING FACTORS does not.

BLOOD PRODUCTS FOR TRANSFUSION

whole BLOOD	packed red blood cells
PLASMA	ALBUMIN
clotting factor VII	clotting factor IX
platelets	cryoprecipitated antihemophilic factor (AHF)
fibrinogen	anti-inhibitor coagulation complex (AICC)
antithrombin III	alpha 1-proteinase inhibitor
IMMUNOGLOBULIN	
Rh immunoglobulin	
granulocytes	

Transfusion Reaction

Blood type incompatibility, though uncommon in transfusion, can lead to reactions spanning the spectrum from mild to fatal. Comprehensive type

and cross-match procedures of donor and recipient blood types prevent most blood incompatibility, though situations of extreme urgency (in which thorough type and cross-match is not possible) and occasionally human error result in incidents in which a blood transfusion recipient receives blood that is incompatible with his or her blood type. As well, blood may contain antigens that conventional type and cross-match procedures do not detect. People who have health conditions (such as SICKLE CELL DISEASE, THROMBOCYTHEMIA, and HEMOPHILIA) that require frequent or numerous transfusions often develop antibodies to other antigens commonly present in blood, increasing their risk for transfusion reaction.

Symptoms of transfusion reaction develop within 24 hours of receiving blood, though often begin during the transfusion, and may include

- FEVER
- chills
- URTICARIA (hives)
- PAIN in the lower back
- generalized physical discomfort

Mild transfusion reactions resolve with minimal medical intervention, such as medications to relieve fever and discomfort. Moderate to severe transfusion reaction may require CORTICOSTEROID MEDICATIONS to thwart the body's IMMUNE RESPONSE. Rarely, transfusion reaction can progress to thromboembolism that blocks the flow of blood through key arteries, including in the LUNGS to cause PULMONARY EMBOLISM, and cardiovascular SHOCK. Such severe complications are potentially fatal and require emergency medical treatment for the specific complications.

Transfusion-Transmitted Infections

Despite comprehensive screening tests and procedures, blood-borne infections remain a risk of blood transfusions. Screening can detect pathogens and antibodies that indicate the presence of infection for a number of blood-borne health conditions including HIV/AIDS, HEPATITIS (HVA, HVB, HVC), and SYPHILIS. Screening tests are only marginally successful at detecting other infections such as CYTOMEGALOVIRUS (CMV) and human T-lymphotropic virus (HTLV). Other pathogens are able to escape detection, notably those responsible for west Nile virus, MALARIA, and CREUTZFELDT-JAKOB DISEASE (CJD) as well as various BACTERIA.

Nearly all infections involve a time gap, the infection's INCUBATION PERIOD, during which the INFECTION is present in the blood though has not yet caused symptoms or antibodies. The risk for transfusion-transmitted infections is highest for blood donated during this phase of infection. Some blood banks are using a technology called nucleic acid testing (NAT), also called nucleic acid amplification testing, that can detect a virus's genetic material in the blood. This allows detection of the infection before the IMMUNE SYSTEM develops antibodies, shortening the window of time during which the PATHOGEN is present and infectious but undetectable.

INFECTIONS THAT BLOOD PRODUCT TRANSFUSIONS CAN TRANSMIT

BABESIOSIS	CREUTZFELDT-JAKOB DISEASE (CJD)
CYTOMEGALOVIRUS (CMV)	HEPATITIS A (HVA)
hepatitis B (HVB)	hepatitis C (HVC)
HIV/AIDS	human T-lymphotropic virus 1 (HTLV-1)
MALARIA	variant CJD (VCJD)
SYPHILIS	
west Nile virus

blood type The pattern of specialized proteins, called agglutinogens or antigens, present on the surface of the red BLOOD cells (erythrocytes). The presence of antigens on the erythrocytes causes the IMMUNE SYSTEM to create oppositional antibodies, which will attack cells bearing the opposing antigens. Antigens and corresponding antibodies begin to develop shortly following birth. The discovery of blood types in the early 1900s made successful BLOOD TRANSFUSION possible, earning researcher Karl Landsteiner (1868–1943) the 1930 Nobel Prize in medicine or physiology. Landsteiner was also among the group of scientists who discovered the rhesus (Rh) factor, another red blood cell antigen, in the 1940s.

ABO Blood Types

There are four blood types: A, B, AB, and O. Each designates the presence or absence of specific blood antigens and antibodies. Each type causes an immune reaction to blood from its opposite type. The exception is type O blood, which has no antigens on its cell surfaces. Type AB blood has antigens A and B on its cell surfaces. Doctors sometimes refer to people who have type O blood as universal donors because people of any blood type can receive emergency transfusions of type O blood (preferably as packed red blood cells containing little of the antibody-carrying PLASMA), and people who have type AB blood as universal recipients because they can receive blood of any type in emergency transfusions.

ABO BLOOD TYPES

Blood Type	Antigens on Erythrocytes	Antibodies in Plasma
A	A	anti-B
B	B	anti-A
AB	A and B	none
O	none	anti-A and anti-B

Rh Blood Types

Blood typing further incorporates tests for the presence or absence of a group of antigens known collectively as the rhesus (Rh) factor. The name derives from the rhesus monkey, the animal in which researchers first isolated the antigens. When the antigens are present on the erythrocytes the designation is Rh positive (Rh+); when the antigens are not present the designation is Rh negative (Rh–). Less than 15 percent of the American population has Rh– blood. Though collectively there are more than 40 identified antigens in the Rh blood type system, nearly all antibody response arises from Rh-D antigens. Most blood type classifications represent the ABO type and Rh status together, as in AB+ or O–.

An immune response occurs when Rh+ and Rh– blood mingle, irrespective of the ABO blood type. The health risk is to the individual whose blood is Rh–. Rh incompatibility is a serious threat to the life of an unborn child and can manifest when a mother who is Rh– conceives a child who is Rh+. The first commingling of Rh-incompatible blood typically does not result in adverse effects because the mother's Rh– blood does not yet contain antibodies against the fetus's Rh+ blood, but the first exposure to Rh+ blood activates ANTIBODY production in the mother. The first child in an Rh-incompatible pregnancy typically is born without complications; however, subsequent pregnancies result in the mother's body producing massive Rh+ antibodies that cross the PLACENTA and destroy the fetus's Rh+ erythrocytes. This condition, called hemolytic disease of the newborn (HDN) or erythroblastosis fetalis, often kills the unborn child.

The standard of PRENATAL CARE in the United States includes blood tests to determine maternal Rh status, with an injection of Rh IMMUNOGLOBULIN to prevent antibody formation in women who have Rh– blood. Rh incompatibility also can cause transfusion reaction when a person who has Rh– blood receives Rh+ blood. Such transfusion reactions can cause serious ANEMIA and cell agglutination (clumping) that can result in death.

Distribution of Blood Types

The most common blood type among Americans is O+ (38 percent); the least common is AB– (1 percent). Genes determine blood type (ABO as well as Rh). Before the advent of DNA sequencing and HUMAN LEUKOCYTE ANTIGENS (HLAS) typing, blood type was the basis of paternity testing. There are enough variations in blood type INHERITANCE PATTERNS, however, to make blood type less than 100 percent reliable for determining parentage, and blood type is no longer legal proof of parentage in the United States.

PERCENTAGES OF BLOOD TYPES AMONG AMERICANS

type O+	38 percent
type A+	34 percent
type B+	9 percent
type O–	7 percent
type A–	6 percent
type AB+	3 percent
type B–	2 percent
type AB–	1 percent

bone marrow The semigelatinous tissue within the center of the BONE. Though its presence is imperceptible in health, the bone marrow is the

foundation of the BLOOD and its circulation and plays a fundamental role in immune function. Red bone marrow is the primary source of new blood cells and is most abundant within the sternum, ribs, vertebrae, and pelvis in an adult. In childhood the bones of the skull and face, and the long bones of the arms and legs, also contain red bone marrow. As the body matures the red bone marrow in these sites transitions to yellow bone marrow, which contains mostly connective tissue and fat. The healthy adult has less than half as much red bone marrow as blood.

About 99 percent of the red bone marrow's output is erythrocytes; erythropoiesis is the process of producing erythrocytes. The red bone marrow also produces platelets (clotting cells) and granulocytes, a type of LEUKOCYTE (white blood cell). The cells that make up the bone marrow are BLOOD STEM CELLS, which continuously replicate to replenish the bone marrow and differentiate into three parent lines, or precursors, that produce blood cells. The parent lines are

- erythroblasts, which produce erythrocytes
- megakaryoblasts, which produce platelets
- myeloblasts, which produce neutrophils, basophils, and eosinophils (the three subtypes of granulocytes)

The red bone marrow also warehouses plasma cells, which are integral to immune function (not related to the PLASMA that forms the fluid base of blood). The red bone marrow is the location where B-cell lymphocytes, which migrate to the marrow from the LYMPH tissues that produce them, come to maturity. Yellow bone marrow produces a few leukocytes in adulthood though primarily functions as a reserve resource for new blood cell production when the red bone marrow cannot meet the body's needs.

DISORDERS THAT AFFECT THE BONE MARROW

ANEMIA	LEUKEMIA
LEUKOPENIA	metastatic CANCER
MULTIPLE MYELOMA	MYELODYSPLASIA SYNDROME
MYELOFIBROSIS	NEUTROPENIA
POLYCYTHEMIA VERA	radiation toxicity
THROMBOCYTHEMIA	THROMBOCYTOPENIA

bone marrow donation The withdrawal of BONE MARROW from a donor for use as a BONE MARROW TRANSPLANTATION or to harvest BLOOD STEM CELLS, usually as treatments for LEUKEMIA, lymphoma, some other cancers, and severe forms of ANEMIA. BONE marrow donation may be autologous (donated for reimplantation into the donor) or allogeneic (donated for another person to receive as a bone marrow transplantation).

Bone marrow donation is a surgical procedure performed in an operating room under general ANESTHESIA. The physician extracts donor bone marrow, which is a thick liquid, using a syringe and a large needle that can pierce the bone. The most common donor site is the iliac crest (hip bone). A single bone marrow donation typically harvests about 1 quart (less than a liter) of red bone marrow mixed with BLOOD. The donor's body replaces the extracted marrow in about four to six weeks. The risks of bone marrow donation are slight. They include postoperative bleeding and INFECTION. The withdrawal site is typically uncomfortable for a few days after the donation.

There is no cost to the donor for the bone marrow donation procedure and care related to it unless the donor is also to be the recipient (autologous donation). Prospective donors register with a bone marrow donor program, which uses blood samples to identify tissue types. The program contacts the prospective donor when there is a need for marrow of his or her tissue type. Unlike blood donated for transfusions, bone marrow cannot be stored.

A less invasive type of donation that appears to achieve the same result is peripheral blood stem cell (PBSC) collection, done through a procedure called HEMAPHERESIS (also called apheresis). Hemapheresis is similar to BLOOD DONATION, in which an intravenous (IV) line withdraws the donor's blood. The blood goes into a blood separator that extracts the blood stem cells and returns the remainder of the blood to the donor via a second

IV line in a different VEIN. Before PBSC the person may receive injections of a medication to stimulate the bone marrow to increase its production of blood stem cells, to increase their numbers in the blood. The blood yields a lower volume of blood stem cells than does bone marrow.

See also BLOOD TRANSFUSION.

bone marrow transplantation A therapeutic procedure to replace the BLOOD STEM CELLS, the functional component of BONE MARROW, with healthy donor BLOOD stem cells. Typically the preparation process for the BONE marrow removes T-cells and sometimes other leukocytes (white blood cells) to lower the likelihood of ANTIGEN response in the recipient. Common reasons for bone marrow transplantation include

- some types of LEUKEMIA
- some types of lymphoma
- some other cancers that have not responded to first line treatments
- severe aplastic ANEMIA

Bone marrow transplantation is a complex and fairly high-risk procedure because the recipient's native bone marrow must first be destroyed, which wipes out the body's IMMUNE RESPONSE capability. Doctors accomplish this through high-DOSE CHEMOTHERAPY or RADIATION THERAPY. After this preparation, the recipient must remain in protective isolation in the hospital to limit exposure to pathogens such as viruses and BACTERIA.

The transplant recipient receives the bone marrow blood stem cells, tissue-matched for compatibility between donor and recipient, via infusion into an intravenous line, much like receiving a BLOOD TRANSFUSION. The transplanted blood stem cells migrate to the bone marrow where they establish themselves (a process called engraftment). The migration and engraftment takes about three to four weeks, after which the transplanted blood stem cells begin producing new blood cells. The immune functions of the bone marrow and blood cells begins to return in about six months, though is not complete for as long as two years. During this replenishment stage the person remains especially vulnerable to INFECTION. As well, some people take IMMUNOSUPPRESSIVE THERAPY to reduce the risk for rejecting the transplanted blood stem cells. Immunosuppression further limits the immune response.

The primary risks of allogeneic (volunteer donor) bone marrow transplantation are infection and, with allogeneic donation, rejection of the transplanted blood stem cells. There is no risk for rejection with autologous donation. Infection, however, can erupt at any time and has high risk for serious or fatal consequences for as long as the person's immune response cannot provide protection. Early intervention with ANTIBIOTIC MEDICATIONS can head off or reduce the severity of many bacterial infections. Frequent blood tests monitor the return of healthy blood cells to the circulation. The success of bone marrow transplantation is highly variable and depends on numerous factors, including the kind of cancer and the general health of the person aside from the cancer. When successful, bone marrow transplantation can put the cancer into extended and sometimes permanent REMISSION.

clotting factors Proteins in the BLOOD that are essential for COAGULATION. Clotting factors circulate in the blood as inert proteins until the coagulation cascade initiates their conversion into participants

CLOTTING FACTORS

Clotting Factor	Common Name	Function
antithrombin	antithrombin III, antithrombin III, COAGULATION inhibitor, AT-III	regulates thrombin, factor IX, factor X, factor XI, and factor XII to inhibit the coagulation cascade
factor I	fibrinogen	forms fibrin clot after activation by thrombin in the final common pathway
factor II	prothrombin	together with factor Xa prothrombinase converts prothrombin into active thrombin, which in turn helps PLATELET AGGREGATION
factor III	tissue factor	initiates extrinsic coagulation cascade following vascular injury cofactor with factors VII, VIII, and IX in activating factor X cofactor in activation of factor VII
factor IV	calcium	required at several points in the coagulation cascade
factor V	proaccelerin or accelerator globulin	necessary to stop coagulation cascade at the end
factor VI	accelerin, factor Va	activated form of factor V together with factor X converts prothrombin to thrombin in the final common pathway

Clotting Factor	Common Name	Function
factor VII	serum prothrombin conversion accelerator (SPCA) or cothromboplastin	activates factor X when calcium and factor III (tissue factor) are present
factor VIII	antihemophilic factor A	activates platelet aggregation and adhesion cofactor with factor IX in activating factor X
factor IX	Christmas factor, antihemophilic factor B, or plasma thromboplastin component (PTC)	cofactor with factor VIII in activating factor X (vitamin K-dependent)
factor X	Stuart factor or Stuart-Prower factor	activated by complex of tenase (factors VII and IX), factor VII, and calcium to enable platelet aggregation Initiates conversion of factor II (prothrombin) to thrombin
factor XI	plasma thromboplastin antecedent (PTA)	in the intrinsic pathway, activates factor IX when calcium is present
factor XII	Hageman factor	activates factor XI, thereby starting the intrinsic pathway binds to exposed collagen at site of intravascular injury
factor XIII	fibrin stabilizing factor (FSF), fibrinoligase, fibrinase, plasma transglutaminase, Laki-Lorand factor, LL factor, LLF, or protransglutaminase	cross-links and stabilizes fibrin clot after activation by thrombin needs calcium as cofactor
high molecular weight kininogen (HMWK)	contact activation factor, Fitzgerald factor, Flaujeac factor, Williams-Fitzgerald-Flaujeac factor, or Williams factor	activates factor XII early in the intrinsic pathway
prekallikrein	Fletcher factor or prokallikrein	activates factor XII at very beginning of the intrinsic pathway
protein C	anticoagulant protein C	limits functions of factor V and factor VIII with cofactor protein S, inhibits thrombin to block fibrin clot formation
protein S	anticoagulant cofactor protein S	limits functions of factor V and factor VIII as cofactor for protein C, inhibits thrombin to block fibrin clot formation
thrombomodulin	fetomodulin	cell surface receptor that binds excess thrombin, thus inhibiting dangerous clot formation

in blood clotting. Clotting factors interact with each other as well as other enzymes in the blood, notably fibrin and thrombin, to form blood clots. Deficiencies of specific clotting factors cause coagulation disorders such as HEMOPHILIA (excessive bleeding) and thrombophilia (excessive clot formation). The LIVER produces clotting factors I (fibrinogen), II (prothrombin), V (proaccelerin), VII (cothromboplastin), IX (PLASMA thromboplastin), and X (Stuart-Prower factor).

coagulation The process, also called the coagulation cascade, through which the BLOOD forms clots. The cells responsible for forming clots are platelets, which interact with each other, collagen, proteins, and other substances in the blood. Specialized proteins in the blood, called CLOTTING FACTORS, activate in cascades, with one activation leading to another in sequence. Coagulation begins with one of two sequences of cascading events: either an extrinsic or an intrinsic trigger sets off a different cascade. Each cascade culminates in clot formation. Current research suggests that coagulation cascades unfold at different paces and with differing thresholds of activation according to the type of tissue or the organ structure involved. This way, the body manages the coagulation process appropriately to the situation.

Coagulation is a beneficial event when it stops bleeding and can become a hazard to health when it occurs inside blood vessels. Insufficient clotting allows extended bleeding, and excessive clotting can result in HEART ATTACK, STROKE, PULMONARY EMBOLISM, and DEEP VEIN THROMBOSIS (DVT). Though the coagulation process includes several inherent checks and balances that ordinarily strike a balance between beneficial and harmful clotting, problems with coagulation can occur and can be life-threatening.

Coagulation disorders occur when certain clotting factors are missing (such as in HEMOPHILIA), which results in excessive bleeding, or when there is an abundance of platelets in the blood (such as in THROMBOCYTHEMIA), resulting in excessive clotting. LIVER disease such as CIRRHOSIS or severe HEPATITIS affects the liver's ability to produce clotting factors—especially factors II, VII, and X—and to metabolize VITAMIN K (which participates in converting a number of clotting factors from inactive to active states), impairing coagulation.

Extrinsic coagulation cascade Any breach in a blood vessel, such as a cut (even microscopic), causes blood to come into contact with tissue factor (clotting factor III), a protein on the surface of epithelial cells (the cells of the SKIN, mucous membranes, and lining of the blood vessels). Tissue factor initiates the extrinsic coagulation cascade, activating the release and interactions of thromboplastin, clotting factor VII, and calcium ions to culminate in the production of clotting factor X.

Intrinsic coagulation cascade Internal clot formation occurs without a breach when the blood comes into contact with a foreign substance in the blood such as an ATHEROSCLEROTIC PLAQUE that activates the body's INFLAMMATION response, resulting in the formation of collagen. Collagen's presence initiates the release of kallikrein and high molecular weight kininogen (HMWK), two substances that activate clotting factor XII. The continued interaction among these substances draws clotting factor XI and clotting factor IX into the process, culminating in the production of clotting factor X.

Clot formation PLATELET AGGREGATION and clot formation begin at the intermediate level of either cascade, when clotting factor X initiates the conversion of clotting factor II (prothrombin) into the enzyme thrombin. Thrombin in turn converts clotting factor I (fibrinogen) to fibrin, a protein that interlaces with collagen (formed by the IMMUNE SYSTEM's inflammation response) to form a clot. The clot attracts additional platelets, extending the coagulation process until the protein thrombomodulin activates protein C, beginning the coagulation inhibition cascade that brings coagulation to a halt.

D–G

disseminated intravascular coagulation (DIC) A secondary COAGULATION disorder arising from an imbalance among the CLOTTING FACTORS in the BLOOD. DIC occurs as a result of a significant underlying health condition such as HIV/AIDS, overwhelming infections, or CANCER, and as a serious complication in PREGNANCY. DIC is a symptom rather than a condition. Indications of its presence include

- PETECHIAE (pinpoint hemorrhages), especially on the roof of the MOUTH (soft palate) and the lower legs
- ECCHYMOSIS (easy bruising)
- hemorrhage (easy bleeding)
- thrombosis (clot formations in the blood vessels, typically the veins)

The diagnostic path includes blood tests, especially fibrinogen and fibrin split products. Treatment for DIC targets the underlying cause, though may include measures such as BLOOD TRANSFUSION to arrest hemorrhaging or ANTICOAGULATION THERAPY when the condition manifests as thrombosis. The outlook, like the treatment, depends on the underlying cause.

eosinophil See GRANULOCYTE.

erythrocyte A red BLOOD cell (RBC). The primary function of erythrocytes is to carry oxygen from the LUNGS to the cells of tissues throughout the body and return carbon dioxide, a metabolic waste, to the lungs for removal from the body. Erythrocytes contain iron and HEMOGLOBIN, a pigmented protein that gives them their red color. Hemoglobin is the substance to which oxygen and carbon dioxide molecules bind for transport through the bloodstream. Erythrocytes account for 99 percent of the blood cells the blood carries.

Erythrocytes lack nuclei, which means they cannot proliferate (reproduce). They have a lifespan of about 120 days. The BONE MARROW thus must continuously produce erythrocytes, which it does at the rate of about 2 million per minute. The SPLEEN and the LIVER filter aging, deteriorating, and defective erythrocytes from the blood circulation. Men have a somewhat higher percentage of erythrocytes in their blood, about 47 percent, than women, who have about 42 percent, primarily because women lose blood each month with MENSTRUATION. The number of erythrocytes in both men and women begins to decline after age 70 because erythropoiesis slows as a natural aspect of aging.

For further discussion of erythrocytes within the context of blood and lymph structure and function please see the overview section "The Blood and Lymph."

See also HEMATOPOIESIS; OXYGEN–CARBON DIOXIDE EXCHANGE.

erythropoiesis See HEMATOPOIESIS.

erythropoietin (EPO) A HORMONE the KIDNEYS produce that stimulates the BONE MARROW to increase red BLOOD cell production. EPO is a protein structure called a CYTOKINE. Specialized cells in the renal cortex, called peritubular fibroblasts, respond to the amount of oxygen in the blood as it passes through the kidney. When the oxygen saturation of the blood is low (HYPOXIA), the peritubular fibroblasts increase EPO production. Normally the bone marrow releases about two million

erythrocytes into circulation every minute. The EPO stimulates the bone marrow to release higher numbers of erythrocytes into the blood circulation, which boosts the amount of HEMOGLOBIN and increases the blood's capacity to carry oxygen.

EPO production falters in serious kidney disease, resulting in ANEMIA. Medications that diminish kidney function may have similar effects. The liver and perhaps other sites in the body also produce small amounts of EPO, though not enough to meet the body's needs when the kidneys fail. Some people experience fluctuations in EPO production, both increases and decreases, after KIDNEY TRANSPLANTATION.

During the 1980s researchers identified and sequenced the GENE responsible for EPO, allowing the synthesis of recombinant erythropoietin in the laboratory. Administered by injection, this form of EPO, epoetin alpha (Procrit, Epogen), can supplement or replace endogenous EPO to stimulate the bone marrow when kidney production falls off or other circumstances cause rapid ERYTHROCYTE depletion and corresponding anemia. Potential side effects of EPO supplementation include increased BLOOD PRESSURE (HYPERTENSION) especially when the cause of anemia is RENAL FAILURE, and thrombosis (the formation of blood clots within the blood vessels) resulting from the increased percentage of erythrocytes in the blood.

granulocyte A type of LEUKOCYTE (white BLOOD cell) so named because its cytoplasm contains granules. The granules, called lysosomes in neutrophils, contain enzymes that digest proteins and carbohydrates, the basic components of cellular structures. Granulocytes are primarily phagocytic; their responsibility is to consume pathogens that lymphocytes and other leukocytes neutralize as part of the body's IMMUNE RESPONSE. Pathologists refer to granulocytes as polymorphonuclear (PMN) because the nucleus of a granulocyte contains multiple lobes. Granulocytes have a short life span in the circulation, typically six to eight hours. After this time some of them migrate into the tissues and continue to function as phagocytes. The liver filters from circulation those that do not migrate and its phagocytic cells, the Kupffer cells, consume them. There are three types of granulocytes, named for the kinds of tissue dyes they accept to emphasize their structures for microscopic examination: basophils, eosinophils, and neutrophils.

Basophils A basophil accepts a base dye such as methylene blue, accounting for its name, which means "base-loving." Basophils respond to the various chemicals injured cells and pathogens release, among them HISTAMINE, serotonin, CYTOKINES, LEUKOTRIENES, and PROSTAGLANDINS. Basophils themselves also release these chemicals, which serves to further incite an inflammatory response as well as summon more leukocytes into action. Basophils filled with HISTAMINE granules are primarily responsible for HYPERSENSITIVITY REACTION and ALLERGY responses. They are abundant in the bronchial tissues during ASTHMA attacks, for example, and in the tissues surrounding an insect bite or sting.

Eosinophils The eosinophil ("eosin-loving") accepts a tissue dye called eosin for examination under the light microscope. Eosinophils, containing enzymes to digest bacteria and other pathogens, also have roles in histamine release (such as in hypersensitivity reactions and asthma) and inflammatory response. Parasitic infections, atopic DERMATITIS, non-Hodgkin's LYMPHOMA, and OVARIAN CANCER are among the conditions that can cause elevated eosinophil levels. Medication reactions, notably with beta blockers and CORTICOSTEROID MEDICATIONS, are among the causes of lowered eosinophil levels. An eosinophil normally circulates about eight hours in the blood and then migrates into the tissues.

Neutrophils The neutrophil ("neutral-loving") stains neutrally for microscopic examination. It is the most abundant type of leukocyte in the blood, making up about 70 percent of the white blood cells in circulation. Neutrophils are the IMMUNE SYSTEM's infantry, maintaining a strong defensive presence in the blood and swarming to attack invading pathogens. Neutrophils that die in the line of duty release toxic chemicals to continue their protective actions. Neutrophils are integral to the body's inflammatory response and are often to blame for autoimmune attacks such as those that occur with RHEUMATOID ARTHRITIS and INFLAMMATORY BOWEL DISEASE (IBD). Numerous health conditions can lower the number of neutrophils in the blood circulation

including infections, serious vitamin B deficiency, RADIATION THERAPY, CHEMOTHERAPY, and cancers such as LEUKEMIA and lymphoma. Some medications, notably antibiotics and NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS), can also decrease the neutrophil level raising the risk for INFECTION.

For further discussion of granulocytes within the context of blood and lymph structure and function please see the overview section "The Blood and Lymph."

H

hematopoiesis The process through which the body generates new BLOOD cells. In the adult, the red BONE MARROW and the LYMPH tissues (primarily the lymph nodes and the SPLEEN) manufacture the blood cells the body needs, with extramedullary resources for ERYTHROCYTE production available as reserves from the LIVER, spleen (erythrocytes), and yellow BONE marrow. Researchers do not fully understand the mechanisms of hematopoiesis though know complex interactions of hormones, proteins, and chemicals regulate the processes by which the body makes new blood cells. There are two major divisions of hematopoiesis: erythropoiesis (production of erythrocytes) and leukopoiesis (production of leukocytes).

Pluripotency, Differentiation, and Proliferation

As best researchers understand the mechanisms of hematopoiesis, all blood cells arise from pluripotent BLOOD STEM CELLS that have the ability to develop into any of the blood cell types. The first level of hematopoiesis occurs when a blood stem cell either proliferates, extending the volume of pluripotent cells, or differentiates into one of two committed lineages, myeloid or lymphoid. The lymphoid lineage will produce lymphocytes and monocytes, and the myeloid lineage will produce erythrocytes, granulocytes (basophils, eosinophils, and neutrophils), and platelets. Each lineage generates a number of differentiations or stages of development. The length of time it takes for a pluripotent cell to produce a mature blood cell varies with the type of blood cell and other physiologic factors, ranging from 6 days for an erythrocyte to 14 days for a neutrophil.

Erythropoiesis

Erythropoiesis begins with committed myeloid cells that differentiate into myeloblasts or proerythrocytes. Myeloblasts will become granulocytes,

HEMATOPOIETIC STRUCTURES

Hematopoietic Structure	Blood Cells the Structure Produces
red BONE MARROW	erythrocytes, platelets, granulocytes, some monocytes
LIVER	erythrocytes on demand (extramedullary resource)
LYMPH nodes	lymphocytes, monocytes
SPLEEN	lymphocytes, monocytes erythrocytes on demand (extramedullary resource)
THYMUS	lymphocytes
yellow bone marrow	limited leukocytes erythrocytes and platelets on demand (extramedullary resource)

the majority of which will be neutrophils. Proerythrocytes will become erythrocytes (more than 99 percent) or platelets (less than 1 percent). Numerous substances influence and regulate erythropoiesis. Among them are

- ERYTHROPOIETIN (EPO), a HORMONE the KIDNEYS secrete that stimulates the bone marrow to increase differentiation of proerythrocytes and thus increase erythrocyte production
- intrinsic factor, or erythrocyte-maturing factor, which the STOMACH secretes to facilitate erythrocyte maturation
- vitamin B_{12}, also called extrinsic factor, which interacts with intrinsic factor
- iron, which is an essential component of HEMOGLOBIN (the protein complex within erythrocytes that binds with oxygen)

An erythrocyte goes through several stages of development before reaching a mature enough stage, that of reticulocyte, to leave the bone marrow. After 24 hours in circulation in the blood, the reticulocyte evolves to its final stage of maturity and becomes a fully functional erythrocyte. Erythrocytes circulate in the blood for about 120 days. The red bone marrow releases 2 million reticulocytes per minute into the blood circulation; the spleen extracts a comparable number of old erythrocytes from the circulation to maintain the correct proportion of erythrocytes in the blood.

Platelets arise from proerythrocytes that differentiate to become megakaryoblasts and then megakaryocytes. The megakaryocytes release fragments of their cytoplasm, which become platelets. While megakaryocytes are the largest cells in the bone marrow, platelets are the smallest particles in the blood. The spleen retains about 30 percent of the platelets the bone marrow produces, releasing them when a COAGULATION cascade sends chemical signals summoning platelets to the site of clot formation.

Leukopoiesis

Leukopoiesis, the production of white blood cells, takes place in both the bone marrow (granulocytes) and the lymph tissues (monocytes and lymphocytes). In general, all three types of leukocytes make up less than 1 percent of the blood cells in circulation. Many factors influence leukopoiesis, including immune status and whether an INFECTION is present in the body. Leukocytes also undergo a series of developmental evolutions before reaching maturity. Lymphocytes the lymph tissues release are immature and migrate to the THYMUS (T-cell lymphocytes) or the bone marrow (B-cell lymphocytes) to mature.

hemapheresis The process of withdrawing BLOOD from the body, filtering it through a machine called a cell separator to extract a desired blood component, and returning the rest of the blood to the person. There are two forms of hemapheresis, therapeutic and donor. Therapeutic hemapheresis, also called apheresis, removes damaged or defective components from the blood, which allows the body to naturally replace the components with healthy structures. Donor hemapheresis collects blood components for use in BLOOD TRANSFUSIONS.

For hemapheresis, the phlebotomist inserts an intravenous needle into a VEIN in each arm. One needle attaches to tubing that allows blood to flow out of the body and into the cell separator. The other needle attaches to tubing that brings the

blood back to the body after the cell separator has extracted the appropriate blood product. The entire process takes about two hours for most blood products. Some people find insertion of the needles uncomfortable and may also have chills and mild discomforts during the hemapheresis or for a short time afterward. There are relatively few risks with hemapheresis.

hematoma Bleeding into the tissues that forms a contained mass. Most superficial hematomas are benign, such as the common hematoma auris, involving the auricle (outer EAR) and BLACK EYE, involving the orbital tissues surrounding the EYE. Such hematomas typically occur as the consequence of blows to the tissues that cause BLOOD vessels to break. As the blood coagulates the mass hardens. A hematoma may take weeks to several months to fully resolve as the body works to dismantle the clot. Most superficial hematomas do not require medical care, though a doctor should evaluate any injury that potentially involves the eye or symptoms of HEARING LOSS.

An internal hematoma that occurs within the skull (subdural or subarachnoid hematoma) is particularly dangerous and even life-threatening because it causes increased pressure that damages the BRAIN. Hematomas that occur within major organs such as the LIVER or the SPLEEN are also serious. These hematomas may be the result of trauma or may occur because of anomalous blood vessel structures (such as hemangioma) that spontaneously rupture. Internal hematomas require medical evaluation and careful monitoring. The doctor may recommend surgical removal of hematomas that threaten the function of vital organs such as the brain or the liver.

hemoglobin A combined protein within erythrocytes (red BLOOD cells) that is crucial to the OXYGEN–CARBON DIOXIDE EXCHANGE. Two proteins come together to form hemoglobin: heme, a reddish pigment that contains iron, and globin. Hemoglobin bonds loosely with oxygen and carbon dioxide molecules, depending on which is in higher concentration.

In the LUNGS, oxygen molecules have the higher concentration and bind with the hemoglobin. As the blood carries the erythrocytes deeper into the body where oxygen concentrations are lower, the bond becomes less stable. When the erythrocytes reach the CAPILLARY BEDS where the concentration of carbon dioxide is higher than the concentration of oxygen, the hemoglobin releases its oxygen molecules and replaces them with carbon dioxide molecules and carries the carbon dioxide back to the lungs where the exchange repeats.

Cigarette smoke contains high levels of carbon monoxide. Heavy smokers may have blood concentrations of carbon monoxide of 7 to 9 percent.

Carbon monoxide binds more strongly with hemoglobin than oxygen or carbon dioxide, forming a tight bond (the compound carboxyhemoglobin) that blocks hemoglobin from binding with either. Only small amounts of carbon monoxide inhaled into the lungs can interfere with the oxygen–carbon dioxide exchange significantly enough to cause poisoning (HYPOXIA) or death. Carbon monoxide begins to cause symptoms of oxygen deprivation when its blood concentration reaches 10 percent, impairs neurologic function at 30 percent, and can cause death at 50 percent. A gas commonly present in the environment, carbon monoxide is a byproduct of incomplete combustion.

hemolysis The destruction and disassembly of erythrocytes (red BLOOD cells). Erythrocytes live in the blood for about 120 days after their release from the BONE MARROW. At the end of this time they either die or the SPLEEN culls them from circu-

lation. The spleen partially dismantles the erythrocytes, reducing toxic heme into BILIRUBIN that the body excretes with the BILE. The LIVER then recycles these components for numerous other uses in the body. Accelerated hemolysis, which results in ANEMIA, can occur with, or characterizes, various disorders.

hemophilia A group of inherited GENETIC DISORDERS in which certain CLOTTING FACTORS are deficient or absent, resulting in clotting dysfunction. People who have hemophilia tend to bleed easily and longer than normal. Some forms of hemophilia carry substantial risk for life-threatening hemorrhage (bleeding).

Types of hemophilia Doctors classify hemophilia according to the deficient clotting factor, which may be missing from the BLOOD, present in subnormal quantities, or present but defective. About 85 percent of people who have hemophilia have hemophilia A, a deficiency of clotting factor VIII (also called antihemophilic factor A). The remaining 15 percent have hemophilia B, a deficiency of clotting factor IX (also called Christmas factor, antihemophilic factor B, or PLASMA thromboplastin). Hemophilia B was once called Christmas disease—named after the family in which doctors first identified the clotting factor IX deficiency—and distinguished this type of hemophilia from the classic hemophilia A. Hemophilia C, which is very rare in the United States, is a deficiency of clotting factor XI (also called plasma thromboplastin antecedent).

Inheritance patterns The most common types of hemophilia, hemophilia A and hemophilia B, are inherited X-linked CHROMOSOMAL DISORDERS, meaning they nearly always only affect males. The daughters of a man who has hemophilia A or B will all carry the defective GENE, though the sons will have normal clotting factor genes. The son of a carrier has a 50 percent chance of having hemophilia; the daughter of a carrier has a 50 percent chance of also carrying the defective genes. Rarely, hemophilia A or B occurs through spontaneous gene MUTATION. In such circumstances it is possible for a woman to have the disorder. Hemophilia C, which primarily affects people who are of Ashkenazi Jewish descent, is an autosomal disorder that affects men and women equally though is very rare.

Symptoms and Diagnostic Path

Excessive bleeding is the most common symptom of hemophilia A or B, which often first manifests after CIRCUMCISION. The more severe the hemophilia, the earlier in life symptoms become apparent. Some men may not experience symptoms until adulthood, while others experience life-threatening hemorrhage with common childhood injuries such as nosebleed (EPISTAXIS) and trauma such as a cut. The diagnostic path includes blood tests that measure clotting times, PLATELET AGGREGATION, blood cell counts, and the presence of clotting factors VIII, IX, and XI, and the von Willebrand factor. The findings of these tests, along with personal and family medical histories, are generally conclusive of the diagnosis.

The amount of functional clotting factor in the blood determines the severity of the hemophilia. Clotting factor presence above 10 percent generally produces only mild to moderate symptoms; clotting factor presence below 1 percent, which occurs in about 70 percent of people who have hemophilia, generally produces severe symptoms. Life-threatening hemorrhage is the most significant consequence of hemophilia.

Treatment Options and Outlook

The goal of treatment is generally to raise the deficient clotting factor to 30 percent, or 50 to 100 percent during episodes of active bleeding, depending on the site. Treatment may be transfusions with fresh frozen plasma or plasma cryoprecipitate, both of which contain clotting factors VIII and IX, or with clotting factor concentrates. The more often these treatments are necessary, however, the greater the likelihood the person will

develop antibodies to the clotting factors that subsequently prevents these treatments from having any effect. In such situations the doctor may administer porcine-derived forms of clotting factor VIII or prothrombin complex concentrate, which bypass some of the steps in the coagulation cascade to avoid ANTIBODY activation.

A promising treatment for mild hemophilia A is the synthetic HORMONE desmopressin. Also called DDAVP, desmopressin is an analog (close chemical relative) of the endogenous hormone vasopressin, which the PITUITARY GLAND secretes. Administered intravenously or via nasal spray, desmopressin causes the body to increase blood levels of clotting factors VIII and IX. However, desmopressin has little effect in people who have hemophilia B. Desmopressin may affect other aspects of the coagulation cascade and can elevate the BLOOD PRESSURE.

Blood product treatments for hemophilia carry the risk of INFECTION with various pathogens that current blood screening technology cannot detect including HEPATITIS A, human T-lymphotropic virus 1 (HTLV-1), west Nile virus, MALARIA, and also CYTOMEGALOVIRUS (CMV). Though infection with human immunodeficiency virus (HIV) was a significant problem during the 1980s, screening procedures in effect today have nearly eliminated the risk for acquiring HIV/AIDS through donated blood products.

Many people who have hemophilia are able to enjoy a high QUALITY OF LIFE with ongoing medical monitoring and lifestyle choices to reduce the risk for traumatic injury. However, complications such as JOINT damage due to frequent bleeding can limit physical activities. GASTROINTESTINAL BLEEDING is also a potential complication.

Risk Factors and Preventive Measures

Genetic inheritance is the only known risk factor for hemophilia. Health experts encourage people who have hemophilia, know they carry the gene defect for hemophilia, or have a family history of unusual bleeding to discuss FAMILY PLANNING with a genetic counselor who can advise of the risks that children will either carry or have hemophilia. Much research currently focuses on perfecting recombinant technologies to provide clotting factor therapies free from risk of infection and antibody development. Other research efforts are exploring the potential for GENE THERAPY that can repair the damaged genes, though this potential has not yet yielded practical results.

leukemia A type of CANCER that affects the BONE marrow's production of leukocytes (white BLOOD cells). Doctors classify leukemia as either myeloid (sometimes called myelocytic) or lymphocytic (sometimes called lymphoblastic), depending on the type of leukocytes affected. Within either classification leukemia can be acute or chronic. The four most common types of leukemia are

- acute lymphocytic leukemia (ALL)
- chronic lymphocytic leukemia (CLL)
- acute myeloid leukemia (AML)
- chronic myeloid leukemia (CML)

LEUKEMIA VS. LYMPHOMA

LYMPHOMA is another type of cancer that can affect the lymphocytes. However, lymphoma is a cancer of the lymphatic tissues that produce and store lymphocytes. Leukemia is a cancer of the BONE MARROW that alters the development and proliferation of the lymphocytes that enter the BLOOD circulation.

There are a number of subtypes within these classifications, usually identified according to the affected cell type or its developmental stage. Though common perception is that leukemia primarily affects children, 10 times as many adults as children develop this type of cancer. Children are more likely to develop acute leukemia and adults over age 60 to develop chronic leukemia, though either form can occur at any age. Some forms of childhood leukemia are fully curable and some forms of adult leukemia are highly manageable. GENETIC PREDISPOSITION and certain environmental factors, such as exposure to industrial chemicals, pesticides, and RADIATION THERAPY or CHEMOTHERAPY, appear to increase an individual's risk for developing leukemia. However, most of the time doctors do not know what causes this leukemia to develop.

How Leukemia Develops

All blood cells arise from pluripotent BLOOD STEM CELLS, "parent" cells within the BONE MARROW that have the ability to form into several different kinds of blood cells. A complex interaction of genetic encoding, chemicals, proteins, molecular functions, and physiologic needs determines the manner in which blood stem cells differentiate (become specific kinds of cells) and proliferate (reproduce themselves). At the first level of differentiation, a blood stem cell establishes its lineage as lymphoid or myeloid. Myeloid stem cells give rise to erythrocytes, platelets, granulocytes, and monocytes. Lymphoid stem cells give rise to lymphocytes. In leukemia, the stem cells are normal though something goes awry at the first stage of differentiation, and one of the lines—lymphoid or myeloid—produces abnormal cells.

In acute forms of leukemia the bone marrow accelerates LEUKOCYTE production and releases immature leukocytes not yet capable of functioning as leukocytes. In relatively short time the immature cells flood the bone marrow, crowding out other cells. The onset of symptoms with acute leukemia is generally rapid because the immature cells the bone marrow releases cannot function yet are entering the circulation at a rate that causes them to quickly become dominant in the blood. In chronic leukemia the bone marrow's rate of production is normal and the leukocytes the marrow releases into the circulation are mature but defective. The onset of symptoms in

chronic leukemia is usually gradual because these cells, though defective, can function to some extent and enter the blood circulation at the normal rate. In all types of leukemia, the defective cells also block the bone marrow from producing platelets and erythrocytes, resulting in dysfunctional COAGULATION (clotting) and ANEMIA.

Acute lymphatic leukemia (ALL) The most common leukemia of childhood, ALL arises when a genetically damaged lymphoid clone cell in the bone marrow proliferates, causing immature lymphocytes, called lymphoblasts or leukemic blasts, to replace healthy lymphocytes in the bone marrow and the blood circulation. The accumulation prevents normal HEMATOPOIESIS, resulting in anemia, coagulation dysfunction, and vulnerability to INFECTION. About 85 percent of ALL involves B-cell lymphocytes and the remaining 15 percent involves T-cell lymphocytes. Doctors diagnose about 4,000 people a year with ALL in the United States.

Chronic lymphatic leukemia (CLL) Doctors diagnose about 8,000 people a year with CLL in the United States, more than 75 percent of them being over the age of 60. In CLL, the proliferating defective lymphocytes function normally. CLL may generate no symptoms or ill effects, in which case doctors generally opt for watchful waiting as the treatment approach. As CLL progresses, however, it causes dysfunctional IMMUNE RESPONSE. Defective lymphocytes that accumulate in the bone marrow eventually suppress bone marrow function.

Acute myeloid leukemia (AML) The most common leukemia among people over age 40, AML arises through the proliferation of a defective myeloid clone cell and manifests in one of seven forms. Doctors designate these forms as subtypes M1 through M7, according to the cells involved. The subtype determines the course of treatment and likelihood for REMISSION. As with ALL, the proliferation of the defective clone prevents normal hematopoiesis with consequent THROMBOCYTOPENIA, anemia, and often NEUTROPENIA. Doctors diagnose about 12,000 people a year with AML in the United States.

Chronic myeloid leukemia (CML) Nearly always a cancer occurring in adulthood, CML results from the translocation of chromosomes 9 and 22, an acquired MUTATION commonly referred to as the Philadelphia, or Ph, CHROMOSOME. Researchers do not know what causes the abnormality, which produces the rampant proliferation of monocytes or granulocytes that function normally. Other hematopoiesis is normal as well. Doctors diagnose about 54,000 people a year with CML in the United States.

Symptoms and Diagnostic Path

Symptoms of leukemia develop when the cancerous cells in the blood circulation begin to outnumber the healthy cells. Early symptoms are insidious and often mimic those of common viral infections. As the leukemia progresses, symptoms become more pronounced and typically include

- unexplained low-grade FEVER
- general malaise or lethargy
- PAIN in the joints
- unintended weight loss
- sweating at night
- loss of APPETITE
- tiredness or fatigue
- easy bleeding or bruising, or the appearance of PETECHIAE (pinpoint hemorrhages beneath the SKIN)

The diagnostic path typically includes physical examination, diagnostic blood tests, and bone marrow biopsy. The physical examination may reveal SPLENOMEGALY (swollen SPLEEN) and LYMPHADENOPATHY (swollen lymph nodes). Characteristic patterns of abnormal cell counts and structures identify the different types of leukemia. In addition to abnormalities in the leukocytes, depletion of erythrocytes and platelets is common. Bone marrow biopsy confirms the diagnosis. Specialized laboratory tests, such as cytologic examination and immunophenotyping, establish the characteristics of the abnormal cells to identify the type of leukemia.

Treatment Options and Outlook

Treatment regimens for leukemia vary with the type of leukemia, the person's age, and the person's general health status aside from the leukemia. Chemotherapy and RADIATION THERAPY,

separately or in combination, remain the mainstay of the therapeutic arsenal, with the objective being to establish remission (a state in which there is no evidence of the leukemia and all blood counts and blood cells are normal). Oncologists use several staging systems for leukemia to identify the kinds of cells, cell lineage, and cell counts.

Chemotherapy is the treatment of choice, with blood stem cell or BONE MARROW TRANSPLANTATION sometimes an option depending on the leukemia's characteristics and stage at the time of diagnosis. Research continues to produce new chemotherapy agents and new combinations of existing agents that appear more successful, though their ability to sustain remission over time remains unknown. The initial phase of chemotherapy typically involves cycles of chemotherapy drugs administered over a period of one to two years, with maintenance oral chemotherapy drugs for another two and a half to three years for ALL. Oncologists may use radiation therapy to treat accumulations of cancerous lymphocytes in the BRAIN, spleen, and lymph nodes such as may occur with ALL. Many people need supplemental BLOOD TRANSFUSION and ANTIBIOTIC MEDICATIONS during chemotherapy.

vincristine	

Across all types of leukemia, about 65 percent of people achieve initial remission with treatment. The rate of sustained remission (five years or longer) is much higher with acute than with chronic forms of leukemia, and in younger (under age 14 years) than older (over age 60) people. For children under age 14 who undergo treatment for ALL, about 80 percent achieve long-term remission such that doctors consider them cured of the leukemia. About 30 percent of adults who have ALL achieve similar long-term remission. Because successful treatment regimens are relatively new, however, doctors do not know what potential health complications, if any, may arise decades after treatment. Long-term survival rates are higher for lymphocytic leukemias than for myeloid leukemias.

Risk Factors and Preventive Measures

The causes of leukemia remain mostly unknown. Doctors do know that about 60 percent of people who have myelodysplasia syndrome eventually develop AML. As well, people who have first-degree relatives (parent, sibling, or child) who acquire ALL are about four times more likely to develop ALL themselves. Researchers have identified a number of potential risk factors associated with leukemia, though the extent and nature of the associations remains unclear. Among them are

- exposure to high-DOSE radiation, including radiation therapy
- previous chemotherapy for other kinds of cancer
- exposure to the industrial chemicals benzene and formaldehyde and their derivative compounds
- cigarette smoking
- infection with human T-cell leukemia virus 1 (HTLV-1)
- DOWN SYNDROME and CHROMOSOMAL DISORDERS that run in families

Most people who develop leukemia do not have any history of exposure to suspected risk factors, however, making prevention recommendations difficult. There are no known methods for preventing leukemia.

leukocyte A white BLOOD cell, also referred to as a WBC. Leukocytes are the foundation of the body's IMMUNE RESPONSE and are phagocytic—that is, they have the ability to consume other cells. They circulate in the blood and the LYMPH as well as reside in tissues throughout the body. There are three basic types of leukocytes: granulocytes, monocytes, and lymphocytes. Each type has several subtypes. The SPLEEN and lymph tissues produce monocytes and lymphocytes; the red BONE MARROW produces granulocytes.

HEALTH CONDITIONS THAT AFFECT LEUKOCYTE COUNTS

ALLERGY response	ASTHMA
AUTOIMMUNE DISORDERS	CHEMOTHERAPY
environmental toxin exposure	HYPERSENSITIVITY REACTION
INFECTION	INFLAMMATION
LEUKEMIA	LEUKOPENIA
LYMPHOCYTOPENIA	LYMPHOMA
many cancers	medication side effects
MONONUCLEOSIS, INFECTIOUS	RADIATION THERAPY
surgery	vitamin B_{12} deficiency

A healthy adult has between 5,000 and 10,000 leukocytes per microliter of blood, with granulocytes accounting for about 70 percent. Increases in certain subtypes of leukocytes suggest particular health conditions. A substantial increase overall in LEUKOCYTE count may indicate a cancer of the bone marrow such as LEUKEMIA or LYMPHOMA. The ratio between erythrocytes (red blood cells) and leukocytes in the blood is also an important diagnostic indicator.

For further discussion of leukocytes within the context of blood and lymph structure and function please see the overview section "The Blood and Lymph."

leukopenia A decline in the number of leukocytes (white BLOOD cells) circulating in the blood to fewer than 4,000 leukocytes per microliter of whole blood. The most common manifestation of leukopenia is NEUTROPENIA, a shortage of granulocytes called neutrophils. Most leukopenia is secondary to other health conditions a person may have, such as viral infections or cancers that involve the BONE MARROW, and circumstances, such as CHEMOTHERAPY. Numerous medications can cause leukopenia as an undesired SIDE EFFECT of treatment. In such situations the doctor will evaluate the relative value of the inherent risks in continuing or discontinuing the causative medication. Leukopenia lowers the body's ability to resist and fight INFECTION and when severe can allow life-threatening infections to invade. Frequent or unusual infections, especially persistent GINGIVITIS or periodontitis, may suggest leukopenia. Treatment targets any infection or other underlying cause.

lymph The fluid that circulates through the LYMPH VESSELS. Lymph is clear and colorless or white with fat, depending on its location. It contains about 90 percent water and carries proteins, globulins, GLUCOSE, electrolytes, and other chemicals dissolved within it. Leukocytes, primarily lymphocytes and monocytes, circulate in the lymph, suspended in the fluid. Lymph originates from and returns to the BLOOD. Fluid from the blood (PLASMA) seeps from the capillaries into the spaces between the cells. This interstitial fluid carries the NUTRIENTS from the blood, surrounding the cells in a bath from which they withdraw the nutrients they need. Leukocytes in the blood move freely between the lymph and the blood. Lymph capillaries draw the interstitial fluid back into the lymph vessels, which carry the lymph they collect through a network of lymph vessels. Ultimately the lymph vessels return the lymph to the blood via its portals into the right and left subclavian veins.

Compared to the blood the HEART pumps through the circulation, the lymph moves leisurely through its network of vessels, achieving a top rate of about 100 milliliters an hour in the major trunk vessels (the lymphatic ducts). It flows primarily as a function of gravity, with some help from the massaging actions of contracting skeletal muscles during movement. Because most of the body's INFECTION-fighting action takes place in the lymph nodes and other lymph tissues, the lymph is the primary pathway for transporting pathogens for destruction by macrophages and other leukocytes in the lymph nodes. The lymph also is the primary channel for the body to carry the residue of infection to other structures and systems that eliminate it from the body (through phagocytosis as well as other means). CANCER cells can overload the lymph, hijacking it to become the pathway for their spread (METASTASIS) to other organs and parts of the body.

For further discussion of the lymph within the context of blood and lymph structure and function please see the overview section "The Blood and Lymph."

lymphadenitis INFLAMMATION or INFECTION of LYMPH nodes. Lymphadenitis characterizes systemic infections such as infectious mononucleosis and regional infections such as SEXUALLY TRANSMITTED DISEASES (STDS). It may affect any lymph nodes in the body though is most noticeable when it affects LYMPH NODE clusters near the surface of the SKIN, such as in the neck, axillae (underarms), and groin (inguinal). The typical symptoms of lymphadenitis are palpable lymph nodes that may range in size from that of a small pea to that of a large marble. The swellings are often painful, and the skin above the area may be reddened (erythematous) and warm to the touch when infection of the lymph nodes themselves is the cause. Diagnosis may require lymph node biopsy when there are no clear signs of infection or when lymphadenitis continues beyond six weeks.

Lymphadenitis without signs of infection may indicate cancer, either affecting the lymph structures (LYMPHOMA) or in METASTASIS from any location in the body. Pathogens or cancer cells traveling through the lymph can initiate such a massive activation of phagocytic response that the resulting action of macrophages and lymphocytes overwhelms the lymph nodes with cellular debris faster than the lymph can carry it away.

See also LYMPH VESSELS; MONONUCLEAR PHAGOCYTE SYSTEM; MONONUCLEOSIS, INFECTIOUS; PHAGOCYTOSIS.

lymphadenopathy Swelling and enlargement of the LYMPH nodes. Lymphadenopathy indicates that the affected lymph nodes are fighting an INFECTION in nearby tissues, and the enlargement is most often benign and normal. A common manifestation of lymphadenopathy is swollen lymph nodes in the neck when a person has a sore THROAT, or under the arm when there is a cut or bruise on the hand or arm. The swollen lymph nodes typically feel firm to the touch and may hurt. As the underlying infection improves, the swelling retreats, and the lymph nodes return to normal size. When lymph nodes throughout the body are swollen, the underlying cause is likely a systemic infection such as a VIRUS. Occasionally persistent lymphadenopathy suggests LYMPHOMA or LEUKEMIA, cancers of the lymph tissues or BONE MARROW.

See also LYMPHADENITIS; LYMPH NODE.

lymphangioma A noncancerous LESION made up of LYMPH VESSELS. Pathologically, doctors classify a

lymphangioma as hamartomatous, (harmartomas are benign tumors) which refers to the lesion's pattern of self-limiting growth. Lymphangiomas are congenital or arise soon after birth, most commonly manifesting as SKIN lesions on the head, back, arms, and legs, though the lesions may involve any external or internal epithelial tissue (skin and mucous membranes). Lymphangiomas grow slowly, then stop growing and remain the same size. Though not cancerous, a lymphangioma may cause problems or symptoms because of its location and size. A lymphangioma in the SMALL INTESTINE, for example, may interfere with the absorption of NUTRIENTS or create an ILEUS (obstruction).

Lymphangiomas that do not cause symptoms do not require treatment as they are self-limiting. A surgeon can operate to remove a lymphangioma that causes symptoms or is cosmetically unsatisfactory. However, the structure of a lymphangioma has no capsule and tends to diffusely infiltrate tissue, making it difficult for the surgeon to remove it completely. If the lymphangioma has not finished growing, it will recur. Most lymphangiomas are benign in that they do not cause symptoms or health problems.

lymphedema Swelling and often discomfort arising from inadequate LYMPH drainage and flow that allows interstitial fluid (fluid between the cells) to accumulate. Lymphedema most often occurs when INFECTION or CANCER that extensively engages the lymphatic system, or when surgery disrupts the LYMPH VESSELS and lymph nodes. Lymphedema is a common consequence of surgery and RADIATION THERAPY as treatments for cancer. Surgeons typically remove adjacent or sentinel lymph nodes, which are most likely to be affected by the cancer, during surgery to remove cancerous tumors to determine the extent to which the cancer has penetrated the tissues or metastasized (spread) to other tissues. Lymphedema can be debilitating when the swelling becomes substantial. Recurrent, progressive lymphedema often develops into fibrosclerosis (scarring and hardening) of the involved tissues.

It is important to distinguish lymphedema from other causes of swelling, such as edema (simple fluid retention) and ASCITES, because though the appearance of the affected area may be similar the treatment approaches differ. In chronic lymphedema the SKIN over the swollen area acquires a characteristic "orange peel" texture, which indicates damage to the underlying tissue. Tissue in the damaged area becomes susceptible to infection and ulceration, as the lymphedema compromises its BLOOD circulation and immune response. While conventional edema improves with diuretic medications, lymphedema does not.

For lymphedema, treatment focuses on improving the flow of fluid into and through the lymph vessels. Compression sleeves and stockings provide gentle, consistent pressure against the affected arm or leg, helping prevent interstitial fluid from accumulating. Some people with severe lymphedema benefit from compression pump therapy, in which a pump gently inflates and deflates pressure cuffs wrapped around the arms or legs, to help squeeze interstitial fluid into the lymph capillaries. Surgery to remove damaged portions of tissue and lymphatic structures is a treatment of end resort that may improve very severe lymphedema when other methods have failed, though itself can cause further or more extensive damage.

Lymphedema is a lifelong concern for most people who develop it, regardless of its cause though particularly after extensive surgery that disrupts the lymphatic structures or in which the surgeon removes lymph nodes. Many people can manage their symptoms and discomfort through preventive measures such as frequent movement or self-massage of involved areas and prompt therapeutic response when swelling begins.

lymph node A small structure of lymphatic tissue. LYMPH nodes, sometimes erroneously called lymph glands, occur individually as well as in beadlike strings within the tissues. The lymph nodes range in size from that of a grain of rice to that of a kidney bean, and appear roughly kidney shaped.

Each lymph node contains high numbers of lymphocytes and macrophages (tissue-resident monocytes), which filter pathogens and cellular

debris from the lymph. Follicles within the lymph node contain B-cells and T-cells, which proliferate and mature in the follicles. The B-cells produce antibodies specific to the antigens the lymph carries into the lymph node. The lymph node adds these antibodies to the lymph as the lymph exits the node. The lymph node's follicles release additional T-cells as necessary to fight INFECTION, responding to chemicals PHAGOCYTOSIS releases. Extensive networks of lymphatic capillaries carry lymph among the lymph nodes as well as to and from the larger LYMPH VESSELS.

Lymph nodes commonly swell when they are actively responding to infection because they fill with the pathogenic cells they filter from the lymph, a circumstance doctors call LYMPHADENOPATHY. LYMPHADENITIS occurs when the infection involves the lymph node itself. The lymph nodes also can become seeding sites for cancer cells that are metastasizing (spreading) to other parts of the body. Most operations to remove cancerous tumors also include removal of adjacent lymph nodes to examine them for the presence of cancer cells, which is key to the STAGING AND GRADING OF CANCER.

lymphocyte A type of LEUKOCYTE (white BLOOD cell) that primarily resides in the LYMPH and lymph tissues. Lymphocytes are the body's primary immune defense and move through the lymph in response to antigens and pathogens. When more rapid deployment is necessary, lymphocytes enter the bloodstream. About 1 percent of the body's lymphocyte population circulates in the blood, making up about 25 percent of the circulating leukocytes. There are two major types of lymphocytes—T-cells and B-cells—and natural killer cells. Each type has different immune responsibilities.

T-Cells

T-cells, which make up about 75 percent of lymphocytes, originate in the BONE MARROW and migrate to the THYMUS to come to maturity. In the thymus T-cells acquire the ability to distinguish between "self" and "nonself," an essential function of determining whether the particles the T-cells encounter are invaders. Mature T-cells carry kinds of antibodies, identified as CLUSTERS OF DIFFERENTIATION, that denote the T-cell's immune function. There are numerous subtypes of T-cells, the most common being

- helper T-cells, which secrete a cytokine called CD4 (for cluster of differentiation 4) that directs the response of other T-cells
- cytotoxic T-cells, which attack invading cells by releasing chemicals that penetrate their cell membranes, which causes them to rupture and die
- suppressor T-cells, which reign in the IMMUNE RESPONSE after the immune attack has squelched the threat
- memory T-cells, which retain the ability to produce antibodies against the same ANTIGEN should it reappear in the body

B-Cells

B-cells, which make up about 10 percent of lymphocytes, originate in the bone marrow and migrate to the lymph tissues to come to maturity and await activation via contact with an antigen. When such contact occurs, the individual B-cell develops antibodies specific to the antigen, differentiates into either a memory B-cell or a PLASMA cell and then proliferates within the lymph tissues, lymph, and bloodstream. Memory cells "remember" the specific antigen and produce antibodies whenever the antigen again enters the body. This process provides long-term protection against pathogens. Plasma cells generate copious antibodies as they replicate, providing an immediate immune response to the PATHOGEN.

Natural Killer Cells

Natural killer (NK) cells are specialized lymphocytes that attack and destroy self cells that have become defective in some way. Researchers believe one function of NK cells is to attack tumors as they are beginning to develop, preventing them from taking root. NK cells also appear to attack cells that viruses hijack, preventing the VIRUS from replicating and causing infection.

For further discussion of lymphocytes within the context of blood and lymph structure and function please see the overview section "The Blood and Lymph."

lymphocytopenia A decline in the number of lymphocytes in the BLOOD to fewer than 1,000 lymphocytes per microliter of whole blood. Lymphocytes circulate in the blood and the LYMPH, their primary role being to identify and attack invading pathogens to prevent and fight INFECTION. Lymphocytopenia often accompanies IMMUNODEFICIENCY disorders, notably HIV/AIDS (in which it may be one of the earliest indications of infection), infections such as TUBERCULOSIS and HEPATIS, and AUTOIMMUNE DISORDERS such as SYSTEMIC LUPUS ERYTHEMATOSUS (SLE) and MYASTHENIA GRAVIS. Other causes include RADIATION THERAPY as cancer treatment, long-term PUVA (psoralen plus ultraviolet light of A wavelength) PHOTOTHERAPY for treatment of PSORIASIS, severe stress, and medications such as CORTICOSTEROID MEDICATIONS. Lymphocytopenia may be transitory, with the LYMPHOCYTE level returning to normal when the underlying cause improves. Depending on the cause, people who have lymphocytopenia may show few symptoms. Treatment targets the underlying condition. The health consequences of lymphocytopenia vary with the overall status of the IMMUNE SYSTEM.

lymphoma A type of CANCER that affects the hematopoietic functions of the LYMPH system that results in the uncontrolled proliferation of lymphocytes, the type of LEUKOCYTE (white BLOOD cell) that the lymph tissues primarily produce. The lymphocytes congregate in the lymph tissues to form tumors.

LYMPHOMA VS. LEUKEMIA

LEUKEMIA and LYMPHOMA are both cancers that can affect the lymphocytes. However, leukemia is a CANCER of the BONE MARROW that alters the development and proliferation of lymphocytes that enter the BLOOD circulation. Lymphoma is a cancer of the lymphatic tissues that produce lymphocytes.

Though there are nearly three dozen identified types of lymphoma doctors assign them to one of two major categories, Hodgkin's lymphoma and non-Hodgkin's lymphoma. Doctors diagnose about 60,000 people with lymphoma in the United States each year. Lymphoma is the fifth most common kind of cancer among American adults and the third most common kind of cancer among children.

How Lymphoma Develops

Lymphomas originate in the reticuloendothelial or clone cells in the lymph structures that produce lymphocytes, notably the lymph nodes and the SPLEEN. Most lymphomas affect B-cell lymphocytes (B-cells) though some affect T-cell lymphocytes (T-cells). Hodgkin's lymphoma involves a specific kind of B-cell called a Reed-Sternberg cell. In all lymphomas, the affected lymphocytes proliferate and migrate to lymph tissues, such as lymph nodes and the spleen. The lymphocytes cluster into tumorous formations that drain the NUTRIENTS and other resources healthy cells require, causing the healthy cells to die and allowing the cancerous lymphocytes to continue proliferating.

A key marker for the extent and severity of lymphoma is whether tumors are present on only one side or on both sides of the DIAPHRAGM. Lymphomas present only on one side of the diaphragm (either above or below) tend to be less aggressive than those that are present in LYMPH NODE regions on both sides of the diaphragm, as well as more responsive to treatment (particularly those above the diaphragm). Cancerous lymphocytes can also metastasize to other kinds of tissues throughout the body, primarily traveling through the lymphatic system. The most common sites for lymphoma METASTASIS outside the lymphatic system are the BRAIN, SKIN, BONE, and BONE MARROW. However, because the lymphatic network extends throughout the interstitial tissues, metastases in advanced disease can appear anywhere.

Hodgkin's Lymphoma

Hodgkin's lymphoma, also called Hodgkin's disease, accounts for about 15 percent of diagnosed lymphomas. It most commonly affects people between ages 16 to 34 and over age 55. The presence of specifically abnormal B-cells, Reed-Sternberg cells, is the hallmark of Hodgkin's lymphoma.

There are five identified subtypes of Hodgkin's lymphoma:

- lymphocyte-predominant (also called nodular lymphocyte predominance)
- nodular sclerosis
- lymphocyte-rich (also called classical)
- mixed cellularity
- lymphocyte-depleted

Treatment regimens and prognoses differ for each subtype. Nodular sclerosis Hodgkin's lymphoma is the most common subtype, accounting for about two thirds of diagnoses, and tends to be moderately progressive. Lymphocyte-predominant Hodgkin's lymphoma tends to progress slowly; lymphocyte-depleted Hodgkin's lymphoma tends to be quite aggressive with rapid progression and frequent metastasis to organs outside the lymphatic system. In general, the higher the number of Reed-Sternberg cells, the more aggressive the cancer.

Non-Hodgkin's Lymphoma

The non-Hodgkin's lymphomas account for about 85 percent of diagnosed lymphoma and most commonly affect people over age 60, though can develop at any age. There are several dozen subtypes of non-Hodgkin's lymphoma, currently classified according to the type of tumor (also called a neoplasm) and its characteristics. Doctors further classify non-Hodgkin's lymphomas as to whether they are aggressive (rapidly growing)—high or intermediate grade—or indolent (slow growing)—low grade.

NON-HODGKIN'S LYMPHOMA SUBTYPES

AIDS-related	anaplastic large cell
angioimmunoblastic	blastic natural killer (NK)
BONE	Burkitt's
CENTRAL NERVOUS SYSTEM (CNS)	cutaneous T-cell
diffuse large cell	diffuse small noncleaved cell
eyelid	follicular
immunoblastic	lymphoblastic
lymphoplasmacytic	mantle cell
marginal zone	MUCOSA-ASSOCIATED LYMPHOID
mycosis fungoides	TISSUE (MALT)
nodal marginal zone	nasal NK/T
small lymphocytic	ocular (EYE)
splenic marginal zone	

Symptoms and Diagnostic Path

Many people do not have symptoms of lymphoma at the time of diagnosis. Rather, the doctor detects characteristic abnormalities in diagnostic blood tests conducted for other reasons, often as part of a ROUTINE MEDICAL EXAMINATION. When symptoms are present they can be vague and generalized, typical of common viral infections though they tend to persist or recur rather than resolving. Such symptoms may include

- painless swellings in the lymph nodes, most noticeable in the axillae (underarms), neck, or groin (LYMPHADENOPATHY)
- unexplained, frequent fevers
- unintended or unexplained weight loss
- profuse sweating at night
- tiredness, fatigue, or lethargy
- unexplained, generalized itching (PRURITUS)

The diagnostic path begins with the doctor's physical examination, which may reveal SPLENOMEGALY (enlarged spleen) or detect enlarged lymph nodes beneath the collarbone or in the abdomen. Diagnostic blood tests and bone marrow biopsy demonstrate the proliferation of lymphocytes. Other diagnostic procedures the oncologist may conduct include tissue biopsy of swellings, COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) to detect the presence of tumors deep within the body, POSITRON EMISSION TOMOGRAPHY (PET) SCAN to examine the lymphatic network, and specialized immunocytology tests to determine the subtype of lymphoma. Based on the diagnostic findings the oncologist assesses the status of the lymphoma, assigning it a stage classification. Oncologists further designate a grade for non-Hodgkin's lymphoma that characterizes the level of aggressiveness. These assessments determine the appropriate treatment regimens and help valuate the prognosis (likelihood of REMISSION and survival).

Treatment Options and Outlook

Treatment regimens depend on the subtype, stage, and for non-Hodgkin's lymphomas the grade of the cancer as well as the person's age and overall health status. The typical treatment approaches, often administered in combinations, include

LYMPHOMA STAGING (HODGKIN'S AND NON-HODGKIN'S)

Stage	Characteristics
stage 1	early disease involves only a single LYMPH NODE region
stage 2	locally advanced disease involves two or more lymph node regions on one side of the DIAPHRAGM
stage 3	advanced disease involves two or more lymph node regions on both sides of the diaphragm
stage 4	widely disseminated disease involves multiple lymph node regions and METASTASIS to other organs such as the BONE or BRAIN
A	no symptoms at time of diagnosis (asymptomatic)
B	symptoms present at time of diagnosis
E	lymphoma is present in an organ outside the lymphatic system with no lymph node involvement

- RADIATION THERAPY, either above the diaphragm only (mantle field radiation) or from the neck to the pelvis (total nodal irradiation)
- CHEMOTHERAPY
- IMMUNOTHERAPY, also called biological response modifier therapy, including monoclonal antibody (MAb) therapy
- BONE MARROW TRANSPLANTATION and peripheral blood stem cell transplantation (PBSCT)
- watchful waiting for indolent (slow-growing and asymptomatic) lymphomas

Treatment results in at least one remission for most kinds of lymphoma. Many people experience extended remissions with few recurrences, and some people experience such long-term remissions as to have the oncologist consider the lymphoma cured. Other lymphomas are more resistant to treatment. Some chemotherapy drugs are effective as single agents, though more commonly oncologists prescribe chemotherapy drugs in combinations that target specific types of lymphoma. Many treatment regimens are cycles that repeat over several months to a year. Numerous complications resulting from treatment may occur, and vary with the treatment regimen, type and stage of lymphoma, and person's age and general health status.

CHEMOTHERAPY DRUGS USED TO TREAT LYMPHOMA

5-fluorouracil	bleomycin
carmustine	chlorambucil
cisplatin	cyclophosphamide
cytarabine	dexamethasone
doxorubicin	etoposide
fludarabine	fluoxymesterone
hydroxydaunomycin	ifosfamide
melphalan	methotrexate
mitoxantrone	pentostatin
prednisone	prednisone
procarbazine	rituximab
tositumomab	vincristine

Risk Factors and Preventive Measures

Researchers do not know what causes lymphoma, though a number of environmental factors appear to increase the risk for developing these forms of cancer. The most significant risk is for people who receive IMMUNOSUPPRESSIVE THERAPY after ORGAN TRANSPLANTATION, who are 100 times more likely to develop non-Hodgkin's lymphoma. Other suspected risk factors include

- HIV/AIDS
- INFECTION with human T-lymphocytic virus 1 (HTLV-1), EPSTEIN-BARR VIRUS, or human herpesvirus 8 (HHV-8)
- infection with *HELICOBACTER PYLORI*, the BACTERIA believed responsible for STOMACH CANCER
- occupational exposure to benzene
- occupational exposure to agricultural pesticides and herbicides, notably organophosphates and chlorophenols
- first-degree relatives (parents, siblings, children) who have lymphoma
- chromosomal TRANSLOCATION and other abnormalities

However, researchers do not know the extent to which these factors influence the development of lymphoma. Many people who develop lymphoma have no history of exposure to these factors, and far more people than not who have exposure do not develop lymphoma. Reducing or eliminating exposure to environmental toxins, treating infections such as *H. pylori,* and maintaining nutritious EATING HABITS can improve health overall. Otherwise, there are no known measures to prevent lymphoma.

lymph vessels An extensive network of channels that collect and circulate LYMPH, a watery fluid containing immune cells and substances as well as pathogens cleansed from the BLOOD and tissues. The lymph vessels, also called lymphatics, are similar in structure to the capillaries and veins of the cardiovascular system but have thinner walls. The lymph vessels carry lymph from the tissues through the lymph nodes, where lymphocytes neutralize or kill and macrophages consume pathogens, then deliver the cleansed fluid to the blood.

The smallest of the lymph vessels are the lymphatic capillaries, which arise from cul-de-sac structures within the interstitial fluid (fluid between the cells) in the tissues surrounding the CAPILLARY BEDS of the cardiovascular system. The shingled, single-cell walls of the lymphatic capillaries are permeable, allowing fluid to seep inside though preventing it from seeping back out. The lymphatic capillaries merge into the afferent lymphatics, somewhat larger lymph vessels that carry the lymph among the lymph nodes. The lymphatic capillaries in the SMALL INTESTINE, called lacteals, are uniquely able to absorb the fatty products of digestion, which they ultimately deliver to the blood.

The larger lymph vessels are not permeable and contain valves to keep lymph moving in only one direction, toward the central body. Their pathways roughly parallel those of the cardiovascular circulatory structures. In the central trunk region the lymph vessels merge into three reservoir-like structures. These structures are the

- CISTERNA CHYLI, which collects lymph from the lacteals and the abdominal lymph vessels
- THORACIC DUCT, which collects lymph from the cisterna chyli and the upper left body
- RIGHT LYMPHATIC DUCT, which collects lymph from the upper right body and head

The thoracic duct parallels the AORTA and drains into the left subclavian vein. The right lymphatic duct drains into the right subclavian vein. The lymph then becomes part of the blood.

methemoglobinemia A BLOOD oxygenation disorder in which methemoglobin, a structure of HEMOGLOBIN molecules that prevents iron from binding with oxygen, accumulates in the BLOOD. The result is diminished or insufficient oxygen delivery to the body's cells. Methemoglobin represents excessive iron molecule structures that are in a ferric state, in which they are unable to bind with oxygen. Normal iron molecules in the hemoglobin are ferrous. Methemoglobin forms naturally in the blood as a process of oxidation (cellular METABOLISM), though an enzyme system that converts ferric iron to ferrous iron continuously restores methemoglobin to hemoglobin. Methemoglobin is normally present in the blood in minute quantities, accounting for less than 1 percent of the total hemoglobin forms. Levels above 10 percent begin to cause symptoms, and levels above 70 percent are fatal.

A potential cause of methemoglobinemia is the illicit use of "nitrite poppers," inhaled isobutyl nitrite, butyl nitrite, and amyl nitrate products that are popular among some recreational DRUG users.

Methemoglobinemia most commonly results from toxic exposure to oxidizing chemicals or drugs. Dozens of industrial chemicals can cause methemoglobinemia, as can numerous medications in the nitrate, chlorate, and sulfonamide families of drugs, as well as topical anesthetics such as benzocaine and lidocaine. Exposure is usually chronic. Other causes of methemoglobinemia include hemoglobin disorders that allow excessive methemoglobin formulation and abnormalities in the blood enzyme system that normally removes methemoglobin from the blood.

Symptoms and Diagnostic Path

Symptoms of methemoglobinemia may mimic those of ANEMIA, such as fatigue and shortness of breath (DYSPNEA) especially with exertion or exercise, though important differences are present to help distinguish methemoglobinemia from other hemoglobin disorders. The most significant is a characteristic CYANOSIS that gives the SKIN a bluish brown color and does not improve with the administration of OXYGEN THERAPY. Blood tests that analyze hemoglobin composition determine the amount of methemoglobinemia in the blood; levels higher than 1 or 2 percent confirm the diagnosis though most people who show symptoms have much higher levels.

Treatment Options and Outlook

Most often, removing exposure to the causative substance allows the blood to recover on its own, usually within 72 hours. The doctor may choose to hospitalize the person until hemoglobin levels return to normal, to make sure the person receives adequate oxygenation. When symptoms are severe or persist, treatment may include methylene blue, a chemical that converts the hemoglobin's iron from ferric to ferrous. The typical therapeutic approach is to administer an intravenous injection of methylene blue to rapidly convert enough methemoglobin to hemoglobin to relieve symptoms, then switch to oral methylene blue until hemoglobin returns to normal. Rarely, a person who is having severe symptoms may require hyperbaric treatment, in which oxygen under pressure can enter the body through the skin to deliver oxygen to the tissues. Hyperbaric

therapy may also be appropriate for people who cannot take methylene blue.

Recovery is generally complete when the cause is toxic exposure. Genetic disorders of the hemoglobin or the enzyme mechanisms that regulate the balance between methemoglobin and hemoglobin may result in chronic methemoglobinemia and consequently the need for ongoing treatment (such as oral methylene blue) to prevent toxic accumulations.

Risk Factors and Preventive Measures

The most common cause of methemoglobinemia is toxic exposure to substances that cause oxidation, which overwhelms the body's normal mechanisms for managing cell metabolism. Avoiding chemicals, including drugs, that may cause methemoglobinemia is not simple, as they number in the dozens and include such commonly used medications as nitrates (cardiovascular) and topical anesthetics. People who have genetic disorders that interfere with hemoglobin production and function have increased risk for methemoglobinemia and should make every effort to avoid known causative agents.

monocyte A LEUKOCYTE (white BLOOD cell), also called an agranulocyte, that has a single-lobed nucleus and contains no granules in its cytoplasm. The BONE MARROW and the LYMPH nodes produce monocytes, which have a two-phase existence in the body. During the first phase, the monocyte circulates in the blood and the lymph, functioning as a PHAGOCYTE that consumes pathogenic particles in the circulation. After about 24 hours the monocyte migrates into the tissue to enter its second phase of life. Once in the tissue the monocyte matures, becoming a fixed phagocytic cell called a macrophage that may acquire a specific name, depending on its location. About half of the body's macrophages migrate to the lymphatic structures. Most of the remainder reside in the LIVER, where they are called Kupffer cells. Macrophages that settle in the layers of the SKIN are Langerhans cells, and those that inhabit the BONE are osteoclasts.

Two to 8 percent of the body's leukocytes are monocytes; a normal monocyte count is 200 to 1100 monocytes per microliter of whole blood. The number of monocytes in circulation may increase with INFECTION, LEUKEMIA, LYMPHOMA, many other types of cancer, and AUTOIMMUNE DISORDERS in which there is active INFLAMMATION and autoimmune activity. The number of monocytes in circulation may decrease in aplastic ANEMIA and with steroid medications.

For further discussion of monocytes within the context of blood and lymph structure and function please see the overview section "The Blood and Lymph."

multiple myeloma A CANCER of the BONE MARROW in which PLASMA cells, also called myeloma cells or myelocytes, proliferate, accumulating as lesions (growths) to develop within the BONE marrow cavities of the bones. The lesions prevent normal functioning of the bone marrow. They also damage bone tissue and weaken the bone structure. Plasma cells derive from lymphocytes that migrate to the bone marrow. Their function is to produce immune antibodies, or immunoglobulins, that are essential for the body's IMMUNE RESPONSE. They generally make up less than 5 percent of the cells in the bone marrow. In multiple myeloma plasma cells make up 10 percent or more of the bone marrow's cells. The cancerous plasma cells of multiple myeloma overproduce certain immune antibodies called monoclonal proteins or M-proteins. M-proteins alter the ways in which immunoglobulins bind with B-cell lymphocytes in the blood, reducing their ability to fight INFECTION.

The M-proteins also activate specialized phagocytic cells in the bone, called osteoclasts, accelerating the deconstruction phase of bone remodeling (the process through which bone tissue continuously replenishes). Osteoclastic activity releases excessive calcium into the bloodstream, affecting numerous body systems, including cardiovascular function and renal (kidney) function. The KIDNEYS produce ERYTHROPOIETIN (EPO), the HORMONE that stimulates the bone marrow to produce erythrocytes (red blood cells). Damage to the kidneys

such as occurs with multiple myeloma reduces EPO production, resulting in moderate to significant ANEMIA. M-proteins can bind with erythrocytes in the blood, further reducing their ability to transport oxygen. M-proteins can also bind with other substances in the blood including hormones and cells such as platelets. M-protein binding with platelets results in COAGULATION (clotting) abnormalities including excessive bleeding or thrombosis (clot formation within the blood vessels).

In the late 1990s researchers achieved a significant breakthrough in identifying the possible causes of multiple myeloma with the discovery of a connection between multiple myeloma and certain infections, notably herpesvirus type 8 (which causes another cancer, KAPOSI'S SARCOMA) and HEPATITIS C. As well, doctors have long noted connections between multiple myeloma and occupational exposure to pesticides (notably DDT) and petroleum products, and to radiation exposure such as RADIATION THERAPY. Multiple myeloma is more common in people over age 55 and accounts for 1 percent of all cancers doctors diagnose in the United States each year. It is more common in men than women and affects twice as many African Americans, though researchers are unsure of the reasons.

Symptoms and Diagnostic Path

About half of people diagnosed with multiple myeloma have no symptoms at the time of diagnosis, when blood tests performed for other reasons reveal the abnormalities consistent with multiple myeloma. Blood tests early in the course of the cancer may produce inconsistent and nonspecific findings that become relevant with subsequent diagnostic procedures. When symptoms are present they may include

- fatigue, especially with exertion
- frequent nosebleeds (EPISTAXIS) or easy bruising
- GASTROINTESTINAL BLEEDING
- PAIN, often in the back or that feels as though it originates in the bones
- excessive thirst
- HEADACHE
- a haze over the field of vision

Diagnostic blood tests typically show elevated blood calcium levels, altered blood cell counts, increased blood proteins, increased blood volume, the presence of M-proteins, and the presence of myelocytes (PLASMA cells) in the blood circulation. NEUTROPENIA and anemia are often present. Diagnostic imaging such as X-rays, COMPUTED TOMOGRAPHY (CT) SCAN, POSITRON EMISSION TOMOGRAPHY (PET) SCAN, and MAGNETIC RESONANCE IMAGING (MRI) allow the oncologist to assess the extent of bone involvement and damage. Bone marrow biopsy reveals high plasma cell counts and abnormal bone marrow structure.

Treatment Options and Outlook

CHEMOTHERAPY is the treatment of choice for multiple myeloma. The first chemotherapy agent developed to treat multiple myeloma in 1958, melphalan, remains the first line DRUG of choice today, commonly given in combination with prednisone, a corticosteroid medication. Oncologists use other chemotherapy agents, usually in combinations with each other and with CORTICOSTEROID MEDICATIONS, to tailor treatment regimens to an individual's age and the cancer's presentation, other health considerations, and preferences. Initial treatment typically produces REMISSION, though RECURRENCE within two years is common. Some people benefit from radiation therapy that targets myeloma lesions within the bones. New treatments continue to emerge as researchers gain understanding of the mechanisms of multiple myeloma.

DRUGS USED TO TREAT MULTIPLE MYELOMA

bortezomib	busulfan
carmusine	cisplatin
cyclophosphamide	dexamethasone
doxorubicin	etoposide
melphalan	prednisone
thalidomide	vincristine

Thalidomide and thalidomide analogs Thalidomide, which debuted in the 1950s as a treatment for MORNING SICKNESS and insomnia in PREGNANCY and quickly gained notoriety for causing BIRTH DEFECTS, emerged in the late 1990s as a successful treatment in some people for multiple myeloma that resists other therapies. Thalidomide sup-

presses the maturation of lymphocytes to plasma cells. Thalidomide analogs (such as Revimid and Actimid) are drugs closely related in chemical structure to thalidomide. Oncologists may administer thalidomide in combination with prednisone or dexamethasone, corticosteroid medications that help suppress bone marrow activity to slow the production of cancerous plasma cells.

Proteasome inhibitors In 2003 the US Food and Drug Administration (FDA) approved the proteasome inhibitor bortezomib (Velcade) for people who have experienced two relapses following conventional treatment approaches. Proteasome inhibitors block the actions of enzymes within cells that are crucial to the cell's ability to divide (reproduce). Clinical studies continue to investigate the effectiveness of these drugs, which appear to cause fewer side effects than conventional chemotherapy, as first-choice treatment.

Bone marrow and stem cell transplantation Autologous BONE MARROW TRANSPLANTATION or STEM CELL transplantation (self-transplantation with harvested cells), achieves remission in many people. For autologous transplantation, the oncologist harvests peripheral BLOOD STEM CELLS (PBSC) or stem cells from healthy areas of bone marrow; administers high-DOSE chemotherapy after cell harvesting to kill the cancerous bone marrow; and administers the harvested bone marrow or stem cells, which then grow to replace the cancerous bone marrow. Allogeneic stem cell transplantation, which uses stem cells from a tissue-matched donor, carries relatively high risks of complications including transplant rejection, infection, and other reactions, but is so far the only hope for a cure of multiple myeloma. Nonmyeloablative (the patient's bone marrow is not destroyed) allogeneic stem cell transplantation reduces the high risks of high-dose chemotherapy. Though not curative it may offer increased survival time.

Adjunctive therapies Oncologists use various medications to mediate the side effects of treatment as well as the complications that arise as the course of the cancer progresses. Among them are:

- Statins (such as Lipitor and Mevacor) counters the osteoclastic (bone destruction) stimulation M-proteins generate. Researchers discovered in the early 2000s that the statin medications used to treat HYPERLIPIDEMIA (elevated blood cholesterol and blood lipid levels) additionally stimulate osteoblastic (bone construction) activity, resulting in increased production of new bone tissue.
- Therapeutic EPO supplementation (Procrit) stimulates bone marrow production of erythrocytes, relieving anemia.
- Bisphosphonates bind to damaged bone cells and so prevent further osteoclastic action (destruction). This allows the body's natural bone remodeling mechanisms to repair the damage and rebuild the bone. However, bisphosphonates present the potential for serious kidney damage.
- ANTIBIOTIC MEDICATIONS aggressively treat the infections that become increasingly common as dysfunction of the IMMUNE SYSTEM progresses.

Lifestyle factors Because multiple myeloma affects bone remodeling, daily weight-bearing exercise such as walking is important to stimulate the body's normal osteoblastic (bone-constructing) mechanisms. These mechanisms further help bone tissue retain calcium, reducing the amounts of calcium that leaches into the circulation. Drinking lots of water to maintain high HYDRATION is also especially important. Staying well hydrated helps offset the tendency of the blood to become hyperviscous (thickened) as a consequence of the changes in its constitution that take place with the multiple myeloma. It also helps protect the kidneys by lowering the concentration of calcium and M-proteins that they must filter from the blood and pass in the URINE. Nutritious EATING HABITS provide the body with the NUTRIENTS it needs to maintain the best health status possible.

Risk Factors and Preventive Measures

Though environmental exposure, notably to pesticides and radiation, appears to play a role in the development of multiple myeloma, researchers do not know the mechanisms of such exposure. Many people who develop multiple myeloma do not have a known history of exposure to substances so far linked with an increased risk for this form of cancer, making it difficult for health

experts to recommend effective preventive measures.

Potential complications of both the multiple myeloma and its treatments present risks that affect the course of the cancer as well as the prognosis (outlook). M-proteins bind with numerous cell types, causing deposits to accumulate. Such deposits on NERVE cells tend to cause NEUROPATHY (pain or insensitivity). Such deposits within organs, such as the LIVER and the kidneys, may adversely affect their functions. Kidney damage may result in kidney failure and the need for dialysis. As well, chemotherapy agents and high-dose corticosteroids, standards of treatment for multiple myeloma, present the potential for numerous adverse effects. Most people who have multiple myeloma experience several periods of remission ranging from six months to two years in duration with each course of treatment.

myelocyte See BONE MARROW.

myelodysplasia syndrome Different constellations of symptoms, all arising from dysfunction of the BONE MARROW and all leading to various cytopenias (low BLOOD cell counts). In myelodysplasia, also called preleukemia, the number of hematopoietic cells within the BONE marrow increases but the produced cells are disordered and often released to the BLOOD while they are immature. Myelodysplasia syndrome most commonly affects people over age 60. Doctors do not know what causes this syndrome though a significant percentage of people who develop myelodysplasia have had exposure to industrial chemicals (notably benzenes) or radiation. Children who develop myelodysplasia often have underlying genetic disorders such as DOWN SYNDROME.

Myelodysplasia may affect any of the blood cells, resulting in a sometimes confusing clinical picture of mixed symptoms such as bleeding (PLATELET involvement) in combination with ANEMIA (ERYTHROCYTE involvement) or with frequent infections (LEUKOCYTE involvement). The SPLEEN often becomes enlarged (SPLENOMEGALY) as it attempts to filter defective blood cells from the blood and activate its hematopoietic functions to increase blood cell production in compensation for the bone marrow's inability to meet the body's needs. In some people myelodysplasia syndrome progresses to chronic or acute LEUKEMIA. Examination of the blood cells in a blood sample and bone marrow biopsy allow the doctor to make the diagnosis. Treatment may include transfusions of the deficient blood components and ANTIBIOTIC MEDICATIONS as necessary to treat infections. The outlook depends primarily on the type of blood cells involved.

See also BLOOD TRANSFUSION; ENVIRONMENTAL HAZARD EXPOSURE; HEMATOPOIESIS; INFECTION; LYMPHOMA.

myelofibrosis A chronic, degenerative condition of the BONE MARROW in which fibrous tissue replaces the red BONE marrow. Researchers do not know what causes myelofibrosis, which typically develops in people between the ages of 50 and 70, but believe it is an autoimmune response from a single defective blood STEM CELL (called a clonal dysfunction). The IMMUNE SYSTEM fails to recognize the deformed cells and produces antibodies to attack them. Because all BLOOD cells originate from BLOOD STEM CELLS, the attacking antibodies cause extensive damage within the bone marrow. The body's efforts to repair this damage result in pervasive SCAR formation that progressively shuts down the bone marrow.

The most apparent consequence is severe ANEMIA, as 99 percent of the bone marrow's production is oxygen-bearing erythrocytes (red blood cells). The shortfall activates the body's reserve erythropoietic functions in the LIVER and the SPLEEN, which begin producing erythrocytes. However, these organs cannot meet the demand and so both begin to enlarge with the effort (HEPATOMEGALY and SPLENOMEGALY, respectively).

Symptoms of myelofibrosis include those of anemia as well as bone PAIN, easy bleeding, and low resistance to infection as a consequence of diminished LEUKOCYTE (white blood cell) production. Blood tests show a low ERYTHROCYTE count, often low leukocyte and PLATELET counts, and characteristic "tear drop" deformity of the erythrocytes. Bone marrow biopsy shows the infiltration of fibrous tissue.

Treatment targets boosting the blood's erythrocytes by BLOOD TRANSFUSION and ERYTHROPOIETIN (EPO)

supplementation to stimulate the remaining red bone marrow to increase its erythrocyte production (erythropoiesis). Occasionally CHEMOTHERAPY and RADIATION THERAPY to suppress bone marrow function, curtailing proliferation of the defective stem cells, slows the condition's progression. BONE MARROW TRANSPLANTATION is sometimes a viable option. The outlook for myelofibrosis is variable; treatment is not curative and ultimately the bone marrow fails completely. Occasionally myelofibrosis evolves into acute myeloid LEUKEMIA, a rapidly progressive type of cancer in which blast cells (immature leukocytes) take over the bone marrow.

neutropenia Lower than normal numbers of neutrophils circulating in the BLOOD. Neutrophils are the most abundant of the three subtypes of granulocytes; the GRANULOCYTE is a type of LEUKOCYTE (white blood cell). Neutropenia, which can be acute or chronic, results in increased susceptibility to bacterial and fungal (yeast) INFECTION. Severe neutropenia can leave the body virtually defenseless against such infection, as neutrophils are the front line of response to invading pathogenic microorganisms.

The causes of neutropenia are numerous. Among the most common are

- acute viral infections such as mononucleosis, CYTOMEGALOVIRUS (CMV), INFLUENZA, HIV/AIDS, and HEPATITIS
- AUTOIMMUNE DISORDERS
- cancers of the BONE MARROW such as LEUKEMIA and MULTIPLE MYELOMA
- LYMPHOMA
- Vitamin B_{12} deficiency
- long-term, chronic ALCOHOL consumption
- RADIATION THERAPY and CHEMOTHERAPY
- adverse DRUG reactions, notably with NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) and penicillin ANTIBIOTIC MEDICATIONS

Chronic neutropenia is common with chronic infections such as HIV/AIDS and with AUTOIMMUNE DISORDERS. The primary symptoms of neutropenia are typically those of the infection that is present. Diagnostic blood tests that show lowered numbers of neutropenia in the blood confirm the diagnosis. Treatment targets the underlying health condition or removes the offending medication. In many people neutropenia is transient and self-limiting.

neutrophil See GRANULOCYTE.

P

phagocyte A white BLOOD cell (LEUKOCYTE) that consumes pathogens during an IMMUNE RESPONSE called PHAGOCYTOSIS. Granulocytes, and in particular neutrophils, are the primary phagocytes in the circulating blood. Macrophages are phagocytes that reside primarily in the LYMPH structures and the tissues. Protein markers on the surface of the PATHOGEN, called opsonins, attract phagocytes to the pathogen's location. The phagocyte extends its wall to encircle the pathogen, then releases enzymes that digest the pathogen. An individual phagocyte may digest up to a dozen pathogenic particles during the course of its existence.

See also BACTERIA; CELL STRUCTURE AND FUNCTION; MONONUCLEAR PHAGOCYTE SYSTEM.

phagocytosis The process through which a PHAGOCYTE (a specialized LEUKOCYTE) consumes a PATHOGEN or other cellular particle. Phagocytosis is a key defense mechanism of the body's IMMUNE RESPONSE and may take place in the BLOOD, primarily the domain of granulocytes (neutrophils and eosinophils), and in the tissues, primarily the realm of tissue-based monocytes (macrophages). When a pathogen invades the body, the immune response sends substances called opsonins to coat its surface. This process, called opsonization, marks the pathogen, attracting phagocytes. The most common opsonins are antibodies and the proteins the complement system produces.

The blood and the LYMPH carry phagocytes to the sites of opsonized pathogens. When the phagocyte reaches the pathogen it extends its cell wall to enclose the pathogen within its cytoplasm. Once enclosure is complete the phagocyte releases enzymes called lysozymes that digest the pathogen, breaking it down into its molecular components which the cell then recycles or releases as metabolic waste. The primary blood-based phagocytes are neutrophils, which respond to pathogens, and eosinophils, which respond to antigens. Monocytes circulate in the blood only for about 12 hours and then migrate into the tissues. Specialized phagocytes in the LIVER, the Kupffer cells, function in a somewhat cannibalistic manner, cleansing expired granulocytes from the circulating blood and recycling their molecular components into the bloodstream for other uses.

phlebotomy The clinical term for puncturing a VEIN with a sterile needle to withdraw BLOOD. Phlebotomy may be diagnostic, such as when drawing blood for diagnostic blood tests, or therapeutic, such as a treatment for HEMOCHROMATOSIS. Phlebotomy may be mildly uncomfortable, as the needle may sting as it penetrates the SKIN and the vein. The blood withdrawal itself is painless. The risks of phlebotomy are minor for most people and include mild bleeding, bruising, and discomfort at the puncture site.

plasma The liquid portion of the BLOOD. Plasma is about 90 percent water and makes up 55 percent of the total blood volume. It contains numerous substances dissolved in it including electrolytes, hormones, enzymes, antibodies, GLUCOSE, and CLOTTING FACTORS (specialized proteins). It also carries the blood cells in suspension. Plasma is available for transfusion as a blood product, in fresh or fresh-frozen form. Plasma derivative products extracted from donated plasma include cryoprecipitated antihemophilic factor (AHF), ALBUMIN, IMMUNOGLOBULIN, and Rh immunoglobulin.

For further discussion of the plasma within the context of blood and lymph structure and function please see the overview section "The Blood and Lymph."

platelet The cellular structure indispensable for COAGULATION (clotting), also called a thrombocyte. Platelets, which are actually cell fragments rather than intact cells, separate from parent cells in the BONE MARROW called megakaryocytes, the largest cells in the BONE marrow. When platelets emerge into the circulation they become the smallest cell particles in the circulating blood. Their small size permits them to travel into any blood vessel, even the tiniest arterioles and venules, to respond to bleeding. Platelets lack nuclei and thus, like erythrocytes, cannot divide. They live in the circulation for about 10 days.

The normal number of platelets in the blood is 130,000 to 400,000 per cubic milliliter. The SPLEEN holds about 30 percent of the blood's platelets within its red pulp, releasing them into the circulation when needed to respond to bleeding. This containment helps reduce the risk for inadvertent agglutination as platelets swirl into contact with one another in the bloodstream.

Any breach in a blood vessel that allows blood to escape results in the release of the enzyme tissue factor (factor III), which attracts droves of platelets to the site. As the platelets agglutinate (come into contact with the damaged site and with one another) they release chemicals such as serotonin, thromboxane, and phospholipids that extend and focus the coagulation cascade.

For further discussion of platelets within the context of blood and lymph structure and function, please see the overview section "The Blood and Lymph."

platelet aggregation The process through which platelets respond to chemical signals in the BLOOD, allowing them to adhere to each other and to collagen fibers in the blood to form the hemostatic plug that will become a blood clot at the conclusion of the COAGULATION cascade. The formation of collagen and the conversion of fibrinogen (clotting factor I) to the enzyme fibrin together initiate a sequence of chemical conversions that alter PLATELET surface proteins as well as attract more platelets to the location of the injury. As the coagulation cascade continues, platelets accumulate. The platelets change shape, developing threadlike extensions called pseudopods that allow them to extend like vines into the weave of collagen fibers. The surface of the platelets continues to undergo chemical changes that attract fibrinogen and release arachidonic acid, which oxidizes to form PROSTAGLANDINS, short-acting hormones that are key players in the IMMUNE SYSTEM'S INFLAMMATION response. Prostaglandins further attract platelets to the site.

Converted CLOTTING FACTORS begin to weave fibers of protein among the fibers of fibrin, thrombin, and collagen, forming a netlike structure that entraps other cells flowing through the blood. When the clot reaches critical mass additional chemical reactions begin to shut down the coagulation cascade, bringing the clotting process to a halt. The surface proteins of circulating platelets revert, and the platelets no longer adhere to each other. The reversion also activates mechanisms within the platelets that cause them to contract, pulling them tightly into the clot structure. Other proteins cause the clot to harden, cementing it in place.

Inflammation of the ARTERY walls, such as occurs with CORONARY ARTERY DISEASE (CAD), attracts platelets in the same manner as do wounds, setting in motion the events of platelet aggregation in ways that are detrimental to health. Doctors often prescribe antiplatelet medications to slow platelet aggregation in people who have had HEART ATTACK OR STROKE, or who have CAD. Most of these medications work by blocking the oxidation of arachidonic acid, which then inhibits prostaglandin formation. The most commonly used antiplatelet medication is aspirin. Platelet aggregation can also occur as a SIDE EFFECT of medications or a dysfunction of coagulation.

polycythemia vera A myeloproliferative condition of the BLOOD in which the red BONE MARROW produces an excessive volume of erythrocytes (red blood cells), platelets, and neutrophils that results in increased cell volume and decreased fluid volume (PLASMA) in the blood. This myeloproliferation (overproduction by the bone marrow) thickens the blood (hyperviscosity), making it more difficult for the cardiovascular system to transport and increasing the risk for thrombosis (blood clots). As the myeloproliferation progresses, the marrow pushes immature, deformed, and defective cells into the blood that are unable to perform the normal functions of their cell types. Polycythemia vera is a chronic and potentially debilitating disorder most commonly diagnosed in people age 60 and older.

Symptoms and Diagnostic Path

Symptoms may not appear until the bone marrow dysfunction is considerably advanced and typically include

- tiredness and fatigue
- weakness
- HEADACHE
- lightheadedness
- easy bleeding or bruising
- PRURITUS (itching)
- SKIN flushing (redness), particularly of the face

The doctor's examination often reveals an enlarged SPLEEN (SPLENOMEGALY), a consequence of the overload on the spleen to remove defective erythrocytes from the circulating blood or to produce additional erythrocytes if those in circulation are too defective to adequately transport oxygen (ANEMIA). Some people also have an enlarged LIVER (HEPATOMEGALY), as the liver too has a role in cleansing dysfunctional erythrocytes from the blood. Diagnostic blood tests characteristically show elevated ERYTHROCYTE, neutrophil, and PLATELET counts, with the hematocrit (percentage of erythrocytes in the blood) greater than 54 percent in men or 49 percent in women. The doctor may also perform a bone marrow biopsy, which demonstrates clusters of megakaryocytes (the parent cells of platelets) and other characteristic alterations in the marrow's structure.

Treatment Options and Outlook

PHLEBOTOMY (therapeutic withdrawal of blood) is adequate treatment for many people who have polycythemia vera, particularly when the diagnosis comes early in the condition. The usual therapeutic approach is daily phlebotomy to remove 300 to 500 milliliters of blood until the hematocrit drops to 45 percent. Weekly to monthly phlebotomy sessions then may keep the condition in check.

When phlebotomy is not sufficient, substances to suppress bone marrow function, called myelosuppressive therapy, can put the condition in REMISSION for up to several years at a time. Myelosuppressive therapy has a high risk for causing acute myeloid LEUKEMIA, however, so current treatment protocols call for its use only in people over age 70.

The most significant and frequent complications of polycythemia vera are thrombosis (the formation of blood clots in the blood vessels), which can lead to HEART ATTACK or STROKE, and acute myeloid leukemia. Without treatment polycythemia vera is generally fatal within two years. With treatment, many people enjoy good QUALITY OF LIFE for 15 to 20 years beyond diagnosis.

Risk Factors and Preventive Measures

Because researchers do not know what causes polycythemia vera, there are no known preventive measures. The condition is uncommon, and more likely to occur in men than women. Polycythemia vera is unusual in a person under age 40. Early diagnosis and treatment improves quality of life and outlook.

R–S

reticulocyte An ERYTHROCYTE (red BLOOD cell) that enters the blood's circulation from the BONE MARROW just before it has reached maturity. Reticulocytes are somewhat larger than erythrocytes and normally make up about 1 percent of the erythrocytes in circulation. A reticulocyte matures into an erythrocyte after being in circulation for about a day. Reticulocytes are still continuing to synthesize (make) HEMOGLOBIN, so contain somewhat less hemoglobin than mature erythrocytes.

An increased number of reticulocytes in circulation indicates the BONE marrow is producing erythrocytes more rapidly than normal. Accelerated erythropoiesis may suggest various underlying causes, such as undetected internal bleeding, hemolytic ANEMIA, and extended exposure to high altitude (which increases the body's need for oxygen). The reticulocyte count also rises in PREGNANCY and with some medications such as NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS), levodopa taken to treat PARKINSON'S DISEASE, and sulfonamide ANTIBIOTIC MEDICATIONS.

A decreased number of reticulocytes in circulation suggests chronic INFECTION, exposure to radiation, aplastic anemia, or iron-deficiency anemia. The reticulocyte count also may drop with CHEMOTHERAPY, the antibiotic chloramphenicol, and the immunosuppressant medication azathioprine typically taken after ORGAN TRANSPLANTATION to prevent organ rejection or severe RHEUMATOID ARTHRITIS.

For further discussion of reticulocytes within the context of blood and lymph structure and function please see the overview section "The Blood and Lymph."

right lymphatic duct A major LYMPH VESSEL that collects LYMPH draining from the right upper body and head. The right lymphatic duct is about a quarter-inch in diameter and two inches long, adjacent to the subclavian VEIN beneath the clavicle (collarbone). It empties into the right subclavian vein, delivering lymph to the bloodstream.

For further discussion of the right lymphatic duct within the context of blood and lymph structure and function, please see the overview section "The Blood and Lymph."

sickle cell disease An inherited genetic disorder of defective HEMOGLOBIN, a protein compound erythrocytes (red blood cells) contain that binds with oxygen. Though the primary effect of sickle cell disease, also called sickle cell ANEMIA, is anemia (insufficient oxygen in the blood), the condition also causes significant PAIN and damage to organs throughout the body. In the United States sickle cell disease is significantly more common in African Americans. Around the world, sickle cell disease is most common among people of African, northern Mediterranean, Indian, and Middle Eastern descent. About 70,000 Americans have sickle cell disease and another 2 million have sickle cell trait. Sickle cell disease is the most common inherited blood disorder.

Sickle cell disease gets its name from the characteristic sickle shape of the erythrocytes. The deformity results from the defective hemoglobin, called hemoglobin S, which the erythrocytes carry. When hemoglobin S releases oxygen during the OXYGEN-CARBON DIOXIDE EXCHANGE, it polymerizes—its structure undergoes molecular changes that cause its molecular weight to increase. This stiff-

ens and hardens the normally flexible erythrocytes, pulling them into a sickle or crescent shape.

The rigidity and inflexibility prevents the erythrocytes from folding and twisting as they pass through the small blood vessels, causing them to create blockages. The blockages cause swelling, pain, and eventually damage to organs and structures throughout the body. People who have sickle cell disease have very high risk for STROKE, HEART ATTACK, acute chest syndrome (blockages in the lungs that cause INFECTION), and loss of vision.

The changes also make the erythrocytes more fragile, and they easily break apart as the flow of blood jostles them around. Sickled erythrocytes die after only about 20 days in the blood circulation, whereas normal erythrocytes live for 90 to 120 days. The shortened lifespan further limits the ability of the blood to transport oxygen, establishing chronic anemia.

ADAPTIVE DEFECT

Researchers believe the gene mutation that causes sickle cell disease originated in the form of sickle cell trait as an adaptation to protect against malaria infection. The sickled erythrocytes resist the parasite that causes MALARIA. In sickle cell trait, the person has some hemoglobin S and mostly normal hemoglobin—an ideal blend for simultaneously maintaining health and thwarting malaria. The adaptation backfires only when two people with sickle cell trait conceive a child, at which time the recessive autosomal inheritance pattern of the mutated hemoglobin gene becomes a risk for passing on too much of a good thing to the child.

The inheritance pattern for sickle cell disease is autosomal recessive, which means both parents must pass the defective hemoglobin gene to their child. People who are carriers of the mutated hemoglobin gene have sickle cell trait, with one mutated and one normal hemoglobin gene. They have small amounts of hemoglobin S though mostly have normal hemoglobin and have no indications of sickle cell disease. However, their children may end up with sickle cell disease if they inherit the sickle cell mutation from each parent. When both parents have sickle cell trait, there is a 1 in 4 chance for the child to have sickle cell disease, a 2 in 4 chance the child will also be a carrier, and a 1 in 4 chance the child will inherit two normal genes.

Symptoms and Diagnostic Path

Symptoms generally begin to emerge when a child is about a year old. For the first year of life the child has an abundant supply of fetal hemoglobin, which has the ability to prevent polymerization of hemoglobin S. However, the child's own hemoglobin gradually replaces the fetal hemoglobin and this protection disappears, typically between age 6 months and 10 months. Early symptoms of sickle cell disease in a child are swollen hands and feet (sometimes called hand and foot syndrome), a consequence of damaged erythrocytes blocking the small blood vessels in the hands and feet to prevent blood from circulating out. Other symptoms include

- pain from blockages
- FEVER
- fatigue from anemia
- diminished vision from damage to the RETINA

People who have sickle cell disease may also have

- frequent infections resulting from damage to the SPLEEN and LYMPH tissues
- jaundice, yellow discoloration of the skin resulting from excessive bilirubin in the blood circulation as the components of the dead erythrocytes accumulate in the LIVER
- delayed growth due to severe anemia

A blood test can detect the presence of hemoglobin S, which affirms the diagnosis. In the United States, hospitals routinely run this test on all newborns. Examination of the erythrocytes under the microscope also shows the characteristic sickle shape.

Treatment Options and Outlook

Treatment for sickle cell disease may include ANALGESIC MEDICATIONS for pain relief, blood transfusions to replace the damaged erythrocytes with healthy erythrocytes (which is effective for the life cycle of the transfused erythrocytes), and the medication hydroxurea (which can reestablish fetal hemoglo-

bin production in some children). BONE MARROW TRANSPLANTATION is sometimes an option for people who have severe symptoms. There is no cure for sickle cell disease. Sickle cell trait does not produce symptoms or develop into sickle cell disease, so it requires no treatment. Many people who have sickle cell trait do not know it.

Risk Factors and Preventive Measures

Because sickle cell disease is an inherited genetic disorder, the only risk factor is heredity. It is a good idea for people who do not know their sickle cell status, especially African Americans, to have the blood test for hemoglobin S before conceiving children. GENETIC COUNSELING can help with family planning decisions when both parents have sickle cell trait.

spleen A soft structure of lymphatic tissue located in the upper left abdomen to the left of the STOMACH and PANCREAS, behind the protective enclosure of the rib cage. Fibrous ligaments anchor the spleen to the stomach, COLON, and left kidney. The spleen holds about 300 milliliters of BLOOD, roughly 4 percent of the body's total blood supply, and contains about a third of the body's platelets (the cells responsible for COAGULATION). Its high blood content gives the spleen a dark red color and a somewhat porous texture. The spleen has two main structural and functional sections that filter the blood for different substances, the red pulp and the white pulp.

White Pulp

The white pulp consists of nodules and follicles, similar to those of other lymphatic tissues such as the LYMPH nodes, arranged in sheathlike structures that encase each of the tiny blood vessels (arterioles) within the spleen. The white pulp has two primary roles, to filter antigens from the circulating blood and to produce lymphocytes (a type of LEUKOCYTE). These functions are interrelated in that the lymphocytes bear antibodies specific to the antigens the white pulp traps. When the lymphocytes enter the circulation of the blood or lymph, their antibodies allow them to intercept and destroy pathogens such as viruses or BACTERIA that carry the antigens.

Red Pulp

The red pulp surrounds the white pulp. In the developing fetus the red pulp produces the majority of blood cells, erythrocytes (red blood cells) and leukocytes (white blood cells) alike, until about the fifth month of PREGNANCY, after which the red bone marrow takes over erythropoiesis (ERYTHROCYTE production). Hematopoietic capability of the red pulp remains available but dormant after birth. Throughout life, the red pulp serves as an extramedullary (out of the marrow) resource that the body can press into action to produce erythrocytes.

The red pulp also filters the blood, culling outdated, defective, or damaged erythrocytes from circulation. Phagocytic cells called macrophages that reside within the red pulp break down the erythrocytes, sending components such as HEMOGLOBIN and BILIRUBIN back into the blood for transportation to the LIVER, which recycles them. The red pulp also filters other cellular debris from the blood.

Potential Health Conditions Involving the Spleen

The spleen's primary vulnerability is trauma, which can cause life-threatening hemorrhage (uncontrolled bleeding). A blow to the upper abdomen, such as may occur in MOTOR VEHICLE ACCIDENTS or with aggressive contact sports, can cause a rupture injury to the spleen. Such a blow also can fracture a rib, causing a penetrating wound to the spleen. SPLENECTOMY (surgical removal of the spleen) then becomes necessary. Though not essential for life, the spleen performs numerous functions vital to the IMMUNE RESPONSE and blood cell maintenance. Other lymphatic structures and the liver can partially compensate for the spleen's loss, though the risk for serious INFECTION significantly increases. There are many health conditions that can cause the spleen to enlarge (SPLENOMEGALY). The spleen also enlarges when fighting systemic infections such as infectious mononucleosis and in some cancers.

For further discussion of the spleen within the context of blood and lymph structure and function please see the overview section "The Blood and Lymph."

See also CANCER; LYMPH NODE; MONONUCLEAR PHAGOCYTE SYSTEM; MONONUCLEOSIS, INFECTIOUS; PHAGOCYTOSIS.

splenectomy A surgical OPERATION to remove the SPLEEN. Though the spleen performs many vital immune and BLOOD-related functions, it is not essential for life. Because the spleen contains 4 percent of the body's blood volume and a third of its platelets, it is vulnerable to life-threatening hemorrhage with trauma. Doctors may also choose to remove the spleen for therapeutic or prophylactic (preventive) reasons in conditions such as chronic myeloid LEUKEMIA and MYELOFIBROSIS.

Splenectomy may be an OPEN SURGERY or a laparoscopic surgery, depending on the reason and the person's overall health status, performed under general ANESTHESIA. Laparoscopic splenectomy, which involves removing the spleen using a lighted endoscope and small tools the surgeon inserts through four or five small incisions in the upper left abdomen, usually requires an overnight stay in the hospital with three to four weeks for full recuperation. Open splenectomy requires a single incision, four to five inches long, through which the surgeon opens the abdominal cavity and removes the spleen. The open surgery may require three to five days in the hospital with four to six weeks for full recovery.

COMMON REASONS FOR SPLENECTOMY

hemolytic ANEMIA	LEUKEMIA
LYMPHOMA	PORTAL HYPERTENSION
THROMBOCYTOPENIA	trauma with hemorrhage
uncontrolled SPLENOMEGALY	

As with any surgery, excessive bleeding and INFECTION are potential risks. Because absence of the spleen compromises the body's IMMUNE RESPONSE, lowered resistance to infection is a common consequence of splenectomy. Doctors recommend pneumococcal PNEUMONIA vaccination before splenectomy when possible and immediately after when splenectomy is an emergency surgery. The doctor may recommend other immunizations, depending on individual health circumstances. People who have had splenectomy must remain diligent in regard to potential infections, even those that are seemingly minor such as COLDS. Many doctors recommend ANTIBIOTIC PROPHYLAXIS (preventive ANTIBIOTIC MEDICATIONS) to offset the IMMUNE SYSTEM's diminished response.

See also SURGERY BENEFIT AND RISK ASSESSMENT.

splenomegaly An enlarged SPLEEN. Splenomegaly signals an underlying health condition and is not itself a disorder. The spleen is a structure of lymphatic tissue. One of its key roles is to remove old or damaged BLOOD cells from circulation. Many circumstances and health conditions that cause increased numbers of blood cells in the circulation can also cause splenomegaly. These range from systemic infections, such as infectious mononucleosis, to blood disorders, such as THROMBOCYTHEMIA, to cancers, such as LEUKEMIA and LYMPHOMA. Some people feel a sense of uncomfortable fullness with splenomegaly, though most people are unaware of the condition until a doctor detects it.

There is no specific treatment for splenomegaly; so treatment targets the underlying cause. Splenomegaly significant enough to extend the spleen beyond the protective boundary of the rib cage presents a risk for injury resulting in hemorrhage, as the spleen contains about 4 percent of the body's total blood volume and a third of its platelets (the cells responsible for clotting).

CONDITIONS IN WHICH SPLENOMEGALY MAY OCCUR

AMYLOIDOSIS	ANEMIA
CIRRHOSIS	congestive HEART FAILURE
HEPATITIS	leishmaniasis
LEUKEMIA	LEUKOPENIA
LYMPHOMA	MALARIA
MONONUCLEOSIS, INFECTIOUS	MULTIPLE MYELOMA
MYELOFIBROSIS	POLYCYTHEMIA VERA
PORTAL HYPERTENSION	psittacosis
SARCOIDOSIS	SICKLE CELL DISEASE
SYPHILIS	SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)
THALASSEMIA	THROMBOCYTHEMIA
THROMBOCYTOPENIA	TUBERCULOSIS

See also HEPATOMEGALY; SPLENECTOMY.

thalassemia A genetic disorder of the BLOOD in which the body fails to produce one or more of the proteins necessary for the synthesis of HEMOGLOBIN, the protein that enables erythrocytes (red blood cells) to carry oxygen. The consequence is ANEMIA (inadequate oxygen to the cells throughout the body). There are two basic types of thalassemia: alpha and beta, designated according to the responsible defunct protein chain. Within these types are a number of subtypes. In general, thalassemia is more common among people of Asian and African heritage (alpha thalassemia) or Mediterranean heritage (beta thalassemia).

Symptoms and Diagnostic Path

Mild thalassemia may produce no symptoms, while severe thalassemia can be life-threatening. Symptoms are generally similar for the major forms of thalassemia and are those of anemia. They may include

- chronic fatigue
- weakness
- HEADACHE
- Shortness of breath, especially with exertion or exercise
- PALPITATIONS

Severe symptoms may involve cardiovascular crisis such as HEART ATTACK. Some forms of thalassemia include excessive iron absorption by the LIVER, HEART, and other organs, resulting in permanent damage such as CIRRHOSIS, LIVER FAILURE, and HEART FAILURE. Long-term thalassemia often results in significant SPLENOMEGALY (enlarged SPLEEN) and permanent changes in BONE structure that weaken the bones (notably with beta thalassemia). In some people the bone changes cause pathologic or spontaneous FRACTURE, which is the first indication of an underlying thalassemia.

The diagnostic path includes blood tests to measure serum iron levels, which are characteristically elevated in severe thalassemia but may be low in mild forms, and to assess hemoglobin composition by hemoglobin electrophoresis. BONE MARROW biopsy demonstrates the altered appearance of developing erythrocytes that characterizes thalassemia. X-rays can confirm changes to the structure of the bones, which are most apparent in the skull and the long bones of the arms and legs.

Treatment Options and Outlook

People who have symptoms as a result of their thalassemia require lifelong BLOOD TRANSFUSION, with either whole blood or packed red cells (erythrocytes), typically every two or three weeks. These transfusions provide normal erythrocytes that can transport oxygen through the bloodstream, with transfusions timed at intervals that approximate the body's normal process of new ERYTHROCYTE release and old erythrocyte cleansing. However, blood transfusions contribute to an escalation of iron accumulation that requires treatment, usually therapeutic CHELATION THERAPY (heavy metals detoxification).

Therapeutic SPLENECTOMY (removal of the spleen) can reduce symptoms when excessive HEMOLYSIS (acceleration of the body's normal process for destroying erythrocytes) contributes to symptoms by stimulating increased erythropoiesis (production of new erythrocytes). BONE MARROW TRANSPLANTATION may become a viable option when other treatment approaches fail to control symptoms and symptoms are severe.

Thalassemia is lifelong. Most people with alpha forms of thalassemia enjoy a good QUALITY OF LIFE,

aside from the intrusion of regular blood transfusions, and normal LIFE EXPECTANCY. Beta forms of thalassemia tend to be more severe and have a less optimistic outlook. The secondary HEMOCHROMATOSIS (iron accumulations in the tissues) can become a significant health factor itself, creating a therapeutic dilemma.

Risk Factors and Preventive Measures

Because thalassemia is genetic and inherited, the primary risk factors are family history and presence of the causative GENE mutations. Doctors advise GENETIC TESTING and GENETIC COUNSELING for people who have family history of thalassemia. It is possible for an individual to carry the gene defect and show no symptoms of the condition, which can result in passing the gene defect, and the disease, to the individual's children.

thoracic duct The largest vessel of the lymphatic system. The thoracic duct collects LYMPH from the CISTERNA CHYLI and the left upper body, and drains into the left subclavian VEIN to deliver lymph to the bloodstream. About the diameter of a pencil, the thoracic duct extends from the cisterna chyli in the central trunk to base of the neck, a distance of about 16 inches, somewhat paralleling the AORTA. Like a vein, the thoracic duct has smooth-MUSCLE walls that rhythmically contract and contains valves to prevent its contents from backflowing. Muscular movement, such as occurs with physical activity or exercise, massages lymph through the thoracic duct toward the subclavian vein. Several branches of lymph vessels feed into the thoracic duct as it courses through the chest, rejoining to form a single segment that intersects with the subclavian vein beneath the clavicle (collarbone).

For further discussion of the thoracic duct within the context of BLOOD and lymph structure and function please see the overview section "The Blood and Lymph."

thrombocyte See PLATELET.

thrombocythemia A condition of the BLOOD in which the body overproduces platelets (also called thrombocytes), resulting in dysfunctional COAGULATION. Thrombocythemia, also called thrombocytosis, is a myeloproliferative disorder that can be primary (an independently occurring disorder, also called essential or idiopathic thrombocythemia) or secondary (a consequence of other health conditions or SPLENECTOMY). Doctors do not know what causes primary thrombocythemia, which occurs most commonly in people over age 50.

COMMON CAUSES OF SECONDARY THROMBOCYTHEMIA

INFECTION	INFLAMMATORY BOWEL DISEASE (IBD)
iron deficiency ANEMIA	LYMPHOMA
RHEUMATOID ARTHRITIS	SARCOIDOSIS
TUBERCULOSIS	Wegener's granulomatosis

Symptoms and Diagnostic Path

The excess platelets in the blood cause disturbances of coagulation that often result in these symptoms, which may be subtle or overt:

- easy bleeding, notably from the mucous membranes, such as frequent nosebleeds (EPISTAXIS), or from the gastrointestinal tract
- easy bruising
- clotting (thrombosis)
- SPLENOMEGALY (enlarged SPLEEN)
- HEADACHE or dizziness
- hemorrhage

A blood PLATELET level higher than 500,000 platelets per microliter (mc/L) of blood typically confirms the diagnosis, though the doctor may choose to do a BONE MARROW biopsy. Bone marrow biopsy shows an abundance of megakaryocytes, the parent cells of platelets, oversize platelets, and platelet fragments.

Treatment Options and Outlook

Treatment for secondary thrombocythemia targets the underlying condition, with resolution of the thrombocythemia after improvement in that condition. Treatment for primary thrombocythemia aims to suppress myeloproliferation (bone marrow cell production activity). Common forms of myelosuppressive therapy are radioactive phos-

phate and the CHEMOTHERAPY agents hydroxyurea and anagrelide. Some people benefit from platelet apheresis, a form of HEMAPHERESIS that removes platelets from the blood and returns all other blood components to the person. The doctor will closely monitor the complete blood count (CBC) as well as platelet function and coagulation during treatment, usually with weekly blood tests.

Primary thrombocythemia is a chronic condition that requires ongoing treatment. Many people will remain relatively symptom-free once treatment stabilizes platelet production. The condition takes a more serious course in some people who may experience worsening symptoms, notably hemorrhage. Rarely, primary thrombocythemia evolves into chronic myeloid LEUKEMIA (CML), a cancer of the bone marrow.

Risk Factors and Preventive Measures

Because doctors do not know what causes primary thrombocythemia, risk factors remain unknown and there are no known preventive measures. Early diagnosis and appropriate treatment offer the most optimal prognosis (outlook) to minimize the level to which the condition affects QUALITY OF LIFE.

See also POLYCYTHEMIA VERA; THROMBOCYTOPENIA.

thrombocytopenia A disorder of the BLOOD in which the blood contains too few platelets (also called thrombocytes), the cells active in COAGULATION (clotting). Thrombocytopenia, also called thrombopenia, is a secondary condition that develops as a consequence of prolonged bleeding, aplastic ANEMIA, blood disorders such as THROMBOCYTHEMIA, and cancers affecting the BONE MARROW.

POTENTIAL CAUSES OF THROMBOCYTOPENIA

acute idiopathic thrombopenia purpura	ANTIDIABETIC MEDICATIONS
AUTOIMMUNE THROMBOCYTOPENIA	aplastic ANEMIA
chronic ALCOHOL consumption	BLOOD TRANSFUSION reaction
CIRRHOSIS	chronic idiopathic thrombopenia purpura
GASTROINTESTINAL BLEEDING	heparin
HIV/AIDS	LEUKEMIA
MYELOFIBROSIS	PLATELET dysfunction
quinidine	rifampin
SEPTICEMIA	sulfa ANTIBIOTIC MEDICATIONS

Certain medications may also cause thrombocytopenia as an undesired SIDE EFFECT. Thrombocytopenia may occur when the bone marrow cannot produce enough platelets or when the SPLEEN and LIVER remove too many platelets from the blood.

Symptoms and Diagnostic Path

The characteristic sign of thrombocytopenia, regardless of its underlying cause, is excessive superficial bleeding. Symptoms include

- PETECHIAE, pinpoint hemorrhages beneath the surface of the SKIN that have the appearance of a RASH
- ECCHYMOSIS, a pattern of easy and excessive bruising with minor bumps and scrapes
- unprovoked bleeding from the nose (EPISTAXIS), gums, URETHRA, and other mucous tissues
- blood in the urine, stool, or vomit
- excessive bleeding with dental procedures or surgery
- signs of intracranial bleeding (bleeding within the skull)

A blood test that shows the low PLATELET count with normal counts and appearance of other blood cells is fairly conclusive of the diagnosis, especially when an underlying condition known to cause thrombocytopenia also is present. The doctor may choose to do a bone marrow biopsy. Because thrombocytopenia can be an early indication of HIV INFECTION, the doctor is also likely to do an HIV antibodies test to determine whether HIV infection is present.

Treatment Options and Outlook

Treatment depends on the underlying condition. Sometimes platelet transfusions are necessary to provide enough platelets for proper coagulation. Thrombocytopenia is not usually a life-threatening condition and typically resolves when the underlying condition improves.

Risk Factors and Preventive Measures

The primary risk factors for thrombocytopenia are the conditions that result in its development. Avoiding these factors, such as alcohol consumption or a medication that is causing thrombocytopenia as a side effect, or treating the condition

dispenses the likelihood for developing thrombocytopenia.

thymectomy A surgical OPERATION, performed under general ANESTHESIA, to remove the THYMUS, a structure of lymphatic tissue located behind the sternum (breastbone) that produces T-cells. Tendrils of the thymus often extend upward toward the THYROID GLAND and downward over the HEART. The loose structure of the thymus can make it challenging to surgically remove.

Thymectomy is the treatment of choice for most cancers of the thymus, which are uncommon. Doctors sometimes use thymectomy to treat severe AUTOIMMUNE DISORDERS, such as MYASTHENIA GRAVIS, as a method to restrict the body's ability to produce T-cells and thus limit the IMMUNE RESPONSE. Thymectomy in childhood has extensive consequences for IMMUNE SYSTEM development though does not appear to alter IMMUNE RESPONSE in adults. Most people require only a one or two day stay in the hospital, and about four to six weeks for full recovery.

thymus A structure of lymphatic tissue located in the upper central chest, behind the sternum (breastbone) midway between top of the HEART and the sternal notch at the base of the THROAT. The thymus is fairly large at birth, spreading in a loosely shaped "H" across the great vessels that emerge from the heart. The tissue of the thymus sometimes extends upward to make contact with the THYROID GLAND and downward to drape over the heart's upper chambers, the atria. Occasionally fragments of thymic tissue exist as unattached, isolated lobules typically remaining in the upper chest and lower neck.

The thymus is most active in youth, serving as the incubator in which T-cells, the lymphocytes crucial for the body's defense against INFECTION, mature and differentiate (acquire their functional characteristics). The thymus typically enlarges as a child approaches PUBERTY, its peak time of activity, then begins to recede. By midlife little more than strands of thymic tissue remain. The thymus also produces hormones—key among them being thymosin, thymulin, thymopoietin, and thymocyte humoral factor—that regulate T-cell maturation.

STATUS LYMPHATICUS: "ENLARGED" THYMUS

In the 1940s and 1950s, conventional medical wisdom blamed the large thymus of childhood for unexplained sudden death in children, conveying upon the condition the diagnostic label *status lymphaticus*. RADIATION THERAPY to shrink the thymus became the prevailing treatment. By the 1960s doctors recognized the thymus was normally large in children and abandoned the diagnosis and its treatment.

Researchers believe the thymus has other functions related to IMMUNE RESPONSE, though remain unable to determine their precise mechanisms. An infant born without a thymus has no ability to develop an IMMUNE SYSTEM; this CONGENITAL ANOMALY is nearly always fatal in infancy. There also appears to be a correlation between the thymus and MYASTHENIA GRAVIS, an autoimmune disorder in which the immune system produces antibodies that target acetylcholine, the NEUROTRANSMITTER that facilitates NERVE signals traveling between nerve cells and MUSCLE cells. An enlarged thymus is common in people who have myasthenia gravis and removing it (THYMECTOMY) often results in dramatic improvement in the condition. The thymus may have a role in other AUTOIMMUNE DISORDERS such as SYSTEMIC LUPUS ERYTHEMATOSUS (SLE) and GRAVES'S DISEASE. Thymoma and thymic CARCINOMA are two forms of cancer that may develop in the thymus. Cancer of the thymus is uncommon.

vitamin K A vitamin that is a crucial catalyst, or coenzyme, in the COAGULATION process (also called coagulation cascade). Vitamin K (naphthoquinone) plays a role in activating seven of the CLOTTING FACTORS in various stages of coagulation, helping convert them from the inactive state in which they circulate in the BLOOD to active proteins that form clots. Vitamin K also is important for new BONE growth and BONE DENSITY. The major forms of vitamin K are phylloquinone (K1), menaquinone (K2), and menadione (K3, synthetic and cannot be converted into K1).

DIETARY SOURCES OF VITAMIN K

Food	Amount of Vitamin K per 1-Cup Serving
Kale, cooked	1,062 micrograms (mcg)
spinach, cooked	888 mcg
collard greens	836 mcg
parsley	324 mcg
Brussels sprouts, cooked	219 mcg
onions, spring	207 mcg
broccoli, cooked	220 mcg
lettuce, leaf (Bibb, Boston)	167 mcg
asparagus, cooked	144 mcg
prunes, stewed	65 mcg
lettuce, romaine	57 mcg
peas, cooked	40 mcg
blackberries, blueberries (fresh)	28 mcg
lettuce, head (iceberg)	13 mcg
turkey, cooked	5 mcg
strawberries, raw	4 mcg

Most of the vitamin K the body uses is in the form of phylloquinone and comes from plant foods in the diet, notably leafy green vegetables such as spinach, kale, and broccoli. Intestinal BACTERIA also synthesize (manufacture) a small amount of vitamin K (menaquinone). Though vitamin K is fat soluble, the body does not maintain a significant store of it. Consequently, health experts have established daily adequate intake values of 90 micrograms per day for women and 120 micrograms per day for men.

The commonly used oral anticoagulant medication, warfarin, inhibits clotting by blocking the actions of vitamin K. Doctors may recommend restricting consumption of foods high in vitamin K for those who are taking ANTICOAGULATION THERAPY or maintaining consistent consumption of vitamin K–containing foods (not to exceed the daily adequate intake value) so the body's levels of vitamin K remain stable.

Because infants often have inadequate levels of vitamin K in their blood at birth, most hospitals in the United States administer vitamin K supplement injections to newborns within 24 hours of birth, which is the current recommendation of the American Academy of Pediatrics. Doctors do not agree on the value or effectiveness of routine vitamin K supplements in other circumstances. Most health experts recommend obtaining the body's supply of vitamin K through dietary sources, which is fairly easy for most Americans to do because a wide variety of foods contain this nutrient. Menadione is the synthetic supplement form of vitamin K.

von Willebrand's disease A hereditary, genetic bleeding disorder resulting from a deficiency or

molecular abnormality of clotting factor VIII. Unlike HEMOPHILIA A, which also results from clotting factor VIII deficiency, von Willebrand's disease affects both men and women equally. Its inheritance pattern is autosomal dominant, meaning a child can acquire the condition when only one parent has the defective GENE. Von Willebrand's disease is the most common bleeding disorder in the United States, affecting about 1 percent of the American population. The condition is mild in most people, though severe trauma or major surgery may cause life-threatening hemorrhage especially in people who do not know they have the disorder.

Symptoms and Diagnostic Path

The most common symptom of von Willebrand's disease is somewhat prolonged bleeding with cuts, wounds, dental procedures, and surgeries. Easy bruising, frequent nosebleeds (EPISTAXIS), and bleeding gums are also common symptoms. Some people may periodically develop PETECHIAE, pinpoint hemorrhages beneath the surface of the SKIN that have the appearance of a RASH. Women who have von Willebrand's disease may have unusually heavy menstrual bleeding. The diagnostic path includes blood tests to measure clotting times, PLATELET AGGREGATION, and the level of von Willebrand factor multimers in the blood. The results of these diagnostic blood tests are usually conclusive for the diagnosis.

Treatment Options and Outlook

No treatment is necessary for people who have mild symptoms, though anyone diagnosed with von Willebrand's disease should carry or wear identification that alerts emergency medical personnel to the condition. Treatment before scheduled surgeries or for bleeding due to trauma is administration of PLASMA cryoprecipitate, which contains concentrated CLOTTING FACTORS, or purified factor VIII concentrate.

People who have von Willebrand's disease should not take NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS), including aspirin, as these medications further decrease PLATELET AGGREGATION and increase bleeding.

Risk Factors and Preventive Measures

As von Willebrand's disease is hereditary, family history is the only known risk factor. People who have von Willebrand's disease may choose GENETIC COUNSELING before deciding to conceive children. Most people who have von Willebrand's disease experience little interference with QUALITY OF LIFE. The condition generally remains stable throughout life. Other health conditions that affect bleeding may result in a compound effect to produce more intense symptoms than either condition alone would otherwise manifest.

THE PULMONARY SYSTEM

The pulmonary system brings oxygen into the body and expels metabolic wastes in the form of gases. Physician specialists who treat conditions of the pulmonary system are internists who have subspecialty certifications in pulmonary medicine (pulmonologists). Physician specialists who operate on the LUNGS and related structures are thoracic surgeons. This section, "The Pulmonary System," presents an overview of the structures and functions of the pulmonary system, a discussion of pulmonary health and disorders, and entries about the health conditions that can affect the lungs and related structures.

Functions of the Pulmonary System

The LUNGS bring life-giving oxygen into the body and remove toxic gaseous wastes from it. An asymmetrical pair, these spongy structures rhythmically expand and compress about 15 to 20 times a minute. Expansion, or inhalation, draws air and oxygen into the lungs; compression, or exhalation, expels carbon dioxide and other gases that are metabolic waste byproducts of cellular activity. The structures of the nasal cavity and the upper airway (THROAT) bring air, containing about 21 percent oxygen, into the body. The NOSE and SINUSES warm and moisturize the air.

Carrying that air to the lungs are the TRACHEA, bronchi, and bronchioles—a branching structure of progressively smaller airways. The air's destination is the alveoli, tiny membranous sacs that cluster grapelike at the ends of the bronchioles. A webbing of capillaries (tiny blood vessels) surrounds each ALVEOLUS, carrying erythrocytes (red BLOOD cells) waiting to receive oxygen molecules and release carbon dioxide molecules. This process, the OXYGEN–CARBON DIOXIDE EXCHANGE, gives the body life.

The lungs: asymmetry in synchronization The lungs fill the thoracic cavity from neck to DIAPHRAGM and sternum to spine. Though paired, the lungs differ somewhat in structure. The right lung is larger than the left lung, containing three lobes to the left lung's two. The left lung must accommodate the HEART, which nestles into an indentation called the cardiac notch. Some anatomists consider the small tail of tissue in the left lung that drops behind the heart, called the lingula, as a structure separate from either lobe of the left lung though most designate it a segment of the left upper lobe. Each lobe of the lung further contains structural divisions called bronchopulmonary segments, 10 among the three

lobes of the right lung and 8 among the two lobes of the left lung. A bronchial cluster—which includes bronchi, bronchioles, alveoli, blood vessels, LYMPH VESSELS, and nerves—branches into each segment.

The cells of the respiratory tract are primarily epithelial cells, the same kind of cells that make up the SKIN. The epithelial cells lining the trachea and bronchi contain cilia, tiny hairlike projections that sweep debris, such as dust and pollen, and excess mucus from the respiratory tract outward to the throat for coughs to expel them from the body. A tissue-thin membrane, the PLEURA, covers the outer surface of the lungs. The pleura secretes serous fluid to lubricate the lungs in their perpetual movement, protecting them from friction and irritation. Lung tissue is highly porous, with the substance of the lungs being about 15 percent solid tissue and 85 percent air and blood.

The heart pumps the body's full volume of blood—about five liters—through the lungs once each minute to pick up oxygen and release carbon dioxide. The blood, which flows through the lungs in a closed circuit from the heart via the PULMONARY ARTERIES and back to the heart via the PULMONARY VEINS, pulses through a dense, meshlike capillary network surrounding the alveoli. Pulmonary and cardiovascular mechanisms maintain an intricate balance between the flow of blood and the flow of air, with the blood flow constantly adjusting to flood into CAPILLARY BEDS surrounding alveoli that have strong air flow and recede from those with diminished air flow. This balance provides the greatest efficiency for getting oxygen into the bloodstream.

The bronchial tree: trachea, bronchi, bronchioles, and alveoli Like a hollow trunk, the trachea supports the treelike bronchial structure that brings air into the lungs. The trachea extends from the back of the throat about four and a half inches down to the midchest, where it branches into the right BRONCHUS and left bronchus. The spine in the back and the sternum in the front protect the trachea's path. The trachea's most vulnerable exposure is at the front of the neck, where it passes in front of the ESOPHAGUS before dropping behind the sternal notch. C-shaped bands of CARTILAGE help protect the trachea as well as give it the rigidity necessary to maintain an open passageway against ever-changing air pressures. Long fibers of smooth MUSCLE complete the posterior wall of the trachea.

The trachea terminates with the branching of the right main bronchus, going to the right lung, and left main bronchus, going to the left lung. Like the trachea, the bronchi contain smooth muscle with rings of cartilage for support and STRENGTH. The smooth muscle fibers of the trachea and the bronchi contract and expand in response to the air pressure changes of inhalation and exhalation. Each bronchus quickly divides to branch to the lung's lobes (lobular bronchi), and further subdivides into segmental bronchi, branching bronchi, and ultimately the very tiny and cartilage-free bronchioles. The alveoli cluster at the ends of the bronchioles.
