The alveoli are the work stations of the lungs, and each lung contains about 150 million of them. Each microscopic alveolus looks like a small sac; an alveolar cluster contains dozens of alveoli that bubble from the end of a bronchiole. The alveolar membrane, the thickness of a single cell, forms the interface between the pulmonary system and the cardiovascular system, allowing the oxygen and carbon dioxide molecules to cross from the air within the lungs and the blood within the capillaries. Their bunched arrangement vastly extends the surface area available for oxygen exchange within the confined space of the chest. The total surface area of the alveoli, if spread out flat, is about the size of a tennis court.

Breathing: mechanics, physics, and molecular exchange The balance between oxygen and carbon dioxide in the blood regulates pulmonary respiration (BREATHING). As carbon dioxide from cellular METABOLISM accumulates in the blood, it reaches a threshold that triggers a sequence of biochemical signals to the brainstem. The brainstem then initiates a RESPIRATORY CYCLE, sending NERVE signals that trigger the diaphragm (the flat, broad muscle that forms the base of the thoracic cavity) and the intercostal muscles (the muscles between the ribs) to contract. In response the diaphragm flattens, pulling the floor of the thoracic cavity downward. The intercostal muscles simultaneously contract to pull the ribs outward and upward. The synchronized movements enlarge the thoracic cavity, drawing air into the lungs. When the diaphragm and the intercostal muscles

relax, the thoracic cavity returns to its resting size and the lungs expel air.

With each breath the EPIGLOTTIS, a flap of cartilaginous tissue at the back of the throat, opens and closes like a valve to allow air to pass in and out of the trachea and to keep other substances (such as saliva, food, and drink) from entering the trachea and lungs. With the changing of air pressure that occurs between inhalation and exhalation, oxygen molecules migrate through the micrometers-thin membrane walls of the alveoli into the blood circulating through the capillaries that surround the alveoli. Carbon dioxide molecules cross back in exchange. The respiratory cycle repeats about 20,000 times every 24 hours, varying in rate according to the body's oxygen needs.

ALTITUDE AND OXYGEN

Though the *percentage* of oxygen in the air remains constant regardless of altitude, the *concentration* of oxygen molecules decreases as altitude increases. The concentration of oxygen molecules in the air is greater at sea level than in the mountains. At a higher altitude the LUNGS must work harder to extract enough oxygen to meet the body's needs. In the short term the body compensates by raising the RESPIRATION RATE—breathing faster. After about 72 hours at a higher altitude, the decreased concentration of oxygen in the air stimulates the BONE MARROW to produce more erythrocytes (red BLOOD cells), which increases the blood's capacity to carry oxygen.

Health and Disorders of the Pulmonary System

The lungs rhythmically pull air into and release air from the body in a choreography the BRAIN coordinates with the HEART RATE and BLOOD PRESSURE to maintain the vital supply of oxygen to tissues throughout the body. Aerobic conditioning through regular physical exercise, not smoking, and maintaining healthy weight are among the key factors that keep the lungs functioning efficiently across the span of life.

Lung capacity peaks during the 20s and gradually declines with increasing age. People who remain aerobically fit continue to have strong pulmonary function despite this decline, as their lungs still have enough reserve to meet the body's needs. People whose lifestyles are sedentary are more likely to experience a decline in lung capacity, apparent in shortness of breath when climbing stairs, when walking distances, or with sudden bursts of physical exertion.

The lungs are subject to few BIRTH DEFECTS. Congenital disorders of the lungs include hereditary disorders, such as CYSTIC FIBROSIS, and conditions resulting from prematurity or inadequate development of the lungs before birth, such as chronic lung disease of infancy. Cardiovascular anomalies, notably structural malformations such as transposition of the great arteries (TPA) or hypoplastic left heart syndrome (HLHS), affect the integration of function between the heart and the lungs.

Cigarette smoking, CARDIOVASCULAR DISEASE (CVD), and long-term exposure to irritants such as industrial chemicals are the leading causes of acquired pulmonary disease. Because the lungs face continual exposure to external pathogens, they are vulnerable to viral, bacterial, and fungal invaders. Immune cells—notably lymphocytes, macro-phages, and neutrophils—reside within the walls of the bronchi, detecting and eliminating most pathogens before they can cause localized INFECTION. However, those that slip through the body's defense mechanisms can cause serious diseases such as PNEUMONIA (viral or bacterial).

HEALTH CONDITIONS THAT CAN AFFECT THE STRUCTURES OF THE PULMONARY SYSTEM

ANTHRACOSIS	APNEA
ASBESTOSIS	ASPERGILLOSIS
ASPIRATION	ASTHMA
ATELECTASIS	BERYLLIOSIS
BRONCHIECTASIS	BRONCHITIS
BYSSINOSIS	CHRONIC OBSTRUCTIVE
CYSTIC FIBROSIS	PULMONARY DISEASE (COPD)
LEGIONNAIRES' DISEASE	INTERSTITIAL LUNG DISORDERS
LUNG CANCER	LUNG ABSCESS
Pneumocystis carinii	PLEURISY
PNEUMONITIS	PNEUMONIA
PULMONARY EDEMA	pulmonary congestion
PULMONARY FIBROSIS	PULMONARY EMBOLISM
RESPIRATORY FAILURE	PULMONARY HYPERTENSION
tuberculosis	SILICOSIS

Inefficient cardiovascular function places significant strain on pulmonary function, influencing

the respiratory rate as well as pressuring the network of blood vessels within the lungs to cause conditions such as PULMONARY HYPERTENSION. Congestive HEART FAILURE develops when the heart is not strong enough to pump blood throughout the body, allowing fluids to seep from the bloodstream and into the interstitial spaces in the lungs. The resulting pulmonary congestion and PULMONARY EDEMA fills the lungs with fluid, restricting the oxygen–carbon dioxide exchange. Exposure to environmental irritants and toxins also can damage the lungs, particularly as a cumulative effect over time, causing repeated INFLAMMATION that can result in SCAR formation (fibrosis).

Traditions in Medical History

Ancient Western and Eastern medical traditions alike correlated the function of the lungs with the role of bringing life-giving air, and the NUTRIENTS it bears, into the body. Greek physician Galen (129–199), whose views framed the perceptions and practices of medicine for nearly 1500 years, postulated the lungs took in and digested air, after which the pulmonary VEIN carried the resulting "vapors" to the heart. Though this hypothesis held the correct intent, its details were enough skewed to thwart genuine understanding of cardiopulmonary circulation for centuries.

The concepts of cardiovascular circulation and pulmonary function finally began to converge with William Harvey's detailed monograph, *Exercitatio Anatomica De Motu Cordis et Sanguinis in Animalibus*, published in 1628. This work, whose title translates as *A Treatise on the Movement of the Heart and Blood in Animals*, provided the first definitive description of the circulation of the blood through the heart, lungs, and blood vessels. Harvey failed to identify the capillary beds and their role in oxygen–carbon dioxide exchange; yet his work established the foundation for later researchers to make this and other discoveries about lung function.

Once physicians understood the basic functioning of the lungs, heart, and blood, they could begin to find the causes of the diseases that disrupted these functions, often with debilitating or fatal results. Throughout documented history, TUBERCULOSIS—consumption, as early cultures called this infection that appeared to "consume" its sufferers—has reigned as one of the most devastating diseases known to afflict humankind. The disease causes inflammation, granulation, and calcification within the inner structures of the lungs, permanently destroying lung tissue. Unchecked, tuberculosis spreads within the infected person to fully involve the lungs and often other organs such as the KIDNEYS, spinal fluid, and bones. Early explanations for tuberculosis, which accounted for about 1 in every 20 deaths across centuries and civilizations, ranged from dietary habits such as eating meat and drinking liquor to environmental exposures such as foul weather and smoke from burning fires. In fact, however, tuberculosis spreads among people through contact with bacteria in the SPUTUM (the mucus, fluids, and debris coughed from the lungs) of those who are infected.

Ancient Egyptian mummies demonstrate BONE damage characteristic of tuberculosis. Even famed Western physician of antiquity and Galen's predecessor Hippocrates (460–400 B.C.E.) wrote of the physical wasting that accompanied tuberculosis and warned against close contact, even by physicians, with those in the end stages of the disease. Not for nearly two millennia after him, however, did physicians make the connection between close contact and the contagiousness of tuberculosis. In 1882 microbiologist Robert Koch (1843–1910) discovered the responsible bacillus, *Mycobacterium tuberculosis*, turning the corner toward finding a true cure for the infectious and debilitating disease. Though a cure was still another 60 years away, isolating those who were ill became the trend. Doctors sent those afflicted with tuberculosis to sanatoriums where fresh air, rest, and nutritious meals formed the core of treatment. It was enough for some, though not most, people to recover or at least to send the disease into inactivity—and it separated the infectious from the healthy, helping slow contagion. Some people underwent more dramatic therapies, such as intentional collapse of the infected lung, to try slow the progression of the disease by starving the tissue of oxygen.

In 1943 biochemist Selman Waksman was able to isolate and cultivate an effective antibiotic, streptomycin, to kill *M. tuberculosis* without also killing the person this stubborn PATHOGEN infected. By the early 1960s researchers had developed a regimen of multiple antibiotics to successfully cure

tuberculosis, and over the next 20 years tuberculosis dramatically subsided in developed countries. Tuberculosis resurfaced as a significant health threat with the emergence of HIV/AIDS in the 1990s, however, with new strains of the bacillus that were resistant to previously successful antibiotics. New generations of antibiotics have become available, though *M. tuberculosis* continues to mutate into resistant forms. Today, this destructive infection of the lungs persists.

With the advent of modern industrialization came a surge of induced diseases, many of which exposed the lungs to various particulates such as coal dust (miner's lung), silica (grinder's rot), and plant fibers (mill FEVER). These and other occupational lung diseases have disabled and killed millions of people through the centuries and continue to threaten health even today despite precautions to reduce the risks of exposure.

Miner's lung (ANTHRACOSIS), also called black lung, once disabled nearly every coal miner who worked longer than a few years in the mines and today remains a significant occupational disease threat. SILICOSIS, long a risk for workers in occupations with exposure to sand dust, appears in the lungs of mummies from ancient Egypt, a consequence of the intensely blowing sands of the region, and in the lungs of contemporary workers in quarries, potteries, and industries that use sandblasting. Although new exposures to asbestos are uncommon, the long time from exposure to the development of disease means symptoms arise in people today whose exposure through employment (such as shipbuilding or insulation work) took place decades ago. Though not as common as before modern ventilation and dust control mechanisms became commonplace, long-term inhalation of cotton fibers by textile workers results in BYSSINOSIS—mill fever.

Today lung disease related to industrial practices remains a key component of public health. The use of respirators, exhaust venting, and exposure limitations helps reduce, but does not completely prevent, occupational lung diseases. Some of these conditions are treatable; others are progressive or cause permanent damage. General air pollution resulting from industrial and motor vehicle exhaust accounts for much ASTHMA, chronic BRONCHITIS, PNEUMONITIS, and other ailments of the lungs. ENVIRONMENTAL CIGARETTE SMOKE (secondhand smoke) has further emerged as a dangerous and potentially lethal toxin of exposure. The air that bears life-giving oxygen also transports, sometimes unknowingly, the agents of lung damage.

Breakthrough Research and Treatment Advances

The unraveling of the human GENOME has produced significant breakthroughs in understanding and treating health conditions affecting all body systems. Key discoveries related to pulmonary disorders have in particular improved treatment for CYSTIC FIBROSIS, once a disease that claimed the lives of its victims before they reached ADOLESCENCE. Today it is more common than not for those who have cystic fibrosis to enjoy reasonable QUALITY OF LIFE into their early 30s, with new treatments based on GENE THERAPY showing great promise for arresting the progress of this debilitating genetic disorder. LUNG TRANSPLANTATION is emerging as a promising, viable treatment for end-stage pulmonary disease resulting from disorders such as cystic fibrosis, pulmonary hypertension, CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD), and PULMONARY FIBROSIS.

A

acute respiratory distress syndrome (ARDS) A complex of symptoms, formerly called adult respiratory distress syndrome, in which respiratory distress and RESPIRATORY FAILURE develop accompanying severe illness or trauma. ARDS involves the whole of both LUNGS, as the lungs become inflamed and fill with fluid. ARDS may develop as a consequence of injury that directly affects the lungs (notably blunt trauma to the chest, near drowning, PNEUMONIA, and smoke inhalation) or when the injury or illness affects other parts or systems of the body. Systemic INFECTION (SEPSIS), DRUG OVERDOSE, and BLOOD TRANSFUSION may also result in ARDS. ARDS can affect people of any age and is life-threatening. Because people who develop ARDS are already very ill, ARDS has a high death rate (about 40 percent). The syndrome may cause complete respiratory failure or lead to total system failure, either of which presents significant challenge for recovery.

Symptoms and Diagnostic Path

People who develop ARDS have generally sustained severe trauma or infection and most are already in the hospital when their symptoms begin. Early symptoms of ARDS include restlessness, TACHYPNEA (rapid, shallow breathing), and HYPOXIA (reduced oxygen to the body's tissues). ARDS progresses rapidly to full involvement of the lungs. Chest X-rays show the filling of the lungs with INFLAMMATION and fluid (called diffuse infiltration). Arterial BLOOD gases show the decreased percentage of oxygen in the blood. Doctors often perform tests on SPUTUM and fluid from the lungs to identify any pathogens, notably BACTERIA, that may be present.

Treatment Options and Outlook

Immediate oxygen supplementation is essential. Many people require MECHANICAL VENTILATION with positive end expiratory pressure (PEEP) to increase the amount of oxygen entering the lungs. Doctors generally administer sedation while the person is on mechanical ventilation, to provide comfort and to prevent the natural tendency to fight the intervention. Treatment primarily is supportive, including close monitoring of cardiovascular and renal (kidney) functions. Because infection, either in the lungs or elsewhere in the body, is often present, many people may also receive intravenous (IV) ANTIBIOTIC MEDICATIONS.

The outlook for full recovery depends on numerous factors including the person's age, general health status, and the ability to reverse the circumstances responsible for the initial development of ARDS. Even medical intervention that begins early in the course of ARDS cannot predict the success of treatment. About 60 percent of people survive the ARDS episode, though the severity of illness can require extensive recuperation.

Risk Factors and Preventive Measures

The primary risk factors for ARDS are sepsis (severe infection) and major trauma, either to the lungs or to the body in general. Though such infection or trauma alerts doctors to the grave risk for ARDS, there are no known measures that can head off the development of ARDS. Public health measures to minimize the risk factors (trauma and infection) are critical. Once ARDS occurs, however, aggressive medical intervention and support provide the best chance for survival.

See also HEART FAILURE; SEVERE ACUTE RESPIRATORY SYNDROME (SARS).

aging, pulmonary changes that occur with The LUNGS and tracheobronchial structures undergo few but significant changes over the course of the life-

span. From moments after birth to near the end of life the lungs function continuously and consistently, bringing air into the body to deliver oxygen to the BLOOD and carrying air out of the body to eliminate carbon dioxide and other gaseous metabolic wastes from the body. The entire respiratory process—BREATHING and oxygenation—takes place under the regulation of the brainstem, without conscious awareness or control.

Before birth, though the lungs go through the movements of breathing they do not oxygenate the fetus's blood. Rather, the fetus draws its oxygen from the mother's blood through the PLACENTA where oxygen molecules migrate across the capillary membranes from the mother's blood supply to the fetus's blood supply. Differences in the cardiovascular system of the fetus further support this mechanism of oxygenation. In the unborn child the HEART shunts blood from the right atrium to the left atrium through an opening in the atrial septum (wall of muscle that separates the right atrium and the left atrium) called the foramen ovale. Blood also passes from the PULMONARY ARTERIES to the AORTA through an opening called the ductus arteriosus, bypassing the lungs.

The newborn's first breath fills the lungs with air, setting in motion a sequence of events that results in the closure of these openings in the heart and the rerouting of blood flow from the right side of the heart to the lungs and from the lungs to the left side of the heart. As the lungs fully expand after a few breaths, they take over complete responsibility for oxygenating the body. The lung tissue produces a chemical called surfactant, a fluid that coats the inner layer of the lung surfaces to maintain appropriate surface tension to keep the alveoli from collapsing with each exhaled breath, much in the same fashion moisture inside a balloon keeps the walls of the balloon from sticking together when the balloon deflates. These changes may lag in an infant born prematurely, giving rise to breathing and oxygenation difficulties until the lungs can more fully develop.

The lungs continue to function in the same responsibility for the remainder of life, with few changes beyond growing as the body grows. Lung capacity (the ability of the lungs to hold air) and diffusing capacity (the ability of the lungs to transfer oxygen to the blood) peak in the early 20s, after which both slowly but steadily decline until by about age 75 they are roughly half what they were at age 25. Beginning at age 35, lung capacity diminishes about 5 percent every 10 years. In the 50s the muscles of breathing begin to stiffen and lose resilience, though in counterbalance changes within the lungs and airways occur to reduce the resistance air encounters during inhalation. Regular aerobic CONDITIONING throughout life can offset many of the functional implications of these changes, allowing strong pulmonary performance well into the 70s or beyond.

The health conditions affecting the lungs before age 30 tend to be acute (of sudden onset and contained duration), often INFECTION such as viral or bacterial BRONCHITIS, pleuritis, and PNEUMONIA. Chronic (ongoing) health conditions affecting the lungs become increasingly common with advancing age, in part because the natural changes in the lungs may precipitate them and in part because other health situations or environmental factors begin to have cumulative consequences.

CARDIOVASCULAR DISEASE (CVD), which becomes more common in middle age and beyond among both men and women, can have as much effect on the structures and functioning of the pulmonary system as do conditions of the lungs. HEART FAILURE, in which the heart cannot pump enough blood to meet the body's oxygen needs, allows fluid to back up into the lungs. The resulting circumstances, pulmonary congestion and PULMONARY EDEMA, flood the alveoli and prevent them from conducting the OXYGEN–CARBON DIOXIDE EXCHANGE. Chronic HYPERTENSION (high BLOOD PRESSURE) diminishes the elasticity of all arteries in the body, including the pulmonary arteries. The resulting stiffness and inflexibility of the arteries can contribute to or exacerbate cardiovascular conditions such as heart failure. Other forms of cardiovascular disease may result in PULMONARY HYPERTENSION, increased pressure within the pulmonary arteries that damages the smaller arteries within the lungs.

External factors also influence pulmonary health throughout life. Cigarette smoking is the single-most destructive exposure the lungs typically face, causing an extremely high risk for progressive disorders such as CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD) and especially for LUNG CANCER. Cigarette smoking accounts for 85 percent

of lung cancer in the United States. Over time breathing exposes the respiratory tract to numerous insults from substances such as environmental pollution, viruses, BACTERIA, pollens, dust, and other materials. These exposures may injure or damage the lungs, resulting in conditions such as ASTHMA, PNEUMONITIS, bronchitis, and pneumonia, as well as infections such as TUBERCULOSIS and INFLUENZA. Such pulmonary conditions can contribute to deteriorating lung functions, particularly in people who have not maintained adequate AEROBIC FITNESS.

Maintaining a steady level of AEROBIC FITNESS through regular physical activity keeps the pulmonary system as healthy as possible for as long as possible, helping offset the changes of advancing age. Aerobic fitness enables the lungs to efficiently extract oxygen from the air and conduct it into the bloodstream. As well, the lungs fill more fully with air on each inhalation, keeping the alveoli open and functioning. This helps keep fluid from accumulating within the alveoli.

alveolus A tiny, thin-walled sac, grouped in clusters at the ends of the smallest airways (bronchioles) deep inside the LUNGS, that is the terminus for each breath of air. A dense mesh of capillaries entwines each alveolus. Oxygen from the air within the alveolus passes across the alveolar membrane to enter the bloodstream, while carbon dioxide and other waste gases pass across the membrane from the BLOOD to the air within alveolus. The clustered formations of the alveoli greatly increase the surface area for OXYGEN–CARBON DIOXIDE EXCHANGE. Each lung contains about 300 million alveoli, which, if spread out, would coat the surface of a tennis court—about 290 square feet. The large surface area is important but so is the very thin interface between the airway and the blood vessel. Many disease states cause this barrier to thicken or distort, which impedes the exchange of oxygen and carbon dioxide (called decreased diffusing capacity).

For further discussion of the alveolus within the context of pulmonary structure and function please see the overview section "The Pulmonary System."

See also BRONCHUS; HEMOGLOBIN; TRACHEA.

anthracosis A lung condition resulting from long-term exposure to coal dust, also called coal worker's PNEUMONOCONIOSIS (CWP) and black lung disease. There are two types of anthracosis: simple and complicated. In simple anthracosis the coal dust coats the LUNGS in wide distribution, and the IMMUNE RESPONSE encapsulates the dust particles without causing scarring (fibrosis). This is the most common type of anthracosis and may generate no symptoms or mild symptoms such as DYSPNEA (shortness of breath) with exertion and chronic COUGH. The doctor may detect simple anthracosis during routine medical examination or screening for lung disease. Diagnosis generally considers X-RAY findings in combination with history of exposure to coal dust. The doctor may also conduct BRONCHOSCOPY to examine the inner bronchial structures, which have a characteristic black appearance.

Complicated anthracosis becomes aggressively fibrotic, though doctors do not know what causes it to do so. It continues to progress even after exposure ends, and may result in disabling obstructive lung disease. Symptoms include worsening cough and dyspnea. About 15 percent of coal workers who have simple anthracosis develop complicated anthracosis.

Improvements in mining techniques and conditions, including environmental filtration systems, have greatly reduced the amount of dust coal mining operations produce. Those who work as cutters, loaders, and continuous mining operators face the highest risk for exposure. In the United States, the Occupational Safety and Health Administration (OSHA) regulates permissible levels of dust and worker exposure. Diagnosis of new cases of anthracosis is steadily declining as a result. Federal health programs provide medical care and other benefits for coal workers who have anthracosis.

See also ASBESTOSIS; BERYLLIOSIS; BYSSINOSIS; CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD); SILICOSIS.

apnea The temporary and involuntary cessation of BREATHING. Apnea may result from neurologic

causes (central apnea), mechanical causes (obstructive apnea), or a combination of both. Central apnea is more common in premature infants, whose nervous systems are not fully developed, and the very elderly, whose nervous systems may be failing. Central apnea is also more common in people who have underlying neurologic disorders or who have heart failure. Obstructive apnea may occur in children who have greatly enlarged tonsils or adenoids and in individuals who have OBESITY. Some people have irregular breathing patterns that are, for them, normal. A doctor should evaluate irregularities in breathing to determine whether the circumstances merit medical intervention.

Most people who have apnea are unaware of apneic episodes, though others who observe them may become alarmed (especially parents or caregivers who notice apnea in young children). Recurrent apnea that occurs during sleep, called OBSTRUCTIVE SLEEP APNEA, is a serious health condition that disrupts the sleeping patterns and results in sleep deprivation though most people are not aware of this because they do not have conscious recollection of the apneic episodes. Researchers believe that severe and persistent obstructive sleep apnea contributes to cardiovascular conditions such as HEART FAILURE.

The diagnostic path includes careful analysis of apnea patterns, taking into consideration the person's age, the onset of the apnea, and adverse effects that may result (including effects resulting from sleep deprivation). The pulmonologist may conduct pulmonary function tests, BLOOD tests to measure levels of erythrocytes (red blood cells) and HEMOGLOBIN in the blood, and X-rays or other diagnostic imaging procedures to look for obstructive causes. A comprehensive NEUROLOGIC EXAMINATION, including ELECTROENCEPHALOGRAM (EEG), may reveal the cause of central apnea.

Treatment targets the underlying cause of the apnea. For some people, surgery to remedy the cause of an obstruction may provide long-term relief (such as TONSILLECTOMY and ADENOIDECTOMY in children who have enlarged tonsils and adenoids). Central apnea that results from damage to the brainstem or other underlying neurologic disorder can be difficult to treat. Oxygen therapy alone may help with some central apneas.

asbestosis Damage to the LUNGS resulting from inhalation of asbestos fibers. During the first half of the 20th century asbestos, a natural substance mined from underground, became common in insulating materials because of its natural heat resistance. In the 1950s researchers linked chronic asbestos inhalation with PULMONARY FIBROSIS and a rare form of LUNG CANCER, mesothelioma, found almost exclusively in people with asbestos exposure. In the 1970s the United States implemented strict regulations that prohibited the use of asbestos in many of its formerly common applications. For people who had occupational exposure to asbestos before these restrictions, however, asbestosis is a significant risk. Millions of Americans live with asbestosis and hundreds die each year from it or from lung cancer associated with asbestos exposure.

Asbestos fibers embed in the tissues of the lungs, causing INFLAMMATION and granulation that eventually leads to fibrosis (SCAR tissue formation). Some forms of asbestos are more hazardous than others. Typically lung damage from asbestos takes 20 years or longer after exposure to manifest. The likelihood of developing health consequences from asbestos exposure correlates directly to the amount of asbestos and the duration of the exposure. Cigarette smokers face increased risk, particularly of lung cancer, as the asbestos and the carcinogenic chemicals in cigarette smoke potentiate each other (intensify each other's actions in the lungs).

Symptoms and Diagnostic Path

Many people do not show symptoms of asbestosis until the damage is fairly advanced. Because of this, health experts recommend people with known asbestos exposure receive annual examinations to monitor the health of their lungs. When symptoms manifest they typically include

- DYSPNEA (difficulty BREATHING) with physical exertion
- dry (nonproductive) COUGH
- chest discomfort, tightness, or PAIN

The diagnostic path includes comprehensive work and health histories, physical examination including AUSCULTATION, chest X-rays, and sometimes other diagnostic imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI). Finger clubbing, in which the ends of the fingers become thick, rales (crackling BREATH SOUNDS), and CYANOSIS (bluish hue to the lips and SKIN that signals inadequate oxygenation) are common signs of lung damage typical of lung diseases such as asbestosis. Doctors assign a numeric classification from grade 0 to grade 4 to indicate the severity of damage, along with letter designations A, B, or C to identify the extent of lung structure affected.

Treatment Options and Outlook

Treatment for asbestosis is largely supportive, as it is not possible to remove the fibers once they embed in the lungs. SMOKING CESSATION is of prime importance, as cigarette smoking in combination with asbestos exposure greatly increases the likelihood of lung cancer. Treatment also targets specific concerns or other problems as they arise. Generalized efforts to promote pulmonary health, such as BREATHING EXERCISES and regular physical activity to improve AEROBIC CAPACITY, increase the efficiency of undamaged lung tissue.

Because the latency period (time between exposure and symptoms) is so long, damage to the lungs can be quite extensive by the time symptoms become apparent. People who know they have had exposure to asbestos should have regular pulmonary examinations to monitor for asbestosis. Though asbestosis can be fatal, many people live without significant complications due to the condition. The most significant consequence of asbestosis is lung cancer, including mesothelioma, a type of lung cancer that only occurs with asbestos exposure.

Risk Factors and Preventive Measures

Asbestosis only occurs as a consequence of asbestos exposure, so eliminating exposure eliminates the risk of developing the condition. Preventive measures for those who continue to have occupational exposure include appropriate protective clothing and respirators.

See also ANTHRACOSIS; BERYLLIOSIS; BYSSINOSIS; LIVING WITH CHRONIC PULMONARY CONDITIONS; SILICOSIS; SMOKING AND PULMONARY DISEASE.

aspergillosis An opportunistic fungal (yeast) INFECTION that can manifest as PNEUMONIA in people who have HIV/AIDS, are undergoing CHEMOTHERAPY to treat cancer, receive IMMUNOSUPPRESSIVE THERAPY

ASBESTOSIS SEVERITY

Grade	Severity	Extent of Lung Damage
grade 0	asymptomatic	asbestos fibers present but no fibrosis
grade 1	mild damage	fibrosis limited to bronchi and bronchioles, no alveolar involvement
grade 2	moderate damage	fibrosis extends to alveoli
grade 3	serious damage	fibrosis extends between alveolar clusters
grade 4	severe damage	fibrosis obliterates alveoli, replacing them with honeycombed SCAR tissue
grade a	mild involvement	scattered bronchial structures are involved
grade B	moderate involvement	fewer than half the bronchial structures are involved
grade C	severe involvement	greater than half the bronchial structures are involved

after ORGAN TRANSPLANTATION, or are otherwise IMMUNOCOMPROMISED. Aspergillosis may also occur as an allergic reaction (called allergic bronchopulmonary aspergillosis or ABPA) in people who have ASTHMA or CYSTIC FIBROSIS, causing airway INFLAMMATION and fluid accumulation in the LUNGS. *Aspergillus*, the infective FUNGUS, is common in the environment, especially in decaying vegetation and in the soil, and in air ventilation ducts in buildings. Hospitals also harbor *Aspergillus*, so aspergillosis can develop as a nosocomial infection. Occasionally aspergillosis takes the form of an encapsulated ball, called an aspergilloma or a mycetoma, that forms within a pocket of healed SCAR tissue from previous damage to the lung such as may remain from TUBERCULOSIS or SARCOIDOSIS.

Symptoms and Diagnostic Path

Symptoms of aspergillosis vary widely and may not appear at all unless the fungus establishes itself within the lungs in a widespread pattern. When symptoms are present they typically include

- HEMOPTYSIS (bleeding from the lungs that appears in the SPUTUM or coughing up BLOOD)
- CHEST PAIN
- FEVER
- COUGH
- rapid or difficult BREATHING (DYSPNEA)

The doctor also may suspect aspergillosis in a person who has been receiving treatment for an apparent bacterial infection without any improvement in symptoms. The diagnostic path typically begins with a chest X-RAY, which shows whether there are infiltrates or obstructions in the lungs. COMPUTED TOMOGRAPHY (CT) SCAN often can provide more detailed visualization of lung structures and anomalies. Though imaging results are not conclusive, they provide leading clues to suggest or rule out aspergillosis. Because aspergillosis spores are so common in the environment, sputum cultures are not usually helpful in making the diagnosis as nearly everyone's sputum is likely to contain some *Aspergillus*. BRONCHOALVEOLAR LAVAGE, in which the pulmonologist rinses cell samples from the walls of the bronchi during BRONCHOSCOPY, or biopsy to obtain tissue samples, may provide more accurate culture results. The individual's health history also plays a key role in making the diagnosis.

Treatment Options and Outlook

Invasive aspergillosis is life-threatening and requires treatment with intravenous (IV) ANTIFUNGAL MEDICATIONS such as amphotericin B, itraconazole, or voriconazole. Recovery depends on the IMMUNE SYSTEM's ability to rally against the infection. In people who are immunocompromised, the challenge may be overwhelming. In such situations aspergillosis can have serious and even fatal consequences. However, most people fully recover with appropriate treatment. Aspergillomas may require surgery to remove them when they cause bleeding (evident as hemoptysis), pain, or difficulty breathing. CORTICOSTEROID MEDICATIONS such as prednisone are usually effective in relieving the symptoms of ABPA, which is an immune reaction to the presence of *Aspergillus,* common in people who have asthma, rather than an invasive infection with the fungus.

Risk Factors and Preventive Measures

People who are taking immunosuppressive therapy, such as after organ transplantation, or who are immunocompromised are vulnerable to invasive aspergillosis because their immune systems cannot fend off this ordinarily innocuous fungus. Aspergillosis is also a risk for people who have HIV/AIDS. Though there are no measures for preventing aspergillosis, those who are susceptible to this fungal infection can minimize the severity of disease by seeking medical diagnosis and treatment at the earliest indication of disease.

See also BRONCHIECTASIS; NEUTROPENIA.

asphyxia The inability of the LUNGS to take in air or conduct the OXYGEN–CARBON DIOXIDE EXCHANGE, depriving the body of oxygen.

Asphyxia is a life-threatening emergency that requires immediate medical treatment.

Asphyxia may occur as a consequence of water or other fluids in the lungs (drowning) that results in suffocation (inability of air to enter the lungs), carbon monoxide poisoning, trauma to the TRA-

CHEA (windpipe), injury to the brainstem affecting the NERVOUS SYSTEM signals that regulate breathing, compression of the neck or chest, electrical shock, cardiovascular collapse, and other circumstances that interfere with BREATHING. A person experiencing asphyxia may require immediate CARDIOPULMONARY RESUSCITATION (CPR) until medical care is available.

See also HYPOXIA.

aspiration Drawing foreign matter, often food or drink, into the airways (TRACHEA and bronchi). The COUGH REFLEX typically activates to expel the matter, though may not succeed if inhalation draws the matter deep into the respiratory tract or the cough reflex is weak. Food, drink, and other substances that coughing does not expel can lodge in the airway to create a partial or complete obstruction.

Aspiration is potentially life-threatening and may require emergency intervention such as the HEIMLICH MANEUVER. A doctor should evaluate the condition of the LUNGS when aspiration occurs.

Material that makes its way deep into the LUNGS is likely to draw BACTERIA and fluid to the site, establishing inflammation, edema, PNEUMONIA, or LUNG ABSCESS. Physical movement such as sitting, standing, and walking may help the respiratory tract propel the substance outward, while inactivity allows the matter to settle into the lungs. Near drowning often results in aspiration of water into the lungs.

A chest X-RAY typically shows the site of INFLAMMATION and fluid collection. Treatment may require BRONCHOSCOPY to retrieve the object and ANTIBIOTIC MEDICATIONS to treat INFECTION. Aspiration pneumonia is a potentially serious condition, particularly in the elderly, infants, and debilitated people who cannot easily move around or who may have trouble with the natural mechanisms that protect the airway, resulting in foreign matter getting into the lungs. Aspiration pneumonia develops when the accumulated fluid becomes infected or interferes with the ability of the lungs to oxygenate the BLOOD.

See also BRONCHUS.

asthma A disease of the airways that results in narrowing of the airways (bronchospasm) and INFLAMMATION in response to a wide range of inhaled irritants such as pollen, mold, smoke, chemicals, and the airborne debris of pests ranging from cockroaches to microscopic dust mites. This narrowing, or airflow obstruction, is usually reversible when the person can eliminate the exposure or through treatment with medications called bronchodilators. Repeated exposure to irritants in susceptible people can result in repeated episodes of inflammation. This pattern can ultimately cause scarring of the airways that is not reversible.

Nearly 18 million Americans have asthma, a third of whom are under age 18. For many of them asthma attacks are mild and infrequent, giving the perception that asthma is a common and, though annoying, harmless condition. However, life-threatening consequences can occur during a severe asthma attack. If the person does not receive rapid and effective treatment, the airway narrowing and inflammation can completely block the flow of air. The person cannot exhale (breathe out) fully, lowering oxygen levels and potentially causing death. Nearly 5,000 Americans die each year as a consequence of asthma or its complications.

Symptoms and Diagnostic Path

An asthma attack generally follows a pattern of symptoms that, though it varies among people who have asthma, tends to be consistent for each individual. Some people first experience DYSPNEA (shortness of breath) or wheezing (a high-pitched whistling sound with exhalation), for example, while other people find a restless night with frequent waking foreshadows an asthma attack that manifests the following day. Common symptoms of asthma attacks include

- dry, nonproductive COUGH
- sense of tightness in the chest
- dyspnea, especially during physical activity
- wheezing
- gasping for air

There are no definitive tests for asthma. The diagnostic path may include tests and procedures,

such as chest X-RAY and complete BLOOD count (CBC), to rule out other causes of symptoms. The pulmonologist will conduct pulmonary function tests to measure the flow and volume of air, typically before and after administration of a bronchodilator medication that relaxes and opens the airways. People who have asthma generally have much improved pulmonary function test results after the bronchodilator, even when they are having no symptoms of asthma at the time of testing. However, the reverse can also be true and the person has normal breathing tests during a time of no symptoms. In such cases, the pulmonologist may conduct a test called a methacholine challenge, administering the DRUG methacholine to see whether it initiates a mild hypersensitivity reaction. A positive response (symptoms appear) is fairly conclusive of an asthma diagnosis.

Treatment Options and Outlook

Treatment for many people who have asthma is a combination of medications to prevent symptoms (long-acting, controller medications) and to provide immediate relief from symptoms that occur (short-acting, rescue medications). Medication regimens vary with the step (classification) and nature of symptoms. Commonly prescribed medications include

- inhaled (and occasionally oral) CORTICOSTEROID MEDICATIONS, which are anti-inflammatory and serve as long-term controller medications
- inhaled and oral beta-2 agonists, which are bronchodilators and may provide short-acting or long-acting relief
- leukotriene modifiers, which are IMMUNE RESPONSE mediators that provide long-term control

The mainstay of asthma treatment is baseline control of the inflammation with long-acting medications. For some people, ALLERGY DESENSITIZATION (when allergy reaction is the clear cause of the asthma) provides further control. Other important steps for managing asthma long-term include monitoring asthma symptoms (such as with peak flow monitoring) and developing an action plan for asthma control. When there is an acute exacerbation of symptoms (an asthma attack), treatment is most likely to succeed when it begins in advance of or immediately on recognition of symptoms. Once an asthma attack is under way, even rescue medications may take time to bring the situation under control.

Lifestyle factors for managing asthma include avoiding known triggers and allergens. Three of the most common triggers are allergic RHINITIS, chronic SINUSITIS, and GASTROESOPHAGEAL REFLUX DISORDER (GERD). Regular physical exercise, though for some people a trigger for asthma attacks, generally improves lung capacity, pulmonary efficiency, and AEROBIC FITNESS. Air-conditioning helps reduce humidity in the air and filter the air of particulates that may cause irritation or exacerbate asthma symptoms. It is important to regularly change the air filters for central heating and cooling systems. ACUPUNCTURE treatments are helpful for reducing the frequency and severity of asthma attacks in some people.

ASTHMA CLASSIFICATION

Classification	Severity	Frequency of Symptoms Without Treatment
step 1	mild intermittent	symptoms occur two days or less each week and two nights or less each month
step 2	mild persistent	symptoms occur up to five days each week and up to five nights in a month
step 3	moderate persistent	symptoms occur at least once during every day and several nights a week
step 4	severe persistent	symptoms occur throughout the day, every day, and most nights

MEDICATIONS TO TREAT ASTHMA

Type of Medication	Common Products	Type of Relief	Asthma Classification
beta-2 agonists, inhaled	albuterol (Airet, Proventil, Ventolin), bitolterol (Tornalate), pirbuterol (Maxair)	short-acting rescue	steps 1, 2, 3, or 4
beta-2 agonists, oral	long-acting: salmeterol (Serevent), albuterol extended release (Volmax, Proventil Repetabs) short-acting: terbutaline (Brethine, Bricanyl)	long-acting: controller medication, especially at night short-acting: rescue	steps 2, 3, and 4
corticosteroids, inhaled	beclomethasone (Qvar, Vanceril), budesonide (Pulmicort), flunisolide (AeroBid), fluticasone (Flovent), triamcinolone (Azmacort)	long-acting controller medication	steps 2, 3, and 4
corticosteroids, oral	methylprednisolone (Medrol), prednisone (Deltasone, Orasone), prednisolone (Prelone)	short-acting controller medication for symptoms that do not respond to other medications rescue	steps 3 and 4
leukotriene modifiers, oral	zafirlukast (Accolate), zileuton (Zyflo)	long-acting controller medication	steps 3 and 4, occasionally step 2
other, inhaled	ipratropium (Atrovent), cromolyn (Intal), nedocromil (Tilade)	short-acting rescue prophylactic when used before intense physical exercise	steps 3 and 4
other, oral	theophylline (Theo-Dur, Theolair, Aerolate, Slo-Phyllin)	long-acting	step 3, occasionally step 2

Risk Factors and Preventive Measures

The key risk factor for asthma attack is exposure to a substance that initiates a hypersensitivity reaction. Most people can easily identify these substances after experiencing a few asthma attacks, and avoiding exposure to known allergens significantly reduces attacks. A wide range of irritants can cause asthma attacks in many people, however, making it impossible to avoid exposure. As well, for some people triggers for asthma attacks include emotional stress and physical exertion, common elements of everyday life.

Health experts have identified a number of factors that appear to increase an individual's risk for developing asthma. Key among them are

- living in cities, where the concentration of particulate pollutants in the air is high
- family history of asthma
- recurrent upper respiratory INFECTION as a child
- cigarette smoking or exposure to ENVIRONMENTAL CIGARETTE SMOKE

- long-term or repeated exposure to chemicals such as cleaning solutions, paints, industrial chemicals used in manufacturing, pesticides and herbicides, and aerosols
- presence of ALLERGIC RHINITIS, atopic DERMATITIS, or chronic SINUSITIS

Viral infections, physical exertion such as with exercise, cold air, sulfite preservatives (common in some foods), some medications, and GASTROESOPHAGEAL REFLUX DISORDER (GERD) also may trigger asthma attacks. Researchers do not know why some people develop hypersensitivity reactions to certain substances while other people, even though their immune systems similarly create antibodies, experience normal reactions. Though researchers believe there are likely genetic factors that underlie allergies, they have yet to isolate them.

atelectasis The collapse of a segment or lobe of the lung, or an entire lung. Atelectasis is fairly common and most often spontaneously corrects itself for full recovery. The collapse may result from obstruction, structural damage to lung tissue, fibrosis that destroys bronchial segments, PNEUMOTHORAX, PLEURAL EFFUSION, and other causes. A form of chronic atelectasis, right middle lobe syndrome, results from chronic INFLAMMATION of the LYMPH nodes near the area, which are beneath the right lung's middle lobe. A common cause of atelectasis is taking shallow breaths, which is common in people coming out of ANESTHESIA but still sedated after surgery or who have abdominal or chest wall pain.

Symptoms and Diagnostic Path

Symptoms of atelectasis vary with the rate of onset and the extent of lung area involved. Rapid collapse may cause sharp PAIN and sudden DYSPNEA and may also cause severe COUGH. Chronic atelectasis or atelectasis that develops gradually may produce few symptoms, though many people develop a persistent, nonproductive cough.

The diagnostic path begins with careful AUSCULTATION for BREATH SOUNDS. Typically the collapsed segment causes displacement within the thoracic cavity of the affected lung, and often the unaffected lung as well as the HEART. Breath sounds may be normal though heard in abnormal locations. The doctor may also hear wheezes or rales, abnormal breath sounds that suggest blocked airways. Chest X-RAY clearly shows the displacement and the extent of the collapse. In the simplest case, coughing and deep breathing may resolve the atelectasis. In other cases, the doctor may desire additional diagnostic imaging such as COMPUTED TOMOGRAPHY (CT) SCAN to precisely identify the site of the atelectasis as well as the possible cause (such as a tumor or an obstruction). BRONCHOSCOPY may allow the pulmonologist to directly visualize the collapsed area and remove an obstruction such as a foreign object or mucus plug, if that is the cause of the collapse. Bronchoscopy also permits BRONCHOALVEOLAR LAVAGE or biopsy, if indicated.

Treatment Options and Outlook

Often, segmental atelectasis requires no treatment beyond watchful waiting or encouraging deep breathing. The lung will correct itself. Infection requires treatment with ANTIBIOTIC MEDICATIONS; inflammation may require treatment with CORTICOSTEROID MEDICATIONS. Other medications that sometimes relieve discomfort and help the lung restore itself include bronchodilators, which relax and open the airways. CHEST PERCUSSION AND POSTURAL DRAINAGE help keep the lungs free from accumulated secretions, and the doctor may recommend the person lie on his or her unaffected side to allow gravity to help restore the collapsed segment. Rarely, the doctor may consider surgery for chronic atelectasis that fails to respond to medical treatment. Most people recover from atelectasis without complications.

Risk Factors and Preventive Measures

Risk factors for atelectasis include obstructive pulmonary conditions such as CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD), CYSTIC FIBROSIS, chronic BRONCHITIS, and BRONCHIECTASIS. Recent surgery with general anesthesia is a common cause of atelectasis. Though avoiding these circumstances

may not be possible, being alert to the possibility of atelectasis allows medical evaluation and intervention before complications such as infection or PNEUMONIA establish themselves.

See also CYSTIC FIBROSIS AND THE LUNGS; LUNG CANCER; SMOKING AND PULMONARY DISEASE; SURGERY BENEFIT AND RISK ASSESSMENT.

auscultation The diagnostic procedure of listening to the LUNGS using a STETHOSCOPE held to various placements on the chest and back. Auscultation allows the doctor to hear normal and abnormal BREATH SOUNDS, the noises of air flowing through the respiratory tract. The doctor typically listens to the same location for each lung, to compare the sounds, and moves in a side-to-side pattern first across the chest from the apex to base (top to bottom) of each lung and then a similar pattern on the back. When conducting a pulmonary examination, the doctor also listens with the stethoscope placed over the TRACHEA at the throat.

There are four normal breath sounds—tracheal, vesicular, bronchial, and bronchovesicular—all heard upon both inhalation and exhalation. Deviations in tone, loudness, frequency, and character of the sounds help the doctor assess the performance of the lungs. Extra sounds, such as rales and wheezes, are abnormal and signal pulmonary ailments such as BRONCHITIS, ASTHMA, and PNEUMONIA. The doctor usually listens to the HEART as well during auscultation, as the HEART SOUNDS provide additional diagnostic information. The doctor uses the diaphragm of the stethoscope to auscultate for breath sounds and the bell of the stethoscope to auscultate for heart sounds.

See also APNEA; BREATHING; DYSPNEA; TACHYPNEA.

B

berylliosis Chronic damage to the LUNGS, also called chronic beryllium disease, resulting from industrial exposure to beryllium, a heavy metal that has many commercial uses and applications in contemporary manufacturing processes. Inhaled beryllium fumes and dust cause irritation to the delicate alveoli that activates the body's IMMUNE RESPONSE. In the United States berylliosis occurs primarily in people who work in the electronics, nuclear, and aerospace industries where beryllium usage is high. People who work in metal machining or alloy reclamation jobs are also at risk. The US Environmental Protection Agency (EPA) classifies beryllium dust and fumes as toxic substances, and the US Occupational Safety and Health Administration (OSHA) has established regulatory guidelines to minimize on-the-job beryllium exposure. Beryllium particles can remain in the lung tissues for six months to several years after exposure.

Berylliosis results from delayed-type hypersensitivity (DTH) in which helper T-cell lymphocytes flood the sites of exposure and encase the beryllium dust particles or the areas of INFLAMMATION, causing granulomas to form. Over time the granulomas evolve into fibromas, well-defined structures of SCAR tissue that replace normal lung tissue. As the penetration of granulomas and fibromas extends deeper into the lungs, the loss of alveolar function cripples the ability of the lungs to pass oxygen to the BLOOD.

Rarely, an individual may develop an immediate response, called acute chemical PNEUMONITIS, to beryllium exposure. Acute chemical pneumonitis requires prompt medical treatment to reduce airway irritation and INFLAMMATION.

Symptoms and Diagnostic Path

Symptoms of berylliosis are similar to symptoms of other chronic inflammatory diseases affecting the lungs, though employment in an occupation involving beryllium use is a key indication of the cause and nature of disease. Symptoms typically include

- chronic, nonproductive (dry) COUGH
- chest tightness or PAIN
- unintended weight loss
- shortness of breath (DYSPNEA), particularly with exertion
- fatigue

The diagnostic path includes chest X-RAY, BRONCHOALVEOLAR LAVAGE, and a specialized test called the beryllium lymphocyte proliferation test (BeLPT). The pulmonologist may also choose to perform high-resolution COMPUTED TOMOGRAPHY (CT) SCAN, which reveals small lesions within the lungs, and bronchial biopsy via BRONCHOSCOPY to further evaluate lesions that imaging procedures show. Pulmonary function tests and sometimes cardiopulmonary exercise testing can help assess the status of lung capacity and the ability of the lungs to oxygenate the blood. Conclusive diagnosis may require varied and numerous tests as well as thorough medical and personal histories, as berylliosis is similar to other interstitial lung diseases including sarcoidosis.

Treatment Options and Outlook

The first line of treatment is removal from the source of beryllium, which for most people means leaving the jobs that require exposure to beryllium. CORTICOSTEROID MEDICATIONS may help suppress the immune response and subdue the

inflammation. However, there is no known medical therapy to treat damage that has occurred to the lungs. Damage that does occur to the lungs is permanent and berylliosis is usually progressive, tending to continue even after exposure to beryllium ends. The resulting damage to the lungs may lead to HEART FAILURE and other cardiovascular health conditions because the HEART cannot pump enough BLOOD to oxygenate the body's tissues. LUNG TRANSPLANTATION may become a viable treatment option for people who develop complete pulmonary failure.

Risk Factors and Preventive Measures

Recent research suggests GENETIC PREDISPOSITION underlies most cases of berylliosis, with mutations or defects affecting the MAJOR HISTOCOMPATABILITY COMPLEX (MHC), which encodes aspects of immune response. The role of genetic predisposition is not entirely clear, though likely explains why some people who have limited exposure develop serious disease whereas others who have prolonged exposure seem to experience no adverse effects. However, berylliosis occurs only in people exposed to beryllium and nearly all such exposure is occupational, though beryllium is a natural mineral present in the environment. Reducing this exposure through appropriate occupational hygiene and protective measures can significantly reduce the risk of disease development.

MANUFACTURING JOBS WITH HIGH RISK FOR BERYLLIOSIS

aerospace alloys	computer electronics
dental alloys (bridges and crowns)	electrode welding
electronic resistors	heat sinks
jet brake pads	jet turbine blades
laser tubes	metal alloy bicycle frames
metal working	nuclear weapons
semiconductor chips	transistors
X-RAY windows	

People who work in industries in which beryllium use is common should be alert to the early symptoms of berylliosis. Contact with or use of products containing beryllium after their production or manufacture does not convey beryllium exposure, however. Screening blood BeLPT tests among people who work with beryllium can identify early indications of immune reactivity, allowing medical intervention to avert extensive damage to the lungs. OSHA recommends the use of powered respirators with high-efficiency particulate air (HEPA) filters and protective clothing in the workplace, as well as safeguards, such as showering and changing into complete street clothes (including shoes) before leaving the workplace.

black lung See ANTHRACOSIS.

breathing The process of drawing air into and expelling air from the LUNGS, also called pulmonary respiration. Specialized centers in the brainstem regulate the rate and rhythm of respiration to harmonize breathing with HEART RATE and BLOOD PRESSURE. Breathing occurs through the mechanical actions of MUSCLE movement. The DIAPHRAGM (the large, flat muscle that extends across the floor of the thoracic cavity) and the intercostal muscles (the muscles between the ribs) contract to expand the thoracic cavity, pulling air into the lungs (inhalation). Inhalation is an active process.

Simultaneously the EPIGLOTTIS, a cartilaginous flap at the top of the throat normally closed across the top of the TRACHEA to prevent food and other materials from entering the lungs, opens to allow the air to pass. The air flows through the trachea into the bronchi, bronchioles, and alveoli. When the diaphragm and the intercostal muscles relax the thoracic cavity returns to its resting position, pressuring air out of the lungs (exhalation) in reverse sequence. Exhalation is a passive process.

Breathing patterns help the doctor assess pulmonary function and respiratory effectiveness. Breathing may be varying combinations of rapid (TACHYPNEA) or slow (bradypnea), regular or irregular, deep or shallow. Though an individual may influence breathing through conscious focus, breathing is an involuntary process under control of the brainstem. The concentration of carbon dioxide in the BLOOD is the primary trigger for initiation of a RESPIRATORY CYCLE (one inhalation and one exhalation), triggering the brainstem to signal the diaphragm and the intercostal muscles to contract.

See also BREATH SOUNDS; HYPERVENTILATION; RESPIRATION RATE.

breathing exercises Methods to improve lung capacity. Breathing exercises are especially helpful for people who have chronic or progressive lung conditions such as CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD), BRONCHIECTASIS, and PULMONARY FIBROSIS. The pulmonologist or respiratory therapist may prescribe specific breathing exercises to accommodate an individual's unique needs and health status. General breathing exercises often recommended include

- belly breathing, which uses the abdominal muscles to help completely fill and empty the LUNGS
- pursed lip breathing, which releases air through lips formed as though to whistle and maintains positive pressure in the airways with exhalation (especially helpful for people who have COPD and other obstructive diseases)
- measured breathing, in which the person breathes in, holds the breath, and breathes out for an equal count at each stage

YOGA breathing is also beneficial for pulmonary health, with yoga breathing exercises to practice in combination with yoga positions as well as simply as breathing exercises. In yoga, the breath is *prana*, the energy of life, and breathing exercises are *pranayama*. Common *pranayama* include

- bellows breathing, in which inhalation is steady and full, with exhalation forceful and rapid
- alternate nostril breathing, in which inhalation is steady and full through one nostril with the fingers holding the other nostril closed, and exhalation through the other nostril, again with the fingers holding the nonbreathing nostril closed
- holding the breath, in which inhalation is steady and full, the lungs hold the breath for as long as is comfortable, and exhalation is steady and slow

For people who have pulmonary health conditions, breathing exercises are more challenging than they sound. It is important to begin slowly and progress steadily. The doctor should approve any planned exercise effort, including breathing exercises. Breathing exercises, including yoga's *pranayama*, are also highly effective for relaxation and stress reduction.

See also AEROBIC EXERCISE; AEROBIC FITNESS; DISABILITY AND EXERCISE; OXYGEN SATURATION; WALKING FOR FITNESS.

breath sounds Characteristic noises the flow of air makes as it courses through the TRACHEA and bronchi. The doctor listens to breath sounds using the diaphragm (flat) side of a STETHOSCOPE placed at various sites on the outside of the chest and the back, a diagnostic method called AUSCULTATION. There are four normal breath sounds, heard with inhalation and exhalation:

- Tracheal breath sounds, hollow sounds heard over the THROAT as air passes through the trachea
- Bronchial breath sounds, harsh sounds heard near the sternum as air passes through the bronchi (large airways in the LUNGS)
- Vesicular breath sounds, rustling sounds heard in most locations on the chest and back as air moves in and out of the alveoli
- Bronchovesicular breath sounds, a mix of harsh and rustling sounds heard just to the sides of the upper sternum on the chest and below the shoulder blades on the back

Normal breath sounds are of nearly equal duration with inhalation and exhalation and are particular to specific locations. Normal breath sounds heard elsewhere are abnormal and indicate the possibility of pulmonary conditions such as ATELECTASIS (collapsed segment of lung), fibrosis (SCAR tissue in the lungs), or other circumstances that cause the lung to shift its physical or functional presence within the thoracic cavity. The absence of normal breath sounds indicates that the segment or lobe of the lung is not receiving air, usually as a result of a significant bronchial occlusion (blockage of a bronchus), severe atelectasis, or lung collapse.

Other breath sounds the doctor can hear through the stethoscope are abnormal and indicate INFECTION or disease. Doctors call these adventitious breath sounds. Among them are

- wheezes, steady high-pitched whistling noise heard with exhalation that is typical of obstructed airways such as might result with ASTHMA, inhaled foreign objects, CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD), and chronic BRONCHITIS
- rales (also called crackles), intermittent crackling noises that may sound fine (like crinkling cellophane) or coarse (like pulling apart a hook and loop fastener) often heard with ACUTE RESPIRATORY DISTRESS SYNDROME (ARDS), PULMONARY EDEMA, BRONCHIECTASIS, and INTERSTITIAL LUNG DISORDERS
- rhonchi, low-pitched, continuous whistling noises heard with exhalation that suggest airways blocked with mucus
- stridor, loud wheezing sounds heard with inspiration when there is an obstruction of the trachea

Stridor is a life-threatening emergency that requires immediate medical attention.

- pleural rub, brushing sounds that indicate INFLAMMATION of the PLEURA (membrane covering the outer surfaces of the lungs) such as occurs with PLEURAL EFFUSION or pleural fibrosis

Breath sounds present important diagnostic information that helps the doctor determine the health status of the lungs as well as assess the progress of conditions under treatment.

See also EPIGLOTTITIS; HEART SOUNDS.

bronchiectasis The dilation of a segment of BRONCHUS. Bronchiectasis may involve several bronchial branches and usually occurs deep within the lung, often in a lower lobe. Though bronchiectasis may be congenital (present at birth) or acquired (develop after birth), congenital bronchiectasis is rare and results when only the core structure of the LUNGS develops and existing bronchi dilate in reaction to the pressure of incoming air. Acquired bronchiectasis commonly develops with chronic lung INFLAMMATION such as results from CYSTIC FIBROSIS or repeated INFECTION (typically chronic BRONCHITIS).

Bronchiectasis represents permanent damage to lung tissue, often with accompanying PULMONARY FIBROSIS (scarring), and loss of lung function in the affected areas. Because of the lung's segmented structure nonaffected segments and lobes of the lung continue to function normally, so the extent to which the bronchiectasis affects respiratory performance depends on the number of segments involved. However, bronchiectasis tends to be progressive.

Suspicion of bronchiectasis becomes valid with the existence of pulmonary conditions known to be predisposing, such as cystic fibrosis and chronic bronchitis. Bronchiectasis may follow recurrent PNEUMONIA, ASPIRATION pneumonia, childhood diseases such as PERTUSSIS (whooping COUGH) in children who have not received IMMUNIZATION, and toxic inhalation (such as smoke or chemical inhalation). IMMUNODEFICIENCY disorders that increase the risk for pulmonary infections also raise the likelihood of bronchiectasis. Symptoms typically develop over months to years and commonly include

- persistent, productive cough more intense in the mornings and just before going to bed
- prodigious SPUTUM production
- HEMOPTYSIS (BLOOD in the sputum)
- wheezing (high-pitched, abnormal BREATH SOUNDS with exhalation)

The diagnostic path includes chest X-rays and COMPUTED TOMOGRAPHY (CT) SCAN. The doctor may further desire BRONCHOALVEOLAR LAVAGE or bronchial biopsy (via BRONCHOSCOPY), sputum cultures, and blood tests. Treatment depends on the findings and may include ANTIBIOTIC MEDICATIONS to treat infections or CORTICOSTEROID MEDICATIONS to treat severe inflammation. Bronchodilator medications may help relax and open undamaged bronchi to improve lung capacity. CHEST PERCUSSION AND POSTURAL DRAINAGE help loosen mucus so the normal mechanisms of the respiratory tract can move it out of the lungs. Rarely, surgery to remove a particularly eroded or chronically infected bronchial segment is necessary. Most people are able to manage bronchiectasis with regular medical evaluation and care (including prompt treatment at the earliest indication of infection).

Regular physical activity and avoiding cigarette smoke are crucial to preserve remaining lung function.

See also ATELECTASIS; AUSCULTATION.

bronchitis INFLAMMATION of the bronchi, the airways that branch from the TRACHEA into the LUNGS. Bronchitis may be viral, bacterial, or the result of irritation such as cigarette smoking or exposure to environmental pollutants. It may also occur as an acute condition that comes on suddenly, runs its course, and heals without lasting damage or persistently recur as a chronic condition.

Acute bronchitis Acute infectious bronchitis is especially common during the "cold and flu" season, when it typically follows a viral INFECTION of the upper respiratory tract. Numerous viruses may be responsible, including ADENOVIRUS, coronaviruses, INFLUENZA viruses, and rhinoviruses. Acute viral bronchitis generally runs its course over a period of five to seven days, during which the person feels and appears ill. A residual COUGH may persist for several weeks after the infection subsides.

Acute irritative bronchitis develops in response to inhaled irritants such as fumes, dust, and smoke (cigarette as well as environmental). Symptoms may be difficult to distinguish from those of ASTHMA, particularly in people who do not have a diagnosis of asthma or who have infrequent asthma attacks. The inhaled substance irritates the lining of the bronchi, causing localized inflammation. Most often, the inflammation and resulting bronchitis subsides over the course of a few days.

Chronic bronchitis Repeated exposure to irritants such as cigarette smoke, occupational chemicals, and environmental pollutants may cause persistent or recurrent bronchial inflammation. By far the most common culprit is cigarette smoking or environmental cigarette smoke exposure (second-hand smoking). The hallmark symptom is persistent, productive cough that continues for three months or longer. Over time, chronic bronchitis may evolve into CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD) or BRONCHIECTASIS, two conditions in which damage to the bronchi is extensive and permanent. People who have chronic bronchitis are more vulnerable to bacterial infections such as PNEUMONIA, as well as to complications such as ATELECTASIS (collapse of a bronchial segment).

Symptoms and Diagnostic Path

The symptoms of acute bronchitis include FEVER, productive cough, sore THROAT, and chest discomfort or PAIN, especially when taking a deep breath. SPUTUM that is thick, yellowish green, and foul-smelling suggests bacterial infection. Red or brown streaks in the sputum indicate bleeding, which may be from the irritation of coughing or signal a different diagnosis. The diagnostic path includes AUSCULTATION to listen to BREATH SOUNDS, which are typically normal. The doctor may request a chest X-RAY to rule out other causes of the symptoms. The doctor may also collect a sputum sample for culture if there is any suspicion the infection could be bacterial.

The primary symptoms of chronic bronchitis are productive cough and DYSPNEA (shortness of breath). Physical exertion tends to exacerbate both. The diagnostic path begins with auscultation, which may reveal abnormalities of breath sounds depending on whether there is damage to the bronchial structures. Chest x-ray may show areas of inflammation as well as atelectasis or bronchiectasis if either is present. The doctor is likely to conduct further diagnostic procedures to rule out other conditions that could cause similar symptoms, such as asthma or, especially in smokers, LUNG CANCER.

Treatment Options and Outlook

Treatment for acute viral bronchitis is primarily supportive and targets symptom relief. The doctor may recommend a cough suppressant or an OVER-THE-COUNTER (OTC) DRUG such as acetaminophen to relieve fever and discomfort. It is important to drink lots of fluids to maintain HYDRATION and to thin bronchial secretions. When fever persists or recurs after acute infectious bronchitis, the likelihood of bacterial infection is high in which case treatment with ANTIBIOTIC MEDICATIONS becomes necessary. Antibiotics are not helpful for viral bronchitis, however. The doctor may prescribe an inhaled corticosteroid medication to suppress the inflammatory response in acute irritative bronchitis. Bronchodilators may also help if the bronchitis causes bronchospasm and wheezing.

The most effective treatment for chronic bronchitis is removing the cause of the symptoms, which most often is cigarette smoking. Chronic bronchitis becomes inevitable at some point in everyone who smokes. People who work in environments with high exposures to fumes, dust, or pollutants should use appropriate protective gear including masks or respirators. Chronic bronchitis that continues unchecked results in permanent damage to the bronchial structures.

Risk Factors and Preventive Measures

Frequent HAND WASHING is the best defense against viral infections of any sort. Upper respiratory viruses spread through droplet contamination, which may occur through direct touch (such as shaking hands) or breathing droplets coughed or sneezed into the air by those who have upper respiratory viruses. In epidemic circumstances, doctors may prescribe antiviral medications such as rimantadine to reduce the risk or severity of infection. Removal from the source of irritation reduces symptoms to improve chronic bronchitis. People who have high risk of respiratory infection, such as those who have chronic lung disease or other chronic health conditions, should receive influenza vaccination (flu shot) every year and pneumonia vaccination every five years.

See also ANTIBIOTIC RESISTANCE; CROUP; HEMOPTYSIS; PNEUMONITIS; SMOKING AND PULMONARY DISEASE.

bronchoalveolar lavage A diagnostic procedure that washes cells from the bronchi and alveoli for laboratory examination. The doctor does bronchoalveolar lavage during BRONCHOSCOPY, blocking a small section of the bronchial segment to instill and then withdraw sterile saline. The solution contains cells from the inner lung structures that can provide diagnostic information. The doctor may also use bronchoalveolar lavage therapeutically, to irrigate (rinse away) thickened mucus or other deposits from the LUNGS in conditions when thick plugs of mucus block the airways and do not respond to other treatments.

See also ALVEOLUS; BRONCHUS.

bronchoscopy A diagnostic procedure in which the doctor uses a flexible, lighted endoscope, inserted through the THROAT and into the airways under sedation or ANESTHESIA, to view the TRACHEA, bronchi, and other structures of the respiratory tract. The doctor also can watch the LUNGS in motion, assessing air movement and filling. Bronchoscopy is an outpatient procedure that takes about an hour. Many people receive mild sedation before the bronchoscopy to help them relax and be more comfortable.

The bronchoscope is a thin, flexible, lighted tube with a tiny camera on the tip. The pulmonologist sprays a topical anesthetic on the back of the throat to block the GAG REFLEX and numb the throat, then inserts the bronchoscope through the MOUTH (or the NOSE, with lubrication) and throat into the trachea. The pulmonologist guides the bronchoscope into the bronchi, which enables examination of the lung to a moderate depth of about four or five branchings of the bronchus. The pulmonologist may use bronchoscopy to obtain tiny tissue samples for biopsy or to perform BRONCHOALVEOLAR LAVAGE to obtain bronchial and alveolar cell samples. Bronchoscopy may also be therapeutic, allowing the pulmonologist to rinse accumulated mucus and debris from the bronchi.

It is common to feel some discomfort after the topical anesthetic wears off, similar to a sore throat. The discomfort generally does not last more than a day or two. Rarely after a biopsy, bronchoscopy may cause a PNEUMOTHORAX, a condition in which air gets in the pleural space (a small area around the lung) and the lung collapses. The risks of bronchoscopy for most people are minimal.

See also ALVEOLUS; BRONCHUS; ENDOSCOPY.

bronchus A secondary branch of the airways that connect the LUNGS and the primary airway, the TRACHEA. The main bronchi branch directly from the trachea at about mid-lung, with the right main bronchus channeling air to the right lung and the left main bronchus directing air to the left lung. Each main bronchus nearly immediately branches into lobular bronchi, three in the right lobe and two in the left lobe. Bronchi become diminishingly smaller as they branch deeper into the lungs. Rings of CARTILAGE give larger bronchi rigidity and support. Smaller bronchi have fewer and thinner cartilage rings, and bronchioles, the tiniest of the bronchi, have thin walls of only

smooth MUSCLE tissue with no cartilage. The bronchi are susceptible to irritation, INFLAMMATION, and INFECTION. When inflamed or irritated the bronchi can cause difficulty breathing (DYSPNEA).

For further discussion of the bronchi within the context of pulmonary structure and function please see the overview section "The Pulmonary System."

See also ALVEOLUS; ASTHMA; BRONCHIECTASIS; BRONCHITIS.

byssinosis A lung disorder resulting from extended exposure to the dust from cotton, flax, or other textile fibers. Also called brown lung, cotton worker's lung, or cotton bract disease, byssinosis is an occupational disease that causes ASTHMA-like symptoms. When detected in its early stages, byssinosis is reversible by eliminating exposure to the responsible irritant. When exposure continues the byssinosis can cause permanent damage to the LUNGS with symptoms similar to those of CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD). In the United States people who work in jobs where they handle unprocessed cotton have the highest risk of developing byssinosis.

The symptoms of byssinosis tend to be worse at the workplace and improve away from the workplace and typically include wheezing and coughing. The diagnostic path focuses on the work history and includes X-rays of the chest and tests to assess pulmonary capacity and function. The most effective treatment is preventing continued exposure, which may involve workplace improvements or changing jobs. Medications to reduce the HYPERSENSITIVITY REACTION the airways have to the fiber dust, such as bronchodilators and sometimes CORTICOSTEROID MEDICATIONS, can relieve or prevent symptoms. Smoking significantly exacerbates byssinosis, so SMOKING CESSATION is crucial to other treatment approaches.

See also ASTHMA; BERYLLIOSIS; OCCUPATIONAL HEALTH AND SAFETY; SARCOIDOSIS; SILICOSIS.

C–E

chest percussion and postural drainage A therapeutic method for loosening and clearing mucus from the LUNGS, used especially in CYSTIC FIBROSIS and BRONCHIECTASIS, when there is ATELECTASIS, and in other pulmonary disorders in which mucus collects and blocks the flow of air. For this treatment, a respiratory therapist or caregiver trained in the method rhythmically claps, with cupped hands, on the SKIN surfaces of the chest and back over the thoracic cavity with the person receiving the treatment in various postures, depending on the location of the clapping. The therapist may choose to use a mechanized percussor instead of the hands, which allows longer and more intensive percussion.

Clapping over the upper chest (near the collarbones) and upper back (near the shoulder blades) loosens secretions in the upper lobes. Clapping over the midchest (nipple line) and midback loosens secretions in the middle lobes. Clapping over the lower chest (below the nipple line) and lower back loosens secretions in the lower lobes. Precise positioning of the hands when clapping can further target specific segments of the lobes. The percussion of the clapping loosens mucus and secretions within the bronchi, which the person then coughs up to remove from the respiratory tract.

See also COUGH; CYSTIC FIBROSIS AND THE LUNGS.

Cheyne-Stokes respiration A pattern of BREATHING in which periods of APNEA alternate with periods of accelerated breathing. Cheyne-Stokes respiration indicates damage to the brainstem or other NERVOUS SYSTEM mechanisms that regulate breathing. This breathing pattern also occurs in severe HEART FAILURE. During the apneic periods, which may last up to 60 seconds, breathing stops. During the accelerated periods, the RESPIRATORY RATE rapidly increases in rate and depth (hyperpnea) then abruptly stops as the cycle returns to apnea. Cheyne-Stokes respiration may reflect an end-stage (near death) breathing pattern in adults, though may persist for an extended time in people who are comatose.

See also DYSPNEA; TACHYPNEA.

chronic obstructive pulmonary disease (COPD) A serious, often debilitating, and potentially fatal condition in which INFLAMMATION and scarring destroy alveoli, bronchioles, and bronchi. The most common cause of COPD is cigarette smoking; 8 of 10 Americans who have COPD are smokers. Uncontrolled ASTHMA and chronic lung diseases such as ASBESTOSIS and SILICOSIS can also progress to COPD. About 16 million people in the United States have COPD and more than 100,000 of them die from it each year.

COPD takes years to decades to develop, and its damage is permanent. The most common presentation is that of chronic BRONCHITIS, in which there is repeated inflammation of the bronchi. Each bout of inflammation results in the formation of SCAR tissue as the damaged area heals. Over time the scar tissue causes the bronchi to narrow, with areas of constriction that severely limit the flow of air. ATELECTASIS (collapse) may occur in affected bronchial structures, reducing the ability of the lung to diffuse oxygen into the bloodstream.

In about 10 percent of people who have COPD the damage extends to the alveoli, the clusters of air sacs where oxygen–carbon dioxide exchange takes place. Repeated inflammation and scarring causes the alveoli to enlarge and lose elasticity, a state called emphysema. The damaged alveoli can take in air but cannot collapse sufficiently to expel

the air completely. A rare form of emphysema is an inherited deficiency of the enzyme alpha-1-antitrypsin (AAT), which regulates the presence of elastin in the tissues of the alveoli. AAT deficiency results in reduced elastin, further limiting alveolar function. Because of the intimate correspondence between the capillary BLOOD supply and alveolar oxygen content, blood supply shifts away from damaged alveoli.

The ultimate damage of COPD, regardless of whether the primary course of disease started as bronchial or alveolar, is so profound that both dimensions of damage eventually overtake the LUNGS and the lungs lose the ability to recoil (return to their normal shape and size), diminishing the ability to exhale. Consequently, people who have COPD can breathe in with relative ease but struggle to move air back out of their lungs. People who have moderate to advanced COPD typically exhale through pursed lips, an effort to more forcefully exhale. Even with this effort, the person may be unable to blow out a match.

As the disease process progresses the less elastic lungs expand within the thoracic cavity, pushing the ribs out and the DIAPHRAGM down to produce a characteristic barrel chest deformity. However, these structural changes further limit the ability of the diaphragm and intercostal muscles to expand the chest for inhalation, restricting the ability of the lungs to draw in air. This generates a characteristic posture adaptation in which the person leans forward to use other muscles in the neck and shoulders to assist with BREATHING. Ordinary movements such as raising the arms (such as to wash or brush the hair) consequently cause shortness of breath because such movements reduce the involvement of these ancillary muscles. In its later stages COPD affects both inhalation and exhalation.

Symptoms and Diagnostic Path

The symptoms of COPD include

- progressive DYSPNEA (shortness of breath)
- wheezing (whistling sounds with exhalation)
- persistent, productive COUGH
- HEMOPTYSIS (bloody SPUTUM)
- edema (swelling due to fluid retention) in the feet, ankles, and lower legs
- CYANOSIS (bluish hue to the lips and SKIN that signals inadequate oxygenation)
- physical signs characteristic of COPD (barrel chest, purse-lip breathing, forward-leaning posture) when emphysema is dominant
- current or previous cigarette smoking

The diagnostic path includes a complete pulmonary workup to evaluate lung capacity and function, which typically show significant reductions. Chest X-rays and COMPUTED TOMOGRAPHY (CT) SCAN show the extent of damage to the lungs as well as displacement of the thoracic structures. The doctor typically does sputum cultures to identify or rule out INFECTION. Diagnostic blood tests often show an elevated ERYTHROCYTE (red blood cell) count particularly in people who have low oxygen levels, indicative of the body's attempt to improve the oxygen-carrying ability of the blood. Diagnostic efforts focus on ruling out other possible causes for symptoms as well as correlating physical findings with history of smoking.

CLASSIFICATION OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD)

Classification	Severity	Symptoms
stage 0	at risk	smokes but has no COPD symptoms
stage 1	mild	chronic COUGH
stage 2	moderate	chronic, productive cough DYSPNEA with exertion
stage 3	severe	chronic, productive cough excessive SPUTUM dyspnea at rest right HEART FAILURE common

Treatment Options and Outlook

The most important element of treatment is SMOKING CESSATION. Although it is not possible to reverse damage that has already occurred, treatment aims to minimize further lung damage and improve function of the remaining lung. Medications such as bronchodilators relax and open the airways,

easing the flow of air in and out of the lungs. CORTICOSTEROID MEDICATIONS reduce inflammation and in some people may also help open the airways. When infection is present, the doctor may prescribe ANTIBIOTIC MEDICATIONS. However, people who have COPD often have extensive bacterial flora, making it difficult for the doctor to determine whether there is an actual infection present. People who have COPD should receive annual INFLUENZA immunizations and PNEUMONIA vaccination every five years. As with all lung diseases, it is important to minimize as much as possible other triggers: SINUSITIS, GASTROESOPHAGEAL REFLUX DISORDER (GERD), and exposure to known ALLERGENS.

For some people surgery to remove the upper lobes of the lungs, called lung volume reduction surgery (LVRS), relieves tension within the thoracic cavity and improves pulmonary function and overall lung capacity. LUNG TRANSPLANTATION may be a viable treatment option for some people, replacing one of the diseased lungs with a donor lung. The criteria for these procedures are stringent and take into account numerous health and lifestyle factors.

Nutritional support is essential for people with advanced COPD, who typically lose significant body weight as the effort to breathe requires intense work from numerous muscles. Regular physical exercise is also important. Though breathing with exertion may severely limit the duration of activity, maintaining physical STRENGTH allows the body to make the most of the available oxygen the lungs can diffuse into the bloodstream. Many hospitals have pulmonary rehabilitation programs with specialists who can teach targeted exercises to improve AEROBIC FITNESS and MUSCLE strength. For many people pulmonary rehabilitation is as effective as any surgical alternatives. Walking remains one of the most effective activities.

Complications of COPD are common, particularly in the later stages. Typical complications include HEART FAILURE, PULMONARY HYPERTENSION and RESPIRATORY FAILURE. Doctors sometimes refer to the combination of right-heart failure and pulmonary hypertension as cor pulmonale. People who have COPD are particularly vulnerable to viral infections such as COLDS and influenza, and often develop secondary bacterial infections such as pneumonia and acute bronchitis.

Risk Factors and Preventive Measures

The leading risk factor for COPD is cigarette smoking. The most effective preventive measure is never to smoke and to avoid exposure to secondhand smoke (ENVIRONMENTAL CIGARETTE SMOKE). Smoking cessation can improve lung capacity and function, though cannot undo damage that has already occurred. Prompt and appropriate treatment of other pulmonary conditions, such as asthma, helps minimize permanent damage that could set the stage for COPD to subsequently develop. Though COPD occurs primarily in people over age 40, this is a consequence of cumulative damage to the lungs over time rather than aging.

See also BRONCHITIS; LIVING WITH CHRONIC PULMONARY CONDITIONS; PNEUMOTHORAX; SMOKING AND PULMONARY DISEASE.

collapsed lung See ATELECTASIS.

cystic fibrosis and the lungs An inherited genetic disorder affecting mucus production and clearance, CYSTIC FIBROSIS alters the functioning of exocrine glands throughout the body and affects nearly all of the body's systems. In the LUNGS, cystic fibrosis causes changes in the consistency and composition of the mucus the lungs secrete. The mucus accumulates along the inner walls of the bronchi, causing irritation and INFLAMMATION that eventually thickens the walls of the bronchi. The mucus becomes thick, creating obstructions in the bronchi that reduce air flow and eventually produce regions of ATELECTASIS (collapsed bronchial segments). The plugs of thickened mucus also attract BACTERIA, resulting in recurrent INFECTION that manifest as BRONCHITIS and PNEUMONIA.

Health experts estimate that about 3 percent of the population in the United States carries the recessive GENE MUTATION for cystic fibrosis. The disorder is 5 to 10 times more common among whites than among other racial populations. Even one generation ago, cystic fibrosis typically caused death by late ADOLESCENCE. Current treatment methods and early diagnosis has extended life expectancy into the 30s for most people who have cystic fibrosis, and many live longer. Cystic fibrosis nearly always affects the lungs and requires continuous therapy to maintain adequate BREATHING and oxygenation.

Symptoms and Diagnostic Path

The symptoms of cystic fibrosis vary according to the body system first affected and usually appear in childhood. Chronic productive COUGH, recurrent bronchitis or pneumonia, and pronounced wheezing are among the indications of pulmonary involvement. The diagnostic path includes chest X-rays and pulmonary function tests, which demonstrate changes in lung structure and function characteristic of cystic fibrosis. Other diagnostic procedures look for nonpulmonary indications of cystic fibrosis such as sinus disease, pancreatic disease, decreased BONE DENSITY, and INFERTILITY. Family history of cystic fibrosis provides strong suspicion of the diagnosis. A positive sweat chloride test and GENETIC TESTING that identifies cystic fibrosis mutations. This provides conclusive diagnosis.

Treatment Options and Outlook

Treatment requires close coordination to target symptoms and disease developments across body systems. Pulmonary treatment aims to keep the airways as open as possible and to prevent infection, or treat infection early and aggressively. IMMUNIZATION to protect against CHILDHOOD DISEASES such as PERTUSSIS (whooping cough), CHICKENPOX, and MEASLES are crucial, as are annual INFLUENZA immunizations (flu shots) and pneumonia vaccination every five years at all ages. CHEST PERCUSSION AND POSTURAL DRAINAGE help clear the airways of mucus accumulations. Though coughing is a frustrating symptom, it is also an important function for removing mucus from the chest. Bronchodilators help improve functioning of the airways and removal of mucus from them.

Moderate to high doses of the NONSTEROIDAL ANTI-INFLAMMATORY DRUG (NSAID) ibuprofen (Advil or Motrin) taken regularly may slow bronchial inflammation and damage in many people, especially children. CORTICOSTEROID MEDICATIONS become necessary when ibuprofen can no longer control the inflammation or when inflammation becomes widespread in the lungs. ANTIBIOTIC MEDICATIONS become necessary to treat infections. People who have cystic fibrosis commonly acquire antibiotic-resistant bacteria, which may necessitate treatment with more powerful intravenous antibiotics. Inhaled antibiotic therapies are also becoming available for treatment as well as prophylaxis (prevention).

Cystic fibrosis has numerous nonpulmonary complications that also require close attention. Dysfunction of the PANCREAS results in malabsorption that may necessitate nutritional support. The nature and severity of symptoms vary widely among individuals. Cystic fibrosis is progressive, however, and these treatments are only supportive. When they fail, bilateral LUNG TRANSPLANTATION is the final, though high-risk, treatment option.

Risk Factors and Preventive Measures

The only risk factor for cystic fibrosis is the recessive gene mutation. Because this mutation is relatively prevalent in the American population, many people do not know they carry it until a child develops the disease. Genetic testing and GENETIC COUNSELING may be helpful for people who have family histories of cystic fibrosis.

See also ANTIBIOTIC PROPHYLAXIS; ANTIBIOTIC RESISTANCE; GENETIC DISORDERS; INHERITANCE PATTERNS; ORGAN TRANSPLANTATION.

diaphragm The thin, flat MUSCLE that forms the floor of the thoracic cavity (chest), establishing a physical barrier between the thoracic cavity and the abdominal cavity. Small openings in the diaphragm allow structures such as the AORTA, inferior VENA CAVA, and ESOPHAGUS to pass through. The lower lobes of the LUNGS and the base of the HEART rest against the diaphragm. The diaphragm attaches to the lower ribs and spine in the back, then rises along the back of the ribs to dome forward to form the base of the thoracic cavity. Contraction of the diaphragm tightens this dome, pulling it downward to expand the thoracic cavity. The diaphragm has two equal halves, each called a hemidiaphragm, and is the primary muscle of BREATHING.

Health conditions that can involve the diaphragm include HIATAL HERNIA, in which weakness in the musculature around the esophageal opening allows the stomach to bulge upward through the opening. Hiatal hernia typically causes an uncomfortable burning sensation and may result in regurgitating food or GASTROESOPHAGEAL REFLUX DISORDER (GERD). HICCUPS are muscle spasms of the diaphragm.

THE HEIMLICH MANEUVER

The HEIMLICH MANEUVER, an emergency procedure for ejecting an inhaled object from the TRACHEA, uses the DIAPHRAGM to generate a forceful exhalation. Placing a sharp, upward thrust into the diaphragm causes the diaphragm to rapidly contract and relax, sending its dome higher into the thoracic cavity than usual. The effect strongly compresses the LUNGS, forcing them to propel air outward. The force of the air dislodges the object.

For further discussion of the diaphragm within the context of pulmonary structure and function please see the overview section "The Pulmonary System."

See also BREATHING EXERCISES.

dyspnea Difficulty BREATHING or shortness of breath. There are numerous causes of dyspnea, most of which relate to cardiovascular or pulmonary disorders. Dyspnea occurs when the body does not receive enough oxygen. As oxygen is the fuel for cellular activity, lack of oxygen means cells cannot function properly. When oxygen insufficiency (HYPOXIA) is systemic (involves all the body) the body begins to conserve oxygen for vital uses. This concurrently slows activity of nonessential cells such as skeletal MUSCLE cells and sends signals to the LUNGS and HEART to increase their productivity.

Dyspnea may occur as a result of intense physical activity, such as exercise, in which case it generally diminishes with improved AEROBIC FITNESS. Dyspnea associated with cardiovascular or pulmonary disease may lessen slightly with pulmonary rehabilitation and improved physical conditioning but typically does not improve substantially unless the underlying disease condition improves. CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD) and HEART FAILURE are the two most common causes of dyspnea. Doctors assess clinical dyspnea according to the degree to which it interferes with normal activities.

See also APNEA; ASPHYXIATION; DISABILITY AND EXERCISE; INTERSTITIAL LUNG DISORDERS; LIVING WITH CHRONIC PULMONARY CONDITIONS.

emphysema See CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD).

GRADES OF DYSPNEA

Grade	Severity	Level of Impairment
grade 1	minimal	shortness of breath with exertion such as climbing multiple flights of stairs, short running such as to catch a bus, or walking uphill
grade 2	mild	shortness of breath with moderate exertion such as climbing a single flight of stairs or walking several blocks on the flat
grade 3	moderate	shortness of breath with mild exertion such as walking one block on the flat; must pause when climbing a single flight of stairs
grade 4	significant	shortness of breath with everyday physical activity; must pause when walking on the flat; must pause every few steps when climbing a flight of stairs
grade 5	incapacitating	shortness of breath with any physical effort including dressing, undressing, showering or bathing; cannot walk more than a few steps without pausing; cannot climb steps

H–I

hemoptysis Bleeding from the LUNGS, which typically manifests through BLOOD in the SPUTUM. Hemoptysis is typically frothy and bright red, though can sometimes be difficult to distinguish from blood that might originate in the ESOPHAGUS or STOMACH.

Hemoptysis that produces a volume of blood greater than the equivalent of two or three teaspoonfuls is a medical emergency that may represent hemorrhage and requires immediate treatment.

Hemoptysis is a symptom of numerous health conditions affecting the lungs, and may appear as blood-streaked sputum or primarily blood with little apparent sputum present. The diagnostic path includes chest X-rays, blood tests, and sputum cultures. Lung hemorrhage is a surgical emergency that generally requires immediate intervention to locate and stop the source of bleeding, commonly a perforated ARTERY. Treatment for less severe bleeding focuses on the underlying cause. The most common cause overall of hemoptysis is BRONCHITIS.

COMMON CAUSES OF HEMOPTYSIS

BRONCHIECTASIS	BRONCHITIS
CYSTIC FIBROSIS	LUNG CANCER
PNEUMONIA	PULMONARY EMBOLISM
TUBERCULOSIS	violent coughing
Wegener's granulomatosis	

See also ANEMIA; GASTROINTESTINAL BLEEDING.

hiccups Dysfunctional or out-of-sequence contractions (spasms) of the DIAPHRAGM. Hiccups generally occur rhythmically in episodes that typically contain four to several dozen contractions. An individual tends to have a personally consistent pattern. Though doctors know the mechanics of hiccups, no one knows what causes hiccups or what, if any, purpose they serve. For most people hiccups are nothing more than an annoyance. However, prolonged attacks can have health consequences.

There is no certain cure for hiccups, though recommended remedies are abundant. Some remedies, such as swallowing a spoonful of sugar or sniffing an ammonia capsule, irritate the airways. Swallowing ice water may activate nerves in the ESOPHAGUS that diffuse the NERVE impulses causing the diaphragm to contract. BREATHING into a paper bag raises the percentage of carbon dioxide in the BLOOD, which alters the brain signals to the diaphragm. It is important that any prospective cure carry little risk of causing harm.

Doctors may treat persistent hiccups with medications that are mildly sedating, such as antiseizure or anticholinergic medications. A mild anesthetic may slow the signals from the brainstem. Mild MUSCLE relaxants and tricyclic antidepressants are also successful in some people. Extended hiccups may result in vasovagal nerve irritation that causes ARRHYTHMIA (irregularities in the heartbeat). In most circumstances of prolonged hiccups, treating underlying health conditions stops the hiccups.

See also HYPERVENTILATION; MYOCLONUS; SPASM.

hyperventilation Rapid, shallow BREATHING that causes carbon dioxide levels in the BLOOD to drop below normal. As the balance between carbon dioxide and other gases in the blood is essential for normal pulmonary and cardiovascular func-

tion, the decrease triggers actions in the body designed to slow the breathing. Key among these is temporary loss of consciousness (fainting), which returns breathing to the involuntary control of the brainstem and restores normal breathing patterns. People who are hyperventilating often feel as if they were not getting enough oxygen, though in fact they are getting plenty. Most often hyperventilation results from emotional stress, panic, or anxiety. Rarely, cardiovascular or pulmonary disturbances cause a similar breathing pattern. Chest X-RAY, blood tests, and ELECTROCARDIOGRAM (ECG) can quickly determine whether this is the case.

The standard treatment for an active episode of hyperventilation is breathing slowly and purposefully. Breathing through only one nostril (holding the other nostril closed with the fingers) helps focus conscious intent on the breathing as well as reduce the amount of air entering the LUNGS.

Though once a common remedy for hyperventilation, BREATHING into a paper bag may allow carbon dioxide levels in the blood to rise too much. Doctors no longer recommend this method.

Once breathing returns to normal the oxygen–carbon dioxide balance in the blood does the same and symptoms such as dizziness or lightheadedness fade. Stress management methods such as MEDITATION and YOGA help lower overall anxiety levels, which reduces hyperventilation episodes. BREATHING EXERCISES are also helpful. Hyperventilation without underlying cardiovascular or pulmonary disease is not harmful to health.

See also HYPOXIA.

hypoxemia See OXYGEN SATURATION.

hypoxia Inadequate oxygen perfusion of the tissues. Hypoxia occurs when the BLOOD cannot deliver adequate oxygen, which may result from pulmonary dysfunction, cardiovascular dysfunction, STROKE, TRAUMATIC BRAIN INJURY (TBI), disorders of the blood such as ANEMIA that affect erythrocytes (red blood cells) or HEMOGLOBIN, and BREATHING disturbances such as APNEA. Hypoxia may involve only a defined organ or area, such as a region of the BRAIN affected by STROKE, or involve the entire body. Permanent tissue damage or tissue death results when hypoxia persists. Symptoms of hypoxia may include CYANOSIS (bluish hue to the lips and SKIN), tiredness, and DYSPNEA (shortness of breath or difficulty breathing). Most hypoxia requires supplemental oxygen with additional treatment that targets the underlying cause.

See also ALTITUDE SICKNESS; DECOMPRESSION SICKNESS; OXYGEN SATURATION; OXYGEN THERAPY; POLYCYTHEMIA VERA.

interstitial lung disorders A broad term for chronic conditions that restrict the ability of the LUNGS to function properly, encompassing more than 150 diseases. Interstitial lung disorders, also called interstitial lung disease as a collective term, are typically obstructive, fibrotic (involve SCAR formation), and progressive. Many arise from occupational exposures such as to asbestos (ASBESTOSIS), silica (SILICOSIS), and coal dust (miner's PNEUMONOCONIOSIS). A variant form that more commonly occurs later in life, idiopathic pulmonary fibrosis (IPF), has no identifiable cause and tends to be more severe in its progression.

The general symptoms, diagnostic paths, and treatment approaches are similar for interstitial lung disorders. Common symptoms include COUGH, DYSPNEA (shortness of breath or difficulty BREATHING), and frequent INFECTION. Treatment targets slowing the progression of the disease, relieving symptoms, and preventing infections. Lung transplantation is sometimes a treatment option for severely progressive IPF. However, many people who have interstitial lung disorders are able to manage their symptoms for years to decades, allowing satisfactory QUALITY OF LIFE.

See also CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD); CYSTIC FIBROSIS AND THE LUNGS; LIVING WITH CHRONIC PULMONARY CONDITIONS.

L–M

Legionnaires' disease A serious and potentially fatal form of PNEUMONIA first identified in 1976 when several hundred people attending a Legionnaires' convention became ill, a number of whom died as a result of the INFECTION. Scientists subsequently isolated the causative bacterium *Legionella pneumophila*. The BACTERIA infect about 18,000 people in the United States each year, about 4,000 of whom die from the disease or its complications. A less severe form of the infection with the same bacteria is Pontiac FEVER, which presents milder forms of similar symptoms (though without subsequent complications). Health experts refer to these infections collectively as legionellosis. Heating and cooling systems in buildings can harbor *L. pneumophila*, which then spread the bacteria through ventilation networks. Frequent and diligent cleaning of these systems is the most effective means for limiting outbreaks of infection.

Symptoms and Diagnostic Path

Legionnaires' disease begins as a typical viral upper-respiratory infection with symptoms that begin 3 to 10 days after exposure and include fever, generalized aches and discomfort, loss of APPETITE, HEADACHE, fatigue, and COUGH. Some people also have gastrointestinal symptoms such as diarrhea. Within a week the symptoms worsen to include coughing up SPUTUM, chest tightness or PAIN, and DYSPNEA (shortness of breath). Some people also experience multiple neurologic symptoms, including confusion and cognitive dysfunction.

A chest X-RAY shows signs of pneumonia, and diagnostic blood tests often show indications of infection in the body. The doctor may order specialized tests to detect the presence of *L. pneumophila* in the sputum or of *L. pneumophila* antigens in the URINE. A key factor in suspecting Legionnaires' disease is knowing the possibility of exposure, either because others have become ill or because the person was at an event at a setting conducive to transmitting Legionnaires' disease, such as a large convention. Other water sources as well as respiratory equipment in hospitals harbor *L. pneumophila,* which has become a common cause of community-acquired pneumonia as well as of NOSOCOMIAL INFECTIONS (hospital-acquired infections).

Treatment Options and Outlook

The primary treatment for Legionnaires' disease is hospitalization for intravenous therapy with the ANTIBIOTIC MEDICATIONS of the macloide or fluoroquinoline class (such as azithromycin or levofloxacin). Illness in some people is mild enough to allow outpatient treatment with oral antibiotics, though others may require hospitalization. As with any severe infection, multiple system failure is a significant risk in people who already have other major health conditions such as CARDIOVASCULAR DISEASE (CVD), DIABETES, or pulmonary disorders. Early diagnosis and treatment are critical; the likelihood of death resulting from the infection increases dramatically when people delay seeking medical care or doctors are unaware of the possibility of the diagnosis. Among people who are otherwise healthy, have normal immune function, and receive prompt treatment, more than 95 percent recover. However, many people continue to have some symptoms, such as fatigue, for several months.

Risk Factors and Preventive Measures

Infection with *L. penumophila* can occur in several venues. People who already have some form of pulmonary compromise, such as ASTHMA or CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD),

seem more likely to contract Legionnaires' disease than people who have healthy lung function with equal exposure to a contaminated source. People who smoke have the highest risk, whether or not they have underlying pulmonary disease. People between the ages of 50 and 70 seem most likely to develop infection after exposure.

The most effective preventive measure is strict maintenance and cleaning of building air-conditioning and heating systems, spas, whirlpools, and other potential sources of culture for the bacteria. Heightened awareness about Legionnaires' disease has resulted in improved diligence. The US Occupational Safety and Health Agency (OSHA) has implemented guidelines for building maintenance. Because the bacteria enter the upper respiratory tract during breathing, there are few personal measures to reduce the risk for infection as often it is not possible or practical to avoid locations that are potential sources of infection.

See also INDOOR AIR QUALITY.

living with chronic pulmonary conditions More than 30 million Americans live with chronic pulmonary conditions such as ASTHMA, CYSTIC FIBROSIS, PULMONARY FIBROSIS, and CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD). Though many chronic pulmonary conditions are far more common among people over age 50, chronic pulmonary disease affects young people too. Chronic pulmonary disease requires most people to make accommodations in their lifestyles, recreational activities, and occupations.

Medical Care

People who have chronic pulmonary conditions require ongoing medical surveillance and treatment such that they may feel they "live at the doctor's office." They often take numerous medications and receive respiratory therapy treatments. Many undergo frequent hospitalizations for attacks, exacerbations, and INFECTION. Compliance with medical treatments plan is essential but not always easy. It is common to feel that medications are no longer necessary when they bring about significant improvement, yet taking medications as prescribed is the most effective way to prevent complications and, in many situations, slow or halt the condition's progress.

Self Care

Various lifestyle factors influence the course of chronic pulmonary conditions. Some are actions a person can and should take to improve his or her pulmonary status. Other actions target overall health and well-being. It is important for each person to take leadership of his or her health and care.

Cigarette smoking Cigarette smoking is the most significant factor in many forms of chronic pulmonary disease. The optimal lifestyle choice for healthy lungs is never to start smoking; the next best decision is to stop smoking. Though it is not often possible to undo damage that has already occurred to the LUNGS, smoking cessation can result in improvement no matter when it takes place.

Breathing exercises BREATHING is such a natural occurrence that few people give it a second thought until it becomes a struggle. BREATHING EXERCISES can increase lung capacity and efficiency, teaching ways to get the most from every breath of air.

Nutritious eating habits Working hard simply to breathe requires a lot of calories. For people who have severe pulmonary conditions, breathing can commandeer most of the calories consumed each day. It is important to get enough calories to meet the body's needs and to infuse the body with vital NUTRIENTS that support health and HEALING.

Regular exercise When simply breathing consumes most of the body's energy, it's easy to slack off exercise. Yet the body requires regular physical activity to function at its most efficient. Though chronic pulmonary conditions often limit physical exertion, many activities remain possible with adaptation. Walking is among the most effective exercises, providing AEROBIC FITNESS as well as strengthening muscles. Some people find the relative weightlessness of swimming allows them to do more with less effort. Nearly everyone, regardless of disease type or stage, can engage in small activities that improve the body's fitness. Structured pulmonary rehabilitation programs help people to make the most of the lung function they do have.

Mental health and emotional balance Coping with the challenges and setbacks of chronic health conditions can be overwhelming. Children who have chronic pulmonary conditions may struggle with peer acceptance and feeling left out of school and social activities. Some people find support groups safe ways to express anger, fear, and worry,

as well as to share information and experiences. Other people take comfort in the solitude of prayer or MEDITATION. Stress relief methods such as YOGA and VISUALIZATION help recenter the thoughts and the mind.

Looking to the Future

Though chronic pulmonary conditions are often limiting or debilitating, many people are able to participate in activities they enjoy. With appropriate medical care and self-care, a long and productive life is not only possible but probable for many people who have chronic pulmonary conditions.

See also LIFESTYLE AND HEALTH; QUALITY OF LIFE.

lung abscess A pocket of INFECTION deep within the lung that isolates itself within a defined area of the lung (having a clear boundary between the infected tissue and the healthy tissue), usually behind a blocked segment of BRONCHUS. A lung abscess often follows a known bacterial INFECTION such as PNEUMONIA or BRONCHITIS in which INFLAMMATION or excessive mucus blocks an airway, though may occur without an obvious precipitating infection. A lung abscess may cause COUGH, chest discomfort or PAIN, chills, bouts of profuse sweating (diaphoresis), and difficulty BREATHING (DYSPNEA). Chest X-RAY or COMPUTED TOMOGRAPHY (CT) SCAN allows the doctor to visualize the location and size of the abscess. Cultured SPUTUM samples often provide evidence of the infective PATHOGEN. Treatment with ANTIBIOTIC MEDICATIONS successfully eradicates most lung abscesses. Sometimes the abscess requires drainage, which the doctor often can do by placing a drain through the skin. Occasionally OPEN SURGERY is necessary to open and clean the abscess, and to débride (trim away) damaged or dead tissue surrounding the abscess. Most people heal completely and without complication with appropriate treatment. An untreated lung abscess can result in serious health consequences including significant loss of lung tissue or SEPTICEMIA (total body infection, also called sepsis).

See also ATELECTASIS; BRONCHIECTASIS.

lung cancer Malignant tumors that grow in the LUNGS. Lung CANCER may be primary (originate in the lungs) or metastatic (spread to the lungs from cancer that originates elsewhere in the body). There are two main types of lung cancer: small cell lung cancer (SCLC), which is particularly aggressive, and non–small cell lung cancer (NSCLC). Malignant mesothelioma is a specific kind of cancer that arises from asbestos exposure. Cigarette smoking causes 87 percent of lung cancer in the United States and nearly all SCLC. Other causes of lung cancer include exposure to carcinogenic (cancer-causing) substances such as radon (the second-leading cause of lung cancer) and asbestos (which, when combined with smoking, compounds the risk for lung cancer).

Doctors diagnose 175,000 people with lung cancer in the United States each year. Lung cancer is the leading cause of death from cancer among men and women alike, taking the lives of 160,000 Americans each year and accounting for 30 percent of all deaths from cancer. The five-year SURVIVAL RATE is about 14 percent, which is very low compared to many other kinds of cancer. A key reason lung cancer is so frequently fatal is that it does not show symptoms until it is quite advanced, making treatment difficult. Doctors are able to diagnose only 15 percent of lung cancers when the initial tumor remains localized (confined to a distinct site within the lung), a point in time where intervention could vastly improve the chance of survival.

Non–Small Cell Lung Cancer (NSCLC)

About 80 percent of lung cancer is NSCLC. There are three types of NSCLC:

- ADENOCARCINOMA, which arises from the mucus-secreting cells in the bronchial structures
- squamous cell CARCINOMA, which arises from the epithelial cells that form the inner lining of the airways
- large cell carcinoma, which commonly originates in the bronchi and contains neither squamous cells nor adenomatous (glandular) cells

Staging and treatment protocols are the same across the types of NSCLC. The most common type of NSCLC is adenocarcinoma, which is moderately aggressive. Large cell carcinoma, which accounts for about 20 percent of NSCLC, tends to be more aggressive than other NSCLC tumors and larger and metastasized at the time of diagnosis.

BASIC STAGING OF NON–SMALL CELL LUNG CANCER (NSCLC)

Stage	Extent of Cancer	Treatment Protocols/Options
stage 0	cancer cells are present only in the lining of the bronchi (carcinoma in situ)	surgery or local therapy
stage 1a	tumor is less than 3 centimeters (cm), does not involve a major BRONCHUS, and has not spread beyond the site of origin	surgery (lobectomy) possible adjuvant RADIATION THERAPY
stage 1b	tumor may be more than 3 cm, may have spread to the PLEURA, or partially blocks a bronchus but has not spread to LYMPH NODES	surgery (lobectomy) probable adjuvant radiation therapy
stage 2a	tumor is less than 3 cm and has spread to adjacent lymph nodes but not to the pleura or sites beyond the lung	surgery (lobectomy or pneumonectomy) adjuvant radiation therapy
stage 2b	tumor may be more than 3 cm, may have spread to the pleura, or partially blocks a bronchus and has spread to local lymph nodes alternately, tumor may be of any size and involves the chest wall, mainstem bronchus within 2cm of carina, or causes atelectasis of the whole lung	surgery (lobectomy or pneumonectomy) adjuvant radiation therapy possible adjuvant chemotherapy
stage 3a	tumor may be of any size and involves the chest wall, mainstem bronchus within 2cm of carina, or causes atelectasis of the whole lung extension to mediastinal lymph nodes	radiation therapy and CHEMOTHERAPY in combination possible surgery
stage 3b	tumor may be of any size but there is extensive, unresectable invasion of local structures and/or distant lymph node involvement	radiation therapy and chemotherapy in combination, possibly in preparation for surgery
stage 4	cancer has spread to locations distant from the lung	palliative chemotherapy or radiation therapy supportive care

STAGING OF SMALL CELL LUNG CANCER (SCLC)

Stage	Extent of Cancer	Treatment Protocols/Options
limited	cancer is present in only one lung though may have spread to adjacent LYMPH nodes	CHEMOTHERAPY, possibly in combination with RADIATION THERAPY possibly surgery if small, localized tumor without further involvement possible prophylactic cranial irradiation (PCI)
extensive	cancer is present in both LUNGS, adjacent lymph nodes, and other organs (disseminated disease)	chemotherapy palliative measures to relieve symptoms

The least aggressive of the three types of NSCLC is squamous cell carcinoma, which most commonly occurs as a consequence of cigarette smoking. Some people have more than one type of NSCLC at the time of diagnosis.

Small Cell Lung Cancer (SCLC)

Cigarette smoking causes nearly all SCLC. Small cell lung cancer has a characteristic appearance microscopically, sometimes described as "oat cell." This type of lung cancer grows rapidly and often has metastasized by the time of diagnosis. The outlook (prognosis) for extensive SCLC is particularly poor, with a one-year survival rate of about 20 percent. About 70 percent of people have extensive SCLC at the time of diagnosis.

Malignant Mesothelioma

Malignant mesothelioma is a rare form of cancer that occurs mostly in people who have had exposure to asbestos, particularly those who have ASBESTOSIS (a condition of damage to the lungs resulting from asbestos exposure). Malignant mesothelioma commonly arises from the PLEURA, the membrane that covers the lung. Other mesothelial membranes in the body include the PERICARDIUM, which surrounds the HEART, and the peritoneum, which lines the abdominal cavity. Malignant mesothelioma may also arise from these membranes, though that is less common. Malignant mesothelioma often does not show symptoms until it is well advanced, invading the lungs and adjacent organs or spreading through the LYMPH vessels to sites throughout the body. Doctors diagnose about 2,000 people with malignant mesothelioma each year in the United States and stage it similarly to NSCLC.

NONMALIGNANT MESOTHELIOMA

A noncancerous form of mesothelioma, benign fibrous mesothelioma, may grow from the PLEURA to reach considerable size, compressing inward on the lung or causing PLEURAL EFFUSION. Treatment is surgery to remove the tumor, which cures the condition. Benign fibrous mesothelioma does not spread and does not return after removal, though new tumors may develop in other mesothelial membranes.

Symptoms and Diagnostic Path

Early symptoms of lung cancer are often general and do not point specifically to a pulmonary condition. These early symptoms include

- fatigue
- HEADACHE
- loss of APPETITE and unintended weight loss
- dizziness, confusion, and memory disturbances
- JOINT aches and BONE PAIN
- FEVER without evidence of INFECTION

As the cancer becomes more established and takes over more of the lung, symptoms are more specific. These more specific symptoms include

- persistent COUGH
- HEMOPTYSIS (coughing up bloody sputum)
- chest or back pain
- wheezing (whistling sound with exhalation)
- DYSPNEA (shortness of breath)

The diagnostic path begins with a comprehensive medical examination including chest X-RAY and diagnostic blood tests. The chest X-ray may show an abnormality that, with an appropriate history, would suggest a diagnosis of cancer. Further diagnostic procedures may include COMPUTED TOMOGRAPHY (CT) SCAN, MAGNETIC RESONANCE IMAGING (MRI), POSITRON EMISSION TOMOGRAPHY (PET) SCAN, and lung biopsy, BRONCHOALVEOLAR LAVAGE, or exploratory THORACOTOMY.

A crucial element of diagnosis and treatment planning is staging, which identifies the extent to which the cancer has spread. Doctors may perform additional diagnostic procedures to determine the lung cancer's stage. Non–small cell lung cancer and malignant mesothelioma follow a standard cancer staging scale. Because SCLC is so extraordinarily aggressive it follows a unique staging scale that primarily defines the disease as either limited or extensive.

Treatment Options and Outlook

Treatment options and outlook vary according to the type and stage of lung cancer as well as the person's overall health status. Recommendations

regarding staging and treatment options are prone to change as more research and clinical trials are available. An important part of the approach to managing care is ensuring access to current treatment protocols that may include investigational regimens. Most treatment protocols combine different therapies for optimal effectiveness. Nutritional support during cancer treatment is important to help the body fight the cancer and heal. The available treatments for lung cancer include

- Surgery, which removes the cancerous tumor and portion of the lung that contains it, is the treatment of first choice for NSCLC that remains relatively confined. When the cancer has spread to several locations within the same lung, the surgeon may remove the entire lung (pneumonectomy). Surgery may also be appropriate for very early stage SCLC, though SCLC is rarely found when it remains in an operable stage. The key risks of surgery include bleeding, infection, and limited lung function due to removal of part of the lung. Before surgery the person undergoes evaluation to estimate the ability to function after removal (resection) of part or all of the diseased lung.
- CHEMOTHERAPY, which launches a widespread attack on cancer cells throughout the body, is usually a second-line treatment that follows surgery (except in SCLC, for which it is often the first-line treatment) and may be the primary treatment for cancers that are inoperable or have already metastasized beyond the lungs. Common side effects of chemotherapy include fatigue, MOUTH sores, temporary HAIR loss, and NAUSEA and VOMITING.
- RADIATION THERAPY targets inoperable tumors or follows surgery to eradicate any residual cancer cells after the surgeon has removed the cancer. Radiation therapy may be preventive, as in prophylactic cranial irradiation (PCI) which targets the BRAIN to lower the risk for malignant METASTASES that might form there (the brain is a common metastatic site for lung cancer). Radiation therapy also may be the first-line treatment for limited SCLC or reserved for palliative, directed therapy (such as to treat an obstruction that develops in the lung).
- Photodynamic therapy (PDT) is a technique in which the oncologist administers a light-sensitive DRUG that the cancer cells absorb and then targets the cells with a laser that generates light waves to activate the drug and kill the cells that contain it. PDT may be the primary treatment for small or inoperable tumors, particularly those located in the airways. PDT increases the SKIN's sensitivity to the sun or other sources of ultraviolet light.
- Investigational treatments are available through clinical trials. Oncologists and thoracic surgeons are aware of what trials are ongoing for certain types of cancer or patient profiles and can suggest those that are appropriate. As well the U.S. Institutes of Health's National Cancer Institute (NCI) maintains a current listing of cancer trials, accessible at the NCI's Web site (www.cancer.gov/clinicaltrials). Investigational treatments in the clinical trial stage have shown promise in research studies and are undergoing testing in people. It is essential to fully understand the potential benefits (personal as well as for the treatment of lung cancer in general) and risks of any investigational treatment when considering whether to participate in a clinical trial.

COMMON CHEMOTHERAPY DRUGS FOR TREATING LUNG CANCER

carboplatin	cisplatin	cyclophosphamide
dexamethasone	docetaxel	doxorubicin
etoposide	gemcitabine	ifosfamide
metoclopramide	paclitaxel	teniposide
topotecan	vincristine	vinorelbine

Risk Factors and Preventive Measures

Although not all lung cancer is associated with exposure to cigarette smoke, the vast majority is. In general, were it not for cigarette smoking lung cancer would be rare. This makes lung cancer one of the most preventable forms of cancer because eliminating exposure to cigarette smoke virtually eliminates the likelihood of developing lung cancer. People who smoke are at greatest risk, though people who live in households or work in environments where they continually breathe the smoke from cigarette smokers face nearly as great of a risk. Exposure to asbestos further compounds

the risk for cancer in people who smoke, making any type of lung cancer more likely as well as presenting the specific risk for malignant mesothelioma. The most effective measures for preventing lung cancer are not smoking and avoiding circumstances in which other people are smoking.

Exposure to radon, a naturally occurring gas that comes from the soil and can become concentrated within indoor areas such as homes and office buildings, is the second-leading cause of lung cancer. Radon is odorless and invisible, though radon detectors can measure its presence. The U.S. Environmental Protection Agency (EPA) has established a level of 4 picocuries per liter of air (4 pCi/L) as the maximum acceptable level. Simple ventilation measures can reduce or eliminate radon from indoor air.

lungs The paired organs in the chest that bring oxygen-bearing air into the body and expel wastes in the form of exhaled gases, primarily carbon dioxide. The right lung has three lobes and the left lung has two lobes. An indentation between the left lung's two lobes, called the cardiac notch, cradles the HEART. The lungs and heart, along with their supporting structures, fill the thoracic cavity (chest). The heart pumps deoxygenated BLOOD to the lungs via the PULMONARY ARTERIES and receives oxygenated blood back from the lungs via the PULMONARY VEINS, circulating the body's entire blood volume through the lungs once every minute.

The TRACHEA (windpipe) carries air from the THROAT into the lungs, branching into the right and left BRONCHUS to deliver air to the right and left lung, respectively. Each bronchus further subdivides into mainstem bronchi going to each lobe of the lung and into progressively smaller bronchial branches within the lungs. The smallest branches are the bronchioles which terminate in the alveoli, grapelike clusters of tiny sacs where the OXYGEN–CARBON DIOXIDE EXCHANGE takes place. A weblike mesh of capillaries (tiny blood vessels) covers each ALVEOLUS. Each lung contains about 300 million alveoli, which gives lung tissue a spongelike appearance.

Each lobe of the lung consists of multiple segments, anatomically and physiologically distinct. A bronchial structure—bronchi, bronchioles and alveoli along with supporting nerves, arteries, and veins—supplies each segment. The three lobes of the right lung contain 10 segments; the two lobes of the left lung contain 8 segments. This structural and functional compartmentalization aids the efficiency of the lung as well as helps protect it in the event of injury (either traumatic or due to disease), enabling portions of the lung to function when others are damaged or diseased.

Lung tissue contains elastin, a substance that, as the name implies, gives the lung tissue elasticity. The lungs have no ability to move on their own but rather function as a pair of synchronized bellows that stretch and rebound with contraction and relaxation of the DIAPHRAGM and the intercostal muscles (the muscles between the ribs). Contraction of these muscles expands the chest, and the lungs stretch to fill the space which pulls air into the lungs. When these muscles relax, the chest returns to its normal size and the lungs rebound, pushing air back out of the lungs. Each combination of inhalation and exhalation constitutes a RESPIRATORY CYCLE. The lungs complete 15 to 20 respiratory cycles each minute in a healthy adult.

HEALTH CONDITIONS THAT AFFECT THE LUNGS

ASBESTOSIS	ASPERGILLOSIS
ASTHMA	ATELECTASIS
BERYLLIOSIS	BRONCHIECTASIS
BRONCHITIS	BYSSINOSIS
CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD)	CYSTIC FIBROSIS
LUNG ABSCESS	LEGIONNAIRES' DISEASE
PNEUMOCONIOSIS	LUNG CANCER
PNEUMONITIS	*Pneumocystis carinii*
PULMONARY EMBOLISM	PULMONARY EDEMA
PULMONARY HYPERTENSION	PULMONARY FIBROSIS
TUBERCULOSIS	SILICOSIS

Oxygen–carbon dioxide exchange, the process of getting oxygen into and removing carbon dioxide from the blood, is the primary purpose of the lungs and is a function of physics in which mole-

cules follow the path of least resistance. During inhalation the air pressure within the alveoli is less than the air pressure outside the lungs. Oxygen molecules pass across the thin alveolar membrane and into the capillaries to enter the bloodstream. During exhalation the air pressure within the alveoli is greater than the atmospheric air pressure, inducing carbon dioxide molecules to cross from the capillaries into the air in the alveoli.

For further discussion of the lungs within the context of pulmonary structure and function please see the overview section "The Pulmonary System."

See also EPIGLOTTIS.

lung transplantation An OPERATION to replace an individual's diseased lung with a healthy donor lung. Doctors performed the first successful lung transplantation in 1983 and now perform several hundred lung transplantations each year. A lung transplantation may involve one lung or both LUNGS. Less commonly a lung transplantation includes both lungs and the HEART, such as to treat primary PULMONARY HYPERTENSION with HEART FAILURE.

Donor lungs come primarily from people who donate their organs upon death. Live lobular donation, in which a living donor undergoes surgery to have a lobe of the lung removed for transplantation (lobectomy), is occasionally a viable option for people who can find a tissue match among two prospective donors (usually family members) willing and medically capable of donating a healthy lung lobe (live lobular donation typically requires two lobes). Doctors most commonly consider living lobular donation as an option for children who have aggressive CYSTIC FIBROSIS.

Many circumstances influence whether an individual is an appropriate candidate for lung transplantation. Because donor lungs are in short supply, the criteria for transplantation are stringent though vary somewhat among transplant centers. In general, lung transplantation recipients must be under age 65, in good health except for their pulmonary conditions, and demonstrate willingness and ability to comply with the post-transplantation care regimen. Transplantation criteria nearly always exclude people who have cancer (lung or other), immunodeficiency disorders, active TUBERCULOSIS, neurologic or neuromuscular disorders, LIVER disease, or renal (kidney) disease.

CONDITIONS FOR WHICH LUNG TRANSPLANTATION IS AN OPTION

CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD)	CYSTIC FIBROSIS
bronchiolitis	BRONCHIECTASIS
primaryPULMONARY HYPERTENSION	alpha-1-antitrypsin deficiency
PULMONARY FIBROSIS	SARCOIDOSIS

Surgical Procedure

The operation for performing a lung transplantation is a THORACOTOMY, done with the person under general ANESTHESIA. The surgery generally takes three to six hours to complete. Typically one surgical team removes and prepares the donor lung and another surgical team removes the diseased lung from the person receiving the lung transplantation. A donor lung remains viable for only four to six hours. Most people are on CARDIOPULMONARY BYPASS during the surgery, though advances in surgical techniques are reducing the need for this. MECHANICAL VENTILATION during recovery and for up to 72 hours after surgery is common. A lung transplant recipient typically stays about 10 days in the hospital after the surgery, the first three to five of them in the intensive care unit (ICU). Recuperation and return to daily activities takes about three to five months for most people.

Risks and Complications

The most significant risk of lung transplantation is rejection of the transplanted lung. This risk is highest during the first four weeks after the surgery and remains a perpetual threat. The risk of death, usually resulting from acute organ rejection, is highest during the first year after the transplant. People who receive organ transplants must take IMMUNOSUPPRESSIVE THERAPY for the remainder of their lives. These medications block the IMMUNE SYSTEM from perceiving the transplanted organ as foreign and attacking it. Immunosuppressive therapy increases the risk for INFECTION. Infections such as INFLUENZA or PNEUMONIA can be life-threatening for people with organ transplants; most transplant programs require organ recipients to agree to receive annual immunizations to help protect

against these infections among their criteria for accepting recipients. Long-term immunosuppression carries numerous risks, including a significantly increased likelihood for developing LYMPHOMA, a cancer of the LYMPH structures.

A major complication that affects up to 50 percent of lung transplant recipients is bronchiolitis obliterans, a condition in which the bronchioles (the smallest airways in the lungs) become inflamed and then fibrotic. The fibrotic (SCAR) tissue blocks the narrow openings of the bronchioles, preventing air from reaching the alveoli. As greater numbers of bronchioles become involved, pulmonary function deteriorates. Bronchiolitis is itself an indication for lung transplantation. CORTICOSTEROID MEDICATIONS can help limit the INFLAMMATION though cannot prevent the condition from developing or progressing.

Outlook and Lifestyle Modifications

Most people who receive transplanted lungs can return to many of their regular activities, including physical exercise, with few restrictions unless complications develop. It is important to avoid cigarette smoke and other substances that may irritate or inflame the lungs, and to minimize exposure to other people who have viral or bacterial infections such as sore throats and other common illnesses. Lung transplantation requires regular medical care for follow-up and evaluation of pulmonary function and lung health, with immediate treatment for potential problems and complications. About 45 percent of people who undergo lung transplantation live five years or longer with their donor lungs.

See also HEART TRANSPLANTATION; ORGAN TRANSPLANTATION; SURGERY BENEFIT AND RISK ASSESSMENT.

mechanical ventilation A method for providing assisted respiration to an individual whose LUNGS cannot maintain respiratory support on their own (RESPIRATORY FAILURE). During mechanical ventilation, a machine (the ventilator) rhythmically pushes air into the lungs through an endotracheal tube or TRACHEOSTOMY tube. An endotracheal tube is a flexible plastic tube inserted through the NOSE or MOUTH into the TRACHEA, with an inflatable cuff that holds it in place. A tracheostomy tube enters the trachea through an incision in the neck, bypassing the upper airways (including the mouth and throat). The lungs continue to do the work of OXYGEN–CARBON DIOXIDE EXCHANGE.

Mechanical ventilation may provide full respiratory support, in which BREATHING occurs only with the ventilator's function, or partial respiratory support, in which the ventilator functions only when the person's natural breathing is insufficient. As with normal respiration the inhalation phase of the RESPIRATORY CYCLE is active, with the ventilator sending air under pressure into the lungs, and the exhalation phase is passive, with the ventilator allowing the thoracic cavity's relaxation to expel air. The ventilator typically utilizes continuous POSITIVE AIRWAY PRESSURE (CPAP), which keeps the trachea, bronchi, and bronchioles from collapsing.

There are numerous applications for, and varying levels of, mechanical ventilation. Temporary mechanical ventilation is customary after major cardiovascular or pulmonary operations and during recovery from major trauma. Other circumstances in which mechanical ventilation is a therapeutic option include

- high-level (cervical and upper thoracic) SPINAL CORD INJURY that affects the nerves regulating contraction of the DIAPHRAGM and intercostal muscles (the muscles of breathing)
- injury to the respiratory centers of the BRAIN and brainstem
- degenerative neurologic conditions that affect respiratory function
- increased respiratory demands that exceed the lungs' ability to deliver, such as in severe infections

The ventilator is primarily a mechanized bellows that fills with air (and supplemental oxygen if necessary) that inflates the lungs using positive pressure. The doctor determines the RESPIRATORY RATE, air volume (amount of air the ventilator delivers), and flow pressure (pressure under which the ventilator delivers air to the person). In some situations the person does not need help with breathing but just needs an endotracheal tube or tracheostomy to protect the airway and minimize the risk of aspirating foreign matter into the lungs. In such a situa-

tion the tube may connect only to an oxygen source without a ventilator.

THE IRON LUNG

One of the first mechanical ventilators was nicknamed the iron lung. This device, which used a vacuum pump within a sealed chamber to cause the chest to rise, debuted during the POLIOMYELITIS epidemics of the 1930s and 1940s. Though cumbersome (it encased the person from toes to neck), the iron lung saved countless lives.

Complications of short-term mechanical ventilation are usually minor and may include sore throat (from the endotracheal tube) and INFECTION. Infection is a greater risk with long-term mechanical ventilation, with PNEUMONIA being the most common. The longer a person receives mechanical ventilation, the more difficult it becomes to wean the person to breathe independently. Long-term mechanical ventilation becomes an element of life support, which raises questions of QUALITY OF LIFE. Doctors encourage adults to establish advance directives to help guide life-support decisions.

See also ACUTE RESPIRATORY DISTRESS SYNDROME (ARDS); CARDIOPULMONARY BYPASS; OXYGEN SATURATION.

middle lobe syndrome See ATELECTASIS.

oxygen–carbon dioxide exchange The process by which oxygen passes from the air in the LUNGS to the HEMOGLOBIN in the BLOOD, and carbon dioxide from the hemoglobin passes into the air in the lungs. Oxygen–carbon dioxide exchange is fundamental to life and is the primary function of the lungs. Oxygen–carbon dioxide exchange takes place between the alveoli, the tiny bubblelike sacs deep within the lungs, and the capillaries, the tiniest blood vessels of the cardiovascular system. The membranous tissue of an ALVEOLUS is only one cell or two cells in thickness. A mesh of capillaries encloses each of the 300 million or so alveoli in the lungs. The walls of the capillaries are also only one cell in thickness. Some disease states cause this interface to thicken, thus making the oxygen–carbon dioxide exchange ineffective.

Oxygen and carbon dioxide molecules (as well as the molecules of other gases such as nitrogen and highly toxic carbon monoxide) can easily pass through the walls of the alveoli and the capillaries, moving in the direction of least resistance. Oxygen molecules move from the alveoli into the capillaries with inhalation. Hemoglobin molecules in the erythrocytes (red blood cells) attract the oxygen molecules, binding with them to carry them through the bloodstream. At exhalation carbon dioxide molecules cross the alveolar membrane to join the gases within the alveoli. Exhalation expels the carbon dioxide into the atmosphere.

Factors that influence oxygen–carbon dioxide exchange include the concentration of oxygen in the air, which is about 21 percent at sea level and decreases with elevation.

Numerous pulmonary conditions affect oxygen–carbon dioxide exchange. Infections such as INFLUENZA and PNEUMONIA can cause the alveoli to fill with fluid, blocking air from reaching the alveolar membranes. Inhaled substances, notably cigarette smoke, can clog small bronchioles, preventing air from reaching the alveoli. Eliminating their causes usually reverses most if not all of these circumstances to restore full function (though damage resulting from long-term cigarette smoking or repeated pneumonia can become permanent). Conditions that cause scarring (fibrosis), such as CYSTIC FIBROSIS, SARCOIDOSIS, PNEUMOCONIOSIS, and untreated TUBERCULOSIS, block air from reaching the alveoli. ATELECTASIS and BRONCHIECTASIS are collapses of lung segments that also block the movement of air into the deep lung tissues. Conditions in which the alveoli rupture and form enlarged sacs, such as alpha-1-antitrypsin deficiency (an inherited genetic disorder), destroy the surface area and reduce the effectiveness of the gas exchange. Both late-stage CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD) and early emphysema-predominant COPD cause scarring and alveolar rupture. Such structural damage is permanent.

See also CYSTIC FIBROSIS AND THE LUNGS; LUNG TRANSPLANTATION; OXYGEN SATURATION; OXYGEN THERAPY.

oxygen saturation The percentage of HEMOGLOBIN molecules in the BLOOD that are bound to oxygen molecules. Normal oxygen saturation of the arterial blood is 96 to 98 percent. Saturation significantly below normal, for instance 88 percent, indicates RESPIRATORY FAILURE and may be life-threatening. Oxygen saturation is an essential measurement for assessing cardiovascular and pulmonary effectiveness. Inadequate oxygen saturation in the blood is hypoxemia.

The primary method for measuring oxygen saturation is pulse oximetry, which is painless and noninvasive. The pulse oximeter consists of two

components, an emitter and a tiny computer chip. The emitter is a small device that fits over the fingertip or on the EAR lobe. It projects beams of red and infrared light, which pass through the tissue to a sensor on the other side. The volume of blood in the tissue at systole (peak contraction of the HEART) is greater, resulting in more light being absorbed than with the lesser volume of blood in the tissue at diastole (relaxation of the heart). The oximeter's computer chip measures this difference and uses it to mathematically calculate the percentage of oxygen the hemoglobin carries.

See also OXYGEN–CARBON DIOXIDE EXCHANGE; OXYGEN THERAPY.

oxygen therapy The administration of oxygen via nasal cannula, face mask, endotracheal tube (tube inserted into the THROAT), or transtracheal catheter (small tube surgically placed through the outside of the throat into the TRACHEA). Oxygen therapy delivers oxygen at a percentage higher than that of normal air, which is 21 percent oxygen at sea level. Oxygen therapy can deliver oxygen from about 25 percent to 100 percent. This boosts the OXYGEN SATURATION of the BLOOD, which becomes necessary when the LUNGS cannot adequately diffuse oxygen into the blood or the HEART cannot circulate oxygenated blood at a level that meets the body's needs.

Oxygen is highly flammable. Do not smoke, have an open flame, or use electrical appliances (including extension cords) in the vicinity of the oxygen supply.

Because 100 percent oxygen can be harmful to body tissues, doctors administer this level of oxygen therapy only to treat respiratory crisis. Supplemental oxygen therapy may be an element of treatment for cardiovascular conditions such as ISCHEMIC HEART DISEASE (IHD) and HEART FAILURE as well as pulmonary conditions such as CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD), PNEUMONIA, severe ASTHMA, and ATELECTASIS.

In the hospital setting the oxygen supply is centralized, with access ports in patient care areas. Oxygen-delivery tubing plugs into the port, with an individualized flow regulator to adjust the percentage of oxygen. Oxygen tanks for home oxygen therapy contain compressed or frozen (liquid) oxygen, with flow regulators and often a device that releases oxygen only on inhalation. Home oxygen therapy may use an oxygen concentrator instead of supplemental oxygen. An oxygen concentrator extracts nitrogen from room air to increase the air's concentration of oxygen. Oxygen concentrators can deliver oxygen only at low flow rates, however, making them useful only for people who require minimal oxygen supplementation. It is important to have adequate supplemental humidification as well during oxygen therapy, as the higher concentration of oxygen is drier than environmental air. Oxygen therapy may be short-term or long-term treatment, depending on the condition that causes its use. The person may also use oxygen therapy continuously, only during sleep, or only during physical activity depending on his or her underlying disease and respiratory needs.

OXYGEN THERAPY

Oxygen Therapy Device	Percentage of Oxygen
nasal cannula	25 to 40 percent
face mask	30 to 50 percent
nonrebreathing mask	50 to 90 percent
transtracheal catheter	up to 100 percent
endotracheal tube	up to 100 percent
bag and mask resuscitator	up to 100 percent

See also OXYGEN–CARBON DIOXIDE EXCHANGE; TRACHEOSTOMY.

P

pleura The membrane that covers the exterior surface of the LUNGS and lines the inside of the thoracic cavity. The pleura has the consistency of wet tissue paper and appears to cling to the lungs. The pleural space (thin area between the two layers of pleura) protects the lungs from contact with other structures within the thoracic cavity, and contains a very small amount of fluid that reduces friction with BREATHING. The pleural space can become irritated, inflamed, and infected, causing conditions such as PLEURISY and PLEURAL EFFUSION.

For further discussion of the pleura within the context of pulmonary structure and function please see the overview section "The Pulmonary System."

See also ALVEOLI; BRONCHUS; INFECTION; INFLAMMATION; THORACIC DUCT; TRACHEA.

pleural effusion An increase in the amount of fluid between the PLEURA. In health there is a very small amount of fluid, only 10 to 20 milliliters, within the pleural cavity. A pleural effusion can contain upward of 2 liters of fluid, though much smaller quantities (less than 400 milliliters) are more common. Pleural effusion compresses the LUNGS, preventing them from fully expanding. Many conditions can cause pleural effusion. Pleural effusion is exudative when it results from INFLAMMATION of the pleura (PLEURISY). Pleural effusion is transudative when pressure changes in the body's fluid balance (osmotic) mechanisms allow more fluid to cross the pleural membrane such as with HEART FAILURE. A hemothorax exists when the excess fluid is BLOOD, and a chylothorax occurs when the excess fluid is LYMPH.

Many people who have pleural effusion have no symptoms. When present, symptoms include

- DYSPNEA (shortness of breath or difficulty BREATHING)
- CHEST PAIN, primarily with inhalation
- fatigue or weakness

The diagnostic path typically includes chest X-RAY, COMPUTED TOMOGRAPHY (CT) SCAN or ULTRASOUND, and THORACENTESIS (withdrawing a sample of the fluid using a syringe with a large needle). Treatment aims to reduce the volume of fluid as well as identify the underlying cause (such as infection). Thoracentesis may also be therapeutic, allowing the pulmonologist to drain away the excess fluid. Doctors generally drain no more than 1.5 liters of fluid at a time because more substantial withdrawal can result in rapid fluid shifts, causing cardiovascular instability and the development of pulmonary edema (fluid accumulation in the lung tissue). Recovery depends on the condition causing the pleural effusion.

See also LUNG CANCER; PULMONARY EDEMA.

pleurisy INFLAMMATION of the PLEURA, also called pleuritis. Pleurisy can develop as a consequence of direct irritation or INFECTION in the pleural space, or as a consequence of infection or INFLAMMATION involving the LUNGS such as TUBERCULOSIS or PNEUMONIA. AUTOIMMUNE DISORDERS can cause inflammation, such as SYSTEMIC LUPUS ERYTHEMATOSUS (SLE) and SARCOIDOSIS. The characteristic symptom of pleurisy is sudden, sharp, and often severe PAIN during inhalation and exhalation that subsides with holding the breath. The pain may occur on only one side of the chest or both sides, and may feel as though it comes from the back or under the shoulder blades, depending on the site of the inflammation. Some people also have a persistent, dry COUGH.

Upon AUSCULTATION with a STETHOSCOPE the doctor can hear an abnormal abrasive sound called a pleural rub, which is the sound of the irritated layers of the pleura rubbing against each other. Chest X-RAY confirms whether there is PLEURAL EFFUSION in which the pleural cavity contains excessive fluid. The doctor may also choose to do an ULTRASOUND or COMPUTED TOMOGRAPHY (CT) SCAN of the thorax.

Treatment targets any underlying cause, when identified. For simple pleurisy, treatment is usually NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) to relieve inflammation and pain. The doctor may also prescribe a cough medicine to control coughing. Most people cover fully and uneventfully from an episode of pleurisy. People who have chronic pulmonary conditions or who smoke may have recurrent pleurisy, which can result in long-term thickening or scarring of the pleura.

See also BRONCHITIS; PERICARDITIS; PNEUMONITIS; SMOKING AND HEALTH.

pneumoconiosis The collective term for pulmonary conditions that result from occupational exposure to dust and fiber irritants. The conditions result in the same end-stage disease, pulmonary fibrosis, though follow different patterns of progression, depending on the substance and exposure patterns. The primary forms of pneumoconiosis that occur in the United States are

- ANTHRACOSIS, also called coal worker's pneumoconiosis (CWP) and black lung disease, which results from inhalation of coal dust
- ASBESTOSIS, which results from inhalation of asbestos fibers and dust
- BERYLLIOSIS, which results from inhalation of beryllium dust
- BYSSINOSIS, also called brown lung and cotton bract disease, which results from inhalation of raw cotton fibers and dust
- SILICOSIS, which results from inhalation of silica dust

U.S. occupational health experts and federal agencies began tracking and reporting deaths due to pneumoconiosis in 1968, as data related to occupational health. The federal Coal Mine Health and Safety Act of 1969, which established levels of dust exposure standards, was the first substantial effort in the United States to reduce such deaths. The Black Lung Act of 1972 further acknowledged the significant occupational health problems of coal workers, expanding the regulatory scope of the 1969 legislation and establishing a program of government-funded health care for coal workers who developed anthracosis (called black lung disease in the legislation and regulations).

Federal regulation controls occupational exposure to other sources of pneumoconiosis, notably silica, as well. Health experts attribute the declining numbers of diagnoses and deaths in all pneumoconioses, except asbestosis, largely to such controls. The number of people diagnosed with and who die from asbestosis continues to climb, however, because the time between exposure and illness is a minimum of 20 years. Regulatory changes will benefit workers who began working in affected occupations in the last decades of the 20th century, though health experts anticipate that asbestosis will keep rising among those whose work history predates regulations as their average age increases. Peak exposure to asbestos in the United States occurred in 1975, according to the U.S. Centers for Disease Control and Prevention (CDC), so health experts expect asbestos-exposure related illness to peak between 2015 and 2020. However, asbestos exposure in general dropped significantly after the late 1970s when federal legislation restricted the use of asbestos in materials such as building insulation, ceiling tiles, and flooring.

The other key factor contributing to diminishing disease and death rates for pneumoconiosis is the declining numbers of people working in occupations where exposure is a hazard. The number of coal miners in the United States dropped by half between the 1980s and the 1990s, for example, as more mining functions have become automated or mechanized. Automation continues to reduce hazardous occupational exposures in most industries.

Symptoms and Diagnostic Path

Dry, nonproductive COUGH and DYSPNEA (shortness of breath), particularly with exertion, are the key symptoms of most forms of pneumoconiosis. Anthracosis, berylliosis, byssinosis, and silicosis

FORMS OF PNEUMOCONIOSIS

Form of Pneumoconiosis	Causative Substance	Occupational Exposure
anthracosis	coal dust	coal mining
asbestosis	asbestos fibers and dust	insulation, aerospace components, brake lining, shipbuilding
berylliosis	beryllium dust	electronics, aerospace manufacturing, metal working, metal reclamation processing
byssinosis	raw cotton fibers and dust	raw cotton processing, textile production
silicosis	silica dust	sandblasting, sand and gravel mining

may show symptoms after relatively short periods of exposure and often improves when exposure ceases. Asbestosis may develop after relatively short exposure though symptoms typically do not become apparent for decades after exposure. The diagnostic path focuses on occupational history and exposure patterns. Diagnostic examination typically includes AUSCULTATION, chest X-RAY, pulmonary function tests, and imaging procedures such as ULTRASOUND, COMPUTED TOMOGRAPHY (CT) SCAN, or MAGNETIC RESONANCE IMAGING (MRI). The pulmonologist may also perform BRONCHOSCOPY, BRONCHOALVEOLAR LAVAGE, or lung biopsy to rule out other causes of symptoms.

Treatment Options and Outlook

The first and most important element of treatment is to end the exposure. Nearly all forms of pneumoconiosis improve with this measure. Permanent damage to the lungs that has already occurred, such as fibrosis, does not reverse though its progression may stop. The disease process of asbestosis is such that damage continues long after exposure ceases. The outlook depends on the form of pneumoconiosis, the length or extent of exposure, and whether the person also smokes. Cigarette smoking significantly worsens both the disease process and the outlook.

Risk Factors and Preventive Measures

Occupational pneumoconiosis develops with exposure to substances that enter and remain in the lungs. Avoiding such exposure is the only certain means of prevention. Workplace measures to reduce exposure to the lowest possible levels include environmental controls to filter or otherwise contain dusts and fibers. Personal protective equipment may include clothing, masks, and respirators.

pneumonectomy See THORACOTOMY.

pneumonia INFLAMMATION of the LUNGS, usually the result of an INFECTION, that causes the alveolar sacs to fill with fluid or pus. Pneumonia is the most serious consequence of INFLUENZA, and in combination with influenza is the seventh leading cause of death in the United States. Pneumonia may be lobar, affecting the entire lobe of the lung, or bronchial, affecting diffuse areas of lung. The more of the lung that is involved, the more serious the consequences. People most vulnerable to infection resulting in pneumonia and complications from pneumonia are the very young, the very old, and those who have immunodeficiency disorders such as HIV/AIDS or other serious health conditions such as CANCER. About two million people in the United States develop pneumonia each year, and about 60,000 die as a result of the infection or its complications.

Pathogens that can cause pneumonia include viruses, BACTERIA, and fungi. The pneumonias that result from these pathogens are contagious—that is, an infected person can pass them to others through sneezing and coughing. SPUTUM (mucus and debris from the respiratory tract) contains the infective agent. Pneumonia also can develop after exposure to bacteria aspirated into the lungs (such as in a person who is weak and vomiting). Nosocomial pneumonias develop from pathogens common in environments such as hospitals and skilled nursing facilities and infect people who are already weak as a result of other health conditions (especially those who are IMMUNOCOMPROMISED).

Viral Pneumonia

A number of viruses can cause pneumonia, the most common of which are influenza A, influenza B, parainfluenza, respiratory syncytial VIRUS, ADENOVIRUS, varicella-zoster virus, EPSTEIN-BARR VIRUS, and coxsackievirus. CYTOMEGALOVIRUS (CMV) pneumonia can develop in people who are IMMUNOCOMPROMISED. ANTIVIRAL MEDICATIONS are available for some of these viral infections and can shorten the course of the infection and lessen the severity of symptoms. Most otherwise healthy people recover fully from viral pneumonia. Bacterial pneumonia may develop secondarily to viral pneumonia.

Bacterial Pneumonia

Pneumonia in people over age 30 is more likely to result from bacterial infection than other causes. *Staphylococcus aureus, Haemophilus influenzae* type b (Hib), *Chlamydia pneumoniae*, and *Streptococcus pneumoniae* are the strains of bacteria most commonly responsible for bacterial pneumonia. *S. pneumoniae* causes the most common form of bacterial pneumonia, pneumococcal pneumonia, which often follows a viral infection of the upper respiratory tract. Hib pneumonia, despite the bacterium's name, has nothing to do with the influenza virus and affects primarily young children. Hib vaccination has nearly eliminated this type of pneumonia among children in the United States. *S. aureus* tends to be opportunistic and accounts for about 20 percent of nosocomial pneumonia. ANTIBIOTIC MEDICATIONS are necessary to treat bacterial pneumonia. Even with antibiotic therapy, however, bacterial pneumonia is a serious illness that can be deadly among the very young and the very old.

Mycoplasmal Pneumonia

Mycoplasma are tiny organisms related to bacteria, commonly called atypical bacteria. The pneumonia they cause is typically mild though tends to linger. A common nickname for mycoplasmal pneumonia as "walking pneumonia" because its symptoms are enough to make people feel unwell though usually not enough to interrupt regular activities. Most people recover without treatment, though antibiotics usually speed recovery. COUGH and HEADACHE may persist for several weeks.

Fungal Pneumonia

Fungi may cause pneumonia in people who take antibiotics for an extended period of time, as antibiotics suppress the NORMAL FLORA (normally present bacteria) that otherwise keep fungi in check. Fungal pneumonias are rare but when invasive in someone who is immunocompromised, they can be life-threatening.

Pneumocystic Carinii Pneumonia

Pneumocystis carinii is an opportunistic pneumonia that occurs nearly exclusively in people who are immunocompromised, including those who have HIV/AIDS, are receiving IMMUNOSUPPRESSIVE THERAPY following organ transplantation, or are undergoing chemotherapy for cancer treatment. During the early days of the AIDS epidemic, *P. carinii* pneumonia was often the first indication that a person had HIV/AIDS. Doctors may prescribe prophylactic ANTIFUNGAL MEDICATIONS for people at risk for *P. carinii* pneumonia. Such prophylaxis has now made *Pneumocystic* pneumonia a relatively rare event in people whose HIV infection is well-managed.

Symptoms and Diagnostic Path

The symptoms of pneumonia vary somewhat with the type of pneumonia, though commonly include

- cough that produces greenish yellow sputum or HEMOPTYSIS (bloody sputum)
- FEVER (sometimes high)
- chills or sweating

- generalized discomfort and aches
- fatigue
- chest discomfort or PAIN, especially with inhalation
- DYSPNEA (shortness of breath) or TACHYPNEA (rapid BREATHING)

Symptoms may develop gradually or come on suddenly. Though the pattern of the symptoms provides good clues as to the cause of the pneumonia, the doctor cannot determine whether the infection is viral or bacterial without sputum or blood tests. Viral pneumonia does not respond to antibiotic therapy, though a good number of people who have viral pneumonia develop secondary bacterial pneumonia that does require antibiotics. The diagnostic path typically includes chest X-ray, which shows the areas of infiltration (fluid or pus accumulation) within the lungs. Other factors that help determine the kind of pneumonia include knowledge of local or regional outbreaks of viral or bacterial pneumonia, history of recent upper respiratory infection or influenza, and the presence of other health conditions such as HIV/AIDS. Sputum culture may also help in the diagnosis although most viruses and atypical bacteria do not readily grow in culture.

Treatment Options and Outlook

Treatment depends on the cause of the infection and may include antibiotics for bacterial pneumonia, antiviral medications or management of symptoms for viral pneumonia, and antifungal medications for fungal pneumonia. Because secondary bacterial pneumonia can develop as a complication of other types of bacteria, symptoms that fail to improve within 10 days or that worsen require further medical evaluation. Most people who are otherwise healthy make full recovery from pneumonia, though may take six to eight weeks to feel back to normal.

Risk Factors and Preventive Measures

The very young, the very old, and those who have serious health conditions of any kind are at greatest risk for pneumonia. Health experts recommend annual influenza IMMUNIZATION and pneumococcal vaccination for people who have such risks. Diligent HAND WASHING and conscientious cough and SNEEZE precautions help reduce the spread of infectious agents. Early diagnosis and appropriate treatment reduce the likelihood of complications.

See also ASPERGILLOSIS; CHEST PAIN; LEGIONNAIRES' DISEASE; NOSOCOMIAL INFECTIONS.

pneumonitis INFLAMMATION of the LUNGS resulting from exposure to an irritant. The inflammation causes the airways to narrow and to increase mucus secretion, reducing the pathways for the flow of air. The major types of pneumonitis are

- aspiration pneumonitis, which develops when foreign matter, such as vomitus or water, enters the airways and lungs
- chemical pneumonitis, which results from inhaling toxic fumes
- hypersensitivity pneumonitis, which is an IMMUNE REACTION to an inhaled substance
- radiation pneumonitis, which occurs as a SIDE EFFECT of RADIATION THERAPY to the chest and lower neck, such as to treat LUNG CANCER, THYROID CANCER, or BREAST CANCER

The primary symptoms of pneumonitis are persistent COUGH and DYSPNEA (shortness of breath). The doctor makes the diagnosis on the basis of the history of the symptoms, including when they began, what circumstances existed, and in particular any known or suspected exposures that occurred. Near drowning, for example, may result in aspiration of water. SWALLOWING DISORDERS may allow food or drink to enter the airways. Chemical pneumonitis and hypersensitivity pneumonitis often result from occupational exposures (and sometimes exposure to pets such as birds) and may indicate the early stages of pulmonary disease related to exposures such as to dusts and fibers. Chest X-ray, arterial BLOOD gases, pulmonary function tests, and chest computed tomography (chest CT) are among the diagnostic procedures that may help identify the extent of pulmonary involvement and its effect on oxygenation.

Treatment is often CORTICOSTEROID MEDICATIONS to relieve inflammation, which may allow the lungs to return to normal function. The doctor may also prescribe ANTIBIOTIC MEDICATIONS to treat

secondary INFECTION if present, or when the cause of the pneumonitis is bacterial infection. Elimination of irritants, when known, prevents the pneumonitis from recurring. Most people recover fully and without complications after the inflammation subsides. Chronic pneumonitis may result in scarring (fibrosis) and permanent damage to pulmonary structures, however.

See also ASTHMA; HYPOXIA; MULTIPLE CHEMICAL SENSITIVITY SYNDROME; PLEURISY; PNEUMOCONIOSIS; PNEUMONIA.

pneumothorax A circumstance in which air gets in the pleural space (membrane space between the pleural linings of the lung and the thoracic cavity). Pneumothorax results in collapse of a portion of, or the entire, lung. Doctors identify different kinds of pneumothorax. They include

- spontaneous pneumothorax, in which the pneumothorax occurs for no identifiable reason or as a consequence of severe lung disease such as CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD) or TUBERCULOSIS
- simple pneumothorax, in which air enters the pleural space and part of all of the lung collapses but there is no pressure on surrounding structures
- tension pneumothorax, in which the pneumothorax occurs and pressure continues to build in the pleural space, putting pressure on the heart and causing potentially life-threatening cardiovascular collapse
- traumatic pneumothorax, in which air enters the pleural cavity as a result of injury or surgery

Symptoms include DYSPNEA (shortness of breath) and sudden, sharp PAIN that worsens with deep BREATHING or coughing. Some people develop CYANOSIS (bluish hue to the lips and SKIN) that indicates the body is not receiving enough oxygen. TACHYCARDIA (rapid HEART RATE), TACHYPNEA (rapid breathing), and HYPOTENSION (low BLOOD PRESSURE) are also common. The diagnostic path includes AUSCULTATION, which often reveals reduced or absent BREATH SOUNDS, and chest X-RAY, which shows the area of lung collapse.

A pneumothorax that involves only a small portion of the lung often heals itself. A larger pneumothorax requires insertion of a chest tube (done with local ANESTHESIA) to remove the air and allow the lung to reinflate. Most people who require such treatment stay in the hospital until the affected lung returns to normal function and the doctor can safely remove the chest tube. About half of people who have one episode of spontaneous pneumothorax have a subsequent episode, though most people do not experience any permanent lung damage. People who are tall and thin are most vulnerable to spontaneous pneumothorax. Spontaneous pneumothorax is also more common among people who smoke.

See also BRONCHIECTASIS.

positive airway pressure Methods to maintain higher than normal air pressure against the inner walls of the bronchi and TRACHEA during BREATHING. Positive airway pressure may be a treatment for ATELECTASIS (collapsed lung), chronic RESPIRATORY FAILURE, and SLEEP APNEA. Positive airway pressure is also an important aspect of MECHANICAL VENTILATION.

The most common method of positive airway pressure is continuous positive airway pressure (CPAP), in which a small pump pushes a steady flow of air through a face mask to maintain enough pressure against the airways to keep them open and unobstructed during sleep. CPAP is a common and an effective treatment for sleep apnea. Bilevel positive airway pressure, or BiPAP, is a flexible variation of CPAP. The conventional CPAP device maintains a constant airway pressure for inhalation and exhalation. BiPAP provides additional pressure or support during inspiration to aid inhalation.

See also BRONCHUS; OXYGEN THERAPY; SLEEP APNEA.

postural drainage See CHEST PERCUSSION AND POSTURAL DRAINAGE.

pulmonary edema Abnormal fluid accumulation within the alveoli and the interstitial tissues of the LUNGS, typically resulting from CARDIOVASCULAR DISEASE (CVD) such as HEART FAILURE or CARDIOMYOPATHY. PNEUMONIA, ACUTE RESPIRATORY DISTRESS SYNDROME

(ARDS), smoke inhalation, near drowning, and high altitude can also cause pulmonary edema.

Pulmonary edema can be a life-threatening condition and requires immediate medical evaluation and treatment.

The accumulated fluid of pulmonary edema limits air from entering the alveoli, affecting the OXYGEN–CARBON DIOXIDE EXCHANGE. The consequence is inadequate oxygen diffusion into the BLOOD with resulting HYPOXIA.

Symptoms and Diagnostic Path

The symptoms of pulmonary edema tend to come on quickly and include

- DYSPNEA (difficulty BREATHING), often severe or worse when lying down
- frothy HEMOPTYSIS (coughing up bloody SPUTUM)
- diaphoresis (profuse sweating or chills with sweating)
- HEADACHE or light-headedness
- COUGH
- Wheezing or gurgling sounds when breathing

Respiratory failure can rapidly develop. The diagnostic path includes AUSCULTATION with a stethoscope to listen to BREATH SOUNDS, which typically reveals rales (crackles). A chest X-RAY shows the accumulated fluid. Arterial blood gases assess the extent of hypoxia. Diagnostic procedures to evaluate cardiovascular function include ELECTROCARDIOGRAM (ECG), ECHOCARDIOGRAM, and CARDIAC CATHETERIZATION if the doctor suspects CORONARY ARTERY DISEASE (CAD) or MYOCARDIAL INFARCTION.

Treatment Options and Outlook

Treatment begins with OXYGEN THERAPY to improve oxygenation and, if the edema is from heart failure, usually diuretic medications to help pull the excessive fluid into the circulation so the KIDNEYS can pass it from the body. Additional treatment targets the underlying cause of the pulmonary edema, which may be cardiovascular or pulmonary. High altitude pulmonary edema (HAPE) requires prompt oxygen therapy with descent to a lower altitude as soon as is feasible. Climbers sometimes underestimate the seriousness of HAPE until symptoms become overwhelming and life-threatening. Any climber, regardless of high-altitude acclimation and climbing experience, is vulnerable to HAPE and all climbers should be familiar with early symptoms.

Pulmonary edema is a serious circumstance that can result in death when not promptly recognized and treated. The underlying cause determines the outcome. When the cause is cardiovascular, treatment may include CORONARY ARTERY BYPASS GRAFT (CABG) or ANGIOPLASTY to improve the flow of blood to the HEART. Medications may strengthen the heart and stabilize HEART RATE in heart failure, improving the heart's ability to pump blood. With appropriate treatment, many people recover completely from pulmonary edema. When the cause is noncardiogenic, such as due to severe infection or ARDS, treatment targets reversing the underlying disease and providing respiratory support until lung function returns to normal.

Risk Factors and Preventive Measures

The primary risk factor for cardiogenic pulmonary edema is cardiovascular disease. The most effective preventive measures are those that reduce the risks for cardiovascular disease: No smoking, maintain appropriate weight, exercise daily, and eat nutritiously. It is also important to take medications for diagnosed conditions such as HYPERTENSION (high BLOOD PRESSURE) as prescribed.

See also ASCITES; ESOPHAGEAL VARICES; PULMONARY HYPERTENSION.

pulmonary embolism A BLOOD clot that blocks the flow of blood through the main pulmonary ARTERY, the right or left pulmonary artery, or branching arteries within the lobes and segments of the LUNGS. Untreated pulmonary embolism can cause respiratory distress or death; about 30,000 people die each year in the United States as a result of pulmonary embolism.

Pulmonary embolism is a life-threatening condition that requires emergency medical care.

Pulmonary embolism is a potential complication of blood clots that develop within the veins,

typically the deep veins of the legs. It most commonly develops as a consequence of venous stasis, in which the blood moves sluggishly through the veins. The blood's slow movement allows blood to pool, permitting clots to begin to form especially on and around the valves in the veins. Clot fragments or the entire clot can break free, floating through the bloodstream.

Because the veins become larger as they approach the HEART, the bloodstream easily carries the clots through the right heart and into the pulmonary arteries and the lungs. Occasionally the clot that causes a pulmonary embolism originates in the heart's right atrium. Large clots can occlude (block) the pulmonary arteries at the point where the right and left pulmonary arteries diverge (bifurcation of the pulmonary artery).

As a consequence of the intimate correlation between alveolar function and the flow of blood through the capillary network that enmeshes the alveoli, the loss of capillary flow resulting from pulmonary embolism effectively shuts down all alveoli beyond (distal to) the site of the occlusion. Any loss of functioning alveoli subsequently limits the ability of the lungs to convey oxygen to the blood. The larger the occluded artery, the more immediate and significant the pulmonary consequences.

Symptoms and Diagnostic Path

The symptoms of pulmonary embolism vary widely and can be subtle or may be as severe and immediate as those of HEART ATTACK, and are similar. Such symptoms include

- sudden, severe CHEST PAIN
- DYSPNEA (difficulty BREATHING)
- diaphoresis (breaking into a cold sweat)
- HYPOTENSION (low BLOOD PRESSURE)
- TACHYCARDIA (rapid heart rate)
- TACHYPNEA (rapid BREATHING)

A person who experiences a massive pulmonary embolism may have little time between feeling fine and going into shock and cardiovascular collapse. Smaller emboli or recurrent (chronic) pulmonary embolism episodes generally produce milder variations of these same symptoms along with productive COUGH and HEMOPTYSIS (blood in the SPUTUM).

The diagnostic path seeks immediately to determine whether the symptoms are cardiovascular (heart attack) or pulmonary. An ELECTROCARDIOGRAM (ECG) does not show evidence of acute cardiac injury in pulmonary embolism, which is the first major point of differentiation. Arterial blood gases show how severely the pulmonary embolism is affecting the body's oxygenation. Diagnostic imaging procedures the pulmonologist may conduct include COMPUTED TOMOGRAPHY (CT) SCAN, MAGNETIC RESONANCE IMAGING (MRI), pulmonary angiography, and a specialized imaging procedure called ventilation/perfusion scan.

Treatment Options and Outlook

Hospitalization with intensive pulmonary support and immediate ANTICOAGULATION THERAPY is necessary for most circumstances of pulmonary embolism. The risk of death is highest within the first few hours of the embolism. Anticoagulation therapy targets preventing the formation of additional emboli. THROMBOLYTIC THERAPY ("clot buster" drugs) to dissolve the clots that have already formed is appropriate for some people. Surgery (either OPEN SURGERY or via catheterization) to mechanically break up the clot may be an option in severe situations. Recovery depends on the extent of lung affected, the existence of any underlying causes or health conditions, and the rapidity of diagnosis and treatment. People who recover from pulmonary embolism often require ongoing anticoagulation therapy though do not have significant permanent lung damage.

Risk Factors and Preventive Measures

Pulmonary embolism is most likely to occur in people who have restricted venous flow due to lower extremity VARICOSE VEINS or incompetent veins (veins that have lost elasticity and valve function), who are physically inactive, or who have recently had surgery or a major trauma (which means the body is forming clots for HEALING and also usually means limited physical movement). People who have untreated ATRIAL FIBRILLATION have increased risk for pulmonary embolism. OBESITY also increases the risk for pulmonary embolism because it exerts additional

resistance against the blood flowing through the veins. People who have an increased tendency to form clots (hypercoagulation) are also at increased risk of developing a clot or pulmonary embolism. Research suggests that as many as 80 percent of people who have DEEP VEIN THROMBOSIS (DVT) experience frequent pulmonary emboli. About half of the people who have one pulmonary embolism experience subsequent episodes.

Prevention often incorporates ongoing ANTICOAGULATION THERAPY in people at risk for pulmonary embolism, including those who have had a previous episode. Support stockings help the leg muscles to work more efficiently in massaging blood through the veins. For someone who has never had a pulmonary embolism, regular physical activity and maintaining healthy body weight help to lower the risk for clot formation. Frequent stretching of the legs, and getting up to walk for a few minutes every hour, can maintain effective circulation and venous return when taking long air flights or train or automobile trips to lower the risk for both DVT and pulmonary embolism. Postoperative recovery and recuperation regimens incorporate early ambulation (walking within hours of surgery) as well as progressive ambulation (walking for longer times and distances as recovery continues). When the person cannot ambulate, preventive measures may include compression stockings and anticoagulant medications.

See also COAGULATION; MYOCARDIAL INFARCTION; PLATELET AGGREGATION; POSTOPERATIVE CARE; STROKE; SURGERY BENEFIT AND RISK ASSESSMENT; WEIGHT LOSS AND WEIGHT MANAGEMENT.

pulmonary fibrosis A condition in which SCAR tissue replaces normal tissue in the alveoli, reducing the ability of the LUNGS to oxygenate the BLOOD. Many conditions of the lungs result in fibrosis, notably CYSTIC FIBROSIS and occupational PNEUMOCONIOSIS. Pulmonary fibrosis may also be idiopathic—that is, develop without an identifiable cause. Once the process of fibrosis begins in the lungs, it tends to be progressive. In many people the progression takes place over decades, resulting in slow decline of pulmonary function. Clubbing of the fingers is a characteristic indication of chronic HYPOXIA (insufficient oxygen reaching the tissues) such as results from pulmonary fibrosis.

Symptoms of pulmonary fibrosis include

- persistent dry COUGH
- DYSPNEA (shortness of breath) that worsens with exertion
- diminishing capacity for physical activity
- fatigue
- chest tightness, discomfort, or PAIN

The diagnostic path includes chest X-RAY, pulmonary function tests, and arterial blood gases. The pulmonologist may conduct additional imaging procedures, such as COMPUTED TOMOGRAPHY (CT) SCAN, to further assess structural changes in the lungs. BRONCHOSCOPY and lung biopsy may be necessary to rule out CANCER or to identify pathologic changes that characterize specific diseases.

Treatment depends on the underlying cause, if the diagnostic path can identify one. Generalized treatment may include CORTICOSTEROID MEDICATIONS to reduce INFLAMMATION, bronchodilator medications to relax and open the airways, and cough suppressants to relieve nonproductive coughing. These methods control symptoms and improve BREATHING in many people who have pulmonary fibrosis, especially in the early and middle stages of the condition. However, progressive pulmonary fibrosis typically results in RESPIRATORY FAILURE for which LUNG TRANSPLANTATION may be the only viable treatment option.

See also BRONCHIECTASIS; CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD); CYSTIC FIBROSIS AND THE LUNGS; INTERSTITIAL LUNG DISORDERS; NAILS.

R

rales See BREATH SOUNDS.

respiration rate The number of respiratory cycles a person completes in one minute. A typical healthy adult has a respiration rate of 15 to 20 per minute, measured by counting each inhalation or each exhalation (a respiratory cycle is one of each). Respiration rate normally is lower at rest and during sleep, and accelerates as well as intensifies with physical activity and exercise. Children have higher respiration rates than adults. The respiration rate typically increases with health circumstances such as INFECTION, FEVER, trauma, PAIN, and strong emotions such as fear. The brainstem regulates the respiration rate, in intimate coordination with other vital functions such as HEART RATE and BLOOD PRESSURE. The respiration rate remains at roughly a ratio of 1 to 4 with the heart rate (one breath for every four contractions of the HEART).

See also BREATHING; CARDIAC CYCLE.

respiratory cycle One repetition of the pattern of inhalation (BREATHING air into the LUNGS), OXYGEN–CARBON DIOXIDE EXCHANGE, and exhalation (breathing air out of the lungs). In health a typical adult completes 15 to 20 respiratory cycles a minute, called the RESPIRATION RATE. The brainstem regulates the respiratory cycle in response to feedback mechanisms from other body systems that indicate oxygen needs and consumption.

See also AEROBIC FITNESS; BREATHING EXERCISES; DYSPNEA; HYPERVENTILATION; TACHYPNEA.

respiratory failure The inability of the LUNGS to diffuse enough oxygen into the bloodstream to meet the body's needs. Respiratory failure may arise from end-stage pulmonary disease, extensive trauma, severe CARDIOVASCULAR DISEASE (CVD) or crisis (such as HEART ATTACK), neurologic damage or injury (such as SPINAL CORD INJURY, TRAUMATIC BRAIN INJURY [TBI], STROKE, or neurodegenerative disorder), or severe INFECTION (sepsis). Respiratory failure may be acute or chronic.

Acute respiratory failure is a life-threatening condition that results from the inability to breathe enough or the inability of the lungs to diffuse adequate amounts of oxygen into the blood, or a combination of both. Symptoms of acute respiratory failure typically are pronounced and include

- extreme DYSPNEA (shortness of breath or difficult BREATHING)
- CYANOSIS (bluish hue to the lips and SKIN)
- HYPOTENSION (low BLOOD PRESSURE)
- cardiovascular SHOCK

Treatment of acute respiratory failure requires oxygen administration and immediate resuscitative breathing or MECHANICAL VENTILATION; without prompt restoration of oxygenation, death is inevitable.

Chronic respiratory failure may also be life-threatening, though commonly the person accommodates the inadequate oxygenation through restricted physical activity and treatments such as OXYGEN THERAPY. Chronic respiratory failure is a consequence of progressive pulmonary disorders such as CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD). Symptoms of chronic respiratory failure may be activity related and often include

- persistent COUGH
- dyspnea, especially with exertion
- diminished cognitive ability or confusion

- cyanosis
- fatigue
- edema (swelling, typically in the hands and feet)

Doctors measure and assess chronic respiratory failure through blood levels of oxygen (which are low) and carbon dioxide (which are high). People who have chronic respiratory failure also commonly have PULMONARY HYPERTENSION. Treatment for chronic respiratory failure attempts to improve oxygenation through OXYGEN THERAPY and medications such as bronchodilators and some situations corticosteroids. The underlying disease and the person's response to therapy are key factors in determining the overall treatment approach. When chronic respiratory failure results from end-stage pulmonary disease, treatment options are limited. Some people are candidates for LUNG TRANSPLANTATION.

See also APNEA; ATELECTASIS; BREATH SOUNDS; BRONCHIECTASIS; OXYGEN–CARBON DIOXIDE EXCHANGE; SUDDEN CARDIAC DEATH.

S

silicosis An obstructive condition of the LUNGS that develops with repeated and usually long-term exposure to crystalline silica (silica dust). Silicosis is a disease of occupational exposure. The silica dust causes irritation and INFLAMMATION of the airways and lung tissue. SCAR tissue forms when the inflammation heals, resulting in fibrosis that gradually overtakes healthy lung tissue. The fibrosis continues extending through the lungs even after exposure ends.

Health experts identify three forms of silicosis:

- chronic silicosis, the most common form, results from long-term exposure (10 to 20 years or longer) and generally is present as a disease entity in the lungs for 5 to 10 years before symptoms lead to its diagnosis
- accelerated silicosis, which shows rapidly progressive symptoms after 5 to 10 years of exposure
- acute silicosis, which occurs with exposure to high concentrations of silica dust and shows symptoms within weeks to months of exposure

A secondary complication, progressive massive fibrosis, may occur with accelerated or chronic silicosis. In progressive massive fibrosis the scarring is severe and results in extensive destruction of lung tissue and loss of lung function.

The US Occupational Safety and Health Administration (OSHA) began regulating silica exposure in the 1990s and currently monitors silica levels as well as cases of silicosis. Employees who work in occupations with silica exposure should wear appropriate protective equipment including filtered respirators to limit as much as possible the amount of silica dust they breathe. About 200 people die each year in the United States as a consequence of silicosis.

Symptoms and Diagnostic Path

The primary symptoms of silicosis are chronic COUGH and DYSPNEA (shortness of breath) that worsens with exertion. People who have acute silicosis may also have FEVER and experience rapid, unintended weight loss. The diagnostic path includes chest X-RAY, imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN, and pulmonary function tests. Characteristic findings with these diagnostic procedures in combination with a history of silica exposure allow the doctor to make a conclusive diagnosis.

People who have silicosis have high risk for developing TUBERCULOSIS, and many have latent (asymptomatic) tuberculosis when tested at the time of the silicosis diagnosis. Health experts recommend routine testing for tuberculosis as part of the diagnostic process for silicosis.

Treatment Options and Outlook

Treatment can only help manage symptoms such as cough. There are no specific treatments for the silicosis, and there is no known method of intervention to prevent the condition's progression. It is crucial to end the silica exposure to end further damage to the lungs, and for those who smoke cigarettes to stop. Treatment may also be necessary for tuberculosis in people who test positive, even if there are no symptoms of the INFECTION. The course of progression often extends over decades, though does result in persistent decline of pulmonary function. Prevention remains the most effective therapeutic approach.

Risk Factors and Preventive Measures

Occupational exposure is the risk factor for silicosis. Appropriate personal protective equipment in combination with work-site dust management methods has the potential to prevent nearly all cases of silicosis. New cases of silicosis have steadily declined in the United States since the implementation of OSHA regulations limiting exposure, a trend health experts expect to continue. Researchers believe the silica dust interferes with the IMMUNE SYSTEM's ability to protect against certain kinds of infection, notably tuberculosis. Health experts recommend annual tuberculosis testing for everyone diagnosed with silicosis.

OCCUPATIONS AT RISK FOR SILICOSIS

abrasive blasting	agricultural plowing
ceramics	foundry core room
foundry shakeout	glass etching
glass manufacturing	jack hammering
masonry work	mineral mining
pottery	quarry work
road construction	rock blasting
rock drilling	rock tunneling
sandblasting	soap and detergent manufacturing

stone cutting	

See also ANTHRACOSIS; ASBESTOSIS; BERYLLIOSIS; BYSSINOSIS; PNEUMOCONIOSIS.

smoking and pulmonary disease Cigarette smoking is the leading cause of health conditions affecting the LUNGS and accounts for 90 percent of LUNG CANCER in the United States. Cigarette smoking is also the leading cause of many forms of CARDIOVASCULAR DISEASE (CVD), including HYPERTENSION, ATHEROSCLEROSIS, ISCHEMIC HEART DISEASE (IHD), CORONARY ARTERY DISEASE (CAD), and PERIPHERAL VASCULAR DISEASE (PVD). Though the correlation between cigarette smoking and lung cancer has been known since the 1940s and widely publicized since the 1964 landmark report *Smoking and Health: Report of the Advisory Committee to the Surgeon General of the Public Health Service*, nearly 49 million Americans currently smoke. About one in six has at least one significant health condition that is a direct consequence of smoking. The longer a person smokes, the higher the risk for developing a smoking-related health condition.

Smoking and Pulmonary Function

The first few puffs of every cigarette paralyze the cilia, the hairlike structures that line the airways and sweep mucus from the lungs. NICOTINE from the smoke immediately passes across the alveolar membrane into the BLOOD, entering the circulation within seconds. A potent central NERVOUS SYSTEM STIMULANT and vasoconstrictor, nicotine causes smooth MUSCLE fibers to contract, contributing to cerebrovascular and cardiovascular disease such as STROKE and HEART ATTACK. Nicotine remains active in the circulation for about 20 minutes after the last puff from the cigarette, keeping the airways constricted.

One of the most hazardous chemicals in cigarette smoke is carbon monoxide, which binds more strongly with HEMOGLOBIN than oxygen. Hemoglobin molecules will not release carbon monoxide to bind with oxygen, thus carbon monoxide blocks oxygen diffusion into the blood. Carbon monoxide levels in the blood can reach 5 to 7 percent with smoking a single cigarette, dropping OXYGEN SATURATION to near 90 percent. The other byproducts of combustion from cigarette smoke can result in direct toxicity to the lungs.

Smoking and Obstructive Lung Diseases

Tar and smoke particulates that enter the airways and lungs with each cigarette cause irritation and INFLAMMATION. Over time SCAR tissue replaces lung tissue as the body attempts to repair itself from repeated damage and protect itself from further damage. This scar tissue gradually destroys the alveoli and bronchioles, the lung's smallest structures, and eventually becomes pervasive within the lungs. The consequence is CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD), which accounts for more than 70 percent of pulmonary disease related to smoking. COPD is the leading reason for LUNG TRANSPLANTATION in the United States and is also the leading form of noncancer lung disease. Once the damage of COPD occurs, it is permanent.

Lung Cancer

Cigarette smoke contains about 4,000 identifiable chemicals, more than 60 of which are identified carcinogens (cancer-causing substances). Among them are tar, arsenic, polycyclic aromatic hydrocarbon (PAH) compounds, formaldehyde, and nitrosamines. Smoking accounts for more than 90 percent of LUNG CANCER in the United States. Among cancers, lung cancer is the leading killer of both men and women. Part of the reason the outlook is so poor for lung cancer is that by the time it shows symptoms it is fairly advanced and often has spread to other organs throughout the body.

Pulmonary Benefits of Smoking Cessation

Much, though not all, of the damage cigarette smoking does will gradually repair itself when the person no longer smokes. The rate of decline of lung function will slow, and chronic cough and sputum production often improve. Cardiovascular risk also drops significantly after smoking cessation. Risk for head and neck and lung cancers also decreases.

See also ANTISMOKING EFFORTS; ASBESTOSIS; ASTHMA; ENVIRONMENTAL CIGARETTE SMOKE; SMOKING AND HEALTH.

sputum The mucus and secretions the pulmonary tract produces, mixed with debris and foreign matter that enter the airways. Sputum is a normal body fluid, though excessive amounts of sputum often signal pulmonary disease. The color and consistency of sputum provide clues about the health of the LUNGS and airways, though are not reliable diagnostic characteristics by themselves. Sputum culture is the only way to know whether an INFECTION is bacterial. A reliable sputum culture requires deep coughing to bring sputum from within the lungs.

stridor See BREATH SOUNDS.

suffocation See ASPHYXIATION.

T–W

tachypnea An abnormally rapid RESPIRATION RATE. BREATHING is also usually shallow. The normal respiration rate for healthy adults is 15 to 20 respiratory cycles per minute. In tachypnea the respiration rate can be two to four times normal. Breathing may appear labored, and when the body is not able to meet its needs the person may look cyanotic (pale or bluish) if the tissues are receiving inadequate oxygen. Tachypnea is a symptom of numerous health conditions ranging from FEVER to serious INFECTION such as PNEUMONIA. In transient tachypnea of the newborn, an infant develops a pattern of tachypneic breathing that lasts 24 to 72 hours after birth. Doctors believe this form of tachypnea, which resolves without treatment or complications, occurs as a mechanism for the infant to clear residual AMNIOTIC FLUID from the LUNGS.

See also CYANOSIS; DYSPNEA; HYPERVENTILATION.

thoracentesis The removal of fluid from the pleural cavity (the space between the pleural surfaces of the lung and thoracic cavity). The doctor typically uses chest X-RAY, ULTRASOUND, or COMPUTED TOMOGRAPHY (CT) SCAN to assess the appropriate site for the thoracentesis and may use any of these imaging procedures to guide the process of the thoracentesis. After anesthetizing (numbing) the SKIN and tissues at the site, the doctor inserts a large-gauge needle between the ribs and into the pleural cavity to withdraw pleural fluid.

Thoracentesis may be diagnostic, in which case the doctor withdraws a small amount of fluid for laboratory examination of the cells and any pathogens it contains. The doctor may conduct diagnostic thoracentesis to evaluate circumstances such as

- CHEST PAIN and other symptoms that suggest PLEURISY or PLEURAL EFFUSION
- mesothelioma, a CANCER related to ASBESTOSIS or asbestos exposure
- identification of infection (bacterial or tuberculosis)
- staging of LUNG CANCER

Thoracentesis may also be therapeutic, such as to drain a major pleural effusion. Potential complications of thoracentesis include vasovagal NERVE stimulation that causes SYNCOPE (fainting) bleeding, INFECTION, bleeding, and PNEUMOTHORAX. Most procedures are uncomplicated and discomfort is usually mild and temporary.

See also ATELECTASIS; STAGING AND GRADING OF CANCER; THORACOTOMY.

thoracotomy A major OPERATION in which the surgeon opens the chest cavity to remove part or all of a lung. Surgeons most commonly perform thoracotomy to treat LUNG CANCER or severe trauma to the lungs. Other reasons for thoracotomy include LUNG ABSCESS that does not respond to antibiotic therapy, CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD) in which there is significant alveolar destruction and lung volume resection may be of benefit, severe BRONCHIECTASIS with bleeding requiring resection of part of the lung, biopsy of lung tissue or suspected tumor, and LUNG TRANSPLANTATION. There are three kinds of thoracotomy:

- wedge resection removes a small segment of lung tissue
- lobectomy removes an entire lobe of the lung
- pneumonectomy removes a whole lung

In lung transplantation, the surgeon first performs pneumonectomy and then transplants the donor replacement lung. Thoracotomy entails a hospital stay of up to 10 days, depending on the kind of surgery, and a recuperation period of two to four months though some people can return to most of their normal activities within six to eight weeks. Additional treatment, such as RADIATION THERAPY or CHEMOTHERAPY for lung cancer, may extend the recuperation period.

Surgical Procedure

The doctor performs thoracotomy with the person under general ANESTHESIA. The placement and length of the incision depends on the kind of thoracotomy and the reason for performing it. The incision must be between the ribs, and the surgeon must either spread the ribs (using an instrument called a rib spreader) or remove a portion of rib to gain access to the thoracic cavity. The surgeon removes the intended segment, lobe, or entire lung, and places tubes that will drain air, BLOOD, and other fluids during HEALING. The operation may take two to six hours, longer for lung transplantation. The person then remains in the recovery room until the anesthesia wears off, with intensive nursing care to maintain BREATHING and other vital functions. Less invasive approaches that use fiberoptic scopes and a smaller incision are now an option, particularly for biopsies. Such MINIMALLY INVASIVE PROCEDURES allow quicker operative times and recuperation.

Risks and Complications

Because thoracotomy breaches the thoracic cavity, there are significant risks involved with this operation. The most common are bleeding, infection, and PNEUMOTHORAX. These risks are potentially life-threatening though are usually readily treatable and survivable. Complications include RESPIRATORY FAILURE and RECURRENCE of the circumstance that made the operation necessary. Removal of a complete lung results in the remaining structures of the thoracic cavity shifting position, which can alter HEART function, gastric (STOMACH) function, and breathing.

Outlook and Lifestyle Modifications

Many people spend the first 48 to 72 hours following surgery in the intensive care unit (ICU). MECHANICAL VENTILATION ensures that the remaining lung structure inflates fully to provide adequate oxygenation. As the healing process progresses the affected lung (after lobar resection), or remaining lung when the operation is pneumonectomy, expands to fill the thoracic cavity and pulmonary function improves. Most people can sustain strong pulmonary function with only one lung when the remaining lung is healthy and overall health is good. Lifestyle modifications and prognosis (outlook) vary with the underlying health condition.

See also SMOKING CESSATION; SURGERY BENEFIT AND RISK ASSESSMENT.

trachea The major airway leading from the THROAT to the LUNGS. The trachea extends about four and a half inches from the top of the throat to the center of the chest. The sternum (breastbone) in the front and the spine in the back protect the trachea for much of its length. The front of the trachea arches more than the back of the trachea, producing an oval rather than round tubular structure with a diameter (from side to side) of about an inch. The trachea terminates in two branches, the right main BRONCHUS that goes to the right lung and the left main bronchus that goes to the left lung.

The trachea is made of smooth MUSCLE tissue along the back wall with 16 to 20 C-shaped bands of CARTILAGE running along its length. The cartilage rings give the trachea stability and resistance against the pressure of air flow into and out of the lungs. Thousands of hairlike structures called cilia line the inner layer of the trachea, the tracheal epithelium. The cilia move in wavelike patterns to push secretions and foreign matter, such as dust and particles, out of the airways. The epithelial cells secrete mucus, which keeps the inner trachea moist. The mucus helps humidify the air as it flows into the lungs, and lubricates the air's passage. The mucus also traps foreign material so the cilia can sweep it from the airways. Coughing expels air rapidly and forcefully from the lungs, pushing SPUTUM (pulmonary mucus and the debris it contains) into the throat for removal from the body.

For further discussion of the trachea within the context of pulmonary structure and function

please see the overview section "The Pulmonary System."

See also ALVEOLUS; EPIGLOTTIS; TRACHEOSTOMY.

tracheostomy A surgical opening created in the TRACHEA to allow air to enter the LUNGS, bypassing the upper THROAT and MOUTH. A tracheostomy may be temporary or permanent. The doctor may perform a tracheostomy when extensive surgery such as to treat laryngeal CANCER results in removing the shared structures of the throat that allow air to flow into the trachea, or when neurologic damage necessitates long-term MECHANICAL VENTILATION. SWALLOWING DISORDERS that impede normal epiglottal function (which keeps food and water from entering the trachea) and SLEEP APNEA that fails to respond to other treatments may also make tracheostomy necessary.

In most cases the doctor performs tracheostomy with the person under general ANESTHESIA. The incision is typically between the second and third or third and fourth tracheal cartilages in the front of the neck, to make an opening about an inch to an inch and a quarter (2 to 3 centimeters) in length. The doctor then inserts a tube into the opening to maintain a passageway into the trachea. The kind of tube and finishing process for the incision depends on whether the doctor intends the tracheostomy to be temporary or permanent. An inflatable cuff may hold the tracheostomy tube in place, though some designs are cuffless. Most tracheostomies use an inner and outer cannula (tube), allowing removal of the inner cannula for cleaning. A device called an obturator allows changing of the entire tracheostomy tube and guides reinsertion of the new tube.

Most people who are conscious are able to resume regular eating and speaking. Speech requires closing off the tracheostomy tube to bring air through the throat and past the VOCAL CORDS. Potential complications of tracheostomy include bleeding after the OPERATION, INFECTION, and blockage of the tube with mucus or foreign material that enters the tube from the outside. Conscientious hygiene, including daily cleansing of the tracheostomy site and tube, is essential. It is important to humidify the air breathed into the tracheostomy, such as with a room humidifier or moist gauze (rewetted as needed) placed over the tube opening. Home health nursing agencies provide education and training in how to care for a tracheostomy for people who have tracheostomies and their family members or caregivers. Even a long-term stoma will heal closed should the person's condition improve such that normal BREATHING ability returns and the doctor can remove the tube.

THE IMMUNE SYSTEM AND ALLERGIES

The IMMUNE SYSTEM protects the body from INFECTION. Allergies represent an inappropriate response from the immune system toward harmless substances. Doctors (MDs and DOs) who treat conditions of the immune system may be internists or immunologists. Doctors who specialize in treating allergies are allergists, and those who specialize in treating RHEUMATOID ARTHRITIS and related AUTOIMMUNE DISORDERS are rheumatologists.

Functions of the Immune System

The immune system's role is to protect the body from infection. Infection, from the immune system's perspective, is any activity from foreign entities that causes damage to cells. It does so through a complex and intricate integration of organs, tissues, cells, and molecules.

Each day the BONE MARROW releases billions of monocytes and granulocytes, also called polymorphonuclear cells (PMNs), into the BLOOD circulation. Monocytes circulate in the blood for about 24 hours and then migrate into the LYMPH tissues, LIVER, and the various MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT) structures throughout the body. Known as macrophages after their migration, these cells participate in ANTIGEN processing as well as continued PHAGOCYTOSIS (consumption of cellular debris). Granulocytes (neutrophils, basophils, and eosinophils) are instrumental in the body's inflammatory response, which is integral to HEALING in normal immune function as well as responsible for much of the distress of a HYPERSENSITIVITY REACTION—ALLERGY—when the immune system malfunctions.

The workhorse cells of the immune system are the lymphocytes, which from birth divide into two camps: B-cell lymphocytes, which patrol the blood and lymph on the alert for invaders, and T-cell lymphocytes, which respond to the call of B-cell lymphocytes when invaders penetrate the body's barriers. B-cell lymphocytes come to maturity in the bone marrow and regulate ANTIBODY-MEDIATED IMMUNITY. T-cell lymphocytes come to maturity in the THYMUS and regulate CELL-MEDIATED IMMUNITY. Lymphocytes circulate in the blood and the lymph, and also reside in lymph organs and tissues throughout the body. The SPLEEN contains about half the body's supply of lymphocytes.

Perhaps more than any other system of the body the immune system is one of molecular function. The entire function of the immune system centers on the ability of immune cells to distinguish cells that belong to the body—self cells—from cells that do not belong to the body—nonself cells. It does so through molecular mark-

ers called antigens. Lymphocytes, natural killer (NK) cells, macrophages, and the complement factors—a collection of substances that, when activated (the COMPLEMENT CASCADE), form potent chemical structures—key onto these antigens like lasers onto targets. Cells bearing self antigens continue unimpeded about their business in the body. Those bearing nonself antigens are tagged for destruction by another set of molecular markers, antibodies, that specialized B-cell lymphocytes called PLASMA cells produce. Each individual antigen generates a different ANTIBODY; millions of antibodies circulate in the blood and lymph.

Filling out the immune system's defense are specialized clusters of lymphoid tissue that line each point of access into the inner body: SKIN, NOSE, airways, gastrointestinal system, and even the blood vessels. These clusters—known collectively as the mucosa-associated lymphoid system—are like guard posts protecting the body's vulnerabilities. MALT contains abundant populations of lymphocytes, mast cells, and macrophages that detect and intercept millions of microbes, viruses, toxins, and irritants before they can breach the inner body.

Health and Disorders of the Immune System

In health the immune system is an amazing network of cells and molecules that patrol every pathway of the body. Most of the time, the immune system goes about protecting and ridding the body from invading pathogens without drawing any notice to its activities. Only when the immune system is too efficient—causing hypersensitivity reactions or autoimmune disorders—or ineffective—allowing infection or cancer—does its existence become unpleasantly apparent.

Inflammation: the front line The immune system's first response primary weapon is INFLAMMATION. Inflammation floods the affected tissues with infection-fighting molecules. Plasma, the liquid component of blood, carries these molecules and delivers them to the site of the infection. The familiar swelling of inflammation is the body's "caution: IMMUNE RESPONSE at work" sign. Inflammation causes PAIN, which encourages if not forces limited activity of the affected area. This allows plasma to thoroughly saturate the area, speeding healing and recovery. Inflammation may also cause FEVER, yet another inducement to take it easy. As unpleasant as these symptoms are, they serve notice that the immune system is on task.

Autoimmune disorders: attacking self cells Inflammation sometimes gets out of hand. The immune response may not recognize that its task is over. Inflammation may become so severe that it impedes the flow of blood, threatening the well-being of the body in other ways. ANTIBIOTIC MEDICATIONS may be necessary to bring in another flank of attack against the PATHOGEN. Or a malfunction of the immune system may erroneously mark self cells as invaders, directing the immune response to attack structures of the body that contain the cells. These are autoimmune disorders—such as RHEUMATOID ARTHRITIS, SYSTEMIC LUPUS ERYTHEMATOSUS (SLE), and type 1 DIABETES.

Allergies: mistaken identity About 50 million Americans have allergies, mostly to pollens, molds, foods, animal dander, and medications. More than 18 million adults and 7 million children in the United States have seasonal allergies that cause ALLERGIC RHINITIS, ALLERGIC ASTHMA, and ALLERGIC CONJUNCTIVITIS—a triad of hypersensitivity reactions known collectively as hay fever. Another 9 million Americans, two thirds of them children, have FOOD ALLERGIES.

With allergies, the immune system turns not against the body itself but against harmless substances the body encounters, misidentifying them as dangerous intruders. Plasma cells then generate antibodies that perceive the molecular markers of these substances—allergens—as harmful and launch an immune response upon detecting their presence. Hypersensitivity reactions cause symptoms that range from annoying to life-threatening. It often is not possible to escape the reach of an ALLERGEN; treatment becomes the only recourse for relieving symptoms.

Immunodeficiency: AWOL Sometimes the immune system fails to function properly because key components are deficient or missing. Genetic errors may result in an absence of T-cell lymphocytes, B-cell lymphocytes, complement factors, immunoglobulins, or other substances necessary to integrate the immune response. Such deficits increase vulnerability to infection and, when severe, threaten life. The most significant acquired immunodeficiency is HIV/AIDS, which results from

infection with a VIRUS that hijacks and then destroys certain T-cell lymphocytes. There are treatments but as yet no cures for most immunodeficiencies, including HIV/AIDS.

Cancer: treacherous betrayal One of the greatest mysteries about immune function is cancer, the unregulated growth of cells. Ordinarily the immune response detects and destroys abnormal cells in the body, even when they are self cells. Cancer represents the ultimate betrayal of the immune system by self cells that dangerously mutate yet maintain enough self-antigens to escape detection. There comes a point in a cancer's development when tumor necrosis factors (TNFs), potent antitumor substances, are no longer able to squelch the errant growth. Some tumors seem able to avoid activating TNFs at all.

DISORDERS OF IMMUNE FUNCTION

ALLERGIC ASTHMA	ALLERGIC CONJUNCTIVITIS
ALLERGIC DERMATITIS	ALLERGIC RHINITIS
ANAPHYLAXIS	ANGIOEDEMA
ANKYLOSING SPONDYLITIS	ATOPY
autoimmune ADDISON'S DISEASE	autoimmune HEPATITIS
BULLOUS PEMPHIGOID	COMMON VARIABLE IMMUNODEFICIENCY (CVID)
dermatomyositis	DISCOID LUPUS ERYTHEMATOSUS (DLE)
DIABETES type 1	GRAFT VS. HOST DISEASE
FOOD ALLERGIES	Hashimoto's THYROIDITIS
GOODPASTURE'S SYNDROME	HYPERSENSITIVITY REACTION
GRAVES'S DISEASE	INFLAMMATORY BOWEL DISEASE (IBD)
HIV/AIDS	MULTIPLE MYELOMA
IgA NEPHROPATHY	MYASTHENIA GRAVIS
LEUKEMIA	PARTIAL COMBINED IMMUNODEFICIENCY (PCID)
lymphoma	POLYMYOSITIS
MULTIPLE SCLEROSIS	RHEUMATOID ARTHRITIS
organ transplant rejection	SCLERODERMA
PEMPHIGUS	SJÖGREN'S SYNDROME
pernicious ANEMIA	SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)
REITER'S SYNDROME	
SARCOIDOSIS	
SEVERE COMBINED IMMUNODEFICIENCY (SCID)	
VASCULITIS	

Traditions in Medical History

Until the discovery of BACTERIA and viruses in the 19th century, doctors had little understanding for how the body contained and fought infection. Recognizing fever as a sign of healing led to efforts to "sweat out" the infection. Bloodletting was long a tradition for treating all kinds of ailments. The body's natural ability and tendency to overcome most infections gave credence to these and other methods. With the recognition of microbes and their role in pathogenesis (process of infection), research leapfrogged to greatly expanded understanding of immune system components and their functions.

Contemporary research has shown that some pre–MICROBE era therapeutic efforts have merit for bolstering immune function. Herbs such as ECHINACEA, GOLDENSEAL, and FEVERFEW boost immune response. Licorice root, turmeric, ginger, white willow (the forerunner of aspirin), witch hazel, and GREEN TEA are effective anti-inflammatory agents. Vitamins and minerals aid the intricate biochemical conversions essential for immune function. Antioxidants clear away molecular debris. Nature, as it turns out, staunchly supports the immune system.

Breakthrough Research and Treatment Advances

One of the most significant breakthroughs in disease management came with the introduction of vaccines in the mid-20th century. Before 1950, infection was the leading cause of death among Americans. The debut of antibiotic medications at the end of World War II was a tremendous stride in the ability to fight bacterial infections. But antibiotics are ineffective against viruses. In 1950 the viral infection POLIOMYELITIS was the leading cause of PARALYSIS among Americans; a decade later vaccination had made polio a rare condition. The World Health Organization (WHO) declared SMALLPOX, the first infection for which there was a successful VACCINE, eradicated in nearly all parts of the world in 1970—another landmark triumph in manipulation of the immune system to protect the body against infection without actually acquiring the infection. Today vaccines have made rare many diseases that were once common killers.

As researchers learn more about immune function and disease processes, the emphasis is shifting from treating the disease to preventing its development. Most CARDIOVASCULAR DISEASE (CVD), the leading cause of death among Americans, stems from a combination of lifestyle factors and inflammatory response. Though doctors have long

believed ATHEROSCLEROSIS (deposits of atherosclerotic plaque within the walls of the arteries) caused inflammation, recent research indicates the reverse is the case: inflammation attracts atherosclerotic deposits. Though further research is necessary to substantiate these findings, the result could be an entirely new perspective and approach for preventing cardiovascular disease.

Other research focuses on manipulating the immune system to "turn off" autoimmune disorders such as type 1 diabetes and rheumatoid arthritis, conditions that contribute to significant disability. Cancer research also is looking to the immune system to treat, cure, and prevent cancer. MONOCLONAL ANTIBODIES (MABS), genetically engineered molecules, can be laced with radioactive isotopes and targeted to the antigens on the cell surfaces of cancer cells, selectively killing them without damaging healthy cells. Researchers also believe it is possible to "teach" the immune system to recognize cancer cells and use its own resources to destroy them. Cancer vaccines are one direction of such research; molecular manipulation is another.

A

active immunity Long-term, acquired immune protection. Active immunity, also called acquired immunity, results from fighting an INFECTION or receiving a VACCINE that stimulates ANTIBODY response. In many circumstances active immunity is lifelong.

See also ANTIBODY-MEDIATED IMMUNITY; CELL-MEDIATED IMMUNITY; PASSIVE IMMUNITY.

aging, effects on immune response At birth the IMMUNE SYSTEM is fairly undeveloped. The infant relies largely on the carryover of maternal immune components for about the first six weeks of its life, while the infant's body builds its own immune system. By age four months, maternal IMMUNITY wears off and the infant's immune system is on its own (though an infant who is BREASTFEEDING continues to receive antibodies and limited immune support from his or her mother). Immunity reaches full STRENGTH in early childhood, a level at which it continues until about age 40.

After age 40, the effectiveness of the immune system begins to diminish. T-cell lymphocytes and macrophages respond more slowly. Levels of complement (protein factors essential for ANTIBODY–ANTIGEN binding) and of antibodies drop off. The immune system is slower to differentiate B-cell lymphocytes to antigen-producing PLASMA cells, and plasma cells produce lower quantities of antibodies. The immune response to disease as well as to vaccines becomes slower and less effective, increasing susceptibility to serious INFECTION (such as INFLUENZA and PNEUMONIA) from pathogens. The amounts and activity of MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT) decrease in areas such as the LUNGS, further reducing the body's ability to reject infection from invading pathogens. Decades of exposure to antigens mean more lymphocytes are sensitized for specific antigens, leaving fewer to become sensitized to new antigens. The IMMUNE RESPONSE summons T-cell lymphocytes less quickly to the scene of an infection.

Changes in antigens and antigen recognition also occur, resulting in a decreased ability of the immune system to distinguish between self and nonself antigens. Cells may acquire a mix of antigens that makes them appear foreign, initiating an inappropriate immune response (autoimmune disorder) that damages an organ or structure. Or the immune system may fail to detect the change in antigens on the surfaces of cell membranes of cells that become cancerous, allowing cancer tumors to develop. AUTOIMMUNE DISORDERS and cancer consequently become more common with advancing age.

Measures to prevent infection can help offset age-related immune changes to some degree. Diligent HAND WASHING and avoiding exposure to other people who have COLDS or influenza may prevent the spread of these infections. ECHINACEA and GOLDENSEAL are herbal remedies that can boost immune function after an exposure to common pathogens. GAMMAGLOBULIN may boost the immune response in circumstances such as exposure to HEPATITIS. Older people often benefit from more aggressive antibiotic therapy—ANTIBIOTIC MEDICATIONS administered early in the infection process—to help them fight infections they do develop.

See also ANTIBODY-MEDIATED IMMUNITY; CELL-MEDIATED IMMUNITY; COMPLEMENT CASCADE; HEALING; IMMUNOSENESCENCE; LYMPHOCYTE; MACROPHAGE; T-CELL LYMPHOCYTE.

allergen A harmless substance, also called a hapten, that causes an exaggerated response from the

IMMUNE SYSTEM called a HYPERSENSITIVITY REACTION. For reasons researchers do not fully understand, the immune system produces antibodies for the substance that result in the IMMUNE RESPONSE perceiving the substance as a foreign invader. When the allergen contacts or enters the body, the antibodies attack it. Nearly any substance can be an allergen. DESENSITIZATION is a treatment for allergies that exposes the person to progressive doses of the allergen to increase the body's tolerance for the presence of the allergen and diminish the hypersensitivity reaction.

COMMON ALLERGENS

almonds	animal dander	aspirin (salicylates)
bee stings	cashews	cockroaches
dust and dust mites	eggs	fish
fragrances and perfumes	fungi	grasses
lanolin	latex	milk
molds	nickel	peanuts
pecans	penicillin	pollens
shellfish	smoke	strawberries
SOY	sulfa	wheat

See also ALLERGY; ALLERGY TESTING; ANAPHYLAXIS; ANTIBODY; ANTIGEN; ASTHMA; LIVING WITH ALLERGIES; MULTIPLE CHEMICAL SENSITIVITY SYNDROME.

allergic asthma A HYPERSENSITIVITY REACTION (allergic reaction) that involves the airways (bronchi). allergic ASTHMA is a type I or IMMUNOGLOBULIN E (IgE) reaction. Mast cells in the bronchial membranes release HISTAMINE, PROSTAGLANDINS, and LEUKOTRIENES. These substances cause itching and swelling of the bronchial membranes, resulting in wheezing and the sensation of chest tightness.

Cockroach droppings are the most frequent cause of allergic asthma. Other common allergens for allergic asthma include pollens (trees, grasses, and weeds), dust and dust mites, cigarette smoke, molds, and pet dander (especially cat dander). About 70 percent of people who have allergic asthma also have ALLERGIC RHINITIS, also called seasonal allergies or hay FEVER.

The diagnostic path focuses on separating allergic from nonallergic asthma. Though the symptoms are the same, the mechanisms and treatment approaches are different. Symptoms of allergic asthma include wheezing, shortness of breath (DYSPNEA), sensation of being unable to get enough air, and coughing. A severe hypersensitivity reaction, ANAPHYLAXIS, may occur if the bronchi swell enough to prevent the flow of air into the LUNGS.

ANAPHYLAXIS is a potentially life-threatening condition that requires immediate care from a doctor or hospital emergency department.

Treatment for allergic asthma may include oral and inhaled ANTIHISTAMINE MEDICATIONS, corticosteroid medications, and leukotriene receptor antagonist medications. Omalizumab (Xolair), a monoclonal antibody administered via subcutaneous injection, dramatically drops IgE levels in the BLOOD circulation, effectively stopping the hypersensitivity reaction before it causes symptoms. The most effective treatment is avoiding known or suspected allergens, though this is not always possible. ALLERGY TESTING can determine the specific allergens responsible for symptoms. DESENSITIZATION, in which the allergist exposes the person to small but increasing doses of the allergen over time, can help reduce the immune response to the allergen.

See also ALLERGIC CONJUNCTIVITIS; ALLERGIC DERMATITIS; ALLERGY; ANTIGEN; ATOPY; BREATH SOUNDS; CYTOKINES; LIVING WITH ALLERGIES; MONOCLONAL ANTIBODIES (MABS).

allergic conjunctivitis A type I (IMMUNOGLOBULIN E [IgE]) HYPERSENSITIVITY REACTION, commonly called an allergic reaction, that affects the membranes that line the inner eyelids (conjunctiva). Sometimes the irritation also reddens the white part of the eye (sclera). Allergic CONJUNCTIVITIS features red and swollen conjunctiva with excessive tearing and itching of the eyes and sometimes a white discharge. PHOTOPHOBIA (heightened sensitivity to light) is common. Because these symptoms also suggest viral or bacterial conjunctivitis (pink eye), which are infections, particularly when the discharge is yellow or green, a doctor should examine the eyes and assess the symptoms to make the correct diagnosis. Treatment differs according to the cause.

EYE irritation that interferes with vision, causes PAIN, or follows injury to the eye requires a doctor's prompt evaluation.

The most common form of allergic conjunctivitis develops seasonally when airborne pollens are high. Some people develop allergic conjunctivitis with exposure to allergens such as dust and pet dander (especially cat dander) as part of a broader ALLERGY picture. People who have seasonal allergies (ALLERGIC RHINITIS), ALLERGIC ASTHMA, or other ATOPY conditions may have a GENETIC PREDISPOSITION for type I hypersensitivity reactions that puts them at higher risk for developing allergic conjunctivitis as well.

Treatment for allergic conjunctivitis combines avoiding the responsible ALLERGEN with EYE drops that contain an antihistamine or, for severe symptoms, a corticosteroid (anti-inflammatory medication that suppresses the IMMUNE RESPONSE). ANTIHISTAMINE MEDICATIONS neutralize the histamine responsible for the allergic response. Systemic antihistamine medications (allergy relief products) may also help, especially when there are accompanying allergy symptoms such as allergic rhinitis. Natural tears eye drops can restore moisture to eyes that are scratchy and dry. Allergic conjunctivitis generally resolves when exposure to the allergen ends, which may be the end of allergy season when seasonal allergies (hay fever) are responsible.

See also ALLERGIC DERMATITIS; DRY EYE SYNDROME; INFECTION; LIVING WITH ALLERGIES.

allergic dermatitis A HYPERSENSITIVITY REACTION (allergic reaction) that affects the SKIN, usually in response to contact with an ALLERGEN. As with all hypersensitivity reactions, the first exposure to the allergen produces no symptoms. In reaction to the exposure, however, the IMMUNE SYSTEM produces antibodies for the allergen. Subsequent exposures to the allergen then do produce symptoms. Abundant immune cells reside in the epidermis, the inner layer of skin that contains living cells, to react to the allergen.

Most allergic dermatitis is a type IV, or delayed, hypersensitivity reaction. Symptoms generally affect only the area of contact and begin to emerge 24 to 36 hours after the contact, though may start within hours to a week later. Sometimes there can be repeated exposure before the hypersensitivity reaction occurs, though most commonly the second exposure triggers the ALLERGY.

A less common but more severe form of reaction is atopic dermatitis, a chronic type I (IMMUNOGLOBULIN E [IgE]) hypersensitivity reaction. Atopic DERMATITIS, commonly called eczema, tends to occur in people who have other chronic hypersensitivity conditions such as ALLERGIC ASTHMA and ALLERGIC RHINITIS. GENETIC PREDISPOSITION is the most significant risk factor for atopic dermatitis. Often there is no apparent contact allergen that sets off an atopic dermatitis attack, and symptoms may continue for several weeks to months or appear to never quite go away.

POISON IVY, POISON OAK, AND POISON SUMAC

The blistering, itchy RASH that some people develop with exposure to poison ivy, poison oak, and poison sumac is an allergic reaction to the resins on the surface of these plants. Repeated contact creates as well as intensifies sensitivity. In a highly allergic person, a reaction may occur through contact with clothing that came into contact with the resins. Contrary to popular belief, the fluid in the rash's blisters does not spread the irritation. The rash appears to spread because the person's sensitivity to the resin increases even as the allergic reaction unfolds.

Symptoms and Diagnostic Path

Allergic dermatitis, sometimes called allergic contact dermatitis, results in URTICARIA (hives) or RASH, often along with itching. BLISTER formation is common. The diagnosis is fairly straightforward when the person knows he or she has had contact with a known allergen. It is sometimes difficult to distinguish allergic dermatitis from other forms of dermatitis. In such situations ALLERGY TESTING, in which the allergist places small amounts of suspect substances in patches on the skin, can often determine the responsible allergen. Many substances, such as detergents and cleaning chemicals, can cause contact dermatitis through direct damage to the cells of the skin. Though symptoms are similar to those of allergic dermatitis, the irritation occurs

as a direct action of the substance rather than as a hypersensitivity reaction.

Treatment Options and Outlook

Treatment may include calamine lotion and cool baths or compresses to relieve itching in combination with oral ANTIHISTAMINE MEDICATIONS or CORTICOSTEROID MEDICATIONS to interrupt the immune response. Cool baths or compresses with colloidal oatmeal can soothe irritated skin. Avoiding further exposure to the allergen prevents subsequent reactions and may, over time, allow the immune response to lessen in severity.

Risk Factors and Preventive Measures

Latex, nickel, chromates, and the dyes in permanent hair coloring solutions are the most common causes of allergic dermatitis. Numerous metal objects, including stainless steel and chrome plating, contain nickel. Spandex contains latex; spandex clothing such as undergarments and athletic wear may cause hypersensitivity reaction in people who are allergic to latex. Chromates, chemicals used in tanning leather, are common in leather shoes, belts, and clothing. The allergen in permanent hair dyes is a chemical called paraphenylenediamine (PPDA), which sometimes is also present in some dyed clothing though is not commonly used in fabric dyes in the United States. The risk for allergic dermatitis is particularly high among people who work in jobs with constant exposure to these common allergens.

allergic rhinitis A HYPERSENSITIVITY REACTION to inhaled allergens. Allergic rhinitis, also called seasonal rhinitis or hay FEVER, affects the mucous membranes inside the NOSE (nasal mucosa). Allergic rhinitis affects about 40 million adults in the United States, making it one of the most common hypersensitivity reactions. The condition tends to develop in childhood and continue through adulthood, though some people who have allergic rhinitis as children seem to outgrow their sensitivities as they become adults.

MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT) infiltrates the nasal mucosa. Within the MALT are numerous mast cells, the surfaces of which harbor IMMUNOGLOBULIN E (IgE) antibodies. These antibodies react within hours to the presence of airborne allergens such as pollens. Allergic rhinitis is most common in the spring and the fall, though some people also experience symptoms in the summer, depending on what allergies they have. Allergic rhinitis is primarily a type I (IgE) hypersensitivity reaction, in which symptoms developing fairly immediately after contact with the ALLERGEN. The most common allergens associated with allergic rhinitis are tree pollens, grass pollens, and weed pollens. Other potential allergens include dust mites, pet dander, and other substances that are continuously present in the environment.

Symptoms and Diagnostic Path

The symptoms of rhinitis range from mild to debilitating. The classic symptoms occur in response to the presence of allergens and include

- nasal congestion
- itching
- sneezing
- RHINORRHEA (runny nose)

Some people also develop

- swollen, itchy, reddened eyes (ALLERGIC CONJUNCTIVITIS)
- dark circles under the eyes ("allergic shiners")
- OTITIS media (middle ear INFECTION)
- PHARYNGITIS (sore THROAT) from postnasal drip (mucus draining down the back of the throat)
- physical irritation of the nose due to frequent sneezing, blowing, and rubbing

The doctor makes the diagnosis based on the presentation of symptoms and the person's description of how the symptoms develop and how long they last.

Treatment Options and Outlook

Treatment combines avoiding the allergen when possible with medications to control symptoms.

Such medications typically include antihistamine nasal sprays, corticosteroid nasal sprays, oral ANTIHISTAMINE MEDICATIONS, and oral decongestant medications. Another classification of DRUG that is sometimes effective for allergic rhinitis is the leukotriene receptor antagonist, which blocks the action of LEUKOTRIENES (other chemicals that mediate the IMMUNE RESPONSE). The leukotriene receptor antagonist medication approved for use in the United States is montelukast (Singulair). Cromolyn sodium nasal spray targets mast cells, reducing their ability to release immune mediator chemicals such as histamine, PROSTAGLANDINS, and leukotrienes. DESENSITIZATION, commonly called allergy shots, is an option for some people. Desensitization works by exposing the IMMUNE SYSTEM to small amounts of the allergen over time to retrain the immune response to ignore the allergen.

Older antihistamine medications such as diphenhydramine (Benadryl) are very effective though cause drowsiness. Newer antihistamine medications such as loratadine (Claritin) are equally effective for most people and cause significantly less drowsiness. Antihistamines block the action of histamines, chemicals that mediate (initiate and facilitate) the processes of the immune response that result in the symptoms. Most antihistamines are available as OVER-THE-COUNTER (OTC) DRUGS that do not require a doctor's prescription. GINGER, available in various preparations, contains a mild antihistamine.

Oral decongestant medications available over the counter in the United States are pseudoephedrine and phenylephrine, though there are several OTC decongestant nasal sprays. Many OTC allergy products combine a decongestant with an antihistamine. Decongestants work by constricting the BLOOD vessels in the nasal mucosa, reducing the availability of fluid to the tissues. Chronic or long-term use of decongestants can result in rebound congestion, a condition in which the nasal membranes swell in the absence of the decongestant. Nose drops and nasal sprays containing saline (salt solution) are often as effective in relieving congestion. They work by soothing the nasal mucosa and flushing away topical irritants, including allergens.

Risk Factors and Preventive Measures

Allergic rhinitis is very common, affecting 20 percent of the American adult population. The most effective measure to reduce symptoms is to limit or eliminate exposure to the allergens that trigger the hypersensitivity response. Many people are able to mitigate symptoms by using allergy medications regularly for the duration of the allergy season.

There appears to be a GENETIC PREDISPOSITION for chronic allergic rhinitis, also called atopic rhinitis, which has more extensive symptoms that tend to be more perennial (ongoing) than seasonal. People who have atopic rhinitis have increased risk for other atopic conditions such as ALLERGIC ASTHMA (also called atopic asthma), atopic CONJUNCTIVITIS, and atopic DERMATITIS. A flare of symptoms in one atopic condition often brings on symptoms in another.

See also ALLERGIC DERMATITIS; ANTIBODY; CORTICOSTEROID MEDICATIONS; IMMUNOTHERAPY; LIVING WITH ALLERGIES; MAST CELL; SINUSITIS.

allergy An abnormal sensitivity to an ordinarily harmless substance, called an ALLERGEN, that produces a HYPERSENSITIVITY REACTION (allergic reaction) in response to the IMMUNE SYSTEM's detection of the substance's presence. A person can have an allergy to nearly any substance. Though researchers understand the mechanisms of hypersensitivity reaction, they do not know what causes the immune system to determine the substance is a potential invader. The first exposure to the substance activates an immune response that stimulates B-lymphocytes (specialized white BLOOD cells) to produce antibodies. Second and subsequent exposures engage the ANTIBODY response, in which the antibodies bind with molecules bearing the allergen to mark them for destruction.

Allergies are common. Symptoms vary according to the allergen. Some symptoms remain localized, affecting only a distinct part of the body (such as in ALLERGIC DERMATITIS or ALLERGIC RHINITIS). Others are systemic, affecting the body as a whole (such as hypersensitivity reaction to a drug or a food item). A severe hypersensitivity reaction can cause life-threatening swelling of the THROAT and airways (ANAPHYLAXIS).

See also ALLERGIC CONJUNCTIVITIS; ALLERGY TESTING; ANGIOEDEMA; ASTHMA; FOOD ALLERGIES; LIVING WITH ALLERGIES.

allergy testing Diagnostic procedures to determine the allergens responsible for HYPERSENSITIVITY REACTION. The most specific ALLERGY test is the allergy SKIN test, also called a scratch test or a patch test. For this test, the allergist uses the inside of the arm or a section of the back to expose the body to suspected allergens. The allergist places a small drop of a solution containing the ALLERGEN on a marked spot on the skin, then uses a sterile picklike instrument to scratch the surface of the skin. This exposes the IMMUNE SYSTEM to the suspected allergen. If a WHEAL (raised welt) forms on the site within 15 minutes, the test is positive for the allergen. For a typical allergy skin test, the allergist may test a number of substances at the same time, each on a different site on the skin. The allergy skin test tells the allergist the precise allergies an individual has. The allergy skin test helps the allergist strategize the most effective treatments and is necessary before DESENSITIZATION treatments.

Though it is rare, a person who has a strong allergy may have an intense reaction during an allergy SKIN test, including ANAPHYLAXIS, that requires urgent medical treatment.

A radioallergosorbent test (RAST) is a blood test that measures the amount of IMMUNOGLOBULIN E (IgE) in the BLOOD circulation when allergy symptoms are present. An amount higher than normal level of serum IgE indicates a hypersensitivity reaction. The RAST does not identify the specific allergen. There is no risk for the RAST to cause a hypersensitivity reaction because it does not expose the person to any allergens.

A food-elimination diet is the preferred allergy test to identify potential FOOD ALLERGIES. The person eliminates specific foods from his or her diet for several weeks, then reintroduces them one at a time and notes whether there are corresponding symptoms. An important part of a food-elimination diet is keeping an accurate food diary that records symptoms and other perceptions during the test. This allergy test is somewhat subjective, though often results in connecting specific foods with allergy symptoms. Another test for food allergies is the food challenge, which takes place in a hospital. The allergist gives the person certain foods, often mixed with other foods, without the person knowing, then observes and documents any symptoms that develop. There is a risk that the food challenge may cause a hypersensitivity reaction that would require immediate medical intervention; this is why the test takes place in a hospital or other emergency-ready facility.

See also ALLERGEN; ALLERGIC CONJUNCTIVITIS; ALLERGIC DERMATITIS; ALLERGIC RHINITIS; ANAPHYLAXIS.

anaphylaxis A severe HYPERSENSITIVITY REACTION (allergic reaction) in which the tissues of the throat swell, preventing air from getting to the LUNGS. Anaphylaxis, also called anaphylactic shock, is a type I hypersensitivity reaction that often develops rapidly, within minutes to an hour of exposure to the ALLERGEN. Hives, ANGIOEDEMA, and airway spasms are the most common symptoms. Some people also experience numbness or tingling of the lips and MOUTH. Though anaphylaxis can be life-threatening, with prompt and appropriate treatment it is seldom fatal.

The first line of treatment is EPINEPHRINE and antihistamine administered by injection, which immediately and effectively stop the progression of the hypersensitivity reaction. When airway (bronchial) symptoms are severe, the doctor may also administer an injectable corticosteroid medication. Swelling and related symptoms usually abate within a few minutes. Supportive treatment for symptoms often includes OXYGEN THERAPY and intravenous fluids. Most people completely recover within a few hours.

Bee stings, peanuts, intravenous penicillin, and intravenous contrast dyes for radiology procedures are the most common allergens responsible for anaphylaxis. However, anaphylaxis is possible with any ALLERGY. Anaphylaxis is fatal for about 200 Americans each year. Some people may benefit from DESENSITIZATION, depending on the allergen responsible for the hypersensitivity reaction, to mitigate the IMMUNE RESPONSE with future exposures. People who know they have severe allergies may get a doctor's prescription for an anaphylaxis

kit, which contains a prefilled syringe of injectable epinephrine.

See also BRONCHUS-ASSOCIATED LYMPHOID TISSUE (BALT); MAST CELL.

angioedema A HYPERSENSITIVITY REACTION (allergic reaction) that produces swelling and fluid accumulation beneath the surface of the SKIN, similar in appearance to URTICARIA (hives). Angioedema occurs in response to HISTAMINE release and typically affects the face, especially around the eyes and lips, and can be life threatening when it is severe or if it develops in the throat. Swelling in the form of welts may also occur on the hands and feet. Hypersensitivity reaction to ingested allergens is the most common cause of angioedema.

Difficulty BREATHING with angioedema is a medical emergency that requires immediate hospital care.

The doctor can diagnose angioedema based on the appearance of the symptoms and the person's exposure to an ALLERGEN. Treatment may include ANTIHISTAMINE MEDICATIONS; CORTICOSTEROID MEDICATIONS; or for severe symptoms, an EPINEPHRINE injection. Cool cloths applied to the sites of the angioedema may further ease discomfort. After the histamine release ends, the body reabsorbs the fluid. Relief improves as the swelling goes down, and symptoms are generally gone within three or four days. Avoiding the allergen prevents the hypersensitivity reaction and the resulting angioedema.

There is a form of angioedema, hereditary angioedema, that is an inherited genetic disorder and not a hypersensitivity reaction. Though there is similar swelling beneath the skin, there is no histamine release.

See also ANAPHYLAXIS; GENETIC DISORDERS; IMMUNE RESPONSE; LIVING WITH ALLERGIES.

antibody A unique molecule that binds with a specific ANTIGEN so the IMMUNE SYSTEM can neutralize or destroy the antigen. Antigens are molecular markers on the surfaces of cells that identify the cells to the immune system. Antibodies are the immune system's infantry, patrolling the BLOOD and LYMPH circulations and responding to fight INFECTION when invading pathogens breach the barriers intended to keep them out of the body. Every time the immune system encounters new antigens it crafts new antibodies—a distinct and unique antibody for each antigen. Though antibodies all derive from IMMUNOGLOBULIN E (IgE), each kind of antibody binds only with its specific antigen. The immune system has the capacity to produce millions of unique antibodies.

B-cell lymphocytes, a type of white blood cell (LEUKOCYTE), produce antibodies each time the immune response presents a foreign antigen. Once sensitized to a specific antigen and programmed to produce antibodies for it, the B-CELL LYMPHOCYTE becomes a plasma cell and circulates in the blood and lymph. Whenever the plasma cell encounters its antigen, it churns out antibodies and releases them into the blood and lymph. Thousands to millions of plasma cells are present in the body for each antibody the immune response generates.

The antibody response is the foundation of ANTIBODY-MEDIATED IMMUNITY, also called humoral immunity, the process by which the immune system prevents reinfection by specific pathogens. Vaccines manipulate antibody-mediated immunity by introducing weakened pathogens (such as viruses and BACTERIA) to stimulate B-cell lymphocytes to produce antibodies against them. The blood and lymph circulations then contain the antibodies though the person has never had the infection.

Blood tests for the presence of specific antibodies help doctors diagnose numerous health conditions and determine whether a person has immunity against viral infections such as RUBELLA (German measles) and infectious mononucleosis. Antibody testing is also a key step in determining the match potential between an organ transplant recipient and the donor organ.

For further discussion of antibodies within the context of the structures and functions of the immune system, please see the overview section "The Immune System and Allergies."

See also ALLERGY; CELL-MEDIATED IMMUNITY; CELL STRUCTURE AND FUNCTION; COMPLEMENT CASCADE; GAMMAGLOBULIN; HYPERSENSITIVITY REACTION; MONOCLONAL ANTIBODIES (MABS); MONONUCLEOSIS, INFECTIOUS; ORGAN TRANSPLANTATION; PATHOGEN; VACCINE; VIRUS.

antibody-mediated immunity The mechanism through which specialized immune cells, primarily B-cell lymphocytes, carry out the IMMUNE RESPONSE to protect the body from extracellular pathogens (disease-causing entities, such as BACTERIA and other microbes, present in the BLOOD or LYMPH that have not invaded the body's cells). Antibody-mediated immunity, also called humoral immunity, encompasses the functions of ANTIBODY production and immune memory. Antibody-mediated immunity functions collaboratively with CELL-MEDIATED IMMUNITY to help protect the body from INFECTION.

Specialized B-cell lymphocytes called PLASMA cells produce antibodies, protein molecules that circulate in the blood and lymph. Exposure to antigens for which they are sensitized activates plasma cells to produce antibodies. The antibodies bind with the antigens that match their ANTIGEN receptors (molecular sites that match the configuration of the antigen). The antibody–antigen bond activates the COMPLEMENT CASCADE, a complex interaction of blood proteins (the complement system) that results in penetration and death of the foreign cell.

Antibody binding also releases various CYTOKINES (protein molecules that serve as chemical messengers) that then activate other processes in the immune response. Immune cells that may respond to these messages include macrophages, granulocytes (basophils, eosinophils, and neutrophils), and T-cell lymphocytes (notably helper T-cells [Th2 cells]). The sequence of events takes about 36 hours to unfold after the IMMUNE SYSTEM recognizes the antigen as foreign. The immune response then works to neutralize the threat.

Memory B-cells circulate in the blood and lymph for an extended period of time. They hold a "memory" imprint of specific pathogens. When the PATHOGEN again enters the body, the memory-B cells remember and immediately ramp up antibody production. This process shortcuts the usual immune response, allowing the immune system to mount a defense before the pathogen can initiate an infection.

See also B-CELL LYMPHOCYTE; CELL STRUCTURE AND FUNCTION; GRANULOCYTE; MACROPHAGE; T-CELL LYMPHOCYTE; VACCINE.

antigen A molecule that resides on the surface of a cell membrane and is capable of stimulating an IMMUNE RESPONSE. Antigen molecules are either lipoproteins (lipid and protein) or glycolipids (lipid and GLUCOSE). Each cell has numerous antigens that that identify it to the IMMUNE SYSTEM. Cells that belong to the body bear antigens that mark them as self cells; the immune system does not react to them. The antigens on cells that are foreign to the body alert the immune system to the presence of nonself cells, which activates an immune response. Foreign or nonself antigens cause the immune system to develop antibodies, unique proteins (immunoglobulins) that inactivate or destroy specific antigens.

ANTIGENS AND BLOOD TYPE

Antigens form the basis of the ABO and rhesus (Rh factor) classification for BLOOD TYPE. Antigens coat the cell membrane surface of erythrocytes (red BLOOD cells) for blood types A, B, and AB. The erythrocytes of type O blood do not have antigens. Erythrocytes may also have Rh antigens, designated as "positive" when used to identify blood type. For example, A+ erythrocytes bear type A and Rh antigens. O– erythrocytes have neither ABO antigens nor Rh antigens.

Antigen Processing

Macrophages, tissue-bound phagocytic white BLOOD cells that start life as monocytes circulating in the blood, are abundant in the LYMPH tissues. They are the immune cells that sound the alarm to the rest of the immune system that nonself antigens are present. When a macrophage encounters a foreign entity, it surrounds and ingests it. As the MACROPHAGE consumes the invader, it displays the invader's antigens on the surface of its cell membrane. This display announces the presence of the antigens to other immune cells, notably T-cell lymphocytes, which then mount a full immune response. Other cells that may serve as antigen-presenting cells include B-cell lymphocytes and dendritic cells. Once T-cell lymphocytes "read" the antigen message the macrophage displays, they respond by attacking and killing the invader. Correspondingly, B-cell

lymphocytes (PLASMA cells) generate antibodies to further target the antigen.

Antigens and Cancer

The antigens on the surface of cancer cells have become a focus of much research into early diagnosis and new treatments for cancer. Cancer cells begin as normal cells in the body, bearing self-cell antigens. As the cells change and become cancerous they develop additional antigens. Blood tests can detect some of these antigens, such as PROSTATE SPECIFIC ANTIGEN (PSA) on PROSTATE CANCER cells. Cancer researchers believe the immune response fails to recognize the mixed antigen population on cancer cells as nonself, which allows the cancer to grow.

For further discussion of antigens within the context of the structures and functions of the immune system, please see the overview section "The Immune System and Allergies."

antihistamine medications Medications that block the action of HISTAMINE, a chemical that acts on the BLOOD vessels during an IMMUNE RESPONSE to allow fluid to flood the tissues. The resulting INFLAMMATION is part of the body's means of delivering INFECTION-fighting agents to the site (such as T-lymphocytes, CYTOKINES, and antibodies). However, this response is exaggerated in a HYPERSENSITIVITY REACTION, during which histamine secretion is excessive or continues after the immune response has neutralized the triggering ANTIGEN.

Large, granulated leukocytes (white blood cells) called mast cells produce, store, and release histamine (as well as serotonin and other chemicals). Mast cells reside in the mucous membranes of the respiratory tract (nasal passages, nasal sinuses, TRACHEA, and bronchi) and the gastrointestinal tract (primarily the STOMACH). Mast cells also store and release serotonin. Histamine is primarily responsible for the inflammatory changes that result in hypersensitivity reaction (allergic reaction).

STABILIZING MAST CELLS TO PREVENT HISTAMINE RELEASE

A different therapeutic approach to managing the HISTAMINE cascade in HYPERSENSITIVITY REACTION is to regulate histamine release at the level of the mast cells, which is most effective as a treatment for ALLERGIC ASTHMA (hypersensitivity reaction of the airways). Drugs called MAST-CELL stabilizers work by preventing the granules in mast cells from releasing histamine (called degranulation) as part of the IMMUNE RESPONSE. Mast-cell stabilizers to treat allergic ASTHMA include cromolyn and nedocromil.

How These Medications Work

Antihistamines work by blocking the ability of histamine to bind with histamine receptors on the surfaces of cell membranes. Antihistamines target the two types of histamine receptors involved with the immune response: H1 and H3. H1 receptors regulate arteriole dilation and capillary permeability. Histamine causes dilation of the arterioles, the body's tiniest arteries, to increase blood flow to the tissues and increases the flow of plasma out from the capillaries into the interstitial spaces, to flood the tissues with antibodies, cytokines, PROSTAGLANDINS, and other molecules essential to the immune response.

When taken at the onset of symptoms (while histamine release is still taking place) or prophylactically (to prevent histamine release, such as to treat seasonal allergies), antihistamine medications relieve the common symptoms of ALLERGY such as itching and sneezing. However, antihistamines cannot reverse the effects of histamine release after they occur or reduce inflammation that has already developed. Antihistamine medications to treat hypersensitivity reaction are available in oral, topical, inhalation, and injection preparations. Doctors may also prescribe antihistamines to relieve NAUSEA, particularly that of motion sickness, and mild anxiety.

First-generation antihistamines, long the mainstay of treatment for allergies, are nonselective. They block both H1 and H3 receptors. H1 blocking subdues symptoms of hypersensitivity reaction. H3 receptors signal BRAIN neurotransmitters in the HYPOTHALAMUS that regulate alertness and the nau-

sea center. Antihistamine medications with H3 blocking capability thus cause drowsiness and relieve nausea as well. Second-generation antihistamine medications are selective. They block primarily H1 receptors and have little effect on H3 receptors; thus they do not generally cause drowsiness and provide little or no relief of nausea. Third-generation antihistamine medications derive from second-generation antihistamines and are purported to have fewer side effects and adverse reactions though functionally are no different. Many antihistamine medications are available in the United States as OVER-THE-COUNTER (OTC) DRUGS, sometimes in combination with a decongestant or other ingredients. Manufacturers often market OTC antihistamines as allergy-relief products. Other antihistamines require a doctor's prescription.

ANTIHISTAMINE MEDICATIONS

First-Generation (Nonselective) Antihistamines	
brompheniramine	chlorpheniramine
dexchlorpheniramine	dimenhydrinate
diphenhydramine	doxylamine
hydroxyzine	phenindamine
pheniramine	pyrilamine
triprolidine	
Second-Generation (Selective H1) Antihistamines	
acrivastine	azatadine
cetirizine	clemastine
cyproheptadine	loratadine
mizolastine	
Third-Generation (Selective H1) Antihistamines	
desloratadine	fexofenadine
levocetirizine	

Therapeutic Applications

Doctors prescribe or recommend antihistamine medications to treat ALLERGIC RHINITIS, ALLERGIC CONJUNCTIVITIS, and ALLERGIC DERMATITIS. Most of the nonselective antihistamines cause significant drowsiness; doctors prescribe or recommend them for intermittent insomnia (difficulty sleeping). Meclizine is an H3 receptor antihistamine effective for nausea and VOMITING, especially that associated with motion sickness. Meclizine has little effect on H1 receptors, however, so does not influence the immune response or relieve symptoms of hypersensitivity reaction.

Some antihistamine medications have other therapeutic applications, such as

- anxiety: hydroxyzine
- sedative and sleep aid: diphenhydramine, doxylamine, hydroxyzine
- nausea and vomiting: dimenhydrinate, diphenhydramine, hydroxyzine
- VERTIGO: dimenhydrinate, diphenhydramine
- early PARKINSON'S DISEASE: diphenhydramine

Risks and Side Effects

In general antihistamine medications cause few side effects other than drowsiness, although can raise BLOOD PRESSURE. People who take other medications to treat chronic health conditions should check with their doctors before taking antihistamines, as antihistamines can exacerbate symptoms or interfere with the actions of other drugs.

antimitochondrial antibodies Autoantibodies the IMMUNE SYSTEM produces that attack the mitochondria within self cells. Mitochondria are the organelles (functional structures) within a cell that generate the energy the cell needs to carry out its activities. Antimitochondrial antibodies are proteins that bind with antigens (other proteins) on the inner walls of the mitochondria, blocking the ability of the mitochondria to convert oxygen to energy. The cell dies as a result.

CONDITIONS IN WHICH ANTIMITOCHONDRIAL ANTIBODIES ARE PRESENT

CIRRHOSIS	PRIMARY BILIARY CIRRHOSIS
PRIMARY SCLEROSING CHOLANGITIS	RHEUMATOID ARTHRITIS
SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)	THYROIDITIS

A BLOOD test called the antimitochondrial ANTIBODY (AMA) titer detects and measures antimitochondrial antibodies in the blood circulation. Their presence indicates various AUTOIMMUNE DISORDERS, notably PRIMARY BILIARY CIRRHOSIS and PRIMARY SCLE-

ROSING CHOLANGITIS, two conditions that damage the LIVER. Normally antimitochondrial antibodies are not present.

See also ANTIGEN; CELL STRUCTURE AND FUNCTION; IMMUNE RESPONSE.

antiphospholipid antibodies Autoantibodies the IMMUNE SYSTEM produces that attack phospholipids, fatty substances in the cell membranes of BLOOD cells and connective tissue cells. Antiphospholipid antibodies interfere with blood clotting (COAGULATION) and are present in a number of AUTOIMMUNE DISORDERS that affect connective tissue, such as RHEUMATOID ARTHRITIS (affecting the joints) and VASCULITIS (affecting the blood vessels). Antiphospholipid antibodies are also present in SYSTEMIC LUPUS ERYTHEMATOSUS (SLE).

Several blood tests can detect and measure the level of antiphospholipid antibodies, reported as a titer. Antiphospholipid antibodies are not normally present. Positive findings when there are no other autoimmune conditions may indicate a diagnosis of primary antiphospholipid syndrome. The primary effect of antiphospholipid antibodies is increased blood clotting, resulting in conditions such as DEEP VEIN THROMBOSIS (DVT), TRANSIENT ISCHEMIC ATTACK (TIA), repeated miscarriage in PREGNANCY, HEART ATTACK, and STROKE.

See also ANTIBODY; ANTIGEN; ANTIMITOCHONDRIAL ANTIBODIES.

atopy A genetically predisposed HYPERSENSITIVITY REACTION. Atopy is typically chronic. The most common forms of atopy are

- atopic ASTHMA, which affects the airways (bronchi)
- atopic DERMATITIS, which affects the SKIN
- atopic rhinitis, which affects the nasal passages (nose)
- atopic CONJUNCTIVITIS, which affects the membranes that line the eyelids (conjunctiva) and the sclera (white) of the EYE

The symptoms of atopic conditions are the classic symptoms of ALLERGY, though tend to appear at the slightest exposure to allergens and linger for an extended time. Atopy is a type I or IMMUNOGLOBULIN E (IgE) hypersensitivity reaction that occurs fairly immediately after exposure to the ALLERGEN. Treatments for atopic conditions target the IMMUNE RESPONSE as well as symptom relief and may include oral and topical ANTIHISTAMINE MEDICATIONS and CORTICOSTEROID MEDICATIONS. Avoiding known or suspected allergens significantly reduces the severity of an atopic attack.

See also ALLERGIC ASTHMA; ALLERGIC CONJUNCTIVITIS; ALLERGIC DERMATITIS; ALLERGIC RHINITIS; BRONCHUS; GENETIC PREDISPOSITION; LIVING WITH ALLERGIES.

autoimmune disorders Health conditions in which the body's IMMUNE RESPONSE loses the ability to identify certain self cells and attacks them. Autoimmune disorders may produce symptoms that are localized (affect a clearly defined part of the body), systemic (affect a body system), or generalized (affect the body as a whole or across several systems). Though researchers do not know what causes the immune response to lose tolerance for certain antigens, causing it to identify self cells as nonself cells, they do know that a person who has one autoimmune disorder is at risk for developing others.

AUTOIMMUNE DISORDERS

autoimmune HEPATITIS	BULLOUS PEMPHIGOID
dermatomyositis	DIABETES (type 1)
DISCOID LUPUS ERYTHEMATOSUS (DLE)	GOODPASTURE'S SYNDROME
GRAVES'S DISEASE	Hashimoto's THYROIDITIS
INFLAMMATORY BOWEL DISEASE (IBD)	MULTIPLE SCLEROSIS
MYASTHENIA GRAVIS	PEMPHIGUS
pernicious ANEMIA	POLYMYOSITIS
REITER'S SYNDROME	RHEUMATOID ARTHRITIS
scleroderma	SJÖGREN'S SYNDROME
SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)	VASCULITIS

Over time the immune attacks permanently damage or destroy tissue. Autoimmune disorders are chronic; though treatment may control symptoms, it does not cure the disorder. Symptoms and outlook vary with the autoimmune disorder. Some autoimmune disorders, such as type 1 DIABETES and GRAVES'S DISEASE, are life threatening without treatment. Treatment is generally IMMUNOSUPPRESSIVE THERAPY with IMMUNOSUPPRESSIVE MEDICATIONS that block certain aspects of the immune response. Further treatment may be necessary to counter the damage the autoimmune

disorder causes, such as INSULIN therapy for diabetes. The course of disease may be unpredictable. Though autoimmune disorders tend to gradually worsen over time, many remain manageable with minimal symptoms or disruption of activities. There are no known preventive measures.

See also COMMON VARIABLE IMMUNE DEFICIENCY (CVID); COMPLEMENT CASCADE; DISEASE-MODIFYING ANTIRHEUMATIC DRUGS (DMARDS); HIV/AIDS; LIVING WITH IMMUNE DISORDERS; MULTIPLE CHEMICAL SENSITIVITY SYNDROME; PARTIAL COMBINED IMMUNODEFICIENCY (PCID).

B

B-cell lymphocyte A type of white BLOOD cell (LEUKOCYTE) responsible for ANTIBODY-MEDIATED IMMUNITY (also called humoral immunity). B-cell lymphocytes are so named because they come to maturity in the BONE MARROW (in contrast to T-cell lymphocytes, which come to maturity in the THYMUS). B-cell lymphocytes produce antibodies in reaction to the presence of antigens. The bone marrow generates millions of B-cell lymphocytes each day. Each B-cell lymphocyte is specific for a unique ANTIGEN.

B-cell lymphocytes may be memory B-cells, which "remember" specific antigens to mobilize a rapid IMMUNE RESPONSE upon detecting their presence, and PLASMA cells, which produce antibodies.

- Plasma cells generate antibodies in response to the presence of antigens.
- Memory B-cells remain in the circulation of the blood and LYMPH, carrying inactive antibodies. Each memory B-cell has antibodies specific to a particular antigen the immune response has previously encountered. When the memory B-cell encounters the antigen again, it immediately begins producing antibodies.

Health conditions that affect B-cell lymphocytes include cancers, such as certain types of LEUKEMIA and lymphoma, and acquired immune and AUTOIMMUNE DISORDERS.

For further discussion of B-cell lymphocytes within the context of the structures and functions of the immune system, please see the overview section "The Immune System and Allergies."

See also CELL-MEDIATED IMMUNITY; HIV/AIDS; T-CELL LYMPHOCYTE.

biological response modifier See IMMUNOTHERAPY.

bronchus-associated lymphoid tissue (BALT) Loosely organized clusters of LYMPH tissue beneath the epithelium (tissue that forms the mucous lining) of the bronchi (inner airways) in the LUNGS. These clusters of lymph tissue have preventive, protective, and cleanup responsibilities within the IMMUNE RESPONSE. They contain

- macrophages and dendritic cells, which are phagocytic cells that consume the debris of pathogens other leukocytes (white BLOOD cells) kill
- T-cell lymphocytes, which destroy PATHOGEN-bearing cells
- B-cell lymphocytes, which produce the ANTIBODY IMMUNOGLOBULIN A (IgA), that helps keep BACTERIA and viruses from adhering to mucous tissues, such as the lining of the nasal sinuses and the bronchi
- M cells (folded, M-shaped cells that engulf pathogens and transport them to phagocytes), which participate in the various stages of ANTIGEN dispensation

BALT, like collections of accessory lymphoid tissue elsewhere in the body, reinforces the presence of the IMMUNE SYSTEM in areas where the body is vulnerable to invasion of pathogens (viruses, bacteria, and other potentially harmful substances). A specific role of BALT is to provide an extra layer of immune protection to block or limit access by viruses that cause infections specific to the lungs, such as INFLUENZA and PNEUMONIA.

For further discussion of BALT within the context of the structures and functions of the immune system, please see the overview section "The Immune System and Allergies."

C

cell-mediated immunity The protective mechanism through which specialized immune cells, primarily T-cell lymphocytes and natural killer (NK) cells, carry out the IMMUNE RESPONSE to protect the body from intracellular pathogens (disease-causing entities, such as viruses and parasites, that invade the body's cells). Cell-mediated immunity encompasses cytotoxic (death of invading cells) and phagocytic (consumption of cellular debris) activities. Cell-mediated immunity functions collaboratively with ANTIBODY-MEDIATED IMMUNITY to protect the body from INFECTION.

Several kinds of T-cell lymphocytes participate in cell-mediated immunity. They include

- cytotoxic T-cells, which respond directly to antigens for which they are sensitized and kill the cells that bear them
- helper T-cells (Th1 cells), also called CD-4 cells, which release CHEMOKINES in response to the presence of the antigen-bearing cells
- memory T-cells, which are essential for long-term immunity against infections such as MEASLES and POLIOMYELITIS (activated through disease or vaccination)
- suppressor T-cells, which bring the immune response to a close when the threat is gone

Macrophages set cell-mediated immunity in action when they display the antigens of a consumed cell. When these are nonself antigens, cytotoxic T-cells respond to kill other cells bearing the ANTIGEN. When the antigen is one the body has previously encountered, memory T-cells sensitized to the particular antigen rapidly convert to cytotoxic T-cells and mount a fast-strike immune response. The ability of cell-mediated immunity to rid the body of nonself-antigen-bearing cells is highly effective for controlling infection though also becomes problematic in ORGAN TRANSPLANTATION. Cell-mediated immunity, with its focus on nonself antigens, is key to GRAFT VS. HOST DISEASE and organ transplant rejection.

The NK cell, a type of granular LEUKOCYTE, does not respond to antigens. Rather, it responds to MAJOR HISTOCOMPATIBILITY COMPLEX (MHC) molecules on the surfaces of cell membranes. Attacking NK cells produce CYTOKINES that weaken the cell membrane of the targeted cells, which indirectly causes the death of the cells. NK cells also respond to tumor antigens and are particularly active in killing cancer cells. Researchers believe NK cells have a limited ability to recognize changes in cells that alter cellular identity (altered self), such as those occurring when cells turn cancerous. However, researchers do not understand the mechanisms of this recognition or to what extent NK cells are able to suppress the growth of cancer cells.

See also HYPERSENSITIVITY REACTION; MACROPHAGE; MONONUCLEAR PHAGOCYTE SYSTEM; NATURAL KILLER (NK) CELL; PARASITE; PATHOGEN; PHAGOCYTE; PHAGOCYTOSIS; T-CELL LYMPHOCYTE; VACCINE; VIRUS.

chemokines Proteins, also called chemotactic CYTOKINES, that draw or direct leukocytes to the scene of INFECTION within the body. Macrophages produce chemokines when they encounter foreign cells, instigating an IMMUNE RESPONSE. Some chemokines act as homing signals, marking the foreign cells so responding immune cells can zero in on them. Other chemokines send out biochemical "alerts" that attract circulating monocytes and lymphocytes.

Chemokines are integral in the process of angiogenesis (the development and growth of

new BLOOD vessels) that occurs when both HEALING and tumor progression (such as in cancer) takes place. Researchers are exploring ways to target chemokines as a means of shutting down angiogenesis, which has the potential to starve tumors.

See also IMMUNOTHERAPY; LEUKOCYTE; LYMPHOCYTE; MACROPHAGE; TUMOR NECROSIS FACTORS (TNFS).

clusters of differentiation A system of classifying lymphocytes according to the collections of antigens on the surface of their cell membranes, also called CD markers. Each CD has a specific role in cell signaling and communication, guiding cell function and response. CDs are critical to the normal function of the IMMUNE SYSTEM. Some of the major CDs are

- CD-1, which populates B-cell lymphocytes and macrophages and has a role in ANTIGEN presentation
- CD-2, which populates T-cell lymphocytes and natural killer (NK) cells and activates T-cells
- CD-3, which populates T-cell lymphocytes and facilitates antigen binding (the ability of T-cell lymphocytes to receive biochemical messages)
- CD-4, which populates T-helper cells (T-cell lymphocytes that direct IMMUNE RESPONSE to INFECTION) and is a key marker for monitoring the progression of HIV/AIDS
- CD-5, which populates B-cell lymphocytes that produce IMMUNOGLOBULIN M (IgM)
- CD-7, which populates T-cell lymphocytes in acute lymphocytic LEUKEMIA (ALL) and is a marker for STEM CELL leukemias
- CD-8, which populates T-suppressor cells (T-cell lymphocytes that end the immune response) and is a key marker for monitoring the progression of HIV/AIDS

CD-4 AND HIV/AIDS

CD-4 has become an important marker in tracking the progression of HIV/AIDS, as HIV-1 and HIV-2 bind with this ANTIGEN to gain access to the body. CD-4 receptors are abundant on certain T-cell lymphocytes called T-helper cells (also called T_4 cells). In health, CD-4 coordinates numerous aspects of the IMMUNE RESPONSE. When pathogens such as HIV bond with CD-4 receptors, they block the ability of CD-4 to signal other immune cells. This communication failure disrupts the IMMUNE SYSTEM's ability to mount an effective immune response. HIV also uses the T-helper cells to replicate itself, further spreading INFECTION. In combination, these events allow OPPORTUNISTIC INFECTION that can overwhelm the body.

colony-stimulating factors (CSFs) Molecules that stimulate the growth of leukocytes (white BLOOD cells) in the BONE MARROW. The body produces minute quantities of CSFs to regulate LEUKOCYTE production, maintaining the various types of leukocytes at appropriate levels to meet the needs of immune function. CSF production increases during INFECTION and other demands for higher quantities of white blood cells.

In the 1990s researchers isolated the genes that encode CSFs, permitting the use of recombinant technology to create synthetic versions of CSFs for therapeutic applications. Today doctors administer CSFs to rapidly restore white blood cell production after IMMUNOABLATION during the course of treatment for some forms of LEUKEMIA and certain other cancers for which BONE MARROW TRANSPLANTATION is a treatment option, and some chemotherapeutic regimens that are known to be very ablative to the white blood cells. Immunoablation uses high-DOSE CHEMOTHERAPY or RADIATION THERAPY to destroy the diseased bone marrow. During the approximately six weeks it takes for the transplanted bone marrow to begin producing new blood cells, the person has no immune function and is extremely vulnerable to infection. CSF therapy dramatically shortens this period of vulnerability, stimulating leukocyte production within days of the bone marrow transplantation.

See also CYTOKINES; GENE; HEMATOPOIESIS; IMMUNE RESPONSE; IMMUNOSUPPRESSIVE THERAPY; RECOMBINANT DNA.

common variable immunodeficiency (CVID) An immune disorder in which the IMMUNE SYSTEM lacks the ability to produce adequate antibodies to protect the body from INFECTION. Though there are normal numbers of B-lymphocytes in the BLOOD circulation, these ANTIBODY-producing cells are lacking IMMUNOGLOBULIN G (IgG), a protein essential for ANTIGEN recognition and antibody production. IgG is the foundation for most antibodies that the immune system produces.

Symptoms and Diagnostic Path

Symptoms of CVID can show up any time after about age 10 though most commonly appear in the late 20s and early 30s. Generally the person has the same type of infection repeatedly, as the immune system is not producing antibodies to protect against the infectious agent. The key symptom is a progressive pattern of recurrent or chronic infections. Infections are most commonly upper respiratory, SINUSES, THROAT, and middle EAR—typically BRONCHITIS, PNEUMONIA, PHARYNGITIS, SINUSITIS, and OTITIS media. Infections may be viral, bacterial, fungal, or parasitic. Some people also have gastrointestinal infections. The severity of infection varies among people who have CVID as well as within an individual from infection to infection. The diagnostic path includes blood tests to measure IgG and antibody levels. Immunoglobulin A (IgA) and immunoglobulin M (IgM) levels may also be low.

Treatment Options and Outlook

The main therapeutic course is reducing exposure to known infection (such as common viral infections) and treatment with ANTIBIOTIC MEDICATIONS at the first sign of infection. GAMMAGLOBULIN injections can bolster the immune system, though the gammaglobulin (which comes from blood or PLASMA donors) may not contain the specific antibodies the person needs. With effective medical management and diligent prevention efforts, most people who have CVID can enjoy relatively normal lifestyles and life expectancy.

Risk Factors and Preventive Measures

Most CVID is acquired, though researchers do not know what causes it to occur. There are no known measures for preventing CVID. CVID occurs more frequently in people who have AUTOIMMUNE DISORDERS such as RHEUMATOID ARTHRITIS or SYSTEMIC LUPUS ERYTHEMATOSUS (SLE). Prompt diagnosis and appropriate treatment are essential for preventing substantial lung damage that can occur from recurrent infections.

complement cascade The series of events that take place when an ANTIBODY binds with an ANTIGEN, activating the complements. Complements are proteins that participate in immune and inflammatory processes, acting primarily to kill antibody-marked cells. The biochemical interactions that take place with their activation ultimately lead to the formation of a protein structure called the terminal complement component or the membrane attack complex. The membrane attack complex penetrates the cell membrane of the antibody-marked cell. This penetration kills the cell and coats it in proteins that mark it for PHAGOCYTOSIS, the process through which LEUKOCYTE (white BLOOD cell) scavenger cells, called phagocytes, consume the debris that remains after the attacked cell dies.

There are about 30 complement proteins, also called complement factors, in the blood circulation. They remain inactive until antibody–antigen bindings or certain other immune responses activate them. Doctors classify activated complements into nine major molecular complexes identified as C1–C9. C1–C4 form the preliminary pathways leading to the formation of the membrane attack complex. C5–C9 collectively form the membrane attack complex. Other proteins interact with the complements to keep their actions in check. Disintegration of the complement complexes begins immediately after their activation to prevent them from damaging other cells.

Blood tests can measure complement activity in the body. Complement activity is often increased in the presence of cancer and decreased with certain AUTOIMMUNE DISORDERS such as SYSTEMIC LUPUS ERYTHEMATOSUS (SLE). Complement activity also diminishes in GRAFT VS. HOST DISEASE.

Deficiencies in various complement complexes increase susceptibility to INFECTION and the risk for disorders of the immune system. People who have deficiencies in the preliminary complement cascade pathways that unfold before the formation of the membrane attack complex are particularly vulnerable to infections such as MENINGITIS and PNEUMONIA. Certain of the pathogens that can cause these infections are encapsulated—viruses and BACTERIA that enclose themselves in capsules, or envelopes. The purpose of this encapsulation is to protect the pathogen against the body's defense mechanisms. When defects weaken those mechanisms, the pathogens gain advantage in establishing themselves—and infection—within the body.

Other complement deficiencies are common in SLE and some forms of VASCULITIS (disorders involving autoimmune INFLAMMATION of blood vessels). Treatment focuses on the symptoms of the consequential disorders, notably aggressive antibiotic therapy for infection. There are, as yet, no treatments to correct complement deficiencies. Doctors recommend meningococcal, pneumococcal, and *Haemophilus influenzae* VIRUS vaccinations for people who have complement deficiencies, to bolster the IMMUNE SYSTEM's ability to protect against infections from these pathogens.

For further discussion of the complement cascade within the context of the structures and functions of the immune system, please see the overview section "The Immune System and Allergies."

corticosteroid medications Anti-inflammatory medications that suppress INFLAMMATION and other aspects of the IMMUNE RESPONSE. Corticosteroid medications are synthetic variations of the body's natural HORMONE CORTISOL, which the ADRENAL GLANDS produce. Corticosteroids come in injectable, oral, inhalant, and topical preparations.

How These Medications Work

Corticosteroid medications work by blocking a number of the pathways in the immune response, key among them those that produce inflammation. They suppress the COMPLEMENT CASCADE, activation of antibodies, and production of eosinophils (white BLOOD cells that become abundant in a HYPERSENSITIVITY REACTION). Eosinophils are also important for fighting INFECTION, so suppressing them reduces the IMMUNE SYSTEM's ability to mount an effective defense when infection occurs. Corticosteroids also act to suppress MAST CELL release of HISTAMINE, LEUKOTRIENES, and PROSTAGLANDINS—biochemicals that facilitate inflammation.

There are three general types of corticosteroids, classified according to how they act in the body: glucocorticoids, mineralocorticoids, and ANDROGENS (the sex hormones). Glucocorticoids have the strongest anti-inflammatory action; most corticosteroid drugs are either glucocorticoids or a combination of glucocorticoid and mineralocorticoid. ALDOSTERONE, another hormone the adrenal cortex produces, is a mineralocorticoid used therapeutically as hormone replacement to treat ADDISON'S DISEASE (a condition in which the adrenal glands fail). However, aldosterone and other mineralocorticoids alone have very little anti-inflammatory action.

CORTICOSTEROID MEDICATIONS

betamethasone	cortisone
desoximometasone	fluticasone
dexamethasone	hydrocortisone
methylprednisolone	mometasone
prednisolone	prednisone
triamcinolone	

Therapeutic Applications

Doctors may prescribe corticosteroid medications to relieve symptoms of moderate to severe hypersensitivity reaction, to prevent GRAFT VS. HOST DISEASE in bone marrow transplant recipients, and to treat chronic inflammatory conditions such as severe OSTEOARTHRITIS, RHEUMATOID ARTHRITIS, ANKYLOSING SPONDYLITIS, PSORIASIS, SYSTEMIC LUPUS ERYTHEMATOSUS (SLE), and INFLAMMATORY BOWEL DISEASE (IBD). Corticosteroids in nasal sprays and inhalant forms are effective treatments for ALLERGIC RHINITIS and ALLERGIC ASTHMA. Systemic corticosteroid medications are also among the treatment options for severe asthma and certain other chronic inflammatory lung conditions.

It is important to take or use corticosteroid products correctly, particularly inhalants and nasal

sprays. Generally, corticosteroids are most effective when taken on a regular schedule to prevent the inflammatory process from developing, though they also can help suppress an inflammatory response after it begins. Because long-term corticosteroid therapy also suppresses the function of the adrenal glands, the body stops producing cortisol and becomes dependent on the external source of corticosteroids (the medication). It is important to reduce the dose over time (taper) when stopping a systemic corticosteroid, to allow the adrenal glands to resume cortisol production. Suddenly stopping systemic corticosteroid therapy can result in a rebound syndrome, with symptoms of inflammation, PAIN, and FEVER.

Risks and Side Effects

Side effects are uncommon with short-term systemic (oral and injection forms), inhalation, or topical corticosteroid use. However, corticosteroids tend to be less effective with repeated or chronic use. Injected corticosteroids, such as to treat inflammation in joints, can cause tissue damage over time. Doctors generally limit corticosteroid injections to prevent such damage. Long-term use of inhaled corticosteroids is often irritating to the tissues of the NOSE or THROAT. Long-term topical corticosteroids can cause thinning and darkening of the SKIN.

Long-term systemic corticosteroid therapy, such as for immunosuppression or to treat severe autoimmune disorders, has numerous side effects that require close monitoring to maintain optimal health. Key among them are increased risks for type 2 DIABETES and OSTEOPOROSIS. Systemic corticosteroids alter the body's hormonal balance and interactions, affecting numerous endocrine functions such as regulatory mechanisms for INSULIN–GLUCOSE METABOLISM and calcium balance in the bones. Systemic corticosteroids also influence thyroid hormones, which may alter overall metabolism to result in side effects such as rapid weight gain (with a characteristic rounded face) and excessive tiredness. Some people experience mood swings, mood disorders, DEPRESSION, or GENERAL ANXIETY DISORDER (GAD) when taking long-term corticosteroid therapy, a consequence of the influence corticosteroids exert on BRAIN neurotransmitters.

Because they suppress the immune response and LEUKOCYTE (white blood cell) production, systemic corticosteroids also increase the risk for infection. Chronic COLDS, URINARY TRACT INFECTION (UTI), CANDIDIASIS (yeast infection), and wounds that are slow to heal are common with long-term systemic corticosteroid therapy. Early treatment with ANTIBIOTIC MEDICATIONS or ANTIFUNGAL MEDICATIONS can help the body fight such infections. Systemic corticosteroids interact with numerous other medications and, because they cause sodium and fluid retention, may increase BLOOD PRESSURE or cause HYPERTENSION.

cytokines A large family of proteins that mediate and regulate the IMMUNE RESPONSE. Leukocytes (white BLOOD cells) produce cytokines. There are more than 100 cytokines, which may act independently or synergistically with other cytokines. Among the actions of cytokines are cell homing and direction (drawing leukocytes to the site of INFECTION or injury), INFLAMMATION response, and stimulation of the numerous molecules that participate in the immune response. Cytokines may act on the cells that produce them (autocrine activity), on cells in proximity to them (paracrine activity), or on cells throughout the body (endocrine activity).

MAJOR TYPES OF CYTOKINES

CHEMOKINES	COLONY-STIMULATING FACTORS (CSFS)
ERYTHROPOIETIN (EPO)	INTERFERONS
INTERLEUKINS	LYMPHOKINES
MONOKINES	TUMOR NECROSIS FACTORS (TNFS)

See also ANTIBODY; ANTIGEN; CELL-MEDIATED IMMUNITY; HISTAMINE; HORMONE; LEUKOCYTE; LEUKOTRIENES.

D

desensitization A therapeutic method in which gradual exposure to an ALLERGEN builds up the body's tolerance for the allergen, diminishing the IMMUNE RESPONSE to encountering it. IMMUNOGLOBULIN E (IgE) is primarily responsible for the symptoms associated with type I HYPERSENSITIVITY REACTION (allergic reaction), initiating the release of histamines, LEUKOTRIENES, and PROSTAGLANDINS. These substances induce INFLAMMATION (swelling), itching, sneezing, coughing, and other physiologic responses that represent the body's attempt to rid itself of the offending substance. Desensitization gradually activates an immunoglobulin G (IgG) ANTIBODY that binds, instead of IgE, with the allergen. Because IgG does not activate mast cells, the binding produces none of the symptoms that characterize a type I hypersensitivity reaction.

In desensitization the allergist injects the person with very small amounts of the allergen ("allergy shots") regularly over a period of three to five years. Relief is generally apparent in about a year. Approximately 80 percent of people who have seasonal allergies respond to desensitization, bringing their hypersensitivity reactions within tolerable parameters or eliminating them entirely. Desensitization, sometimes called allergy IMMUNOTHERAPY, is also highly effective for allergies to pet dander (especially cats), molds, and insect stings. Desensitization may be a therapeutic option for severe FOOD ALLERGIES that are difficult to manage by avoiding the food.

Desensitization injections carry the risk for instigating a severe hypersensitivity reaction including ANAPHYLAXIS, though this is rare. Some people experience temporary discomfort with the shots. Most people who undergo desensitization treatment have few side effects, however, and find the long-term benefit of reduced hypersensitivity reaction greatly improves their QUALITY OF LIFE.

See also ALLERGIC ASTHMA; ALLERGIC CONJUNCTIVITIS; ALLERGIC RHINITIS; ALLERGY; ALLERGY TESTING; ASTHMA; COUGH; HISTAMINE; LIVING WITH ALLERGIES; MAST CELL; SNEEZE.

disease-modifying antirheumatic drugs (DMARDs) Medications that alter the IMMUNE RESPONSE slow or stop the progression of certain degenerative, AUTOIMMUNE DISORDERS. The most common use of DMARDs is to treat RHEUMATOID ARTHRITIS. DMARDs provide relief from symptoms such as INFLAMMATION and PAIN, and in many people also reduce the JOINT deformities associated with rheumatoid arthritis and other degenerative conditions that result from the same disease process (such as ANKYLOSING SPONDYLITIS).

DISEASE-MODIFYING ANTIRHEUMATIC DRUGS (DMARDS)

anti-TUMOR NECROSIS FACTORS (TNFS)	azathioprine
chloroquine	cyclophosphamide
cyclosporine	etanercept
gold salts	hydroxychloroquine
infliximab	leflunomide
methotrexate	penicillamine
sulfasalazine	

How These Medications Work

DMARDs work by altering or suppressing the immune response. Some of the DMARDs are immunosuppressive CHEMOTHERAPY drugs (such as methotrexate and cyclosporine), though researchers do not fully understand how they work to reduce autoimmune inflammation. Other DMARDs are antimalarial medications that suppress immune function by blocking the action of

enzymes involved in the inflammatory process. Anti-TNFs are MONOCLONAL ANTIBODIES (MABS) that block the release of TUMOR NECROSIS FACTORS (TNFs), CYTOKINES that influence inflammation during the immune response.

Therapeutic Applications

Because DMARDs can have significant and serious side effects, doctors prescribe them when other therapies are no longer effective. The most common use of DMARDs is to treat rheumatoid arthritis. Doctors also may prescribe DMARDs to treat another degenerative autoimmune arthritis, ankylosing spondylitis, and sometimes to treat other autoimmune conditions such as MYASTHENIA GRAVIS and SYSTEMIC LUPUS ERYTHEMATOSUS (SLE).

Risks and Side Effects

DMARDs can have significant and harmful side effects including DIARRHEA, RASH, ANEMIA, LEUKOPENIA, and increased risk for INFECTION, particularly OPPORTUNISTIC INFECTION, as a consequence of immunosuppression. Methotrexate can cause irreversible CIRRHOSIS and lung damage. A rare and potentially fatal adverse reaction to methotrexate is TOXIC EPIDERMAL NECROLYSIS (also called Stevens-Johnson syndrome). Chloroquine and hydroxychloroquine can cause vision disturbances and RETINOPATHY (permanent damage to the RETINA, resulting in VISION IMPAIRMENT).

DMARDs may also interfere with the actions of other medications. It is important to check with the doctor before using any additional medications, incuding over-the-counter products. Because of the potential risks these side effects have, doctors prescribe most non-MAb DMARDs for people whose conditions are not responding to other treatments.

See also CORTICOSTEROID MEDICATIONS; NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS).

F

5-aminosalicylate (5ASA) medications Drugs taken to treat INFLAMMATORY BOWEL DISEASE (IBD), an autoimmune disorder that causes mild to severe INFLAMMATION and irritation to the COLON (bowel). People who have IBD typically experience alternating periods of exacerbation and REMISSION; in severe IBD the symptoms are often debilitating. The aminosalicylates, or 5ASAs, appear to work by suppressing the local IMMUNE RESPONSE in the mucosal lining of the SMALL INTESTINE and COLON.

Though researchers do not fully understand what causes IBD, they do know there are high levels of LEUKOTRIENES and PROSTAGLANDINS in the BLOOD circulation when IBD flares up. Researchers believe the 5ASA medications block these biochemicals from release, thus inhibiting inflammation. These drugs may also block the actions of TUMOR NECROSIS FACTORS (TNFS), CYTOKINES that also participate in the inflammatory response.

5-AMINOSALICYLATE (5ASA) MEDICATIONS

balsalazide (Colazal)
mesalamine (Asacol, Canasa, Pentasa, Rowasa)
olsalazine (Dipentum)
sulfasalazine (Azulfidine)

The 5ASAs are most effective when administered via rectal suppository or ENEMA, or by absorption-delayed oral medications (drugs that are specially coated to dissolve in the SMALL INTESTINE rather than the STOMACH) as these ROUTES OF ADMINISTRATION deliver the drug directly to the involved tissues. Pharmacologically, the 5ASAs are similar to aspirin. The most common side effects include HEADACHE, NAUSEA, and RASH (which occur most frequently with sulfasalazine and not so much with the other 5ASAs). The 5ASAs are effective for treating symptoms during exacerbations as well as for extending remission (preventing symptoms from reemerging).

See also AUTOIMMUNE DISORDERS; CORTICOSTEROID MEDICATIONS; NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS).

food allergies Hypersensitivity reactions to consumed foods. Food allergies affect about nine million Americans, two thirds of them children under the age of six. Allergies to peanuts, milk, wheat, shellfish, strawberries, and eggs are among the most common. Some people are allergic to preservatives or other substances used to prepare foods. Children tend to outgrow many food allergies; however, many adults develop food allergies later in life.

Unpleasant responses—such as STOMACH irritation, FLATULENCE (intestinal gas), and episodes of DIARRHEA—to certain foods are common but are not necessarily food allergies. An ALLERGY results in the activation of antibodies that triggers a HYPERSENSITIVITY REACTION, an excessive IMMUNE RESPONSE in which the IMMUNE SYSTEM responds to a particular food as though it were a harmful substance. The COMPLEMENT CASCADE floods the BLOOD circulation with antibodies, mast cells release HISTAMINE and PROSTAGLANDINS, and various types of leukocytes mobilize to attack the ALLERGEN.

Though some symptoms may be the same—such as stomach upset and diarrhea—the difference between food intolerance and food allergy can literally be life threatening: ANAPHYLAXIS, the most severe kind of hypersensitivity reaction, is an ever-present danger with food allergies. Of particular concern are ingredients that may not be obvious, such as peanut oil or soy, and may be present in processed foods as cross-contaminants.

Symptoms and Diagnostic Path

A hypersensitivity reaction to a food produces symptoms that may include

- itching and swelling around the face, on the lips, and in the MOUTH
- nasal congestion
- wheezing or difficulty BREATHING
- sensation of a lump in the THROAT
- gastrointestinal PAIN (resulting from swelling in the intestinal mucosa)
- moderate to extensive diarrhea

More generalized symptoms such as SKIN rash, hives (URTICARIA), and ANGIOEDEMA are also possible. Symptoms may occur within minutes to 2 hours after eating the food. Anaphylaxis may develop with any hypersensitivity reaction, even when previous reactions have been mild.

ANAPHYLAXIS is a medical emergency that requires immediate treatment from a doctor. Tingling and swelling of the lips, tongue, and THROAT 20 to 60 minutes after eating a food for which there could be an allergy are possible indications of anaphylaxis.

When there is a clear connection between a specific food and a hypersensitivity response, identifying the allergen is fairly straightforward. When the connection is not clear, the diagnostic path can be arduous and may include

- blood tests to measure IMMUNOGLOBULIN E (IgE) levels
- ALLERGY TESTING with suspect substances
- elimination diet

The elimination diet involves removing suspected foods or foods that are common allergens from the diet, usually for two weeks, and then reintroducing them one at a time until symptoms recur. The last food reintroduced is the likely allergen. An elimination diet is appropriate only for people who have mild to moderate hypersensitivity reactions. The risk for anaphylaxis is too great to use the elimination diet approach in people who have had severe allergy symptoms such as wheezing, breathing difficulty, or urticaria (hives). No single diagnostic approach works for all food allergies; diagnosis becomes a process of drawing conclusions based on symptoms.

COMMON FOOD ALLERGIES

cow's milk	eggs
peanuts	shellfish (lobster, shrimp, crab)
soy	strawberries
tree nuts (almonds, cashews, walnuts, pecans)	wheat (including flour)

Treatment Options and Outlook

A moderate hypersensitivity reaction may require treatment with ANTIHISTAMINE MEDICATIONS; a serious reaction may require a course of oral CORTICOSTEROID MEDICATIONS to halt the immune response and relieve the discomfort of the symptoms. Many hypersensitivity reactions to foods produce mild symptoms that go away without treatment. A doctor should evaluate symptoms that do not improve within a few days.

The most effective long-term treatment is to avoid the allergen. This is not always as easy as it sounds because often variations of the allergen are ingredients in prepared or baked foods. Peanuts, eggs, milk, soy, and wheat are common in many foods. Cross-contamination is also a concern, particularly among processed foods manufactured in facilities that use various ingredients in different products. An ice cream manufacturer may make a flavor that has nuts, for example, and then use the same equipment to make a flavor that does not have nuts. Even residue not visible to the eye can be sufficient to cause a hypersensitivity reaction in someone who is highly allergic. Labels on packaged foods include information about whether the product comes from a facility in which cross-contamination is possible. People who have food allergies must ask about obvious as well as hidden ingredients when eating away from home.

DESENSITIZATION (allergy shots) is a therapeutic option for people who have allergies to foods that are especially common or who have severe hypersensitivity reactions. Though it takes up to two years for desensitization to reach its maximum effectiveness, most people notice a reduced hypersensitivity reaction within six months.

Risk Factors and Preventive Measures

People who have other allergies or who have family members who have food allergies are more likely to develop food allergies. There are no measures to prevent allergies, food or otherwise. Identifying and avoiding foods that cause hypersensitivity reactions are the most effective methods for preventing those reactions and their unpleasant symptoms. Many people who have food allergies are able to manage them by carefully reading product labels and asking about ingredients when eating away from home.

See also ANTIBODY; ANTIGEN; BREATH SOUNDS; CARBOHYDRATE INTOLERANCE; CELIAC DISEASE; FOODBORNE ILLNESSES; LACTOSE INTOLERANCE; LEUKOCYTE; LIVING WITH ALLERGIES; MAST CELL.

gammaglobulin A solution of immunoglobulins collected from the PLASMA of donated BLOOD or from donated plasma. The highest concentration is of IMMUNOGLOBULIN E (IgE). Health-care providers administer gammaglobulin by intramuscular or intravenous injection to provide rapid immune protection for exposure to infectious diseases such as HEPATITIS. Though the protection is temporary, it helps prevent INFECTION until the person's IMMUNE SYSTEM can produce the necessary antibodies. Gammaglobulin is the treatment of choice when there is widespread public exposure to infectious diseases, such as may occur in schools and day-care centers.

See also ANTIBODY; ANTIGEN; IMMUNITY.

graft vs. host disease A life-threatening condition in which the immune cells (leukocytes and lymphocytes) contained in allogeneic transplanted BONE MARROW (the graft, from a donor source) produce antibodies that attack other organs in the organ transplant recipient's body (the host). BONE MARROW TRANSPLANTATION (or BLOOD STEM CELLtransplantation) is the primary treatment for cancers of the BLOOD such as LEUKEMIA, lymphoma, and MULTIPLE MYELOMA. Doctors may also use bone marrow transplantation to treat some types of cancer that do not respond to other therapies, severe aplastic ANEMIA, and severe SICKLE CELL DISEASE.

Graft vs. host disease is not a threat with autologous (self) bone marrow transplantation, which re-infuses blood stem cells previously withdrawn from the person. The condition occasionally develops after solid ORGAN TRANSPLANTATION and in IMMUNOCOMPROMISED people who receive BLOOD TRANSFUSIONS.

The immune cells of the transplanted bone marrow generate antibodies that commonly attack the recipient's LIVER, gastrointestinal tract (especially the STOMACH and SMALL INTESTINE), and SKIN. Damage can be rapid and severe. When the condition involves multiple organs, as is common, catastrophic multiple system failure is very possible. Graft vs. host disease accounts for more deaths after 100 days past the bone marrow transplantation than any other cause, including the cancer under treatment.

Symptoms and Diagnostic Path

Acute graft vs. host disease occurs within 100 days after the transplantation. About 30 percent of bone marrow transplant recipients experience acute symptoms, which may include

- skin RASH
- DIARRHEA
- INFECTION

Chronic graft vs. host disease develops or continues beyond 100 days from transplantation, though typically chronic disease tends to first manifest between 3 and 12 months after the transplant. The perpetual attacks that are the hallmark of chronic graft vs. host disease result in fibrotic (SCAR-related) changes to the skin, liver, and LUNGS. About 70 percent of people who receive bone marrow transplants experience some degree of chronic symptoms, which typically include

- dry, itchy skin
- discolored or taut skin
- HAIR loss or graying
- weight loss
- shortness of breath with exertion (DYSPNEA)

- chronic fatigue
- dry eyes and MOUTH

The diagnostic path includes blood tests to measure blood cell types and counts, ANTIBODY levels, and liver enzymes. In particular, CD-4+ and CD-8+ T-lymphocytes are abundant. Tissue biopsies also show evidence of damage due to the immune attack. Doctors classify graft vs. host disease into four stages, according to the severity of symptoms; stage 1 is the mildest and stage 4, the most severe.

Treatment Options and Outlook

At present the most successful treatment is IMMUNOSUPPRESSIVE THERAPY. Ideally, prophylactic immunosuppression prevents graft vs. host disease. When symptoms occur, immunosuppression can minimize the consequences and limit damage. Immunosuppression itself carries significant risk, however. The risk for infection, especially an OPPORTUNISTIC INFECTION the IMMUNE SYSTEM could normally keep at bay, is very high. CORTICOSTEROID MEDICATIONS, the cornerstone of immunosuppressive therapy, cause serious side effects with long-term, systemic use. As well, some immunosuppressive agents are chemotoxic (they work by killing cells) and have harmful side effects. The balance between sufficient immune suppression and adequate immune function is delicate.

Other treatment options include MONOCLONAL ANTIBODIES (MABS), which bind with the ANTIGEN receptors on the cell membrane surfaces of the cells in the organ. However, the body may develop antibodies against the MAbs. Though the first treatment is successful, subsequent efforts with the same MAbs will initiate an immune attack against the MAbs. A number of clinical trials are exploring investigational treatments for graft vs. host disease. A key challenge in treatment is that, although doctors fully understand what happens during graft vs. host disease, the mechanisms by which events occur remain unknown.

Risk Factors and Preventive Measures

Anyone who has bone marrow transplantation is at risk for graft vs. host disease. Optimal matching of HUMAN LEUKOCYTE ANTIGENS (HLAS) before trans-

ACUTE GRAFT VS. HOST DISEASE STAGING

Stage	Degree of Severity	Symptoms
1	mild	SKIN RASH affecting less than 25 percent of the skin surface, often starting on the hands and feet no other symptoms
2	moderate	skin rash affecting more than 25 percent of the skin surface mild gastrointestinal discomfort and DIARRHEA mild JAUNDICE
3	severe	extensive SUNBURN-like rash over most of the body STOMACH discomfort, abdominal cramping, diarrhea frequent or chronic INFECTION nutritional deficiencies moderate jaundice and LIVER dysfunction
4	life threatening	skin blisters and peeling skin over most of the body gastrointestinal PAIN bloody diarrhea severe jaundice and significant liver dysfunction or LIVER FAILURE serious INFECTION or OPPORTUNISTIC INFECTION malabsorption of NUTRIENTS

plantation provides the most successful circumstance for preventing graft vs. host disease. When precise HLA matching is not possible, screening for and selectively removing some T-cell lymphocytes (CD-4+ and CD-8+) from the donor organ that carry antibodies likely to attack the recipient can reduce the risk for graft vs. host disease. The risk for graft vs. host disease is also higher for people who receive blood stem cells extracted from donated blood (rather than from bone marrow donation), except cord stem cells extracted from umbilical blood.

granuloma An accumulation of granulocytes (also called polymorphonuclear leukocytes [PMNs]) and other cells that contain and enclose an area of INFLAMMATION at the site of cell injury, usually due to INFECTION. The effect is to "wall off" the area so the infection cannot spread. The resulting construction is fibrous (SCAR-like). Over time the PATHOGEN causing the infection within the granuloma dies but the granuloma remains. Granulomas may form anywhere in the body. CYTOKINES are instrumental in facilitating the process of granuloma formation, directing the actions of the involved immune cells.

Granulomas in the LUNGS commonly result from HISTOPLASMOSIS and other fungal infections. Granuloma inguinale is a sexually transmitted disease (STD). Granulomas are also characteristic of TUBERCULOSIS, Hansen's disease (leprosy), and SARCOIDOSIS. Any underlying infectious disease requires appropriate treatment. The doctor may surgically remove granulomas that cause discomfort or are unsightly. The granuloma itself usually causes no problems and does not require treatment.

See also FUNGUS; GRANULOCYTE; LEUKOCYTE; PHAGOCYTE; PHAGOCYTOSIS; SEXUALLY TRANSMITTED DISEASES (STDS).

gut-associated lymphoid tissue (GALT) Loosely organized, nonencapsulated clusters of LYMPH tissue beneath the epithelium (tissue that forms the mucous lining) of the gastrointestinal tract from the ESOPHAGUS to the COLON. T-cell lymphocytes, B-cell lymphocytes, and macrophages primarily inhabit GALT. The role of GALT is to block NORMAL FLORA BACTERIA (bacteria that are normally present in the gastrointestinal tract to aid digestion) from penetrating into other tissues or the BLOOD circulation. GALT also helps prevent gastrointestinal viruses from causing INFECTION. The presence of GALT in the lining of the STOMACH increases with aging. GALT also includes the small, nodelike lymphoid structures called PEYER'S PATCHES that pepper the SMALL INTESTINE. Peyer's patches intensify the presence of the IMMUNE SYSTEM and are the sites of much ANTIBODY activity from B-lymphocytes.

H

hay fever See ALLERGIC RHINITIS.

healing The processes and mechanisms by which the body repairs itself. Healing represents complex and cascading interactions among various of the body's systems and mechanisms. Among the first to respond are the COAGULATION cascade, to stop bleeding, and the IMMUNE RESPONSE, which mobilizes T-cell lymphocytes, macrophages, antibodies, the COMPLEMENT CASCADE, and the release of CYTOKINES and PROSTAGLANDINS. Fibroblasts (cells that build collagen) converge at the site about 48 hours after the injury occurs to begin construction of SCAR tissue. After about six weeks the healing process turns its focus to remodeling the collagen tissue, restoring the tissues at the site of the injury to relatively normal structure and appearance. This final phase of healing lasts six months to two years, depending on the extent of the injury.

Disease processes influence healing as well. Chronic conditions such as DIABETES and PERIPHERAL VASCULAR DISEASE (PVD), themselves likely the result of inflammatory dysfunction of some sort, damage the fine networks of nerves and BLOOD vessels that intertwine through the tissues, limiting the ability of these structures to carry signals (nerves) and transport molecules and cells vital to immune function (blood vessels). Serious injury—whether from disease process, trauma, or major surgery—affects endocrine and hormonal activity throughout the body, which influence the rate and processes of healing. Serious injury temporarily stuns the THYROID GLAND, for example, resulting in reduced production of thyroid hormones and consequential slowing of METABOLISM (EUTHYROID SICK SYNDROME).

Although researchers can map the physiologic steps of healing, much of healing remains a mystery. Researchers do not fully understand what starts, regulates, and ends the healing process. Many integrations across neurologic, endocrine, and immune functions are factors in healing. Some researchers are exploring connections between emotions and the numerous biochemical substances that are key to the healing process. Researchers know, for example, that emotional stress influences the release of numerous hormones in the body and the release of these hormones—such as the hormone CORTISOL, a powerful immunosuppressant—directly affects the functions of the IMMUNE SYSTEM. Research has shown that pain is a stressor and affects the rate of healing. Studies continue to explore the relationship between the mind and healing.

histamine A chemical that acts as an IMMUNE RESPONSE mediator. Large, granulated leukocytes called mast cells, which reside in the mucous membrane lining of the respiratory and gastrointestinal tracts, store histamine in their granules and release it during the immune response. Mast cells are most abundant in the nasal passages (including the SINUSES), the TRACHEA, and the bronchi. Histamine receptors on the surfaces of cell membranes determine how histamine affects the cell. ANTIHISTAMINE MEDICATIONS, the cornerstone of treatment for type I HYPERSENSITIVITY REACTION (allergic reaction), work by blocking histamine receptors.

Though there is only one form of histamine, its release can activate any of three types of histamine receptors: H1, H2, and H3. CYTOKINES,

PROSTAGLANDINS, and other biochemical messengers determine histamine release and what histamine binding will occur. Each histamine receptor regulates a different response:

- H1 receptors are on cell membrane surfaces of arteriole and capillary cells. H1 binding causes the arterioles to dilate (open) and the capillaries to increase the permeability of their walls. The effect of these actions is to allow additional fluid to seep from these blood vessels into the interstitial spaces (spaces between cells). The fluid floods the cells with INFECTION-fighting molecules, notably antibodies and cytokines. IMMUNOGLOBULIN E (IgE) binds with antigens and allergens, triggering H1 release. H1 is primarily responsible for type I hypersensitivity reactions such as ALLERGIC RHINITIS and ALLERGIC ASTHMA. Common antihistamine medications that block H1 receptor binding include diphenhydramine, chlorpheniramine, and hydroxyzine.
- H2 receptors are in parietal cells of the STOMACH. H2 binding acts to increase the flow of gastric acid in the stomach. Excessive secretion of histamine binding with H2 receptors is primarily responsible for GASTROESOPHAGEAL REFLUX DISORDER (GERD). Medications to limit histamine secretion and H2 receptor binding include H2 ANTAGONIST (BLOCKER) MEDICATIONS such as cimetidine and ranitidine.
- H3 receptors are neuroreceptors in the CENTRAL NERVOUS SYSTEM with high concentration in the areas of the HYPOTHALAMUS that regulate alertness. H3 binding decreases NEURON (NERVE cell) secretion of histamine, serotonin, acetylcholine, EPINEPHRINE, and NOREPINEPHRINE. The effect is to reduce alertness, which takes place as a natural aspect of the circadian cycle (body's rhythm of sleep and wakefulness). These neurotransmitters also affect the NAUSEA center. The antihistamine medications doxylamine and hydroxyzine are highly effective H3 receptor blockers.

Doctors typically consider only H1 receptor binding in the context of the immune response and focus primarily on whether its actions to initiate INFLAMMATION are helpful or counterproductive.

human leukocyte antigens (HLAs) Unique proteins (antigens) present on every nucleated cell (cell that has a nucleus) in the body. Also called histocompatibility locus antigens, HLAs allow the IMMUNE SYSTEM to identify cells as self (belonging to the body). Genes on CHROMOSOME 6, in a region called the MAJOR HISTOCOMPATIBILITY COMPLEX (MHC), regulate HLAs. Each person has unique HLAs. The nomenclature (naming convention) for HLAs identifies the ALLELE and GENE locus (position on the chromosome), designating the former with a letter and the latter with a number.

HLAs have various immune roles, including identification of self and nonself cells. This function makes HLAs of crucial importance in ORGAN TRANSPLANTATION. Incompatibility in HLAs can result in GRAFT VS. HOST DISEASE and rejection of the transplanted organ. IMMUNOSUPPRESSIVE THERAPY to subdue the IMMUNE RESPONSE in people who have organ transplants in part targets HLAs. Some research suggests that HLAs also may play crucial roles in the development of AUTOIMMUNE DISORDERS such as SYSTEMIC LUPUS ERYTHEMATOSUS (SLE), MULTIPLE SCLEROSIS, and SJÖGREN'S SYNDROME.

Though there are nearly endless configurations of HLAs, there are three broad groups of HLAs: HLA-A, HLA-B, and HLA-DR. Each set of three is called a haplotype. Every person has two specific HLAs from each of the three groups, for a total of two haplotypes (six HLAs). Each parent passes one haplotype to each child. Tissue matching for organ transplantation compares the donor's six HLAs with the recipient's six HLAs. The more that match, the more likely the organ transplant will be successful. The fewer that match, the greater the risk that the recipient's immune system will attack the donor organ.

The other key factor in HLA matching is immune reactivity (ANTIBODY reaction). It is possible to develop antibodies to HLAs that, even with a match, make it almost certain that the recipient will reject the organ. The most common cause for HLA antibodies is exposure to nonself HLA as a result of BLOOD TRANSFUSION. HLA matching is not a

component of blood typing. It is possible to have immune reactivity to multiple HLA proteins, which increases the difficulty of locating a good match for organ transplantation. Typically transplant centers like to see a match on four or more of the HLAs. A match of three or fewer strongly suggests the recipient will reject the transplanted organ.

humoral immunity See ANTIBODY-MEDIATED IMMUNITY.

hypersensitivity reaction A symptomatic interaction between antibodies and allergens that causes an exaggerated and harmful response in the body, commonly called an allergic reaction. Hypersensitivity reactions range from mild to life threatening in severity and symptoms.

ANAPHYLAXIS, the most severe hypersensitivity reaction, is a life-threatening emergency that requires immediate medical attention.

There are four types of hypersensitivity reaction, classified according to the way in which the ALLERGEN or ANTIGEN activates the reaction. The classic allergic reaction is the type I hypersensitivity reaction, with exposure to an external substance (the allergen) initiating the IMMUNE RESPONSE. Types II, III, and IV hypersensitivity reactions are endogenous (within the body) responsible for IMMUNE DISORDERS (other than due to IMMUNODEFICIENCY) and AUTOIMMUNE DISORDERS.

Type I Hypersensitivity Reaction: IgE Antibody Reaction

IMMUNOGLOBULIN E (IgE), the foundation lipoprotein for ANTIBODY formation, mediates type I hypersensitivity reactions. With exposure to an external allergen, the immune response floods the BLOOD circulation with antibodies. Mast cells, basophils, and eosinophils (white blood cells that have specialized immune functions) participate in type I hypersensitivity reactions. Mast cells release HISTAMINE, PROSTAGLANDINS, and other biochemicals that set in motion interactions among various proteins and cells that guide further immune activity.

Symptoms generally occur within 15 to 30 minutes of exposure, though sometimes can emerge 10 to 12 hours after exposure. Anaphylaxis (also called anaphylactic shock) is the most severe type I hypersensitivity and is life threatening. ALLERGIC RHINITIS, ALLERGIC CONJUNCTIVITIS, ALLERGIC ASTHMA, ATOPY, and FOOD ALLERGIES are type I hypersensitivity reactions. Type I hypersensitivity reactions tend to run in families, causing researchers to suspect genetic underpinnings for the allergies.

A type I hypersensitivity reaction occurs in two stages: the induction stage, the first exposure during which the IMMUNE SYSTEM produces antibodies for the particular antigen or allergen, and the elicitation stage, during which the immune response activates the antibodies to attack the antigen or allergen. There are no symptoms during the induction stage. Each subsequent exposure to the antigen or allergen triggers the elicitation stage, resulting in symptoms. The elicitation stage lasts as long as there is allergen–antibody interaction, though symptoms may continue for some time (hours to days) afterward.

Regardless of what form symptoms take (SKIN RASH, tingling around the MOUTH, DIARRHEA), a type I hypersensitivity reaction is a systemic response—it affects and involves the body as a whole. Sensitization to an allergen is long term or lifelong because the antibody-bearing PLASMA cells (B-cell lymphocytes that specialize to produce antibodies) circulate indefinitely in the blood.

Type II Hypersensitivity Reaction: Cytotoxic Reaction

Immunoglobulin G (IgG) and immunoglobulin M (IgM) mediate cytotoxic reactions, also called antibody-mediated hypersensitivity reactions. Type II reactions occur as a result of interactions between antibodies and antigens on cell membrane surfaces. The immune response activates the COMPLEMENT CASCADE, which results in the release of biochemicals that kill the antigen-bearing cells. T-cell lymphocytes and natural killer (NK) cells also participate. Symptoms of a type II hypersensitivity reaction typically emerge within a few minutes to several hours after antibody–antigen binding.

Hemolytic ANEMIA, BLOOD TRANSFUSION reactions, Rhesus (Rh) blood reactions (erythroblastosis fetalis), PEMPHIGUS, GOODPASTURE'S SYNDROME, and many DRUG allergies (notably penicillin) are type II hypersensitivity reactions.

Type III Hypersensitivity Reaction: Immune Complex (IC) Reaction

IgG and IgM also mediate type III hypersensitivity reactions, though through different mechanisms from those that occur in type II hypersensitivity reactions. Type III hypersensitivity reactions occur when unattached antigens enter the blood circulation and activate an immune response that results in the formation of an immune complex, a conglomeration of immune proteins (immunoglobulins), platelets, neutrophils, and immune-related substances that surround the antigens. Eventually these clumps fall out of the blood circulation and settle into tissues. Type III antibodies are autoantibodies—that is, antibodies that target the body's own antigens.

Researchers do not know what precipitates the immune response in most type III reactions, though viruses such as HEPATIS A, serum sickness, and drug reactions are sometimes accountable. Symptoms develop 3 to 10 hours after the immune complex forms. ASPERGILLOSIS, SYSTEMIC LUPUS ERYTHEMATOSUS (SLE), GLOMERULONEPHRITIS, polyarteritis and other forms of VASCULITIS, and RHEUMATOID ARTHRITIS are type III hypersensitivity reactions.

Type IV Hypersensitivity Reaction: Delayed Reaction

T-cell lymphocytes (primarily helper T-cells) mediate type IV hypersensitivity reactions, also called delayed-type hypersensitivity (DTH) or cell-mediated hypersensitivity reactions. Type IV reactions take days to weeks to manifest. The rash of poison ivy, poison oak, and poison sumac represents a type IV hypersensitivity reaction. GRANULOMA is also a typical type IV hypersensitivity reaction, often to BACTERIA or fungi the body is unable to completely eliminate. Common therapeutic applications of a type IV hypersensitivity reaction include the tuberculin skin test to detect the presence of *Mycobacterium tuberculosis* and skin patch ALLERGY TESTING.

Symptoms and Diagnostic Path

Symptoms vary with the type and severity of the hypersensitivity reaction. Itching and skin rash or URTICARIA (hives) are common with type I hypersensitivity reactions. Symptoms may involve the airways (allergic asthma) or gastrointestinal tract (food allergies). Contact reactions typically involve the surface of the skin though may also produce widespread systemic symptoms. The diagnostic path may include blood tests to assess the types and levels of blood cells present in the circulation as well as to detect the types and quantities of immunoglobulins. Allergy testing can help isolate the specific allergens for type I hypersensitivity reactions. The doctor may conduct further diag-

HYPERSENSITIVITY REACTION TYPES AND SYMPTOMS

Type of Reaction	Symptoms	Typical Onset from Exposure
type I (IgE antibodies)	URTICARIA (hives), SKIN RASH, wheezing itching	15 to 30 minutes
type II (cytotoxic)	redness and swelling due to cell or tissue death	minutes to several hours
type III (immune complex)	redness and swelling (erythema and edema) pain	3 to 10 hours
type IV (cell mediated)	redness and hardness (erythema and induration) PAIN	48 to 72 hours (nongranuloma) 3 to 4 weeks (granuloma)

nostic testing to rule out other possible causes of the symptoms.

Treatment Options and Outlook

Antihistamine medications are the most effective intervention early in the onset of a type I hypersensitivity reaction, the classic allergic reaction. These medications block histamine receptors on cell membrane surfaces, effectively breaking the chain reaction effect of the immune response. The longer the hypersensitivity reaction has been under way, the less effective antihistamine medications are because the reaction moves beyond histamine release and binding. Treatment for anaphylactic symptoms is injection with EPINEPHRINE, a potent NEUROTRANSMITTER and HORMONE that effectively halts the immune response. Doctors reserve epinephrine for life-threatening hypersensitivity reactions because the drug has numerous and significant effects on cardiovascular and pulmonary function.

CORTICOSTEROID MEDICATIONS are effective for severe type I reactions and type II, III, and IV reactions. Other IMMUNOSUPPRESSIVE MEDICATIONS such as methotrexate and cyclosporine act through different mechanisms to interrupt the immune response. DISEASE-MODIFYING ANTIRHEUMATIC DRUGS (DMARDS) use various mechanisms to achieve similar results. MONOCLONAL ANTIBODIES (MABS) are showing great promise for treating hypersensitivity reactions in some people. The appropriate treatment selections depend on the type and severity of the hypersensitivity reaction and any other health conditions the person may also have.

TREATMENT OPTIONS FOR HYPERSENSITIVITY REACTION

Treatments	Effects	Effective for Type of Reaction
ANTIHISTAMINE MEDICATIONS	block HISTAMINE binding	type I
CORTICOSTEROID MEDICATIONS	suppress COMPLEMENT CASCADE, ANTIBODY activation, and eosinophil production suppress mast cell release of histamine, LEUKOTRIENES, and PROSTAGLANDINS	type II, type III, type IV type I when severe or nonresponsive to other treatment
DISEASE-MODIFYING ANTIRHEUMATIC DRUGS (DMARDS)	suppress various immune response pathways	type III
EPINEPHRINE injection	stop the immune response	type I when severe or anaphylactic
immunosuppressive agents other than corticosteroids	suppress various immune response pathways	type III and type IV
leukotriene receptor antagonist medications	block leukotriene binding	type I when ASTHMA present
MAST CELL stabilizers	prevent degranulation within mast cells to block the release of histamine, leukotrienes, and prostaglandins	type I when asthma present
MONOCLONAL ANTIBODIES (MABS)	block antibody–ANTIGEN binding	type I when asthma present type III and type IV
NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS)	block the actions of prostaglandins	type III

Risk Factors and Preventive Measures

The sole risk for hypersensitivity reaction (types I, II, and III) is exposure to an allergen; the most effective prevention is avoiding such exposure. This approach is often easier said than done, especially when the allergen is an ubiquitous substance such as pollen or mold. Doctors often recommend taking antihistamine medications on a regular schedule during times when pollen counts are high to reduce hypersensitivity reactions among people who have seasonal allergies. Desensitization effectively reduces or prevents hypersensitivity reactions to specific allergens for many people, providing permanent relief.

I

immune disorders Chronic conditions of the IMMUNE SYSTEM that affect the IMMUNE RESPONSE and the body's ability to protect and defend itself against INFECTION. Immune disorders generally result from a deficiency or absence of some component or structure of immune function. Such a deficiency may be primary, which is congenital (present at birth), genetic (inherited), or acquired (develops during life). People who have had their spleen surgically removed (SPLENECTOMY) also have reduced immune response, which results in increased susceptibility to infection.

IMMUNE DISORDERS

AUTOIMMUNE DISORDERS	COMMON VARIABLE IMMUNE DEFICIENCY (CVID)
HIV/AIDS	IMMUNOGLOBULIN A (IgA) deficiency
HYPERSENSITIVITY REACTION	IgM deficiency
IgA NEPHROPATHY	SEVERE COMBINED IMMUNODEFICIENCY (SCID)
IgE deficiency	Wegener's granulomatosis
PARTIAL COMBINED IMMUNODEFICIENCY (PCID)	
TOXIC EPIDERMAL NECROLYSIS	

Frequent or chronic infection is the primary symptom of an immune disorder other than HYPERSENSITIVITY REACTION (allergy). BLOOD tests for immunoglobulins and antibodies generally can diagnose immune disorders. Hypersensitivity reactions generate symptoms according to the type of reaction and may include symptoms of ALLERGIC RHINITIS, ALLERGIC CONJUNCTIVITIS, ALLERGIC DERMATITIS, or ALLERGIC ASTHMA. ALLERGY TESTING is the preferred diagnostic approach for identifying the allergens responsible for hypersensitivity reaction, though often a person knows the cause of an allergy.

Immune disorders are generally chronic, which means treatment can improve symptoms but not cure or end the condition. Common medication therapies for immune disorders include ANTIHISTAMINE MEDICATIONS, NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS), CORTICOSTEROID MEDICATIONS, leukotriene receptor antagonists, MAST CELL stabilizers, and DISEASE-MODIFYING RHEUMATOID DRUGS (DMARDS). The particular medication regimen depends on the immune disorder and the individual's symptoms.

See also ANTIBODY; ATOPY; GENETIC DISORDERS; IMMUNITY; IMMUNOCOMPROMISED; IMMUNODEFICIENCY; LEUKOTRIENES; LIVING WITH IMMUNE DISORDERS.

immune response The multiple mechanisms and processes through which the body identifies and reacts to antigens. The immune response is the body's primary means of protecting itself from INFECTION. There are three independent yet complementary immune response pathways: ANTIBODY-MEDIATED IMMUNITY (also called humoral immunity), CELL-MEDIATED IMMUNITY, and the COMPLEMENT CASCADE. As well, the immune response stimulates activity from the NERVOUS SYSTEM and the endocrine system.

The immune response relies largely on ANTIBODY–ANTIGEN binding. Antigens are molecules that identify cells to the IMMUNE SYSTEM. Antibodies are molecules the immune system produces to bind with nonself antigens—antigens on cells that do not belong to the body. With antibody–antigen binding, the antibody releases proteins called opsonins that mark the antigen-bearing cell for destruction by killer T-cells and natural killer (NK) cells. Monocytes (in the BLOOD circulation) and macrophages (in the tissues) consume the cellular debris remaining after the marked cell's destruction. Antibody–antigen binding also activates the complement cascade, a biochemical response that

produces proteins that attach to and damage the cell membrane of cells that the immune response identifies as nonself.

A key feature of the immune response is INFLAMMATION, the process by which the body increases the ability of PLASMA, the liquid component of blood, to seep into the tissues (interstitial spaces). HISTAMINE and PROSTAGLANDINS are the primary agents of the inflammatory response. Inflammation floods the tissues with immune molecules to extend the immune response beyond the blood and the LYMPH. Inflammation also serves to contain the infection, keeping it from spreading beyond its point of origin to other areas of the body.

For further discussion of the immune response within the context of the structures and functions of the immune system, please see the overview section "The Immune System and Allergies."

immune system The structures, substances, and processes that protect the body from INFECTION. These include organs, tissues, cells, and molecules. The immune system functions in close collaboration with the NERVOUS SYSTEM and the endocrine system.

The main organs and tissues of the immune system include

- BONE MARROW
- THYMUS
- SPLEEN
- lymph nodes
- BLOOD
- LYMPH
- adenoids and tonsils
- APPENDIX
- MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT)
- SKIN
- tears
- saliva

The primary cells of the immune system include

- B-cell lymphocytes (PLASMA cells, memory B-cells)
- T-cell lymphocytes (helper T-cells, cytotoxic T-cells, memory T-cells, suppressor T-cells)
- granulocytes (neutrophils, eosinophils, and basophils)
- macrophages and dendritic cells
- mast cells
- monocytes
- M cells
- natural killer (NK) cells

Key molecules of the immune system include

- HUMAN LEUKOCYTE ANTIGENS (HLAS)
- complement factors
- CLUSTERS OF DIFFERENTIATION
- IMMUNOGLOBIN
- antigens
- antibodies
- PROSTAGLANDINS
- HISTAMINE
- LEUKOTRIENES
- CYTOKINES (CHEMOKINES, INTERLEUKINS, MONOKINES, INTERFERONS, LYMPHOKINES, COLONY-STIMULATING FACTORS [CSFS], and TUMOR NECROSIS FACTORS [TNFS])

For further discussion of the structures and functions of the immune system, please see the overview section "The Immune System and Allergies."

See also ANTIBODY; ANTIGEN; ANTIBODY-MEDIATED IMMUNITY; B-CELL LYMPHOCYTE; CELL-MEDIATED IMMUNITY; COMPLEMENT CASCADE; GRANULOCYTE; IMMUNE RESPONSE; LYMPH NODE; LYMPHOCYTE; MACROPHAGE; MAJOR HISTOCOMPATIBILITY COMPLEX (MHC); MONOCYTE; NATURAL KILLER (NK) CELL; PSYCHONEUROIMMUNOLOGY; T-CELL LYMPHOCYTE.

immunity An established base of protection against INFECTION. Immunity may be innate, pas-

sive, or acquired. INNATE IMMUNITY, also called natural immunity, is present at birth and provides effective protection against a broad base of common pathogens. Innate immunity is limited in scope. PASSIVE IMMUNITY is ANTIBODY-specific but present without activation of the IMMUNE RESPONSE. A newborn has passive immunity based on the antibodies present in his or her mother's BLOOD. BLOOD TRANSFUSION, PLASMA transfusion, and administration of GAMMAGLOBULIN also convey passive immunity to the recipient. Passive immunity is short term. The body develops acquired immunity through exposure to antigens via infection or vaccination. Acquired immunity is ANTIGEN-specific and long term, often lifelong.

For further discussion of immunity within the context of the structures and functions of the IMMUNE SYSTEM, please see the overview section "The Immune System and Allergies."

See also ANTIBODY-MEDIATED IMMUNITY; CELL-MEDIATED IMMUNITY; PATHOGEN; VACCINE.

immunoablation The therapeutic destruction of the body's IMMUNE RESPONSE, typically to prepare for BONE MARROW TRANSPLANTATION or STEM CELL transplantation. Immunoablation is usually a step in the treatment process for certain cancers and AUTOIMMUNE DISORDERS, such as severe MULTIPLE SCLEROSIS. High-DOSE CHEMOTHERAPY and RADIATION THERAPY are the most common methods of immunoablation. The goal is to remove all T-cell lymphocytes from the BLOOD, which destroys the body's CELL-MEDIATED IMMUNITY. Until the person's IMMUNE SYSTEM restores immune functions, the person is extremely vulnerable to any INFECTION. A person who has undergone immunoablation stays in a hospital in strict isolation until immune function returns after bone marrow or stem cell transplantation.

See also CANCER TREATMENT OPTIONS AND DECISIONS; LEUKEMIA; MULTIPLE MYELOMA; T-CELL LYMPHOCYTE.

immunocompromised Any circumstance in which the IMMUNE SYSTEM lacks the capacity, as the consequence of an acquired health condition or a medication SIDE EFFECT, to protect the body from INFECTION. DIABETES is the most common reason people become immunocompromised. People who are taking IMMUNOSUPPRESSIVE THERAPY after ORGAN TRANSPLANTATION or to treat severe AUTOIMMUNE DISORDERS are also immunocompromised. People who are immunocompromised often struggle to fight off common infections such as COLDS and URINARY TRACT INFECTION (UTI) and are vulnerable to OPPORTUNISTIC INFECTION (an infection that a healthy immune system would easily rebuff).

See also ANTIBIOTIC PROPHYLAXIS; IMMUNE DISORDERS; LIVING WITH IMMUNE DISORDERS.

immunodeficiency The absence of IMMUNE SYSTEM components essential for proper IMMUNE RESPONSE and protection from INFECTION. Immunodeficiency may be congenital (present at birth) or acquired (develop later in childhood or adulthood). As well, immunodeficiency is a consequence of therapies intended to compromise immune function, such as RADIATION THERAPY, CHEMOTHERAPY, and IMMUNOSUPPRESSIVE THERAPY.

Congenital immunodeficiency is genetic (the result of a GENE MUTATION) and may be inherited. Inherited immunodeficiencies can include IMMUNOGLOBULIN deficiencies, disorders of B-cell lymphocytes, disorders of T-cell lymphocytes, and complement disorders. A child born without a THYMUS or a SPLEEN will have multiple immunodeficiencies because these structures are crucial for LEUKOCYTE (white BLOOD cell) formation and maturation.

Acquired immunodeficiency generally occurs as a result of infections, AUTOIMMUNE DISORDERS, or severe trauma (such as BURNS) that challenges the immune system's capabilities. Conditions such as DIABETES and CYTOMEGALOVIRUS (CMV) infection commonly cause immunodeficiency. The HIV/AIDS infection is one of the most serious acquired immunodeficiencies, as it eventually destroys the immune system.

Immunodeficiency disorders are not currently preventable or curable; diligent treatment can usually keep disease progression and symptoms in check. Treatment for immunodeficiency disorders depends on the cause of the disorder and the symptoms it creates. Medications and IMMUNOTHERAPY (biologic response modification) allow many people who have immunodeficiency disorders live fairly normal lifestyles.

See also ANTIBODY-MEDIATED IMMUNITY; B-CELL LYMPHOCYTE; CELL-MEDIATED IMMUNITY; COMMON VARI-

ABLE IMMUNODEFICIENCY (CVID); COMPLEMENT CASCADE; IMMUNE DISORDERS; LIVING WITH IMMUNE DISORDERS; PARTIAL COMBINED IMMUNODEFICIENCY (PCID); SEVERE COMBINED IMMUNODEFICIENCY (SCID); T-CELL LYMPHOCYTE.

immunoglobulin A protein structure the IMMUNE SYSTEM produces. Immunoglobulins are the foundation molecules for the formation of antibodies. Immunoglobulins circulate in the BLOOD. The immunoglobulin's class designation reflects its molecular structure, which in turn dictates the action of the immunoglobulin. The five major classes of immunoglobulin provide different kinds of antibodies:

- Immunoglobulin A (IgA) is the main immunoglobulin in the body's secretions (tears, saliva, and mucus) and in colostrum, the first discharge from the mother's breasts after childbirth. It is the second most abundant immunoglobulin in the blood circulation. IgA boosts the IMMUNE RESPONSE capacity of the various MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT) structures. IgA blood levels decrease in lymphoblastic leukemias and increase in certain AUTOIMMUNE DISORDERS, notably RHEUMATOID ARTHRITIS and SYSTEMIC LUPUS ERYTHEMATOSUS (SLE).
- Immunoglobulin D (IgD) resides on the surface of the cell membrane of B-cell lymphocytes. Its primary role is to bind with antigens. IgD blood levels increase with chronic infections and certain myelomas.
- Immunoglobulin E (IgE) produces the antibodies responsible for HYPERSENSITIVITY REACTION as well as primary INFECTION-fighting antibodies. It also is the immune response's main defense against parasitic infection. IgE is the least abundant of the immunoglobulins in the blood circulation. Blood levels of IgE rise with hypersensitivity reactions.
- Immunoglobulin G (IgG) is the most abundant and versatile of the immunoglobulins. It makes up 75 percent of the immunoglobulin in the blood circulation. IgG binds with many types of leukocytes and activates the COMPLEMENT CASCADE. IgG is the only immunoglobulin that can cross the placental barrier between mother and fetus. IgG blood levels increase with infection and rheumatoid arthritis and decreases with lymphoblastic LEUKEMIA.
- Immunoglobulin M (IgM) is the third most abundant class of immunoglobulin in the blood circulation. The first contact with an ANTIGEN causes a B-CELL LYMPHOCYTE to produce IgM. IgM antibodies help collect cellular debris for more efficient PHAGOCYTOSIS. Blood levels of IgM increase with infectious mononucleosis, MALARIA, SLE, and rheumatoid arthritis.

Immunoglobulins collected from donated blood and PLASMA are blended to produce GAMMAGLOBULIN, a therapeutic form that boosts the nonspecific immune response.

For further discussion of immunoglobulins within the context of the structures and functions of the immune system, please see the overview section "The Immune System and Allergies."

See also ANTIBODY; ANTIBODY-MEDIATED IMMUNITY; LEUKOCYTE; LYMPHOCYTE; MONONUCLEOSIS, INFECTIOUS; VACCINE.

immunosenescence A decline in immune function and IMMUNE RESPONSE that occurs with aging. Researchers believe immunosenescence accounts for the increase in cancer and infections such as INFLUENZA and PNEUMONIA in people of old age. The decline occurs in both CELL-MEDIATED IMMUNITY (sometimes called cytotoxic immunity), in which T-cell lymphocytes attack and kill foreign antigens, and humoral immunity, in which B-cell lymphocytes generate the antibodies that circulate in the BLOOD. Though immunosenescence appears a normal physiologic process in that it happens to everyone as they grow older, researchers question whether it is an intrinsic function under genetic regulation or an extrinsic reaction to environmental factors, ranging from EATING HABITS to toxic exposure.

See also AGING, EFFECTS ON IMMUNE RESPONSE; ANTIBODY; ANTIGEN; APOPTOSIS; B-CELL LYMPHOCYTE; CELL STRUCTURE AND FUNCTION; LYMPHOCYTE; T-CELL LYMPHOCYTE.

immunosuppressive medications Drugs that limit or suppress some aspect of the IMMUNE RESPONSE. Immunosuppressive medications such as cyclosporine work by many different mechanisms

with the goal being to block the body's rejection of a transplanted organ or bone marrow and to prevent GRAFT VS. HOST DISEASE. Common immunosuppressive medications include

- CORTICOSTEROID MEDICATIONS, which inhibit the production of eosinophils, suppress the COMPLEMENT CASCADE, and block the activation of antibodies
- DISEASE-MODIFYING ANTIRHEUMATIC DRUGS (DMARDS), which block the immune response in such of a way as to alter, at least temporarily, the course of the disease
- cytotoxic agents, which kill cells (cells that replicate rapidly, such as BLOOD cells, are more greatly affected)

Doctors prescribe immunosuppressive medications to treat AUTOIMMUNE DISORDERS, HYPERSENSITIVITY REACTION, and to prevent an immune response that targets a transplanted organ. Often doctors prescribe these medications in combination to quell the immune response on several fronts. This allows lower dosages for each type of medication, reducing the overall amount of medication the person must take and minimizing side effects. The approach also provides greater relief in severe presentations of chronic inflammatory diseases such as RHEUMATOID ARTHRITIS and SYSTEMIC LUPUS ERYTHEMATOSUS (SLE).

Immunosuppressive medications have numerous side effects, DRUG interactions, and risks specific to the medication. In general, the primary risk of immunosuppressive medications is INFECTION, particularly OPPORTUNISTIC INFECTION. Though doctors try to maintain a balance of immune suppression that controls symptoms yet allows the body to protect itself from infection, IMMUNOSUPPRESSIVE THERAPY opens the gateway for pathogens to invade. Aggressive antibiotic therapy then becomes necessary to eradicate the infection.

See also ANTIBIOTIC MEDICATIONS; ANTIHISTAMINE MEDICATIONS; CHEMOTHERAPY; DRUG INTERACTION; LIVING WITH IMMUNE DISORDERS; ORGAN TRANSPLANTATION; PATHOGEN.

immunosuppressive therapy Treatments that limit or suppress the IMMUNE RESPONSE. Such treatment may incorporate IMMUNOSUPPRESSIVE MEDICATIONS such as CORTICOSTEROID MEDICATIONS, DISEASE-MODIFYING ANTI-RHEUMATIC DRUGS (DMARDS), CHEMOTHERAPY, RADIATION THERAPY, and MONOCLONAL ANTIBODIES (MABS).

Doctors may prescribe short-term immunosuppressive therapy (two to six weeks) to treat moderate to severe type I HYPERSENSITIVITY REACTION or to reduce INFLAMMATION due to injury. Long-term immunosuppressive therapy is generally a treatment option for chronic AUTOIMMUNE DISORDERS such as SYSTEMIC LUPUS ERYTHEMATOSUS (SLE) and RHEUMATOID ARTHRITIS. People who have had organ transplants must take lifelong immunosuppressive therapy to reduce the risk for organ rejection and GRAFT VS. HOST DISEASE. The risk for complications and side effects rises the longer a person is on immunosuppressive therapy.

Immunoablation (the administration of high-DOSE chemotherapy or radiation therapy) wipes out the immune response altogether by killing the BONE MARROW, which removes all leukocytes and their subtypes from the IMMUNE SYSTEM's resource arsenal. This form of immunosuppressive therapy prepares the body to receive BONE MARROW TRANSPLANTATION or STEM CELL transplantation, which then rebuilds the immune system from the marrow up.

See also COMPLEMENT CASCADE; LEUKOCYTE; LIVING WITH IMMUNE DISORDERS; ORGAN TRANSPLANTATION; PROSTAGLANDINS.

immunotherapy The therapeutic use of biologic agents to manipulate the mechanisms of the IMMUNE SYSTEM. Immunotherapy, also called biologic response modification, is an effective method for reducing INFLAMMATION and other aspects of the IMMUNE RESPONSE to treat inflammatory AUTOIMMUNE DISORDERS such as RHEUMATOID ARTHRITIS. Immunotherapy is also a treatment option for many forms of cancer. The common types of immunotherapy are

- CYTOKINES such as INTERLEUKINS and INTERFERONS, which boost the cytotoxic (cell-killing) actions of T-cell lymphocytes and natural killer (NK) cells
- COLONY-STIMULATING FACTORS (CSFS), which stimulate the growth of leukocytes and lymphocytes (white BLOOD cells) in the BONE MARROW

- MONOCLONAL ANTIBODIES (MABS), which stimulate specific ANTIBODY activity

Vaccines are among the most effective and basic forms of immunotherapy. A VACCINE introduces a substance such as a VIRUS or strain of BACTERIA into the body at a level significant enough to stimulate an immune response yet mild enough to avoid establishing INFECTION in most people. Researchers are now exploring ways to apply the principles of vaccines to cancer treatment and CANCER PREVENTION. CANCER VACCINES, currently in investigational studies, attempt to modify the immune response by creating antibodies that will recognize the antigens on cancer cells should the cancer recur after initial treatment.

See also CANCER TREATMENT OPTIONS AND DECISIONS; GENE THERAPY; LEUKOCYTE; LYMPHOCYTE; NATURAL KILLER (NK) CELL; T-CELL LYMPHOCYTE; VACCINE.

inflammation The release of fluid (PLASMA) from the BLOOD vessels into the tissues, facilitating the movement of key immune proteins and other molecules to the site of injury or INFECTION. Inflammation is the mechanism of the IMMUNE RESPONSE for containing and mitigating whatever damage has occurred. PROSTAGLANDINS, which mast cells release, are the primary instigators of the inflammatory response. Inflammation occurs as a coupling of increased blood circulation to the area with increased capillary permeability (the amount of fluid the capillaries allow to escape into the spaces between cells). Though inflammation accompanies infection, it does not always indicate that an infective process is under way.

Plasma, the liquid portion of the blood, contains numerous immune elements, including antibodies, CYTOKINES, and complement factors. Swelling, which is the hallmark of inflammation, indicates that this mechanism is succeeding in getting the necessary immune elements to the site. IMMUNOGLOBULIN E (IgE) and certain of the cytokines are instrumental in the inflammation process. Inflammation typically causes swelling, PAIN, FEVER, and often redness of the SKIN at the site of the inflammation. When joints are inflamed, as in RHEUMATOID ARTHRITIS, the JOINT often feels stiff and has limited range of motion. TENDONITIS and BURSITIS are also common presentations of inflammation.

Treatment for inflammation is often NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS), DISEASE-MODIFYING ANTIRHEUMATIC DRUGS (DMARDS), or CORTICOSTEROID MEDICATIONS, depending on the cause. When appropriate, ice to the local area provides relief from pain and helps contract the blood vessels to slow the flow of blood. The latter, in turn, reduces the amount of fluid that enters the tissues. Reducing use of the affected area facilitates HEALING and the body's reabsorption of the excess interstitial fluid, though movement to keep the joints from stiffening is also important. PHYSICAL THERAPY, TAI CHI, YOGA, and MASSAGE THERAPY are among the methods that help maintain mobility and FLEXIBILITY. Treatment also targets the circumstance causing the inflammation whenever possible, such as any underlying injury or condition.

For further discussion of inflammation within the context of the structures and functions of the immune system, please see the overview section "The Immune System and Allergies."

See also ANALGESIC MEDICATIONS; ANTIBODY; ANTIGEN; COMPLEMENT CASCADE; MAST CELL.

innate immunity The level of immune protection with which an individual is born. Researchers believe innate immunity, also called natural immunity, is the result of genetically encoded PATHOGEN recognition—that is, GENE-regulated ability to identify and mount an IMMUNE RESPONSE to neutralize certain BACTERIA, viruses, and other substances capable of causing INFECTION or otherwise doing harm to the body. The immune cell receptors recognize key characteristics of molecular structure common to many pathogens, called pathogen-associated molecular patterns (PAMPs), rather than specific pathogens. Their response does not require prior exposure before activation; thus PAMPs respond immediately to the presence of pathogens that fit the pattern. Innate immunity is species specific, which is why most infections cannot pass from one species to another. Pathogens capable of infecting multiple species are those that mutate for each species.

For further discussion of immunity within the context of the structures and functions of the

immune system, please see the overview section "The Immune System and Allergies."

See also ANTIBODY-MEDIATED IMMUNITY; CELL-MEDIATED IMMUNITY; VIRUS.

interferons CYTOKINES (molecules on the surface of cell membranes that direct cell activity) that block the activity of viruses and mediate numerous aspects of the IMMUNE RESPONSE. There are more than a dozen type 1 INTERFERONS, the most abundant of which are interferon-alpha and interferon-beta. B-cell lymphocytes and T-cell lymphocytes produce type 1 interferons, which primarily direct the functions of macrophages and natural killer (NK) cells in responding to viruses. Activated T-cells produce interferon-gamma, which is the only type 2 interferon. Interferon-gamma helps regulate INFLAMMATION.

Interferon-alpha and interferon-beta have strong tumor-suppression actions, which has led to their therapeutic use for certain kinds of cancer. Oncologists (doctors who specialize in treating cancer) administer recombinant forms of interferons (interferons that are synthesized in a laboratory using RECOMBINANT DNA technology) by injection to treat chronic myeloid LEUKEMIA, hairy cell leukemia, malignant melanoma, and some types of lymphoma. Doctors also use therapeutic interferons to treat HEPATITIS C and MULTIPLE SCLEROSIS. Pegylated interferons are synthesized to include polyethylene glycol, which delays the rate at which the body absorbs injected interferons.

See also B-CELL LYMPHOCYTE; CHEMOKINES; INTERLEUKINS; LYMPHOCYTE; LYMPHOKINES; MACROPHAGE; NATURAL KILLER (NK) CELL; T-CELL LYMPHOCYTE; VIRUS.

interleukins CYTOKINES that influence the growth, proliferation, and activity of leukocytes and other BLOOD cells. Leukocytes produce interleukins. There are 12 major interleukins, identified as interleukin 1 (IL-1) through IL-12. Among those significant to LEUKOCYTE development are

- IL-3, which influences blood stem cell differentiation into the various types of blood cells; leukocyte differentiation into granulocytes, monocytes, and lymphocytes; GRANULOCYTE differentiation into basophils; and LYMPHOCYTE differentiation into B-cell lymphocytes and T-cell lymphocytes
- IL-5, which influences leukocyte differentiation into eosinophils
- IL-7, which stimulates the BONE MARROW to produce lymphocytes

The interleukins also regulate the actions of leukocytes—monocytes, neutrophils, basophils, macrophages, B-cell lymphocytes, T-cell lymphocytes, natural killer (NK) cells, mast cells, PLASMA cells—in the IMMUNE RESPONSE, notably the INFLAMMATION process. The role of interleukins in the production and activity of basophils and neutrophils, the cells of the immune response largely responsible for inflammation, has come under scrutiny as a key factor in the development of conditions such as ATHEROSCLEROSIS. Research is under way to investigate methods to manipulate interleukin production and levels to reduce the inflammatory response in such circumstances, thus diminishing or eliminating the disease process. Other research is investigating therapeutic administration of interleukins to treat HIV/AIDS. Doctors currently use some synthesized interleukins therapeutically (notably IL-2) to treat certain types of cancer.

See also B-CELL LYMPHOCYTE; BLOOD STEM CELLS; INTERFERONS; LEUKOCYTE; MACROPHAGE; MAST CELL; MAJOR HISTOCOMPATIBILITY COMPLEX (MHC); MONOCYTE; NATURAL KILLER (NK) CELL; T-CELL LYMPHOCYTE.

leukotrienes Molecules that instigate INFLAMMATION during an IMMUNE RESPONSE. Mast cells secrete leukotrienes in response to stimulation by IMMUNOGLOBULIN E (IgE). Leukotrienes are derived from arachidonic acid, which is the same base source (precursor) as that of PROSTAGLANDINS, the other primary agents of inflammation. The actions of leukotrienes are most apparent in ASTHMA, in which they cause the bronchioles (tiny bronchi deep within the LUNGS) to constrict. Leukotriene release becomes more rapid with each HYPERSENSITIVITY REACTION. Leukotrienes also attract eosinophils, which cause swelling in the bronchial mucosa (mucous membrane lining of the bronchi). In inflammatory responses outside the pulmonary system, leukotrienes attract neutrophils with similar effect (swelling and discomfort). Eosinophils and neutrophils are types of granulocytes.

See also GRANULOCYTE; HISTAMINE; MAST CELL.

living with allergies About 50 million Americans live with allergies—to pollens, animal danders, latex, fragrances, foods, drugs, and other substances—that cause them to alter their lifestyles. Most people can reduce exposure to allergens enough to lessen symptoms.

Outdoor Allergens

The primary outdoor allergens are pollens and molds. Pollen is the powdery and often microscopic granules that are the male cells of plants. The plant disperses pollen into the air, which carries it to other plants. The dusting of pollen on plants of the same species fertilizes them, permitting them to propagate. The pollens most likely to cause a HYPERSENSITIVITY REACTION are grasses and trees. Tree pollens are highest in early spring and grass pollens (including weeds) are highest in early summer. Both tree and grass pollens remain high through summer and into early autumn in most regions of the United States. Molds are also microscopic, airborne substances, though correlate to weather conditions rather than seasons. Molds are highest when the weather is cool and wet. Raking leaves in the autumn is a major risk for exposure to molds.

Many weather reports include local pollen counts and mold counts. Counts that are moderate to high are likely to cause ALLERGY symptoms in people who are allergic; very high counts may cause symptoms in people who do not typically have seasonal allergies. Because pollens and molds are airborne, it is difficult to escape them. Allergists recommend ANTIHISTAMINE MEDICATIONS or DESENSITIZATION to mitigate symptoms. Staying indoors is not usually an effective or practical strategy.

Steps that may help include taking off outdoor clothing immediately upon coming indoors and washing the face, arms, hands, and other exposed areas with soap and water (showering is best). Washing the hands especially helps limit spreading pollen to the NOSE and EYE via contact. Some people can reduce their symptoms by wearing a mask over the face and nose during outdoor activities when pollen and mold counts are high. As well, pollen counts are highest in the early morning. Central air-conditioning in the home and in the car helps filter pollens and other particulates.

Being outdoors brings the risk of exposure to other allergens as well. People who are allergic to the sting of bees and wasps have a high risk of exposure during spring and summer when plants are in bloom. Wasps and related stinging insects become active in the autumn, especially in

wooded areas or areas where there is mud. Contact with poison ivy, poison oak, or poison sumac can cause symptoms any time of the year, though this is more of a problem in spring and summer.

Indoor Allergens

Indoor allergens are commonly dust, insect droppings, and pet dander. Cockroach droppings are the prime cause of ALLERGIC ASTHMA in urban areas, especially in children. Cockroaches are attracted to moisture and food debris; keeping living areas dry and clean reduces the attraction. Dust mite droppings are also a significant cause of allergic ASTHMA and ALLERGIC RHINITIS. Dust mites also prefer humid environments, though their food source is the microscopic flakes of SKIN that people continually shed. These flakes accumulate in bedclothes and bed linens especially. Keeping the bedroom dry and washing sheets once a week in hot water helps reduce the dust mite population.

About 80 percent of American households have pets. About the same percentage of people who have allergies are allergic to pet dander (most often cat dander). Some studies have found animal dander is as pervasive in the indoor environment as is pollen in the outdoor environment. Desensitization is the recommendation of most allergists for people who are allergic but want to have pets. Though desensitization may take three to five years to become fully effective, it is a permanent solution. There are no pets that are "low allergy." The length of an animal's coat has little relationship to its ability to evoke an allergic reaction. Other measures include washing the hands and changing the clothes after handling an animal, and keeping pets out of the bedroom.

Central heating and air-conditioning are effective for controlling humidity as well as filtering the air. Central vacuum systems are also helpful because they deposit vacuumed debris outside the living area, usually into a container in the garage or basement. High-efficiency particulate air (HEPA) filters can remove many kinds of allergens from the air.

See also ALLERGEN; ALLERGY TESTING; QUALITY OF LIFE.

living with immune disorders Living with an immune disorder requires special attention to circumstances that increase the risk for INFECTION. IMMUNE DISORDERS increase susceptibility to infection either as a direct result of the disease process or, in AUTOIMMUNE DISORDERS, as a consequence of the medications necessary to keep symptoms in check. The most important factor for controlling the symptoms of immune disorders is taking medications as prescribed. Immune function is complex, and often the therapeutic approach combines different kinds of medications to achieve an overall balance to the best extent possible within the parameters of the disease process. Though many complementary approaches are beneficial, some may interfere with conventional treatments and medications.

Nutritious EATING HABITS and regular physical activity benefit the IMMUNE SYSTEM in innumerable ways. The appropriate NUTRIENTS give the body the building blocks—amino acids—it needs to make the components of the IMMUNE RESPONSE. Autoimmune conditions may restrict physical activity, yet physical activity helps maintain optimal function. PHYSICAL THERAPY and MASSAGE THERAPY are conventional means for improving range of motion, STRENGTH, and FLEXIBILITY. YOGA, TAI CHI, and qi gong are alternative approaches that can do the same, along with MEDITATION to help relieve stress and improve mental clarity and focus. BIOFEEDBACK and HYPNOSIS are other methods to manage symptoms and establish a sense of control or peaceful coexistence with the condition. Numerous studies suggest a surprisingly intricate relationship between stress, emotion, and immune function, making stress management particularly important with chronic immune dysfunction.

Efforts to prevent the chronic infections that often accompany immune disorders or the use of IMMUNOSUPPRESSIVE MEDICATIONS to treat autoimmune disorders include limiting exposure to other people who are sick (such as during cold and flu season). Frequent HAND WASHING is an effective means for containing pathogens.

See also LIVING WITH ALLERGIES; HYPERSENSITIVITY REACTION; PATHOGEN; PSYCHONEUROIMMUNOLOGY; QUALITY OF LIFE; STRESS AND STRESS MANAGEMENT.

lymphokines CYTOKINES that convey biochemical messages among lymphocytes (a type of white

BLOOD cell) to direct their actions during an IMMUNE RESPONSE. B-cell lymphocytes and T-cell lymphocytes both secrete lymphokines. Lymphokines activate and coordinate numerous immune functions across the spectrum of the immune response. They also stimulate cell growth and activation and stimulate MACROPHAGE activity.

See also B-CELL LYMPHOCYTE; COMPLEMENT CASCADE; INTERFERONS; INTERLEUKINS; LEUKOCYTE; LYMPHOCYTE; MONOKINES; T-CELL LYMPHOCYTE.

M

macrophage A MONOCYTE that leaves the BLOOD circulation and takes up residence in the tissues. Once there, the cell undergoes several changes:

- It greatly enlarges.
- It develops pseudopods (footlike projections) that permit it to move through tissue.
- It increases the amount of lysozyme its granules contain, increasing its ability to consume cellular debris.

Macrophages, the IMMUNE SYSTEM's tissue-based scavengers, are part of the MONONUCLEAR PHAGOCYTE SYSTEM. They engulf, dismantle, and consume the carcasses of cells that other immune cells destroy and of cells that die naturally (APOPTOSIS). They also absorb and breakdown the particulate debris from toxins, BACTERIA, viruses, and other substances. Macrophages also respond to the inflammatory process, contributing to INFLAMMATION and the formation of granulomas. As well, macrophages are key to ANTIGEN presentation and processing, the mechanism by which T-cell lymphocytes and B-cell lymphocytes recognize nonself antigens. As the macrophage dismantles a substance, it displays the substance's antigens, along with the relevant MAJOR HISTOCOMPATIBILITY COMPLEX (MHC), on the surface of its cell membrane for lymphocytes to detect. Lymphocytes ignore debris that belongs to the body. Debris that is foreign activates an IMMUNE RESPONSE.

For further discussion of macrophages within the context of the structures and functions of the immune system, please see the overview section "The Immune System and Allergies."

See also B-CELL LYMPHOCYTE; GRANULOMA; LYMPHOCYTE; NATURAL KILLER (NK) CELL; T-CELL LYMPHOCYTE; VIRUS.

major histocompatability complex (MHC) The group of genes, located on CHROMOSOME 6, that determine the HUMAN LEUKOCYTE ANTIGENS (HLAS) the body's cells carry on their cell membranes. HLAs are unique proteins that cell membranes display to identify themselves to the IMMUNE SYSTEM. There are three types of MHC:

- Class I MHC encodes the HLAs that all nucleated cells and platelets in the body carry to identify them as self cells (the body's own cells).
- Class II MHC encodes the HLAs that lymphocytes, macrophages, dendritic cells, and other substances involved in ANTIGEN processing carry. These HLAs are fundamental to ANTIBODY-MEDIATED IMMUNITY and are also responsible for GRAFT VS. HOST DISEASE and organ rejection in people who undergo ORGAN TRANSPLANTATION.
- Class III MHC encodes the immunoglobulins from which the immune system forms antibodies.

MHC is central to antigen processing. When a MACROPHAGE or dendritic cell (phagocytes, also called scavenger cells, in the MONONUCLEAR PHAGOCYTE SYSTEM) consumes cellular debris, it displays the antigens of the debris alongside its own HLA. This comparison display allows T-cell lymphocytes to recognize the cellular debris as self or nonself and respond accordingly. Self antigen evokes no reaction; nonself antigen mobilizes the IMMUNE RESPONSE.

See also ANTIBODY; CELL-MEDIATED IMMUNITY; COMPLEMENT CASCADE; GENE; IMMUNOGLOBULIN; LYMPHOCYTE; MACROPHAGE; PHAGOCYTE; PHAGOCYTOSIS; PLATELET; T-CELL LYMPHOCYTE.

mast cell A granulated LEUKOCYTE that resides in tissues throughout the body. When the IMMUNE RESPONSE stimulates mast cells, they release PROSTAGLANDINS, HISTAMINE, and other biochemicals from their granules. Mast cells are primarily responsible for the symptoms that are the hallmark of the HYPERSENSITIVITY REACTION: INFLAMMATION, itching, SKIN RASH, coughing, and sneezing. Mast cells have an abundant presence in the tissues of mucous membranes such as the NOSE, pulmonary tract (TRACHEA and bronchi), and gastrointestinal tract. Mast cells also infiltrate the connective tissues. They respond to the stimulation of complement factors and to IMMUNOGLOBULIN E (IgE) antibodies.

For further discussion of mast cells within the context of the structures and functions of the immune system, please see the overview section "The Immune System and Allergies."

See also ANTIBODY; COMPLEMENT CASCADE; COUGH; LIVING WITH ALLERGIES; MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT); SNEEZE.

monoclonal antibodies (MAbs) Antibodies produced in a laboratory using RECOMBINANT DNA technology. MAbs derive from cloned mouse SPLEEN cells (hence the designation "monoclonal") containing the desired ANTIBODY fused with human myeloma cells. Mouse cells have proteins very similar to the proteins of human cells. Human myeloma cells, because they are cancer cells, have the ability to replicate without limitation. The myeloma cells arise from B-cell lymphocytes, which produce antibodies.

When scientists fuse the two cells together, they achieve cells (called hybridomas) that combine the desired ANTIGEN sensitization with the ability to endlessly replicate antibody-producing cells. After fusion, scientists can attach radioactive molecules for diagnostic imaging or to deliver fatal radiation to specific cells (called conjugated MAbs). Doctors then can inject MAbs into people to stimulate the IMMUNE RESPONSE as a mechanism for fighting INFLAMMATION (such as in RHEUMATOID ARTHRITIS) and certain types of cancer or to specifically target certain cells for death without affecting other cells. Indiscriminate cell death is a significant limitation of current CHEMOTHERAPY.

A key limitation of therapeutic MAbs is that the body recognizes them as nonself and configures antibodies against them. MAbs are highly effective for the first treatment, then may be less effective or initiate a HYPERSENSITIVITY REACTION in subsequent treatment efforts.

THERAPEUTIC MONOCLONAL ANTIBODIES (MABS)

abciximab (ReoPro)	alemtuzumab (MAb Campath)
bevacizumab (Avastin)	cetuximab (Erbitux)
daclizumab (Zenapax)	infliximab (Remicade)
lym-1 (Oncolym)	muromonab-CD3 (OKT3)
omalizumab (Xolair)	rituximab (Rituxan)
tositumomab (Bexxar)	trastuzumab (Herceptin)

For further discussion of MAbs within the context of the structures and functions of the immune system, please see the overview section "The Immune System and Allergies."

See also B-CELL LYMPHOCYTE; CANCER TREATMENT OPTIONS AND DECISIONS; IMMUNOTHERAPY; INTERFERONS; INTERLEUKINS; MOLECULARLY TARGETED THERAPIES.

monokines CYTOKINES that convey biochemical messages among monocytes (white BLOOD cells in the blood circulation) and macrophages (white blood cells that reside in the tissues). Monokines direct the actions of these immune cells during the IMMUNE RESPONSE, stimulating and coordinating numerous functions. There is some overlap between monokines and LYMPHOKINES (which lymphocytes produce).

See also COMPLEMENT CASCADE; IMMUNE SYSTEM; INTERFERONS; INTERLEUKINS; LEUKOCYTE; LYMPHOCYTE; MACROPHAGE; MONOCYTE.

mononuclear phagocyte system The combined activity of the IMMUNE SYSTEM's phagocytes—monocytes in the BLOOD circulation and macrophages in the tissues—to consume cellular debris. These cells are scavengers within the body, responsible for cleaning up after B-cell lymphocytes, T-cell lymphocytes, and natural killer (NK) cells. They also clear the debris that results from normal cell death (APOPTOSIS). They are called mononuclear because their cell structure contains a single nucleus; neutrophils, which are also phagocytes, have multiple nuclei (and are called polymorphonuclear). The COMPLEMENT CASCADE (an interaction of proteins or

factors that begins with ANTIBODY–ANTIGEN binding) is the primary alert mechanism that activates the mononuclear phagocyte system. Monocytes and macrophages work in a coordinated fashion, communicating via CYTOKINES (cell-originated biochemical messages) with other cells involved in the IMMUNE RESPONSE.

For further discussion of the mononuclear phagocyte system within the context of the structures and functions of the immune system, please see the overview section "The Immune System and Allergies."

See also B-CELL LYMPHOCYTE; CELL STRUCTURE AND FUNCTION; GENE; GRANULOCYTE; MACROPHAGE; MONOCYTE; NATURAL KILLER (NK) CELL; PHAGOCYTE; PHAGOCYTOSIS; T-CELL LYMPHOCYTE.

mucosa-associated lymphoid tissue (MALT) A loosely organized collection of LYMPH tissue that underlies and integrates with epithelial tissue (the lining of mucous membranes) throughout the body. MALT reinforces the body's immune presence and response in areas of the body that provide direct interface with the external environment. These areas, such as the gastrointestinal tract and the LUNGS, are most vulnerable to breaches that could allow pathogens to enter the body to cause INFECTION.

MALT contains clusters of phagocytic cells such as macrophages and dendritic cells, which consume cellular debris, as well as T-cell lymphocytes and B-cell lymphocytes. T-cell lymphocytes attack and kill invading pathogens, and B-cell lymphocytes produce antibodies to protect against future invasion by the same pathogens. There are several types of MALT; each has specific functions, according to its location in the body. Among them are

- BRONCHUS-ASSOCIATED LYMPHOID TISSUE (BALT), which strengthens the body's defense against INFLUENZA and PNEUMONIA
- GUT-ASSOCIATED LYMPHOID TISSUE (GALT), which helps protect against invasion by gastrointestinal viruses
- NOSE-ASSOCIATED LYMPHOID TISSUE (NALT), which intensifies the body's resistance to airborne viruses such as those that cause COLDS
- SKIN-ASSOCIATED LYMPHOID TISSUE (SALT), which helps block BACTERIA, fungi, and other pathogens from passing through microscopic breaks in the SKIN
- VASCULAR-ASSOCIATED LYMPHOID TISSUE (VALT), which infiltrates the epithelium of the BLOOD vessels

MALT may be the site of solid tumors that develop in LYMPHOMA (sometimes called MALT lymphoma). The most common MALT site for such an occurrence is the gastrointestinal tract. Researchers believe these lymphomas develop when a constant assault, such as a persistent infection, engages the MALT site. B-cell lymphocytes accumulate to fight the infection. When their accumulation persists over time, which is abnormal, the B-cell lymphocytes turn cancerous. The connection with MALT lymphomas that arise from GALT is *HELICOBACTER PYLORI* infection, which also has a strong connection to STOMACH CANCER. Researchers believe *H. pylori* may account for 85 percent or more of gastrointestinal MALT lymphomas, many of which grow in the STOMACH. Treatment is highly successful when the diagnosis of MALT lymphoma occurs early in the CANCER's development because the tumors grow slowly and lack aggression in spreading.

For further discussion of MALT within the context of the structures and functions of the immune system, please see the overview section "The Immune System and Allergies."

See also ANTIBODY; B-CELL LYMPHOCYTE; FUNGUS; LYMPHOCYTE; MACROPHAGE; METASTASIS; MONONUCLEAR PHAGOCYTE SYSTEM; PATHOGEN; PHAGOCYTE; PHAGOCYTOSIS; T-CELL LYMPHOCYTE; VIRUS.

multiple chemical sensitivity syndrome A constellation of symptoms that result from exposure to common chemicals at levels that do not normally cause response or reaction. Multiple chemical sensitivity syndrome is difficult to diagnose and treat. Symptoms are often broad ranging. There remains disagreement among medical experts (doctors and researchers) about the diagnostic criteria and causes of the syndrome. Some believe multiple chemical sensitivity syndrome is a component of GENERALIZED ANXIETY DISORDER (GAD)

or PANIC DISORDER. Others believe it is a HYPERSENSITIVITY REACTION. Symptoms of multiple chemical sensitivity syndrome often include

- PALPITATIONS and CHEST PAIN
- fatigue and shortness of breath (DYSPNEA)
- difficulty sleeping
- cognitive disturbances

The diagnostic path is primarily clinical, based on the person's symptoms. Though BLOOD tests can detect changes in immune indicators such as IMMUNOGLOBULIN levels, LEUKOCYTE activity, and complement factors, the changes are inconsistent from one person to the next and do not necessarily correlate either to symptoms or exposures.

Treatment is avoidance, whenever possible, of environments and circumstances that exacerbate symptoms. Because the substances and their quantities or exposures to them are common, however, it is often hard for the person to avoid exposure. Medications typically given to treat hypersensitivity reactions, such as ANTIHISTAMINE MEDICATIONS or CORTICOSTEROID MEDICATIONS, do not relieve the symptoms and discomforts of multiple chemical sensitivity syndrome. For most people the syndrome is chronic, with symptoms waxing and waning. Multiple chemical sensitivity syndrome can have a significant affect on QUALITY OF LIFE.

See also CHRONIC FATIGUE SYNDROME; COGNITIVE FUNCTION AND DYSFUNCTION; COMPLEMENT CASCADE; FIBROMYALGIA.

N

natural killer (NK) cell A granular LYMPHOCYTE (white BLOOD cell with granules in its cytoplasm) that has cytotoxic (cell-killing) functions within the IMMUNE RESPONSE. NK cells belong to the CELL-MEDIATED IMMUNITY pathway of the immune response and do not require ANTIGEN presentation to target a cell for destruction. NK cells are particularly involved in killing tumor cells. They release molecules that puncture or perforate (make molecular holes in) the cell membrane of the cell under attack. This assault may directly kill the cell or cause accelerated APOPTOSIS (planned cell death) that the target cell itself initiates in response to the damage it experiences.

For further discussion of natural killer cells within the context of the structures and functions of the immune system, please see the overview section "The Immune System and Allergies."

See also ANTIBODY-MEDIATED IMMUNITY; B-CELL LYMPHOCYTE; MACROPHAGE; T-CELL LYMPHOCYTE.

nonsteroidal anti-inflammatory drugs (NSAIDs) Medications that relieve INFLAMMATION by suppressing the action of PROSTAGLANDINS, which are responsible for the inflammatory response. There are several types of prostaglandins, most of which are biochemical messengers that have numerous roles in routine cellular activity. Other prostaglandins are the agents of inflammation. The prostaglandins that incite inflammation do so by summoning numerous other biochemicals to the site of an injury, ultimately resulting in fluid accumulation and swelling at the site.

Three NSAIDs are available in over-the-counter (OTC) preparations as well as stronger prescription-only products: ibuprofen, naproxen, and ketoprofen. All other NSAIDs available in the United States (except aspirin) require a doctor's prescription.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS)	
aspirin	diclofenac
diflunisal	etodolac
fenoprofen	flurbiprofen
ibuprofen	indomethacin
ketoprofen	meclofenamate
mefenamic acid	meloxicam
naproxen	oxaprozin
nabumetone	piroxicam
sulindac	tolmetin

How These Medications Work

NSAIDs work by blocking the action of cyclooxygenase (COX), the enzyme that allows cells to convert arachidonic acid (a dietary fatty acid found in meats) into prostaglandins. The two main forms of COX are cyclooxygenase 1 (COX-1) and COX-2. Many types of cells in the body contain COX-1, but COX-2 occurs primarily in mast cells. COX-1 is responsible for prostaglandin synthesis for these roles. Prostaglandins are also the agents of inflammation. Mast cells contain COX-2, which enables them to synthesize large quantities of prostaglandins during an IMMUNE RESPONSE.

Most NSAIDs are nonselective; they block both COX-1 and COX-2. Though this action effectively relieves inflammation and associated symptoms (such as PAIN and FEVER), it also interferes with various general functions of cells throughout the body. One consequence of this interference is STOMACH upset. Gastric cells contain an abundance of COX-1 and synthesize forms of prostaglandin that help protect the lining of the stomach. Suppressing COX-1 activity reduces this protection. As

well, the NSAID preparations are generally acids, which further irritate stomach tissues.

Therapeutic Applications

Doctors prescribe or recommend NSAIDs for pain relief and to reduce fever and inflammation, such as from musculoskeletal injuries. NSAIDs have widespread therapeutic applications and are among the most commonly used medications in the United States. Though all NSAIDs share the same mechanism of action, some are more effective for specific conditions. Ibuprofen, naproxen, and ketoprofen are effective for general relief. Other NSAIDs more aggressively block COX, making them especially useful for moderate OSTEOARTHRITIS, RHEUMATOID ARTHRITIS, and inflammatory disorders such as SYSTEMIC LUPUS ERYTHEMATOSUS (SLE).

The original NSAID is aspirin, first isolated and used as a therapeutic preparation in the late 1800s. Aspirin, a nonselective COX inhibitor, remains the most commonly used medication in the world, primarily for its ability to relieve pain and fever. In the 1970s cardiologists began recommending daily aspirin for people at high risk for HEART ATTACK. During an inflammatory response prostaglandins combine with other substances to make the surfaces of platelets (clotting cells) sticky. This encourages PLATELET AGGREGATION, the first step of COAGULATION (clot formation). Blocking prostaglandin synthesis reduces the likelihood for BLOOD clots to form in the blood vessels. This effect is unique to aspirin among the NSAIDs; other NSAIDs have only very mild antiplatelet effect.

In the late 1990s and early 2000s several selective COX-2 NSAIDs became available. These COX-2 inhibitors had the ability to selectively target and block only COX-2, allowing COX-1-mediated prostaglandin synthesis to continue unimpeded while preventing COX-2-mediated synthesis to reduce inflammation. However, widespread use of COX-2 inhibitors revealed that these medications carried increased risk for heart attack, and several were withdrawn from the US market. Nonselective (classic) NSAIDs do not appear to carry the same risk, though may increase the risk for heart attack in people who have recently had OPEN HEART SURGERY.

People who have recently had OPEN HEART SURGERY or HEART ATTACK should check with their doctors before taking any nonsteroidal anti-inflammatory drug (NSAID) preparation, including cold and flu products that contain an NSAID.

Risks and Side Effects

The most common risk of NSAIDs is gastric upset and PEPTIC ULCER DISEASE. Extended use of an NSAID diminishes the amount of prostaglandins in the stomach, reducing the ability of the gastric mucosa (stomach lining) to protect itself from the acid normally present in the stomach as well as the acid of the NSAID itself. Some NSAIDs have more of this affect. Other common side effects include allergic reaction and interaction with other drugs. NSAIDs interact with numerous drugs as well as with each other. TINNITUS (ringing in the ears) is an early indication of excessive NSAID consumption. Long-term, high-DOSE NSAID use can cause permanent kidney and LIVER damage and failure of these organs.

See also ASPIRIN THERAPY; CORTICOSTEROID MEDICATIONS; DISEASE-MODIFYING ANTIRHEUMATIC DRUGS (DMARDS); DRUG INTERACTION; EAR; IMMUNOSUPPRESSIVE MEDICATIONS; KIDNEYS; LIVER FAILURE; MAST CELL; PLATELET; RENAL FAILURE.

nose-associated lymphoid tissue (NALT)

Loosely organized collections of LYMPH tissue embedded in the mucous membrane lining (mucosa) of the nasal passages and sinus cavities. Nasal mucous, which the nasal mucosa secretes, is one of the body's front-line protective mechanisms, providing a physical barrier that repels or traps foreign substances such as BACTERIA, viruses, toxins, and inhaled particles. Many pathogens gain entry to the body through the NOSE. NALT contains numerous B-cell lymphocytes and T-cell lymphocytes that detect and respond to invading pathogens. Macrophages, eosinophils, and other phagocytic cells are also concentrated in NALT to clean up cellular debris that NALT traps or collects.

The mucous membrane lining of the nose is the first point of contact for inhaled allergens. Its mast

cells quickly initiate an IMMUNE RESPONSE by releasing HISTAMINE and other biochemicals to stimulate LYMPHOCYTE activity. This HYPERSENSITIVITY REACTION results in the common symptoms of ALLERGIC RHINITIS (seasonal allergies). In 2003 the US Food and Drug Administration (FDA) approved the first nasal VACCINE for INFLUENZA (the flu). It was the first to capitalize on the immune response NALT can generate to provide systemic (bodywide) IMMUNITY for the influenza strains the vaccine contains.

For further discussion of NALT within the context of the structures and functions of the immune system, please see the overview section "The Immune System and Allergies."

P–R

partial combined immunodeficiency (PCID) An immune disorder in which the IMMUNE SYSTEM is missing key components. Most often people who have PCID lack certain leukocytes (white BLOOD cells), which impairs their ability to form antibodies (develop IMMUNITY) and fight INFECTION. The abnormality might be with cell differentiation, maturity, or function. Sometimes PCID involves deficits of complement factors, the specialized proteins that activate ANTIBODY–ANTIGEN binding. Symptoms of PCID vary somewhat, depending on the immune deficit though generally include frequent infections and autoimmune reactions. Common infections are PNEUMONIA and CANDIDIASIS (thrush). OPPORTUNISTIC INFECTION may also occur. Autoimmune reactions often involve the SKIN, appearing as atopic DERMATITIS and other rashes.

The diagnostic path typically includes blood tests that measure the types and quantities of white blood cells, IMMUNOGLOBULIN, and complement factors. GENETIC TESTING may identify the presence of GENETIC DISORDERS that have IMMUNODEFICIENCY components. Treatment varies according to the immunodeficiency and severity of symptoms, though usually includes ANTIBIOTIC MEDICATIONS to control infections and GAMMAGLOBULIN injections to bolster the IMMUNE RESPONSE.

See also ANTIBODY-MEDIATED IMMUNITY; CELL-MEDIATED IMMUNITY; COMMON VARIABLE IMMUNODEFICIENCY (CVID); COMPLEMENT CASCADE; IMMUNE DISORDERS; LEUKOCYTE; LIVING WITH IMMUNE DISORDERS; RASH; SEVERE COMBINED IMMUNODEFICIENCY (SCID).

passive immunity IMMUNITY (protection from INFECTION) that occurs without activation of the IMMUNE RESPONSE. A newborn has passive immunity from the antibodies in his or her mother's BLOOD at the time of birth and continues to receive limited ANTIBODY protection for the duration of BREASTFEEDING. Passive immunity also occurs when a person receives GAMMAGLOBULIN that contains antibodies present in the blood (PLASMA) of the donors who are the source for the gammaglobulin.

For further discussion of immunity within the context of the structures and functions of the immune system, please see the overview section "The Immune System and Allergies."

See also ACTIVE IMMUNITY; INNATE IMMUNITY.

Peyer's patches Small, nodular clusters of lymphoid tissue scattered throughout the mucous membrane lining of the SMALL INTESTINE. Though not encapsulated as are LYMPH NODES, Peyer's patches are more distinct and organized than other MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT). Peyer's patches are elements of GUT-ASSOCIATED LYMPHOID TISSUE (GALT), a subset of MALT. GALT lies beneath the epithelial tissue (mucosal lining) of the gastrointestinal tract. Peyer's patches contain concentrations of B-cell lymphocytes that actively produce antibodies. They also contain some T-cell lymphocytes and phagocytic cells to enhance the IMMUNE RESPONSE in the small intestine.

For further discussion of Peyer's patches within the context of the structures and functions of the immune system, please see the overview section "The Immune System and Allergies."

See also ANTIBODY; B-CELL LYMPHOCYTE; LYMPHOCYTE; PHAGOCYTE; T-CELL LYMPHOCYTE.

prostaglandins A large family of fast-acting lipid mediators primarily responsible for initiating INFLAMMATION, FEVER, and PAIN during the IMMUNE RESPONSE. Prostaglandins are also vital for numerous functions throughout the body. Thromboxane, one of the prostaglandins, facilitates PLATELET

AGGREGATION to aid COAGULATION (BLOOD clotting). Other prostaglandins facilitate calcium transport to and from cells, the onset and progression of labor during CHILDBIRTH, and the functions of other hormones. Prostaglandins are also responsible for discomforts related to their release, such as after injury when inflammation results or when menstrual cramps (DYSMENORRHEA) occur.

Prostaglandin activity is autocrine (affects only cells that secrete it) or paracrine (affects cells within immediate proximity of the secreting cells). Prostaglandin activity is also intense but short lived, though the symptoms of the resulting inflammation continue for some time after prostaglandin release stops. Mast cells are the main source of prostaglandin synthesis and secretion. Epithelial cells (surface cells of the SKIN and mucous membranes) and platelets also produce as well as respond to prostaglandins.

PROSTAGLANDINS AND THE PROSTATE GLAND

The researchers who discovered prostaglandins in the 1930s isolated the first member of this biochemical family from SEMEN—the secretions of the PROSTATE GLAND. They named it for this connection. Over the following decades further research identified a number of prostaglandins and determined that nearly every cell in the body contains some form of prostaglandin. Aspirin was the first DRUG to block the synthesis of prostaglandins.

The enzymes cyclooxygenase 1 (COX-1) and COX-2 facilitate the synthesis of prostaglandins from arachidonic acid, an essential fatty acid (a fatty acid the body requires for health but cannot synthesize from other substances so must obtain from dietary sources) found in red meats and peanuts. Arachidonic acid is also the foundation for LEUKOTRIENES, other biochemicals also involved in the inflammatory response. The enzyme lipoxygenase facilitates the conversion of arachidonic acid to leukotrienes. COX-1 is primarily in the STOMACH, KIDNEYS, and walls of the blood vessels; it maintains the prostaglandins necessary for the body's normal functioning. COX-2 is present in the tissues and becomes active during an inflammatory response.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS), including aspirin, block the action of COX, preventing prostaglandin production. This action provides pain relief, reduces fever, and mitigates the swelling associated with inflammation. Though much therapeutic focus is on blocking prostaglandin production, there are numerous therapeutic applications for synthetic prostaglandins. Therapeutic administration of synthetic prosta-glandin E_1 (PGE_1) maintains a patent ductus arteriosus in infants born with serious congenital heart defects. Prostaglandin E_2 (PGE_2) and prostaglandin F_2 (PGF_2) cause the UTERUS to contract, either initiating or strengthening labor.

See also CONGENITAL HEART DISEASE; CRAMP; HORMONE; IMMUNE RESPONSE; IMMUNOGLOBULIN; MAST CELL; PLATELET.

psychoneuroimmunology The interrelationships between emotions, neurologic function, and the IMMUNE SYSTEM. In the 1970s researchers discovered receptors for neuropeptides on cells throughout the body, including the immune system. The BRAIN produces neuropeptides, protein-based structures that convey biochemical messages related to cognition (thought and logic) and emotion. Neuropeptides include endorphins and enkephalins, substances connected to perceptions of SATIETY and pleasure.

Though researchers do not yet understand how neuropeptides affect IMMUNE RESPONSE, they do know emotional stress affects physical health. They also know that the immune system affects neurologic functions, which is one reason people feel irritable and cranky when they are sick. It appears that the primary messengers for immune-to-neural communication are the CYTOKINES immune cells produce during the immune response, notably INTERLEUKINS, which are capable of activating NERVE impulses that convey signals to the brain. Researchers continue to explore ways to use these connections for health, HEALING, and disease prevention.

See also MIND–BODY CONNECTION.

reticuloendothelial system See MONONUCLEAR PHAGOCYTE SYSTEM.

rheumatoid arthritis A chronic, autoimmune disorder in which nodules and INFLAMMATION develop within the synovial capsules of the joints, causing erosion of the BONE and connective tissues, eventually deforming the JOINT. Synovial membranes encapsulate the joints and secrete synovial fluid, which lubricates the structures of the joint so they move smoothly and freely against each other. The antibodies that characterize rheumatoid arthritis attack the cells of the synovial membrane, causing inflammation and an IMMUNE RESPONSE that treats the cells as though they were invaders. The repeated inflammation over time results in fibrosis (scarring) that destroys the ability of the cells to produce synovial fluid and constricts the movement of the joint.

About two million Americans have rheumatoid arthritis, two thirds of them women. Rheumatoid arthritis most commonly develops between the ages of 20 and 50, though can occur in children (juvenile rheumatoid arthritis). Although treatments and lifestyle strategies can reduce inflammation and relieve symptoms, at present there is no cure for rheumatoid arthritis.

IS IT RHEUMATOID ARTHRITIS OR OSTEOARTHRITIS?

Arthritis is any condition of INFLAMMATION that affects the joints. OSTEOARTHRITIS is the form most people identify; about 20 million Americans have osteoarthritis. Though both forms involve inflammation of the joints, the two conditions are quite different. In osteoarthritis inflammation occurs in response to damage, usually that of repeated wear and tear, within the joints. In rheumatoid arthritis, the inflammation occurs first as a malfunction of the IMMUNE RESPONSE and causes damage to the joints. Osteoarthritis is more common in people over age 65, whereas rheumatoid arthritis usually arises before age 50.

Symptoms and Diagnostic Path

The symptoms of rheumatoid arthritis typically include

- PAIN and swelling in the joints, especially the small joints of the hands and fingers
- stiffness in the joints, especially upon awakening or after long periods of inactivity
- low-grade FEVER
- fatigue and weakness
- rheumatoid nodules, painless bumps under the SKIN that develop at pressure points
- joint deformity as the disease progresses

The diagnostic path includes BLOOD tests to detect antibodies and other indications of inflammation. Many people who have rheumatoid arthritis have a specific ANTIBODY called rheumatoid factor, though not all people who have rheumatoid arthritis have this antibody, and conversely, rheumatoid factor may be present in people who do not have rheumatoid arthritis. Blood levels of C-REACTIVE PROTEIN also can indicate whether inflammation exists in the body. X-rays can help the doctor evaluate and monitor damage to the joints and bones.

Treatment Options and Outlook

Treatment typically blends lifestyle measures to protect affected joints from undue stress and medications to relieve inflammation and pain. Daily exercise and activity that puts each affected joint through its complete range of motion help keep SCAR tissue from contracting (tightening) within the synovial capsule, maintaining relative freedom of movement. Activities such as YOGA and TAI CHI also improve FLEXIBILITY, range of motion, and balance. Omega-3 fatty acids and folic acid may block steps in the inflammatory response that reduce its intensity. Stress management methods such as MEDITATION help people to cope with the challenges of a chronic health condition.

Mild rheumatoid arthritis symptoms, especially pain, often respond to NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS). Acetaminophen may also relieve pain, though it does not reduce inflammation. Topical preparations such as capsaicin and complementary therapies such as ACUPUNCTURE and REIKI may provide relief from pain and other symptoms. Medications for moderate to severe symptoms may include CORTICOSTEROID MEDICATIONS, which suppress the inflammatory response, and DISEASE-MODIFYING ANTIRHEUMATIC DRUGS (DMARDS), which block the immune response in various ways, depending on the med-

ication. Combinations of medications often provide the greatest relief. Surgery to replace seriously damaged joints with prosthetic joints becomes a treatment option when other therapeutic approaches cannot contain symptoms.

MEDICATIONS TO TREAT RHEUMATOID ARTHRITIS

acetaminophen	adalimumab
anakinra	aspirin
azathioprine	cyclosporine
etanercept	gold salts
hydroxychloroquine	ibuprofen
infliximab	ketoprofen
leflunomide	methotrexate
methylprednisolone	naproxen
prednisolone	prednisone
sulfasalazine	

Risk Factors and Preventive Measures

Researchers believe rheumatoid arthritis develops when various genetic, environmental, and hormonal factors converge. But specific risk factors remain elusive. There are no known measures to prevent rheumatoid arthritis from developing. Early diagnosis and treatment of juvenile rheumatoid arthritis are important to maintain optimal joint structure, integrity, and function. Prevention efforts focus on minimizing the consequences that the inflammation of rheumatoid arthritis causes, to preserve joint function as well as QUALITY OF LIFE.

See also AUTOIMMUNE DISORDERS; CHONDROITIN; GLUCOSAMINE; JOINT REPLACEMENT; LIVING WITH IMMUNE DISORDERS; RHEUMATIC HEART DISEASE; SAME; SCAR; STRESS AND STRESS MANAGEMENT; VASCULITIS; X-RAY.

sarcoidosis An inflammatory disorder in which multiple granulomas (nodules of hardened LYMPH and fibrous tissues) form in organs and tissues throughout the body. Sarcoidosis most commonly affects the LUNGS, LIVER, lymph nodes, eyes, and SKIN, though can affect any body structure. The granulomas typically have alternating growth and REMISSION stages, though generally cause permanent scarring. Though most people who have sarcoidosis develop small granulomas and have mild symptoms, sarcoidosis can be severe when the granulomas clump together to form large enough lesions to interfere with an organ's functions. Sarcoidosis that affects the HEART can cause life-threatening ARRHYTHMIA with high risk for SUDDEN CARDIAC DEATH.

Symptoms and Diagnostic Path

Most often sarcoidosis begins in the lungs, causing pulmonary symptoms, and in the lymph nodes. Symptoms are specific for the organ system involved. Generalized symptoms may include

- fatigue, weakness, and malaise (general sense of not feeling well)
- weight loss and loss of APPETITE
- FEVER
- night sweats and sleep disturbances
- SPLENOMEGALY (enlarged SPLEEN)
- HEPATOMEGALY (enlarged liver)
- enlarged, tender lymph nodes
- HEADACHE
- ERYTHEMA NODOSUM (red, painful skin lesions most commonly appearing on the shins)

The diagnostic path begins with BLOOD tests, chest X-RAY, and pulmonary function tests (95 percent of people who have sarcoidosis have lung involvement). The doctor may conduct other diagnostic procedures, depending on the symptoms and the necessity to rule out other causes for them. Though various procedures can show characteristic evidence of sarcoidosis, there are no conclusive diagnostic tests for sarcoidosis. Imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN and MAGNETIC RESONANCE IMAGING (MRI) can reveal the extent of damage present as a consequence of the granulomas.

Treatment Options and Outlook

Long-term treatment (up to a year) with CORTICOSTEROID MEDICATIONS reduces the INFLAMMATION that causes symptoms and mitigates the consequential damage. Topical medications can improve skin symptoms. Severe or resistant symptoms may require IMMUNOSUPPRESSIVE THERAPY or IMMUNOTHERAPY. Even with treatment, sarcoidosis remains a chronic condition with alternating periods of remission (no symptoms) and exacerbation (resumed or intensified symptoms).

MEDICATIONS TO TREAT SARCOIDOSIS

azathioprine	cyclophosphamide
etanercept	hydroxychloroquine
infliximab	methotrexate
pentoxifylline	prednisone
tetracycline	thalidomide

Risk Factors and Preventive Measures

There are no clear risk factors for sarcoidosis, though it is more common and often more severe in African American women. Nor are there any known measures to prevent sarcoidosis from developing. Researchers believe many people have undetected sarcoidosis, making this inflammatory

disorder far more common than doctors have long believed. Early diagnosis and treatment can minimize the consequences of the inflammation and fibrosis and allow improved QUALITY OF LIFE.

See also AUTOIMMUNE DISORDERS; EYE; GRANULOMA; IMMUNE DISORDERS; LIVING WITH IMMUNE DISORDERS; LYMPH NODE; OFF-LABEL USE; SCAR.

seasonal allergies See ALLERGIC RHINITIS.

severe combined immunodeficiency (SCID) A rare, genetic immune disorder in which an infant is born with severely deficient immune capability due to the absence of leukocytes. Because the infant receives PASSIVE IMMUNITY from his or her mother at birth (and through BREASTFEEDING), the deficiency often is not apparent until age three to six months or when the infant begins to receive routine immunizations. Doctors may suspect SCID if there are other family members who have IMMUNODEFICIENCY disorders. Most often the infant's immune status becomes suspect when there are recurrent or severe infections that a healthy IMMUNE RESPONSE would accommodate. Some babies develop deep abscesses, such as in the LIVER. Others have chronic OTITIS media (middle EAR INFECTION) or SINUSITIS (sinus infection).

Early diagnosis and treatment are essential. When doctors suspect and test for SCID within the infant's first three months of life, a BONE MARROW TRANSPLANTATION can provide the ability to produce lymphocytes, essentially curing the immunodeficiency. Most often, however, parents and doctors do not suspect an immune problem until the child is six months to a year old. By that time other features of the IMMUNE SYSTEM have developed enough to reject a BONE MARROW transplant unless IMMUNOABLATION first destroys the child's own bone marrow.

Bone marrow transplantation after age six months requires extended IMMUNOSUPPRESSIVE THERAPY to allow the new BLOOD STEM CELLS to take root and become self cells within the body. The child may also need ANTIBIOTIC PROPHYLAXIS and GAMMAGLOBULIN injections to bolster the immune response until the transplant fully takes hold. Without treatment SCID is fatal by two years of age and often in the first year of life. With bone marrow transplantation the child has a good chance for normal development and a relatively healthy life.

See also ABSCESS; COMMON VARIABLE IMMUNE DEFICIENCY (CVID); GENETIC DISORDERS; INHERITANCE PATTERN; LEUKOCYTE; LIVING WITH IMMUNE DISORDERS; LYMPHOCYTE; PARTIAL COMBINED IMMUNODEFICIENCY (PCID).

Sjögren's syndrome An autoimmune disorder that affects the glands that provide moisture for the mucous membranes, notably the lacrimal (tear) glands and the SALIVARY GLANDS. Sjögren's syndrome exists in one of three forms:

- primary, in which the only structures it affects are the exocrine glands and the main symptom is dryness
- secondary, in which Sjögren's syndrome appears in conjunction with another autoimmune disorder, typically RHEUMATOID ARTHRITIS, scleroderma, or SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)
- ocular, in which symptoms affect only the eyes (lacrimal glands)

Symptoms and Diagnostic Path

Symptoms depend to some extent on the affected glands, which nearly always include the salivary glands and the lacrimal glands. The lack of moisture to the eyes can cause corneal ABRASIONS and PHOTOSENSITIVITY. However, symptoms may involve glands in mucous tissues throughout the body. Dryness affecting other mucous membranes may result in

- frequent nosebleeds (INFLAMMATION of the nasal passages)
- PERICARDITIS (inflammation of the membrane sac surrounding the HEART)
- BRONCHITIS (inflammation of the airways in the LUNGS)
- VAGINITIS (inflammation of the VAGINA)

There are no specific tests to diagnose Sjögren's syndrome. A Schirmer's test determines the moisture content of the eyes; salivary gland biopsy can reveal fibrosis and granulation typical of the inflammatory process. Doctors generally consider

the diagnosis conclusive when a person has three consecutive months of symptoms that include

- extremely dry MOUTH and swollen salivary glands
- dry, irritated membranes around the eyes and crusty accumulations on the eyelids
- inflammation of the joints

Treatment Options and Outlook

Treatment focuses on restoring moisture to the affected tissues. These efforts may include artificial tears EYE drops, moisturizing mouth rinses, vaginal moisturizing creams, and saline nasal sprays for the NOSE. Dental hygiene is crucial because the lack of saliva fosters the growth of BACTERIA and consequential DENTAL CARIES (cavities). Drinking water helps maintain moisture throughout the body. At present Sjögren's syndrome remains a chronic disorder for which there is no cure.

Risk Factors and Preventive Measures

Sjögren's syndrome affects predominantly women, with onset between the ages of 40 and 55. However, there are no known measures for preventing its development. Preventive measures instead focus on minimizing damage to the involved organ systems.

See also AUTOIMMUNE DISORDERS; CORNEA; DRY EYE SYNDROME; EPISTAXIS; LIVING WITH IMMUNE DISORDERS.

skin-associated lymphoid tissue (SALT) A loose organization of LYMPH cells and tissues that incorporates with the epidermis, the SKIN's living layer. The skin, as the body's primary interface with the external environment, is the foremost barrier to INFECTION. SALT, also called the skin IMMUNE SYSTEM (SIS), is very active. It contains large populations of mast cells, lymphocytes, and macrophages called Langerhans's cells. Its role is to intercept pathogens and other substances that manage to penetrate the physical barrier of the skin. These encounters are the basis for many of the antibodies the IMMUNE RESPONSE forms, particularly those related to allergies (HYPERSENSITIVITY REACTION).

Hypersensitivity reactions often involve dermatologic symptoms such as RASH and URTICARIA (hives). Numerous dermatologic conditions are IMMUNE DISORDERS or AUTOIMMUNE DISORDERS. Infections such as HIV/AIDS and HUMAN PAPILLOMAVIRUS (HPV) that deplete the systemic immune system result in reduced numbers of immune cells in SALT, increasing the skin's vulnerability to infection.

For further discussion of SALT within the context of the structures and functions of the immune system, please see the overview section "The Immune System and Allergies."

See also ANTIBODY; ANTIGEN; B-CELL LYMPHOCYTE; BRONCHUS-ASSOCIATED LYMPHOID TISSUE (BALT); INFECTION; KAPOSI'S SARCOMA; LYMPHOCYTE; MACROPHAGE; MAST CELL; MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT); NOSE-ASSOCIATED LYMPHOID TISSUE (NALT); OPPORTUNISTIC INFECTIONS; PATHOGEN; PHAGOCYTE; T-CELL LYMPHOCYTE; VASCULAR-ASSOCIATED LYMPHOID TISSUE (VALT); VIRUS.

systemic lupus erythematosus (SLE) A chronic autoimmune disorder in which the IMMUNE RESPONSE creates antibodies that attack the cells of various organs. SLE is a type III HYPERSENSITIVITY REACTION (immune complex reaction) that most commonly develops between the ages of 15 and 40. Nine times as many women than men have SLE, and SLE is three times more common in African American women than women of other ethnicities.

Symptoms and Diagnostic Path

The symptoms of SLE vary widely in nature and severity and are often transient (come and go). Symptoms also vary depending on the affected organ systems, making it difficult to view them collectively as indications of a single disorder. The main symptoms of SLE may include

- characteristic "butterfly" RASH across the NOSE and onto the cheeks
- fatigue, often extreme
- painful and inflamed joints
- FEVER
- enlarged lymph nodes
- loss of HAIR
- CHEST PAIN, particularly with deep BREATHING or exertion
- sensitivity to sunlight

The diagnostic path is one of exclusion. It can take months to years for doctors to rule out other causes of the symptoms and settle on the suspicion of SLE. BLOOD tests that detect antinuclear antibodies (ANAs) suggest SLE. Many people who have SLE also have other antibodies, including anti-Ro and anti-La. However, not all do, and some people have these antibodies and do not have SLE. Some people who have SLE have decreased complement factors, though other conditions can cause the same finding.

Treatment Options and Outlook

Treatment incorporates various medications, singly or in combination, that target symptoms. The most commonly used medications are NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS), antimalarial medications, CORTICOSTEROID MEDICATIONS, and IMMUNOSUPPRESSIVE MEDICATIONS. SLE is a chronic condition that medications can regulate to permit a relatively normal lifestyle. Stress exacerbates symptoms and precipitates flareups. Most people learn to identify when a flareup of symptoms is pending and to take appropriate interventions (medications and relaxation techniques) to mitigate their effects.

MEDICATIONS TO TREAT SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)

cyclophosphamide	dexamethasone
hydrocortisone	hydroxychloroquine
ibuprofen	methotrexate
mycophenolate mofetil	naproxen
prednisone	

Risk Factors and Preventive Measures

The main risk factors for SLE are being female and being African American. Researchers do not know why gender and ethnicity influence the development of SLE. Preventive measures focus on reducing the complications of symptoms through prompt medical intervention and lifestyle practices, such as nutritious EATING HABITS and daily physical activity, that support health.

See also ANTIBODY; AUTOIMMUNE DISORDERS; DISCOID LUPUS ERYTHEMATOSUS (DLE); LIVING WITH IMMUNE DISORDERS; LYMPH NODE; MIND–BODY CONNECTION.

T-cell lymphocyte The type of white BLOOD cell (LEUKOCYTE) responsible for CELL-MEDIATED IMMUNITY. T-cell lymphocytes come to maturity in the THYMUS during childhood, which is why they are called T-cells. During the maturation process, T-cell lymphocytes "learn" how to recognize self and nonself antigens so they can distinguish between cells that belong to the body and cells that are foreign. Such a safeguard is necessary to keep T-cell lymphocytes from attacking the body's own cells. The thymus destroys lymphocytes that do not learn this distinction. After the thymus releases mature T-cell lymphocytes into the blood circulation, they differentiate into several subtypes. These include

- cytotoxic T-cell lymphocytes, also called killer T-cells or CD8 cells, which respond to nonself antigens to kill the cells that bear them
- helper T-cells, also called CD4 cells, which release CYTOKINES that stimulate B-CELL LYMPHOCYTE and cytotoxic T-cell lymphocyte activity
- memory T-cells, which carry specific antibodies and circulate in the blood for rapid activation should the same ANTIGEN reappear
- suppressor T-cells, which call off the IMMUNE RESPONSE when the threat to the body ends

The SPLEEN, the lymph nodes, and the MUCOSA-ASSOCIATED LYMPHATIC TISSUE (MALT) throughout the body contain millions of T-cell lymphocytes. T-cell lymphocytes also circulate in the blood and the LYMPH. T-cell lymphocytes may also be the source of disease, such as in HIV/AIDS (the VIRUS attaches to CD4 helper T-cells) and cutaneous T-cell lymphoma (CTCL), a form of cancer.

For further discussion of T-cell lymphocytes within the context of the structures and functions of the immune system, please see the overview section "The Immune System and Allergies."

See also ANTIBODY; ANTIBODY-MEDIATED IMMUNITY; CLUSTERS OF DIFFERENTIATION; LYMPH NODE; MAJOR HISTOCOMPATIBILITY COMPLEX (MHC); NATURAL KILLER (NK) CELL.

transforming growth factors (TGFs) CYTOKINES in the BLOOD circulation that attach to the surfaces

of cell membranes. Transforming growth factor alpha (TGF-alpha) stimulates the cells to grow, divide, and differentiate (cell proliferation). Lymphocytes and macrophages produce TGF-alpha. TGF-beta stimulates interleukin 1 (IL-1) production and blocks the response of lymphocytes in the inflammatory process. Lymphocytes, macrophages, and platelets secrete TGFs.

See also INFLAMMATION; INTERFERONS; INTERLEUKINS; LYMPHOCYTE; MACROPHAGE; PLATELET; TUMOR NECROSIS FACTORS (TNFS).

tumor necrosis factors (TNFs) CYTOKINES that kill tumor cells and participate in the inflammatory response. Leukocytes (white BLOOD cells) produce TNFs under stimulation from INTERLEUKINS. Tumor necrosis factor alpha (TNF-alpha), also called cachexin or cachectin, is the most active in these processes. Recombinant TNF-alpha is a treatment option for certain types of cancer. The spice turmeric (active ingredient curcumin) and the catechins in GREEN TEA also boost TNF-alpha. Overactive TNF production contributes to inflammatory AUTOIMMUNE DISORDERS such as RHEUMATOID ARTHRITIS and INFLAMMATORY BOWEL DISEASE (IBD). Doctors sometimes use therapeutic MONOCLONAL ANTIBODIES (MABS), such as infliximab and etanercept, to block TNF-alpha.

See also INFLAMMATION; LEUKOCYTE; RECOMBINANT DNA.

V

vaccine A substance that initiates an IMMUNE RESPONSE to produce antibodies that prevent INFECTION by the particular PATHOGEN. Vaccines contain attenuated live (weakened) or killed pathogens such as viruses or BACTERIA. The antigens of these pathogens activate the body's immune response, stimulating B-cell lymphocytes to produce antibodies specific to them. Genetic engineering makes it possible to produce large quantities of many vaccines in relatively short order. There are four types of vaccines:

- Attenuated vaccines contain live but weakened viruses to produce the strongest immune response. Laboratory manipulation of the VIRUS can establish narrow parameters of survival for the virus the vaccine carrier, such as temperature or acidity. These manipulations reduce the risk that the vaccine could cause infection, though such a risk exists. Often an attenuated vaccine requires only a single DOSE to establish full and long-term IMMUNITY.
- Inactivated vaccines contain killed bacteria or viruses. These pathogens still carry the antigens that will stimulate the immune response to produce antibodies but are incapable of causing infection. Though safer than attenuated vaccines, inactivated vaccines often require multiple doses or provide limited immunity.
- Acellular vaccines, also called subunit vaccines, contain particles of the virus or bacteria. These particles carry enough ANTIGEN to stimulate an immune response but are not complete enough to cause infection.
- Toxoid vaccines generate antibodies for the toxins certain bacteria generate when they cause infection. Tetanus and DIPHTHERIA are illnesses due to such toxins and the vaccines for them provide antibodies for the toxins rather than the bacteria that cause the illness.

Vaccines prevent many infectious diseases that were once major killers. Vaccination has essentially eliminated SMALLPOX worldwide, for example, and is close to eliminating POLIOMYELITIS. Some vaccines, such as for tetanus and pertussis, require multiple doses or periodic booster doses to establish full immunity. Because vaccines are effective for only the specific pathogens they contain, rapidly mutating pathogens such as the INFLUENZA virus require a new vaccine for each strain.

VACCINES

ANTHRAX	CHICKENPOX/shingles (varicella zoster viruses)
CHOLERA	diptheria, tetanus, acellular PERTUSSIS (DtaP)
DIPHTHERIA	HEPATITIS A (HAV)
Haemophilus influenzae type b (Hib)	INFLUENZA
hepatitis B (HBV)	MEASLES
LYME DISEASE	measles, MUMPS, RUBELLA (MMR)
meningococcal vaccine	pertussis
monkeypox	pneumococcal vaccine
mumps	RABIES
plague	rubella
POLIOMYELITIS	tetanus
rotavirus	typhoid
rubeola	
TUBERCULOSIS	
yellow FEVER	

Vaccines may not be effective in establishing immunity in people who are IMMUNOCOMPROMISED. Some people have allergies to the ingredients of the vaccine. Vaccines that contain attenuated live viruses sometimes use the preservative thimerosal,

which contains mercury. Because this heavy metal can cause neurologic damage, the United States has initiated a cooperative effort among vaccine manufacturers to develop thimerosal-free vaccines. Most recommended vaccines are now available without thimerosal or with minimal amounts of thimerosal.

People who travel should receive vaccines appropriate for the regions they intend to visit. The US Centers for Disease Control and Prevention (CDC) maintains a schedule of recommended travelers' immunizations at its Web site (http://www.cdc.gov).

vascular-associated lymphoid tissue (VALT) Loosely collected clusters of LYMPH tissue throughout the inner, mucosal layer of the walls of the BLOOD vessels. Researchers discovered VALT in the late 1990s and remain unsure of its role and functions. There do appear to be correlations between LYMPHOCYTE activity in VALT and cardiovascular conditions such as ATHEROSCLEROSIS, which many cardiologists now believe results from an inflammatory process rather than creates INFLAMMATION. Researchers do not know, however, whether VALT attempts to fight the inflammation or contributes to it. Researchers are also investigating the relationship between VALT and dissecting aortic ANEURYSM, a life-threatening condition in which the layers of the walls of the abdominal AORTA begin to separate. The separations weaken the wall of this major ARTERY, creating substantial risk for the arterial wall to rupture.

For further discussion of VALT within the context of the structures and functions of the immune system, please see the overview section "The Immune System and Allergies."

vasculitis A group of AUTOIMMUNE DISORDERS in which the epithelium (lining) of the BLOOD vessels becomes inflamed. The INFLAMMATION causes localized PAIN and swelling. There are numerous forms of vasculitis. They share common characteristics

TYPES OF VASCULITIS

Type of Vasculitis	Unique Symptoms	Treatment and Outlook
allergic granulomatosis and angiitis (Churg-Strauss syndrome)	primarily occurs in adults who have atopic bronchial ASTHMA affects BLOOD vessels of the LUNGS and musculoskeletal system eosinophilia (excessive number of eosinophils) and eosinophilic PNEUMONIA	CORTICOSTEROID MEDICATIONS sometimes resolves spontaneously though often is chronic course of disease may be progressive untreated eosinophilic pneumonia is life threatening
Behçet's syndrome	primarily occurs in adults who are in their 30s and is more common in men affects small arteries and veins serving epithelial tissue (SKIN and mucous membranes) and the eyes recurrent, painful ulcers in the MOUTH and VULVA that occur in clusters vision disturbances and UVEITIS inflammatory response with minor trauma such as scratches skin rashes	topical corticosteroid medications for mild skin symptoms colchicine, NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS), dapsone, or thalidomide to control ulcerations IMMUNOSUPPRESSIVE MEDICATIONS for severe symptoms that do not respond to other treatments tends to be chronic with extended periods of REMISSION (several years) PHYSICAL THERAPY and physical exercise as tolerated to maintain joint FLEXIBILITY and range of motion

and symptoms though each of which has unique traits. Vasculitis may be acute (come on suddenly, run its course, and be over) or chronic (symptoms persist or come and go). Though vasculitis can affect any kind of blood vessel in the body, it most often involves arteries.

Symptoms and Diagnostic Path

Each type of vasculitis has unique symptoms. All types of vasculitis have in common these general symptoms:

- weight loss and loss of APPETITE

Type of Vasculitis	Unique Symptoms	Treatment and Outlook
giant cell arteritis (temporal arteritis)	primarily occurs in adults over age 50 affects arteries in the upper body, notably the neck and head (carotid network) severe HEADACHE, jaw PAIN, and scalp tenderness blind spots (scotoma), blurred vision, and other vision disturbances	high-DOSE corticosteroid medications for two to four weeks long-term corticosteroid therapy delayed treatment establishes high risk for blindness resulting from optic NEUROPATHY tends to be chronic
Henoch-Schönlein purpura	primarily occurs in children under age 6 purplish RASH on the legs and feet acute illness that lasts about 2 weeks affects blood vessels of the skin, joints, gastrointestinal tract, and KIDNEYS	complete recovery without treatment (self-limiting course of disease) possible complications, though uncommon, include RENAL FAILURE and GASTROINTESTINAL BLEEDING
hypersensitivity vasculitis (leukocytoclastic vasculitis)	affects small arteries in the skin, kidneys, gastrointestinal tract, lungs, and joints palpable (raised) PURPURA, commonly on the legs	corticosteroid medications or immunosuppressive medications when involvement is systemic symptoms can be recurrent
KAWASAKI'S DISEASE (mucocutaneous LYMPH NODE syndrome)	occurs primarily in children under age 5 acute onset with high FEVER lasting five days to two weeks fever does not drop with aspirin or acetaminophen inflamed and reddened eyes, reddened and chapped lips, peeling skin, and joint pain	high-dose, intravenous GAMMAGLOBULIN aspirin most children fully recover without complications risk for coronary ARTERY INFLAMMATION and aortic ANEURYSM requires lifelong monitoring for CARDIOVASCULAR DISEASE (CVD)
microscopic polyangiitis	more common in adults over age 50 affects arteries in the kidneys, skin, lungs, and that serve PERIPHERAL NERVES fever purpura and other skin rashes neuropathy and loss of NERVE function to feet and hands alveolar hemorrhage (bleeding into the tiny air sacs in the lungs)	corticosteroid medications in combination with immunosuppressive medications trimethoprim/sulfamethoxazole (antibiotic therapy)

Type of Vasculitis	Unique Symptoms	Treatment and Outlook
polyarteritis nodosa	affects arteries in the LIVER, gastrointestinal tract, kidneys purpura and skin ulceration pain in the joints and large muscles abdominal pain HYPERTENSION	aggressive, high-dose corticosteroid medications at diagnosis immunosuppressive medications for nonresponsive or severe symptoms long-term corticosteroid therapy to control chronic disease antihypertensive therapy untreated or severe disease has high risk for death complications include renal failure, LIVER FAILURE, and HEART FAILURE
polymyalgia rheumatica	primarily occurs in adults over age 60 severe pain and inflammation in the large joints (knees, hips, shoulders)	NSAIDs corticosteroid medications chronic symptoms requiring long-term treatment may indicate underlying giant cell arteritis
Takayasu arteritis	affects the AORTA and other large arteries most common in women between ages 20 and 35 pain and weakness in the back and arm on the affected side lower BLOOD PRESSURE in the arm on the affected side headache, dizziness, and vision disturbances hypertension	corticosteroid medications immunosuppressive medications for severe symptoms ANTICOAGULATION THERAPY such as aspirin or warfarin spontaneous resolution in about 95 percent of people possible complications include STROKE, HEART ATTACK, severe hypertension, aortic aneurysm, and heart failure
thromboangiitis obliterans (Buerger's disease)	most common in men aged 20 to 40 who smoke affects blood vessels in arms, hands, legs, and feet leg cramps with walking (INTERMITTENT CLAUDICATION) altered sensation or loss of sensation in feet (paresthesia) ulcerations on fingers and toes with rapid progression to GANGRENE (tissue death)	SMOKING CESSATION rest until inflammation subsides regular walking to improve circulation and muscular support for blood vessels aggressive treatment for ulcers that develop AMPUTATION of gangrenous digits or extremities chronic condition that requires diligent lifestyle management to minimize symptoms
Wegener's granulomatosis	more common in men over age 40 affects blood vessels in the NOSE, SINUSES, THROAT, lungs, and kidneys, often causing ulcerations chronic PNEUMONITIS chronic GLOMERULONEPHRITIS forms multiple granulomas	immunosuppressive medications corticosteroid medications with mild symptoms and early diagnosis trimethoprim/sulfamethoxazole (antibiotic therapy) treatment eliminates symptoms in 50 percent of people severe or untreated symptoms can be fatal outlook best with early diagnosis and treatment

- fatigue
- FEVER
- MUSCLE aches and PAIN
- JOINT pain and swelling

The doctor may conduct BLOOD tests to measure ANTIBODY types and levels, blood cell counts, and sedimentation rate and C-REACTIVE PROTEIN level (the latter two are indicators of inflammation in the body). Diagnostic imaging procedures such as Doppler ULTRASOUND, MAGNETIC RESONANCE IMAGING (MRI) COMPUTED TOMOGRAPHY (CT) SCAN, and angiogram can demonstrate any damage to or obstruction (blockage) of the arteries and veins. Sometimes a biopsy of the involved blood vessel is necessary to confirm the diagnosis.

Treatment Options and Outlook

Some types of vasculitis are self-limiting and do not require treatment. For most, treatment may include NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS), CORTICOSTEROID MEDICATIONS, and IMMUNOSUPPRESSIVE MEDICATIONS that have cytotoxic (cell-killing) effects (such as azathioprine and cyclophosphamide). The person may take one kind of medication or a combination of medications, depending on the symptoms and their severity. Nutritional EATING HABITS and daily physical exercise such as walking also aid HEALING and improved function.

Risk Factors and Preventive Measures

Doctors do not know what causes most vasculitis, though people who have autoimmune disorders are more likely to develop some type of vasculitis. Because some forms of vasculitis have potentially severe or life-threatening complications, early diagnosis and treatment are essential for optimal recovery or disease management. Many of the medications doctors prescribe to treat vasculitis have significant side effects such as OSTEOPOROSIS so it is important to be vigilant about such conditions.

INFECTIOUS DISEASES

Infectious diseases are illnesses that result from INFECTION *with microorganisms, also called microbes. Doctors who treat people who have infectious diseases are internists (who treat adults) or pediatricians (who treat children) who subspecialize in infectious diseases.*

This section, "Infectious Diseases," presents an overview discussion of illness due to infection and entries about systemic infectious diseases (illnesses that affect the body as a whole), their treatments, and preventive measures. Other sections in *The Facts On File Encyclopedia of Health and Medicine* discuss infections specific to individual body systems.

Health, Infection, and Disease

An infection occurs when microbes—bacteria, fungi, parasites, viruses—and other pathogens (infectious agents) such as prions invade the body. The infection causes illness (becomes a disease) when it alters in some deleterious fashion the functions of the body. Some infectious diseases are primarily a health concern only to the people who have them, such as NECROTIZING FASCIITIS, TOXIC SHOCK SYNDROME, and CANDIDIASIS. These illnesses are noncommunicable; they do not spread to other people.

sIn some situations infections affect people who have no contact with one another but somehow share a generalized source of contamination. These infections, such as occur with WATERBORNE ILLNESSES in which drinking water or recreational water contains pathogens that people consume, or in LEGIONNAIRES' DISEASE, in which building heating and air-conditioning systems disperse *Legionella pneumophilia* bacteria to all who breathe the building's air, are communicable. Though contact among infected individuals may spread the infection, the typical mode of transmission is contact with the common source.

Numerous infections spread from one person to another, directly such as through touching or sharing bodily fluids or indirectly through sneezing or coughing. These illnesses are not only communicable but also contagious: they spread easily, rapidly, and often extensively. MEASLES, for example, is one of the most highly contagious communicable diseases; 90 percent of people exposed to the virus become ill with the disease. COLDS, infectious mononucleosis (EPSTEIN-BARR VIRUS infection), and INFLUENZA are among the most common contagious diseases in the United States.

Epidemics occur when large numbers of people become ill with a communicable or contagious disease. Throughout history these waves of infection decimated families, cities, countries, and even entire civilizations. Smallpox, measles, bubonic plaque, gonorrhea, syphilis, and influenza are among the infections that raged through populations. An infectious disease is endemic when it is always present at relatively the same rate of infection within a certain geographic region, environment, or population of people. Malaria is endemic in Africa, for example, and consistently sickens thousands of people.

Until the 1950s geographic boundaries confined most infectious diseases, not because pathogens (disease-causing microbes) had much regard for natural or national borders but because few people traveled very far from home. The advent of commercial air flight changed all that. By the 1970s air travel could whisk a person literally halfway around the world in less time than it

took to drive from San Francisco to Seattle. Few infectious diseases today remain localized, though the risk of infection with them varies widely. HIV/AIDS, SEVERE ACUTE RESPIRATORY SYNDROME (SARS), and INFLUENZA stand as stark evidence that microbes, too, travel the world.

CONTAGIOUS INFECTIOUS DISEASES

ANTHRAX	CHICKENPOX
CHLAMYDIA	COLDS
DIPHTHERIA	ENCEPHALITIS
GENITAL HERPES	GONORRHEA
HEMORRHAGIC FEVERS	HEPATITIS
INFLUENZA	MEASLES
MENINGITIS	MONONUCLEOSIS, INFECTIOUS
MUMPS	SCARLET FEVER
RUBELLA	STREP THROAT
SEVERE ACUTE RESPIRATORY SYNDROME (SARS)	SYPHILIS
TRICHOMONIASIS	TUBERCULOSIS
TYPHOID FEVER	

Infectious Diseases in Medical History

Infectious diseases have mystified and plagued humanity for ages. Tuberculosis, smallpox, cholera, typhoid FEVER, and the plague itself ("Black Death") were for centuries the leading causes of disability, disfigurement, and death. Mummified remains from ancient Egypt show evidence of smallpox and tuberculosis. Disfigurement resulting from smallpox was so common through the 18th century that artists routinely painted portraits that discreetly masked or simply did not portray the extensive scars the disease left on the faces of those who survived the illness. Hippocrates wrote of "phthisis"—Greek for consumption, an apt name for tuberculosis, the disease that slowly wasted away the lives of those infected. Manuscript fragments recovered from 7th century China reference measles. Ancient Greek documents record outbreaks of "pestilence" that were likely epidemics of measles, smallpox, and perhaps plague.

For centuries doctors believed infectious diseases like tuberculosis represented some sort of inborn weakness in a family because family members often had the same illness, generation after generation. Of course, doctors today know the true reason such illnesses affected entire families: infectious diseases like tuberculosis spread from person to person, and living in close contact makes it easier if not inevitable for them to spread.

The birth of vaccination and the death of a scourge In the summer of 1796, eight-year-old James Phipps became the first success story in an effort that would reach fruition nearly 200 years later. Country doctor Edward Jenner (1749–1823) made two scratches on the boy's arm with a lancet dipped in the fluid from a smallpox sore. Nothing happened. Not then, not 14 days later when the characteristic sores of smallpox should have started erupting. The scratches healed and James remained healthy.

Six weeks earlier, Jenner had performed a similar procedure using the fluid from a cowpox sore, a much milder form of illness that doctors today know develops from infection with a virus closely related to the virus that causes smallpox. Edward Jenner did not know this but had observed that milkmaids and farm hands who recovered from cowpox did not get smallpox. Young James became ill with cowpox, as Jenner expected he would, and then soon recovered—also as Jenner expected he would. Ironically, as an adult James Phipp nearly lost his life to another infectious disease endemic throughout history, tuberculosis.

In 1966 the World Health Assembly formalized a global smallpox eradication program with vaccination, Jenner's discovery, as its foundation. The first year of the program, 15 million people throughout the world contracted smallpox; nearly a third of them died. Ten years later, on October 26, 1977, Somalian Ali Mao Moallin became the last person in the world to acquire naturally occurring smallpox (he survived). In 1980, the World Health Organization officially declared smallpox eradicated worldwide and advised countries to end vaccination programs.

Today vaccination is the cornerstone of infectious disease control and preventive medicine. Vaccines confer IMMUNIZATION for numerous infectious diseases. Many countries, including the United States, routinely administer set schedules of vaccines to children, giving them lifelong immunity that protects them from infection with diseases such as POLIOMYELITIS, MUMPS, MEASLES, CHICKENPOX, RUBELLA, PERTUSSIS (whooping COUGH), and *Haemophilus influenzae* type b (Hib).

Microbes and the mechanisms of infection As early as the 16th century some scientists postulated the existence of unseen organisms as accountable for disease. The development of the microscope gave proof to the existence of such organisms; proving their connection to disease was more difficult. The first to succeed did so in a major way. German physician Robert Koch (1843–1910) isolated and cultivated *Mycobacterium tuberculosis*, the MICROBE responsible for the Western world's most pervasive and devastating disease. By the 19th century, tuberculosis infected so many people that it was more common than not. What puzzled doctors was why some people became ill and others did not.

Koch solved this mystery in 1882 when he demonstrated the ability of *M. tuberculosis* to cause tuberculosis infection. The methods of vaccination successful in preventing smallpox, anthrax, and other infectious diseases did not work with tuberculosis, however. Not until biochemist Selman Waksman (1888–1973) discovered streptomycin, a powerful antibiotic, in 1943 were doctors finally able to gain the upper hand against tuberculosis. Waksman received the Nobel Prize in Physiology or Medicine in 1952 for his work.

Through their work to understand a disease prevalent among livestock in the 19th century, foot-and-mouth disease, German researchers Friedrich Loeffler (1852–1915) and Paul Frosch (1860–1928) expanded the spectrum of pathogens. The pair postulated the existence of a particle smaller than bacteria caused the infectious disease. However, they lacked the technology to visualize such a particle. The development of the electron microscope in 1939 gave scientists the ability to see these smallest of infective agents, viruses.

Breakthrough Research and Treatment Advances Molecular medicine advances in the late 20th century gave another enormous boost to the fight against infectious diseases. In 1995 the bacterium *Haemophilus influenzae,* an insidious microbe responsible for numerous pulmonary and gastrointestinal diseases, became the first pathogen for which researchers unraveled the genetic code. The advance led to improvements in vaccines and treatments for *H. influenzae* infections as well as other bacterial diseases.

Molecular medicine also has provided tremendous breakthroughs in understanding the modus operandi of viruses such as HIV (human immunodeficiency virus), a Machiavellian retrovirus that subverts the immune system itself to perpetuate its own survival. These breakthroughs have paved the way for new antiviral medications that target specific molecular mechanisms of HIV, slowing its progress, and show promise for the development of a vaccine that can prevent HIV infection and AIDS.

As researchers gain insight into the adaptive mechanisms of pathogens such as bacteria and viruses, they are able to develop new drugs—and drugs that work in new ways—to treat the infections these pathogens cause. This is particularly important in light of the alarming rise in DRUG-resistant infections in diseases such as tuberculosis, GONORRHEA, and staphylococcal pneumonia. New viruses also threaten public health, placing renewed emphasis on vaccines and infection control measures to stop their spread. Though the control and eradication of many infectious diseases represent many of medicine's greatest triumphs, many of medicine's greatest challenges remain these same factors.

A

abscess A localized INFECTION containing pus, a fluid-based collection of white BLOOD cells, BACTERIA, and the debris resulting from the IMMUNE SYSTEM's efforts to fight the infection. Though an abscess may cause severe PAIN and compromise the function of organs in which it occurs, an abscess represents the success of the immune system to contain and enclose the infection. An abscess can develop anywhere in the body. Symptoms vary with the abscess's location though typically include pain and swelling in the area of the infection. There often is FEVER as well. An abscess on the SKIN or near the surface of the skin may form a red nodule or an open sore. Treatment is ANTIBIOTIC MEDICATIONS when the infection is bacterial. A deep, internal abscess may require surgery to drain the pus so HEALING can take place.

See also BARTHOLIN'S CYST; FURUNCLE; HEPATIC ABSCESS; LUNG ABSCESS; PERITONSILLAR ABSCESS.

adenovirus A VIRUS family that causes INFECTION of mucous membrane tissues throughout the body. Adenoviruses are responsible for a wide range of illness including upper respiratory infection, viral CONJUNCTIVITIS, GASTROENTERITIS, and URINARY TRACT INFECTION (UTI). These infections primarily affect children age 10 and younger. Infection with one adenovirus confers immunity to that strain of virus; vulnerability to infection with other strains of adenovirus remains. Adenoviruses are highly contagious and are particularly adept at mutating and adapting. They primarily spread through

- person-to-person direct contact, such as touching
- indirect contact, such as by touching doorknobs or furniture a person infected with the virus has touched, leaving viral particles behind, or by handling tissues an infected person uses
- airborne particles, such as enter the air via sneezing and coughing
- fecal contamination, such as through changing diapers or lack of HAND WASHING after using the bathroom

The INCUBATION PERIOD (time from exposure to onset of symptoms) is usually less than 10 days and often only 2 or 3 days. Adenoviral infection seldom causes serious illness and is self-limiting (goes away on its own after running its course). Symptoms depend on the location of the infection. The doctor may take mucus samples to test for the presence of BACTERIA, as the symptoms of bacterial and viral infections are often similar. Bacterial infection requires antibiotic therapy; ANTIBIOTIC MEDICATIONS are not effective against viral infections. Treatment for adenoviral infection targets symptom relief. Because adenoviruses are so pervasive, preventing infection is nearly impossible. The most important step to minimize the risk for infection is frequent hand washing with soap and warm water. People who are IMMUNOCOMPROMISED should avoid indoor crowds to the extent possible to reduce their exposure to people infected with adenoviruses.

See also COLDS; DIARRHEA; FOODBORNE ILLNESSES; SNEEZE/COUGH ETIQUETTE.

amebiasis A parasitic INFECTION of the gastrointestinal tract. The PARASITE responsible is *Entamoeba histolytica*, a single-cell organism (an ameba) that enters the body by drinking water or eating food that contains *E. histolytica* in cyst form. The cyst is a protective encasing within which the ameba

may sustain itself in a dormant stage for weeks to months outside a host (organism that provides NUTRIENTS for a parasite). Once within the SMALL INTESTINE the cyst ruptures and the ameba emerges to enter its active stage. In this active stage the ameba, called a trophozoite, travels to the COLON (large intestine) where it feeds on intestinal BACTERIA. As the population of trophozoites increases, they burrow into the intestinal mucosa (mucous lining of the colon). Substances trophozoites secrete to digest the substances they consume cause ulcerations (sores) that produce symptoms.

Symptoms and Diagnostic Path

The symptoms of amebiasis, also called amebic dysentery, begin two weeks to four months after ingesting the contaminated food or water. They include

- abdominal cramping or ABDOMINAL PAIN
- frequent bowel movements or DIARRHEA (which may be bloody)
- FEVER

The diagnostic path includes microscopic examination of stool samples to detect the presence of either cysts or trophozoites. The doctor may also conduct sigmoidoscopy to examine the colon for the characteristic ulcerations and to rule out other causes of the symptoms.

Occasionally trophozoites penetrate far enough into the intestinal mucosa to enter the BLOOD circulation, which transports them to other organs and extends the infection. The LIVER is the most common site for distant infection, where it presents as a HEPATIC ABSCESS, though the LUNGS and the BRAIN may also become involved. In locations other than the colon the trophozoites can cause abscesses, resulting in serious or life-threatening illness. Symptoms of systemic infection depend on the affected area.

Treatment Options and Outlook

Treatment for enteric or systemic infection is a combination of ANTIBIOTIC MEDICATIONS. Appropriate treatment cures the infection; inadequately treated or untreated amebiasis becomes chronic with cycles of alternating RECURRENCE and REMISSION of symptoms. Until recently doctors believed it was possible to have an *E. histolytica* infection without symptoms. However, although it is possible to have an *E. histolytica* infection with very mild symptoms, infectious disease specialists have determined a closely related and nearly identical ameba, *E. dispar*, is the cause of infection when no symptoms are present. *E. dispar* is benign and does not require treatment.

ANTIBIOTIC MEDICATIONS TO TREAT AMEBIASIS

diloxanide furoate	iodoquinol
metronidazole	paromomycin
tinidazole	

Risk Factors and Preventive Measures

Amebiasis is most common in countries where community sanitation is poor. People who travel in such countries or are immigrants to the United States from such countries, are at highest risk for amebiasis. The infection spreads through direct contact with fecal contamination, such as by eating vegetables from contaminated soil or drinking contaminated water. People who have amebiasis can spread the infection to other people. Diligent HAND WASHING and safe food preparation are effective measures for preventing the spread of amebiasis. Travelers to countries where sanitation is substandard should follow precautions that include eating only foods that are thoroughly cooked and drinking only bottled or canned beverages (without ice) or water boiled for a minimum of one minute.

See also BOWEL MOVEMENT; DRINKING WATER STANDARDS; FOODBORNE ILLNESSES; FOOD SAFETY; GASTROENTERITIS; PERSONAL HYGIENE; PROTOZOA; WATERBORNE ILLNESSES.

antibiotic medications Drugs that kill BACTERIA and certain other microorganisms. Antibiotic medications are the mainstay of treatment for bacterial INFECTION. Broad-spectrum antibiotics are capable of killing numerous types of bacteria; narrow-spectrum antibiotics kill specific types or strains of bacteria. There are seven primary classifications of antibiotic medications—aminoglycosides, cephalosporins, macrolides, quinolones (fluorquinolones), penicillins, sulfonamides, and tetracyclines—that contain over 100 different drugs.

COMMON ANTIBIOTIC MEDICATIONS

Aminoglycosides		
gentamicin	neomycin	tobramycin
Cephalosporins		
cefaclor	cefadroxil	cefepime
cefdinir	cefoperazone	cefoxitin
cefprozil	cefprozil	ceftazidime
cefuroxime	cephalexin	cephradine
loracarbef		
Macrolides		
azithromycin	clarithromycin	erythromycin
Quinolones (Fluoroquinolones)		
cinoxacin	ciprofloxacin	enoxacin
gatifloxacin	levofloxacin	lomefloxacin
moxifloxacin	nalidixic acid	norfloxacin
ofloxacin	sparfloxacin	trovafloxacin
Penicillins		
amoxicillin	amoxicillin/ clavulanate	penicillin V potassium
Sulfonamides		
cotrimoxazole	trimethoprim	trimethoprim/ sulfamethoxazole
Tetracyclines		
doxycycline	minocycline	tetracycline

How These Medications Work

Antibiotics are either bacteriocidal (kill bacteria directly) or bacteriostatic (kill bacteria by preventing them from reproducing). Some antibiotics are effective against anaerobic bacteria (bacteria that thrive in low-oxygen environments) and others against aerobic bacteria (bacteria that require normal atmospheric oxygen concentrations to survive). Just as the strains of bacteria share common traits yet have distinguishing features, the antibiotics within a particular class have similarities and differences. Doctors match bacteria and antibiotic for greatest EFFICACY. Individual variations among people also influence antibiotic effectiveness.

Therapeutic Applications

Antibiotic medications are effective for treating bacterial infections. They have no effect on viral infections or fungal infections. Laboratory analysis of fluid or tissue samples, called culture and sensitivity, is usually necessary to determine whether an infection is bacterial. The analysis involves attempting to grow the bacteria in the laboratory, then determining which antibiotics can kill the bacteria. Types of bacteria are sensitive to specific classes of antibiotics, so knowing the general classification of the bacteria is generally sufficient for the doctor to prescribe an antibiotic medication that will kill it.

Risks and Side Effects

Antibiotic medications have numerous side effects, ranging from HYPERSENSITIVITY REACTION (allergy) to LIVER or kidney damage. Allergy to penicillin is the most common DRUG allergy. Some antibiotics diminish the effectiveness of oral contraceptives (birth control pills). Most antibiotics increase the possibility for fungal (yeast) infection because they disturb the balance of NORMAL FLORA. Common consequences of this effect are antibiotic-related DIARRHEA and oral or vaginal CANDIDIASIS (yeast infection of the mouth or vagina).

ANTIBIOTIC RESISTANCE is a significant concern. Numerous strains of bacteria have adapted to become resistant to the antibiotics commonly used to treat the infections they cause. Factors that contribute to antibiotic resistance include overprescribing of antibiotics and failure to take antibiotic medications for the full course of prescribed treatment. These factors expose bacteria to antibiotics without killing them, giving the bacteria opportunity to adapt in ways that block the actions of the antibiotics in future generations of the bacterial strain. It is essential to take antibiotic medications only when necessary and for the full course of treatment.

See also ANTIBIOTIC PROPHYLAXIS; ANTIFUNGAL MEDICATIONS; ANTIVIRAL MEDICATIONS.

antifungal medications Drugs that kill fungi (yeast). Antifungal medications are available for topical or systemic treatment. Some fungal infections require both. Antifungal medications work through various mechanisms to interfere with the ability of fungi to survive or reproduce. Broad-spectrum antifungal medications are effective for treating a variety of fungal infections; narrow-

spectrum antifungals are effective in treating specific fungal infections.

Topical preparations may be lotions, creams, ointments, sprays, powders, or suppositories. Oral preparations may be tablets and liquids to swallow. Oral preparations to treat fungal infections involving the MOUTH (THRUSH) may be liquids to swish around the mouth or tablets (troche or lozenge) to allow to dissolve in the mouth. A variety of topical antifungal medications is available as over-the-counter products that do not require a doctor's prescription. These products are to treat common fungal and yeast infections such as vaginal CANDIDIASIS and athlete's foot and jock itch (TINEA INFECTIONS).

COMMON ANTIFUNGAL MEDICATIONS

ciclopirox	clioquinol
clotrimazole	fluconazole
flucytosine	griseofulvin
itraconazole	ketoconazole
miconazole	naftifine
nystatin	oxiconazole
terbinafine	tolnaftate

Topical antifungal preparations may cause irritation to the SKIN or mucous membranes, though this is uncommon. Systemic antifungal medications may interact with other medications and have possible side effects that vary with the DRUG. It is important to tell the doctor or pharmacist of all health conditions and medications taken to treat them, including OVER-THE-COUNTER (OTC) DRUGS and herbal products, to minimize the risk for ADVERSE REACTION and DRUG INTERACTION.

See also ANTIBIOTIC MEDICATIONS; ANTIVIRAL MEDICATIONS; FUNGUS; INFECTION.

antiviral medications Medications to shorten the course and lessen the severity of illness due to viral INFECTION as well as reduce viral shedding to minimize contagiousness. Some antiviral medications are able to prevent viral infection from developing after exposure to the VIRUS. Antiviral medications mark a fine line because they must destroy viruses without damaging the cells that host them. Most antiviral medications accomplish such a task by substituting inactive molecules for key enzyme molecules in the virus's efforts to replicate.

Antiviral medications are the mainstay of therapy for HIV/AIDS. Doctors also use antiviral medications to treat viral infections such as CHICKENPOX, HERPES SIMPLEX, HERPES ZOSTER (shingles), GENITAL HERPES, INFLUENZA, and chronic HEPATITIS B. Antiviral medications have numerous and sometimes serious side effects that vary with the medication. It is important for the doctor to know all medications a person takes, including OVER-THE-COUNTER (OTC) DRUGS and herbal remedies, to minimize the risk for ADVERSE REACTION and DRUG INTERACTION.

COMMON ANTIVIRAL MEDICATIONS

acyclovir	adefovir
alpha-interferon	amantadine
famciclovir	foscarnet
lamivudine	oseltamivir
penciclovir	ribavirin
rimantadine	valacyclovir
zanamivir	

See also PREVENTIVE HEALTH CARE AND IMMUNIZATION; VACCINE.

anthrax An illness resulting from INFECTION with the bacterium *Bacillus anthracis*. Anthrax is a naturally occurring infection among wild and domestic livestock (such as cows, sheep, goats, and antelope). Anthrax is rare in people in the United States, though more common in people who live, work, or travel to countries where anthrax is more common in livestock. The BACTERIA can cause infection in people who are exposed to sick animals, such as workers on farms and in slaughterhouses. Ranchers and farmers in the United States vaccinate their livestock against anthrax. An anthrax VACCINE is also available for people.

Symptoms and Diagnostic Path

Symptoms of anthrax depend on the form of illness. Anthrax in people can take three forms:

- Cutaneous anthrax, which accounts for 95 percent of human anthrax infections, results when *B. anthracis* enters an opening in the SKIN, such as a small scratch, and causes ulcerated sores on the skin. It is highly treatable with ANTIBIOTIC MEDICATIONS and nearly everyone who receives

antibiotic therapy recovers without complications.

- Inhalation anthrax results when a person breathes *B. anthracis* into the LUNGS, where the infection causes life-threatening PNEUMONIA. Inhalation anthrax requires urgent intravenous antibiotic therapy and intensive medical care. It is difficult to avoid respiratory collapse and cardiovascular shock, which are often fatal.
- Gastrointestinal anthrax results from eating meat contaminated with *B. anthracis*. It causes NAUSEA, VOMITING (often bloody), FEVER, ABDOMINAL PAIN, and profuse DIARRHEA. Many people recover, but the illness can be life threatening.

The diagnostic path includes a comprehensive history of potential exposure to livestock or livestock products and BLOOD tests to identify the presence of characteristic antibodies. The doctor may also culture body fluids to look for *B. anthracis*.

Treatment Options and Outlook

Antibiotic therapy is the mainstay of treatment for all forms of anthrax. The earlier treatment begins, the more effective it is. Untreated anthrax in any form can be serious or fatal. A person who has anthrax cannot spread the infection to others, though health-care providers follow diligent infection control protocols when treating people who have anthrax.

ANTIBIOTIC MEDICATIONS TO TREAT ANTHRAX	
ciprofloxacin	doxycycline
levofloxacin	penicillin

Risk Factors and Preventive Measures

Exposure to potentially contaminated livestock or livestock products (meat, hides, fur) is the primary risk for naturally acquired anthrax. A vaccine to prevent anthrax is available; however, current guidelines recommend its administration only to people at high risk for exposure to *B. anthracis* or after suspected exposure to *B. anthracis*. Multiple doses over 18 months, with annual boosters, are required to establish and maintain IMMUNITY.

In the late 1990s anthrax emerged as a worldwide bioterrorism threat, with concern for the possibility of widespread infection after intentional contamination of the US mail with *B. anthracis* caused two dozen Americans to become ill with anthrax, five of whom died from the inhalation form. At present public health experts recommend the vaccine in combination with antibiotic therapy to prevent illness in people exposed to *B. anthracis*.

See also ANTIBODY; FOODBORNE ILLNESSES; SMALLPOX.

B

babesiosis An illness that results from INFECTION with the parasitic protozoan *Babesia microti*. Most people who have babesiosis do not have symptoms; the infection causes illness primarily in people who are IMMUNOCOMPROMISED or who have had SPLENECTOMY (surgical removal of the SPLEEN). The bite of the *Ixodes* tick, found in the northeastern United States, is the mode of transmission. Babesiosis is rare in other parts of the United States.

B. microti infects the erythrocytes (red BLOOD cells), causing alterations in their cell membranes that affect their ability to carry oxygen. Hemolytic ANEMIA is a key consequence of babesiosis. Symptoms may include FEVER, COUGH, and shortness of breath (DYSPNEA). The doctor uses blood tests to diagnose babesiosis. The tests show the damage to the erythrocytes and the presence of antibodies. Treatment with ANTIBIOTIC MEDICATIONS cures the infection. Rarely, a person may develop the life-threatening complication ACUTE RESPIRATORY DISTRESS SYNDROME (ARDS).

ANTIBIOTIC MEDICATIONS TO TREAT BABESIOSIS

atovaquone	azithromycin
clindamycin	quinine sulfate

See also ANTIBODY; ERYTHROCYTE; GIARDIASIS; LYME DISEASE; PROTOZOA.

bacteria Single-cell microorganisms (microbes). Bacteria are the most ancient and primitive life forms known, with fossils dating back more than 3 billion years. A bacterium's structure is very simple, consisting of a rigid cell wall that supports and contains the cytoplasm, fragments of RNA, and a single strand of DNA within a nonencapsulated (unbordered) nucleus. Though bacteria are capable of independent existence, most require a symbiotic relationship with a host organism. The bacteria provide needed functions for the host in exchange for NUTRIENTS and safe haven.

Many types of bacteria exist in and on the body in just such a symbiotic partnership; these are part of the body's NORMAL FLORA. Bacteria in the gastrointestinal tract digest food, for example. *Bifidobacterium bifidum, Lactobacillus acidophilus,* and *Saccaromyces boulardii* are some of the more abundant bacterial families that reside in the small intestine. However, when normal flora bacteria are able to establish themselves in tissues other than their natural habitat or their numbers become abundant, they cause INFECTION. *Escherichia coli*, for example, are abundant normal flora in the COLON, where they work to prepare the residue of digestion for elimination from the body. *E. coli* also synthesize VITAMIN K, which is essential for COAGULATION (BLOOD clotting). When *E. coli* escape from their habitat, however, they cause infections such as VAGINITIS or URINARY TRACT INFECTION (UTI).

THE "BAD" *E. COLI*: O157:H7

The bacterial family *Escherichia coli* is extensive and ubiquitous—its many strains live in the gastrointestinal systems of nearly all animals. *E. coli* O157:H7, NORMAL FLORA in cattle, is a family member of great notoriety for the potential of severe illness it presents in people. The toxin this strain releases can destroy red BLOOD cells in such volume that the KIDNEYS fail, a condition called HEMOLYTIC UREMIC SYNDROME. *E. coli* O157:H7 enters the human food chain as a foodborne illness.

Bacteria that cause infection are pathogens. Most pathogenic bacteria exist in the natural envi-

ronment, they are harmful to human health, and the IMMUNE SYSTEM establishes mechanisms to stop, contain, or attack them should they enter the body. Bacteria can cause infection and illness by destroying the cells they invade or by releasing toxins. ANTIBIOTIC MEDICATIONS treat bacterial infections.

Traditional classification systems view bacteria according to their physical (morphologic) characteristics because these are the traits perceptible with the use of a microscope, the first tool available for viewing microbes. These characteristics provide basic information about the particular bacterial family that is important to doctors when choosing antibiotic medications to treat bacterial infections. Methods made available through advances in molecular medicine during the latter years of the 20th century, such as ribosomal analysis and DNA sequencing, allow improved understanding of how bacteria function both to support health and to cause illness.

ILLNESSES CAUSED BY BACTERIAL INFECTION

ABSCESS	ANTHRAX
APPENDICITIS	bacterial MENINGITIS
BOTULISM	CAMPYLOBACTERIOSIS
CHLAMYDIA	CHOLERA
COLD SORE	CONJUNCTIVITIS
DIPHTHERIA	EPIGLOTTITIS
FOLLICULITIS	FURUNCLE
GONORRHEA	HERPES ZOSTER
INFECTIOUS ARTHRITIS	LEGIONNAIRES' DISEASE
LISTERIOSIS	LYME DISEASE
MASTOIDITIS	NECROTIZING FASCIITIS
ORBITAL CELLULITIS	OSTEOMYELITIS
PERICARDITIS	PERITONSILLAR ABSCESS
PNEUMOCOCCAL PNEUMONIA	RHEUMATIC HEART DISEASE
ROCKY MOUNTAIN SPOTTED FEVER	SCARLET FEVER
SEPTICEMIA	STAPHYLOCOCCAL SCALDED SKIN SYNDROME
STREP THROAT	
SYPHILIS	TUBERCULOSIS
TYPHOID FEVER	

See also CELL STRUCTURE AND FUNCTION; CHILDHOOD DISEASES; *ESCHERICHIA COLI* INFECTION; NUTRITIONAL THERAPY; PATHOGEN.

botulism A potentially life-threatening illness resulting from INFECTION with the anaerobic bacterium *Clostridium botulinum*. The BACTERIA are naturally present in soil, where they encase themselves in spores. In the body, the bacteria release a toxin that blocks the release of acetylcholine, a NEUROTRANSMITTER that facilitates NERVE impulses from neurons to MUSCLE cells, causing PARALYSIS that may range in severity from mild to life-threatening. There are three types of botulism:

- Foodborne botulism results from eating improperly canned or cooked foods contaminated with *C. botulinum* spores. Because the bacteria are anaerobic, they thrive in the relatively oxygen-free environment of canned, bottled, or otherwise contained foods. Foodborne botulism most commonly causes gastrointestinal symptoms such as abdominal cramping and DIARRHEA, though can cause systemic symptoms that may include paralysis of the chest muscles.
- Wound botulism develops in traumatic injury wounds that close over after the injury, trapping bacteria within them. Usually the injury involves some sort of contact with soil. This type of botulism can result in the infection commonly called gas GANGRENE. Often treatment requires surgery to open and clean the wound, removing damaged and dead tissue, along with administration of intravenous ANTIBIOTIC MEDICATIONS.
- Infant botulism occurs in children under age one year whose gastrointestinal tracts are not fully developed. The most common source of *C. botulinum* that causes infant botulism is unpasteurized honey. In an older child or adult the NORMAL FLORA and environment of the gastrointestinal tract would neutralize the few *C. botulinum* spores honey typically contains, but the infant's system lacks the maturity to do this.

Symptoms and Diagnostic Path

Symptoms begin 2 to 10 days after exposure. Early neurologic symptoms include vision disturbances, difficulty swallowing and speaking, and drooping eyelids (PTOSIS). As the infection progresses, paralysis may develop throughout the body. In foodborne botulism symptoms also include NAUSEA, VOMITING, and diarrhea. In wound botulism, there may also be PAIN and swelling at the wound site though usually the wound appears normal.

The diagnostic path includes a comprehensive NEUROLOGIC EXAMINATION and testing for the presence of *C. botulinum* in either a stool sample or sample of the suspected food source.

Treatment Options and Outlook

Treatment in older children and adults is hospitalization and prompt administration of trivalent ABE ANTITOXIN to counter the effects of the toxin the *C. botulinum* bacteria produce. Additional treatment for wound botulism is intravenous antibiotics, usually high doses of penicillin or clindamycin. Treatment for infant botulism is the antibiotic amoxicillin. With prompt and appropriate treatment many people fully recover from botulism, though some people have weakness, paralysis, or other neurologic symptoms.

Risk Factors and Preventive Measures

C. botulinum spores are present in soil and thus can contaminate vegetables and fruits. The risk for infection occurs with improperly canned or processed foods because the *C. botulinum* bacteria thrive and vastly multiply in the anaerobic environment. It is not possible to detect their presence by the appearance, smell, or taste of the contaminated food, though often the can or jar lid bulges. Home-canned foods are more commonly the source of foodborne botulism. Infants under one year should not eat honey or foods that contain honey, as unpasteurized honey is a common source of *C. botulinum* spores that are not a health risk to adults but can cause illness in infants. Wound botulism may develop even when the person takes antibiotics because the broad-spectrum antibiotics typically prescribed are not effective against *C. botulinum*. Diligent cleansing of injuries that have soil contamination reduces the risk for wound botulism.

See also ANTIBIOTIC MEDICATIONS; BOTULINUM THERAPY; FOODBORNE ILLNESSES; FOOD SAFETY; GUILLAIN-BARRÉ SYNDROME; NEURON; WATERBORNE ILLNESSES.

C

campylobacteriosis An illness that results from INFECTION with the bacterium *Campylobacter jejuni.* The BACTERIA are commonly present in domestic birds such as chickens and turkeys without causing illness in the birds; the typical source of infection in people is undercooked poultry (especially chicken) or cross-contamination that occurs from improper handling and preparation of poultry. Health experts estimate that half the chickens slaughtered for market in the United States carry *C. jejuni*, though proper handling prevents cross-contamination and thorough cooking kills the bacteria so it does not cause infection. It is not possible to tell whether *C. jejuni* contaminates raw chicken; appropriate FOOD SAFETY measures are essential when preparing any poultry or meat. Other animal-based foods may also be the source of *C. jejuni*, nobly unpasteurized milk. Campylobacteriosis is one of the most common FOODBORNE ILLNESSES.

Symptoms and Diagnostic Path

Symptoms develop two to five days after consuming contaminated food or water and include DIARRHEA, abdominal cramping, and FEVER. Some people also have NAUSEA and VOMITING. The diarrhea may be slightly bloody. Many people do not seek medical treatment because the infection is self-limiting and generally runs its course in a few days. The doctor can positively identify *C. jejuni* as the culprit through cultures of stool samples, though this is not usually necessary.

Treatment Options and Outlook

Campylobacteriosis is self-limiting, with symptoms ending within five days. Most people who develop campylobacteriosis require only supportive treatment such as increased fluid consumption to prevent DEHYDRATION until the diarrhea runs its course. The doctor may prescribe an antibiotic medication such as erythromycin when symptoms are severe or recur. Rare complications of campylobacteriosis include GUILLAIN-BARRÉ SYNDROME, an autoimmune disorder that causes neurologic symptoms, including MUSCLE weakness and PARALYSIS. Though Guillain-Barré syndrome is rare, health experts believe campylobacteriosis triggers about 40 percent of cases.

Risk Factors and Preventive Measures

Proper food handling, thoroughly cooking chicken and other poultry, and drinking pasteurized milk are highly effective measures for preventing campylobacteriosis. Preventive food safety measures include

- wash hands with warm water and soap after handling raw poultry and meat
- use separate utensils, cutting knives, and cutting surfaces for preparing poultry and meats
- wash food preparation surfaces, knives, and utensils with hot water and soap immediately after using them

See also HAND WASHING; WATERBORNE ILLNESSES.

candidiasis An illness resulting from INFECTION with fungi (also called yeasts) from the *Candida* family, most commonly *Candida albicans,* though other *Candida* species may also cause infection. Candidiasis, commonly called yeast infection (or THRUSH when it involves the MOUTH), affects the mucous membranes of the mouth, ESOPHAGUS, urinary tract, or VAGINA. *Candida* may also affect the perineal area, such as in DIAPER RASH.

Yeasts and bacteria are NORMAL FLORA (microorganisms present in health) that keep each other in

balance. They are vital for numerous body functions such as digestion. Candidiasis develops when there is a disturbance of the balance that allows *Candida* to flourish, such as a change in the acid balance (pH) of the tissues, suppression of normal flora bacteria with antibiotic therapy, compromised immune function, and excessive moisture. Candidiasis is the most common cause of ESOPHAGITIS, VAGINITIS in women, and diaper rash in infants.

Chronic candidiasis may indicate an underlying health condition such as DIABETES and is often the first sign of HIV INFECTION. A doctor should conduct a comprehensive health examination in people who have four or more episodes of candidiasis in a year.

Symptoms and Diagnostic Path

Symptoms of candidiasis vary with the site of infection. In the mouth there are white patches on the tongue and inner cheeks (oral mucosa). Candidal vaginitis produces a characteristic "cheesy" discharge and intense itching. Candidal diaper rash appears as red, fragile blotches or sores with white pustules. In candidal esophagitis the doctor can see characteristic ulcerations on endoscopic examination. Invasive candidiasis may present with FEVER along with indications of LIVER disease such as JAUNDICE, neurologic impairment when infection involves the CENTRAL NERVOUS SYSTEM, cardiovascular compromise with candidal ENDOCARDITIS (infection of the lining of the HEART), or RENAL FAILURE when infection involves the KIDNEYS.

The diagnostic path for superficial (oral, esophageal, perineal, or genital) candidiasis includes taking samples of the white patches or discharge for examination under the microscope, which reveals the presence of abundant *Candida* colonies. BLOOD cultures show *Candida* growth in invasive candidiasis.

Treatment Options and Outlook

Superficial candidiasis is common and easily treatable with ANTIFUNGAL MEDICATIONS. HEALING occurs without residual consequences, though infection may recur when conditions are favorable. Invasive or systemic candidiasis, which occurs when the *Candida* enter the blood circulation, is a very serious infection that requires treatment with intravenous antifungal medications. Invasive candidiasis can be life-threatening in IMMUNOCOMPROMISED people.

ANTIFUNGAL MEDICATIONS TO TREAT CANDIDIASIS

amphotericin-B	clotrimazole
econazole	fluconazole
flucytosine	ketoconazole
micafungin	miconazole
nystatin	

Risk Factors and Preventive Measures

DIABETES, long-term use of CORTICOSTEROID MEDICATIONS, antibiotic therapy, and HIV/AIDS are among the key risk factors for candidiasis. A normal course of ANTIBIOTIC MEDICATIONS prescribed to treat bacterial infection may cause candidal vaginitis; women who are susceptible to vaginal candidiasis should discuss prophylactic antifungal therapy with their doctors. Preventive measures for candidal diaper rash, a consequence of both pH change (from URINE contact with the SKIN) and excessive moisture, include frequent diaper changes and application of protective cream or ointment to keep the perineal area clean and dry.

See also ENDOSCOPY; FUNGUS; OPPORTUNISTIC INFECTION; TINEA INFECTIONS.

carrier A person who has a bacterial or viral INFECTION but does not show symptoms or become ill because of the infection and yet can pass the infection on to other people. A third of people who have infectious HEPATITIS are carriers, for example. In some circumstances treating the infection eliminates it so the person cannot pass the infection to others. In other circumstances, such as hepatitis B VIRUS (HBV) infection, there is no effective treatment and the person is capable for life of transmitting the infection.

See also BACTERIA; GENETIC CARRIER; MODES OF TRANSMISSION; PARASITE.

chickenpox A common childhood illness that results from INFECTION with the varicella-zoster VIRUS, a member of the herpesvirus family. Chickenpox, also called varicella disease, is highly contagious, spreading through direct contact and

exposure to airborne droplets containing the varicella-zoster virus. The INCUBATION PERIOD (time from exposure to illness) is 10 to 21 days.

Symptoms and Diagnostic Path

The first symptoms are general and include FEVER, HEADACHE, loss of APPETITE, and sometimes NAUSEA and VOMITING. Within two days the characteristic pox emerge. These fluid-filled blisters cover the body and sometimes even occur within the MOUTH, on the surface and sometimes the inside of the eyelids, and in the VAGINA. The blisters itch intensely. In two or three days the fluid within the blisters oozes out and a crust forms, after which the itching subsides. However, new batches of blisters may continue to emerge in clusters for three to five days after the first outbreak.

Diagnosis is straightforward as the pox are characteristic and the illness is so highly contagious that it affects large numbers of people. Many health-care providers do not want to see people who are likely to have chickenpox because of the contagiousness and because treatment is supportive, not therapeutic. The person is contagious from two days before the onset of symptoms until all the pox crust over.

Treatment Options and Outlook

Most people do not require treatment other than supportive care to improve comfort. Such care may include

- calamine lotion applied to the blisters to relieve itching
- oral ANTIHISTAMINE MEDICATION to relieve itching
- acetaminophen or NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) such as ibuprofen to relieve headache, fever, and general discomfort
- tepid baths with oatmeal in the water to relieve itching

Isolation is important until all the pox have blistered. Schools may require children to remain home until the crusts are no longer apparent. Most people recover and are able to return to normal activities within 7 to10 days. The pox heal without scarring unless they become infected, which may happen with excessive scratching.

Do not give aspirin to anyone who has chickenpox, as doing so creates the risk for developing REYE'S SYNDROME. Reye's syndrome is a serious neurologic condition that can be fatal.

ANTIVIRAL MEDICATIONS can significantly lessen the severity and length of illness when taken within 24 hours of the first pox. However, doctors typically reserve antiviral medications for people at risk for severe illness—infants under one year of age, pregnant women, and people who are IMMUNOCOMPROMISED—because the normal course of illness is short and has very low risk for significant complications. The most common complication of chickenpox is bacterial infection of the pox that results from scratching, which introduces BACTERIA into the blisters. Complications that are rare though possible include ENCEPHALITIS, PNEUMONIA, and REYE'S SYNDROME.

The varicella-zoster virus remains in the body after the illness of chickenpox runs its course, retreating to the NERVE roots where it apparently enters a stage of dormancy. In 90 percent of people the virus never re-emerges; however, in about 10 percent of people the virus causes HERPES ZOSTER (shingles) years to decades after chickenpox.

Risk Factors and Preventive Measures

Exposure to the varicella-zoster virus is the only risk factor for chickenpox. It is very difficult to avoid exposure because the MODES OF TRANSMISSION are multiple. As well, the extremely contagious nature of the infection coupled with the extended incubation period means exposure often occurs before people realize they are ill; outbreaks of chickenpox are typically widespread. A VACCINE for chickenpox is part of the routine IMMUNIZATION schedule for children in the United States. The vaccine prevents chickenpox in about 85 percent of people who receive it and significantly reduces the severity and length of illness in those who acquire the infection.

See also BLISTER; CHILDHOOD DISEASES; MEASLES; MUMPS; OCULAR HERPES ZOSTER; PREVENTIVE HEALTH CARE AND IMMUNIZATION; RUBELLA; SNEEZE/COUGH ETIQUETTE.

chlamydia Illness resulting from INFECTION with the bacterium *Chlamydia trachomatis*. Chlamydia is one of the most common SEXUALLY TRANSMITTED DISEASES (STDS) in the United States, infecting an estimated three million people each year. However, fewer than a third seek treatment because their symptoms are mild or they do not have symptoms and do not know they have chlamydia. Half of men and two thirds of women who have chlamydia experience no symptoms, though they nonetheless pass the infection to their sex partners. Doctors sometimes call chlamydia the "silent STD" for this reason. A woman may also transmit chlamydia to her infant during vaginal childbirth.

Symptoms and Diagnostic Path

When symptoms are present, they generally appear within three weeks of exposure. Men may experience a discharge from the PENIS and PAIN with URINATION. Women may experience vaginal discharge and burning with urination in the early stages of infection, and later may have pelvic pain, low BACK PAIN, discomfort or pain with SEXUAL INTERCOURSE, and vaginal bleeding between periods.

The diagnostic path includes a physical examination (with PELVIC EXAMINATION for women) and laboratory testing of discharge samples to detect the presence of *C. trachomatis* bacteria. Because chlamydia often does not cause symptoms, diagnosis may occur as a consequence of ROUTINE MEDICAL EXAMINATION.

Treatment Options and Outlook

Treatment is with oral (by MOUTH) ANTIBIOTIC MEDICATIONS. It is important for sex partners to also receive treatment because when they do not, reinfection will occur. Appropriate antibiotic therapy eliminates the infection. People who receive treatment recover fully. However, scarring and other damage that occurs because of long-term infection in a woman is typically permanent, and can result in INFERTILITY.

Untreated chlamydia has significant consequences for women, about half of whom develop PELVIC INFLAMMATORY DISEASE (PID). PID is a leading cause of ECTOPIC PREGNANCY and of infertility. The infection damages and scars tissue in the FALLOPIAN TUBES, blocking the pathway by which OVA (eggs) travel from the OVARIES to the UTERUS. Scarring may also affect the uterus, preventing implantation in the earliest stages of PREGNANCY. Untreated chlamydia increases a woman's risk for HIV infection.

ANTIBIOTIC MEDICATIONS TO TREAT CHLAMYDIA

amoxicillin	azithromycin
doxycycline	erythromycin
levofloxacin	ofloxacin

Risk Factors and Preventive Measures

Nearly all chlamydia infections in adults occur as a result of vaginal, oral, or anal sex with someone who has the infection. Women in particular often are reinfected after they receive treatment but their sex partners do not. Infants may acquire chlamydia from their mothers during birth and may develop chlamydial CONJUNCTIVITIS (infection of the tissues around the eyes) or PNEUMONIA. Safer sex practices, such as monogamous relationships and condom use, are the most effective measures for preventing chlamydia. Health experts recommend annual chlamydia screening for sexually active women who are under age 25 or have multiple sex partners.

See also GENITAL HERPES; GONORRHEA; HUMAN PAPILLOMAVIRUS (HPV); REITER'S SYNDROME; SCAR; SEXUAL HEALTH; SEXUALLY TRANSMITTED DISEASE (STD) PREVENTION; SYPHILIS.

cholera An illness resulting from INFECTION with the bacterium *Vibrio cholerae*. The BACTERIA release a toxin in the SMALL INTESTINE that disrupts the electrolyte balance, drawing vast amounts of water into the small intestine and causing sudden, profuse DIARRHEA. The diarrhea in turn causes severe DEHYDRATION. The incubation period (time from exposure to illness) is a few hours to a few days.

Cholera nearly always occurs in conditions of poor sanitation and is endemic (constantly present) in many areas of the world where community sanitation is chronically substandard. Infection results from drinking water contaminated with *V. cholerae*, eating raw shellfish harvested from contaminated water, or eating uncooked foods rinsed with contaminated water.

BLOOD TYPE AND CHOLERA SUSCEPTIBILITY

For reasons researchers do not understand, people who have BLOOD TYPE O have twice the likelihood of contracting cholera than others, and people who have blood type AB seldom become infected.

Though the profuse, watery diarrhea of cholera has a characteristic appearance and smell, the doctor may perform a stool culture to confirm the diagnosis. Treatment is oral rehydration solution (ORS) to replace the massive loss of fluid that occurs with the diarrhea, which can exceed a quart an hour. Doctors may prescribe tetracycline to shorten the course of illness when symptoms are especially severe, though most people recover with appropriate rehydration.

Cholera is rare in the United States, though people who travel to parts of the world where cholera is endemic are at risk for infection. Preventive measures include frequent HAND WASHING; drinking only bottled beverages or water purified through boiling, chlorination, or iodinization; and avoiding raw foods.

See also DRINKING WATER STANDARDS; WATERBORNE ILLNESSES.

coccidioidomycosis An illness resulting from INFECTION with the spores of the fungus *Coccidioides immitis*, which occurs naturally in the soil in desert environments, inhaled into the LUNGS. Coccidioidomycosis affects the respiratory tract, primarily the lungs. About half of people infected with *C. immitis* do not become ill. The IMMUNE SYSTEM can successfully neutralize small numbers of *C. immitis* spores before they cause illness, though the person will test positive for infection. Exposure to high numbers of spores is more likely to result in illness. Among those who develop symptoms of coccidioidomycosis, commonly called valley FEVER, illness may be acute, chronic, or disseminated. In people who are IMMUNOCOMPROMISED, coccidioid omycosis may occur as an OPPORTUNISTIC INFECTION.

Symptoms and Diagnostic Path

The most common form of coccidioidomycosis is acute, in which symptoms develop within four weeks of exposure. Symptoms include

- nonproductive (dry) COUGH and CHEST PAIN
- FEVER
- fatigue
- chills and night sweats
- diminished APPETITE and weight loss
- HEADACHE
- MUSCLE and JOINT PAIN
- RASH
- LYMPHADENOPATHY (swollen LYMPH nodes)

The diagnostic path includes chest X-RAY and coccidioidin SKIN test. The skin test is positive 21 days after exposure. BLOOD tests may also show elevated antibodies.

Treatment Options and Outlook

Though the infection is self-limiting and resolves within three to six months without treatment in most people, doctors often prescribe ANTIFUNGAL MEDICATIONS to eradicate the infection more quickly and reduce the likelihood for complications, which may include MENINGITIS. Most people recover without residual effects. Some people develop chronic infection, in which symptoms recur. About 1 percent of people develop disseminated disease (also called progressive), in which the infection enters the blood circulation and travels to other structures and organs. Extended, sometimes lifelong, treatment with antifungal medications is required for chronic and disseminated coccidioidomycosis. People who are immunocompromised, take IMMUNOSUPPRESSIVE THERAPY, or are of Filipino or African American heritage have especially high risk for disseminated disease.

ANTIFUNGAL MEDICATIONS TO TREAT COCCIDIOIDOMYCOSIS

amphotericin B	fluconazole
itraconazole	ketoconazole

Risk Factors and Preventive Measures

The primary risk factor for coccidioidomycosis is exposure to soil, especially dust, containing *C. immitis* spores. Public health officials often note spikes in reported infections after desert dust storms. Farm and ranch workers, construction workers, and archaeologists have increased risk

for infection through continued exposure to soil and dust.

See also ASTHMA; BRONCHITIS; HISTOPLASMOSIS; PLEURAL EFFUSION; PNEUMONIA.

colds Common illnesses resulting from INFECTION with one of more than 200 variations of rhinovirus, a family of highly contagious viruses that infiltrate the nasal mucosa (mucous membranes that line the inside of the NOSE and the SINUSES). Because so many variations of rhinovirus can cause colds, most people get several colds a year. Children may get 8 to 10 colds in a year; adults may get half as many. Colds are the most common viral infections.

Symptoms and Diagnostic Path

The characteristic symptoms of a cold affect the nose and sinuses and represent the IMMUNE SYSTEM's efforts to rid the body of the VIRUS rather than the actions of the virus itself. Symptoms of a cold include

- runny nose (rhinitis) and sinus congestion
- sneezing
- yellowish green nasal discharge

Some people develop sore THROAT (PHARYNGITIS) and COUGH as a consequence of postnasal drip, and the sinus congestion often causes HEADACHE. Colds do not typically cause FEVER or MUSCLE aches; these and other more extensive symptoms suggest a different viral infection such as INFLUENZA (the flu). In children, EAR infections (OTITIS media) may occur as a secondary illness because the congestion clogs the eustachian tubes, causing fluid to accumulate in the middle ear.

Treatment Options and Outlook

Colds are self-limiting, generally running their course in five to seven days. Treatment is supportive, targeting relief of symptoms. Many over-the-counter (OTC) cold products contain decongestant medications, cough suppressants, ANALGESIC MEDICATIONS, and sometimes ANTIHISTAMINE MEDICATIONS. Drinking plenty of fluids is important to help loosen nasal secretions, particularly when taking decongestant medications that dry out the mucous membranes. Chicken soup, a time-honored folk remedy, may boost the immune system's efforts to fight the infective VIRUS. ANTIBIOTIC MEDICATIONS are *not* effective in treating viral infections. Doctors may prescribe ANTIVIRAL MEDICATIONS to people at risk for complications, generally those who are IMMUNOCOMPROMISED. Antiviral medications can shorten the course of the cold. Complications that may develop include BRONCHITIS and PNEUMONIA, both of which can have serious health consequences for people who lack a strong IMMUNE RESPONSE.

Risk Factors and Preventive Measures

Rhinoviruses are ever present. They tend to cause infection (colds) during times when people are together indoors for extended periods of time—winter. The rhinovirus particles travel through the air and attach themselves to surfaces such as doorknobs. The most effective measure for preventing colds is diligent HAND WASHING. Minimizing exposure to large crowds of people (such as in shopping malls, theaters, and restaurants) lowers the risk for exposure to viruses that cause colds. There is some evidence that the herbal product ECHINACEA can prevent or lessen the severity of colds. Zinc supplements boost immune function, helping the body resist infection with rhinoviruses.

See also ALLERGIC RHINITIS; EUSTACHIAN TUBE; SNEEZE/COUGH ETIQUETTE.

cryptococcosis An illness that results from INFECTION with the FUNGUS *Cryptococcus neoformans*, which is abundant in soil worldwide. Cryptococcosis may affect the MENINGES (membranes covering the BRAIN and SPINAL CORD), the LUNGS, or the SKIN. Infection is most likely in people who are IMMUNOCOMPROMISED and is a particular risk in those who have HIV/AIDS, Hodgkin's lymphoma, or SARCOIDOSIS. Though typically a mild and self-limiting illness, cryptococcosis disseminate (become widespread throughout the body).

Most people have mild, generalized symptoms of illness such as HEADACHE, muscle aches, COUGH, and chest tightness. Significant exposure to *C. neoformans* or compromised immune function causes more severe symptoms. Culture of body fluid samples provides definitive diagnosis. Mild cryptococcosis does not require treatment and most people recover without complications. Doctors prescribe

ANTIFUNGAL MEDICATIONS to treat severe symptoms or cryptococcosis in people who are immunocompromised (including those who have HIV/AIDS); long-term treatment may be necessary.

ANTIFUNGAL MEDICATIONS TO TREAT CRYPTOCOCCOSIS		
amphotericin B	fluconazole	flucytosine

See also CANDIDIASIS; COCCIDIOIDOMYCOSIS; CRYPTOSPORIDIOSIS; OPPORTUNISTIC INFECTION.

cryptosporidiosis An illness that results from INFECTION with the PARASITE *Cryptosporidium parvum,* which lives in the gastrointestinal tract of numerous animals and passes into the environment, primarily bodies of fresh water such as rivers and lakes, through the feces. The parasites form cysts that are highly resistant even to chemical disinfectants such as chlorine.

People acquire infection with *C. parvum* through drinking or unintentionally swallowing (such as when swimming) contaminated water. The parasites may also be present in foods rinsed or prepared with contaminated water. The INCUBATION PERIOD is 2 to 10 days and the illness lasts about 2 weeks. During the incubation period and when symptoms are present, the infection is contagious and the person may pass it to others. Proper HAND WASHING and other PERSONAL HYGIENE measures are essential to reduce this risk.

The primary symptom of cryptosporidiosis is profuse, watery DIARRHEA. In addition to the diarrhea, many people have abdominal cramping and low-grade FEVER. Treatment is supportive, emphasizing fluid replacement to prevent DEHYDRATION due to the diarrhea. People who are IMMUNOCOMPROMISED may require hospitalization for adequate fluid replacement and medical management of the diarrhea. Most otherwise healthy people fully recover after the infection runs its course.

See also AMEBIASIS; CYCLOSPORIASIS; DRINKING WATER STANDARDS; FOODBORNE ILLNESSES; GIARDIASIS; OPPORTUNISTIC INFECTION; WATERBORNE ILLNESSES.

cyclosporiasis An illness that results from INFECTION with the PARASITE *Cyclospora cayetanensis.* The *Cyclospora* come to maturity in warm, moist environments after excretion in the feces of people who have the infection. This parasite, unlike most, cannot cause immediate infection so people who are infected are not contagious. People acquire infection with *Cyclospora* through eating foods or drinking water contaminated with the parasites. The *Cyclospora* infect the SMALL INTESTINE, causing abdominal cramping and watery DIARRHEA. Some people also have low-grade FEVER and generalized discomfort.

The incubation period (time from infection to illness) is five to seven days. Diagnosis is through laboratory examination of stool samples, which reveals the *Cyclospora* cysts. Treatment is a course of therapy with ANTIBIOTIC MEDICATIONS, usually the combination antibiotic drug trimethoprim-sulfamethoxazole (TMP-SMZ), along with diligent rehydration. Most people recover rapidly and completely with treatment. Without treatment, relapses of symptoms are common and can continue over a period of several months before full recovery occurs.

See also COCCIDIOIDOMYCOSIS; CRYPTOCOCCOSIS; CRYPTOSPORIDIOSIS; FOODBORNE ILLNESSES; FOOD SAFETY; OPPORTUNISTIC INFECTION; WATERBORNE ILLNESSES.

cytomegalovirus (CMV) A member of the herpesvirus family, also called human herpesvirus-5 (HHV-5). Like other herpesviruses, CMV is ubiquitous throughout the world—85 percent of Americans have CMV INFECTION by age 40. However, CMV infection primarily causes illness only in people who are IMMUNOCOMPROMISED, such as people who have HIV/AIDS or who take long-term IMMUNOSUPPRESSIVE THERAPY after ORGAN TRANSPLANTATION. CMV is also a significant risk for the unborn child of a woman whose initial infection with the VIRUS occurs during PREGNANCY. CMV virus crosses the PLACENTA to the fetus, causing congenital CMV infection. Most infants are born unharmed; however, CMV infection can affect hearing, vision, and intellectual capacity.

When CMV infection causes illness, symptoms typically include NAUSEA, VOMITING, DIARRHEA, JAUNDICE, and FEVER. The person often has an enlarged and tender LIVER (HEPATOMEGALY) and SPLEEN (SPLENOMEGALY). Doctors may suspect infectious mononucleosis or HEPATITIS, though tests for these conditions come back negative. A BLOOD test can

detect the presence of CMV antibodies to confirm the diagnosis of CMV infection. Though most people recover without complications, CMV infection can be serious or fatal in people who are immunocompromised. ANTIVIRAL MEDICATIONS are not very effective in treating the infection; treatment primarily targets symptoms.

See also ANTIBODY; EPSTEIN-BARR VIRUS; HERPES SIMPLEX; HERPES ZOSTER; MONONUCLEOSIS, INFECTIOUS; OPPORTUNISTIC INFECTION.

D–E

diphtheria An illness that results from INFECTION with the bacterium *Corynebacterium diphtheriae*. Routine childhood IMMUNIZATION has made diphtheria rare in the United States, though the infection can occur in people who do not receive a booster VACCINE every 10 years and is common in other parts of the world.

Infection may involve the NOSE and THROAT (respiratory diphtheria) or the SKIN (cutaneous diphtheria). *C. diphtheriae* BACTERIA that infect the throat produce a toxin that causes a thick layer of cells and mucus to accumulate in the throat, forming a membrane that impairs BREATHING. Respiratory diphtheria is life threatening and requires urgent administration of diphtheria ANTITOXIN, which counters the toxin the *C. diphtheriae* bacteria produce, in combination with ANTIBIOTIC MEDICATIONS to kill the *C. diphtheriae* bacteria (typically erythromycin or penicillin G). Diphtheria that occurs in the United States is most often cutaneous. Cutaneous diphtheria causes painful, red sores on the skin. Antibiotic therapy is often adequate to treat the infection, though sometimes doctors also administer diphtheria antitoxin.

The INCUBATION PERIOD for either type of diphtheria is two to five days after exposure. The infection is contagious for up to two weeks after symptoms emerge. The course of uncomplicated illness is four to six weeks. Respiratory diphtheria (especially when untreated) may result in complications that include MYOCARDITIS (INFLAMMATION and infection of the HEART MUSCLE), NEURITIS, RESPIRATORY FAILURE, and death. Childhood immunization with booster vaccines every 10 years is the most effective means of prevention. Some people are carriers of *C. diphtheriae* bacteria, which requires human hosts for survival. Carriers have the infection present in their bodies but do not become ill, though they can pass the infection to others. ANTIBIOTIC PROPHYLAXIS prevents infection in people who are exposed to *C. diphtheriae*.

See also CHILDHOOD DISEASES; PREVENTIVE HEALTH CARE AND IMMUNIZATION.

encephalitis INFLAMMATION and INFECTION of the BRAIN. Encephalitis usually results from infection with a VIRUS and is potentially life threatening. Infection can enter the brain via pathogens that are small enough to pass across the BLOOD–BRAIN BARRIER or that are able to follow neural pathways (the routes of nerves) into the brain. The most common cause of encephalitis is infection with an arbovirus transmitted through the bite of a mosquito or tick. Other viruses that typically cause common infections may affect the brain to cause encephalitis, and encephalitis may develop as a complication of viral infection (and less commonly bacterial infection) elsewhere in the body. TOXOPLASMOSIS, a parasitic infection, may also cause encephalitis.

VIRUSES THAT CAN CAUSE ENCEPHALITIS

CYTOMEGALOVIRUS (CMV)	California VIRUS
eastern equine virus	EPSTEIN-BARR VIRUS
HERPES SIMPLEX virus (HSV)	LaCrosse virus
MUMPS virus	Powassan virus
RUBELLA virus	rubeola (MEASLES) virus
St. Louis virus	varicella zoster viruses
West Nile virus	western equine virus

Symptoms and Diagnostic Path

The symptoms of encephalitis differ somewhat in children and in adults. Children often become lethargic, confused, irritable, and sensitive to light;

older children may complain of severe HEADACHE. Adults often exhibit changes in mental alertness, cognitive ability, and emotional stability and may have severe headache. Both children and adults may have seizures, FEVER, NAUSEA, and VOMITING.

Diminished awareness or loss of consciousness that accompanies or follows other symptoms of encephalitis is an indication of serious INFECTION that requires urgent medical attention.

The diagnostic path includes LUMBAR PUNCTURE to determine the presence of pathogens or white BLOOD cells, or excessive fluid or increased pressure in the spinal column, any of which may indicate infection. Blood tests may show the presence of certain viruses. Diagnostic procedures such as electroencephalogram (EEG) and COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) can show abnormalities of brain function and structure that are characteristic of encephalitis.

Treatment Options and Outlook

Mild viral encephalitis generally runs its course within five to seven days and does not require treatment beyond ANALGESIC MEDICATIONS such as acetaminophen to relieve fever and headache. ANTIVIRAL MEDICATIONS can reduce the severity of symptoms and length of illness for some forms of viral encephalitis, notably those resulting from viruses in the herpes family, though have no effect against encephalitis resulting from arboviruses. CORTICOSTEROID MEDICATIONS to suppress the inflammatory response can reduce intracranial swelling and pressure that commonly accompanies encephalitis. Bacterial encephalitis, which is much less common than viral encephalitis and usually a secondary infection, requires treatment with antibiotic medications. Antibiotics are not effective against viral infections.

Recovery depends on the severity of symptoms and the causative PATHOGEN. Though viral encephalitis is generally more mild than bacterial encephalitis, it can be fatal, particularly in infants, the very elderly, and people who are IMMUNOCOMPROMISED. People who have mild encephalitis recover completely and without residual complications. More severe illness may result in permanent brain damage and corresponding cognitive dysfunction, memory impairment, LEARNING DISORDERS, PARALYSIS, SEIZURE DISORDERS, or speech disorders.

Risk Factors and Preventive Measures

The risk for viral encephalitis is greatest during times of the year when mosquito and tick activity is highest, typically May through October in most parts of the United States. Other risks include living in close contact, such as in dormitories and institutions, and infection elsewhere in the body that migrates to the brain. Prevention efforts include public health measures to control mosquito populations and individual efforts to minimize exposure to mosquitoes and ticks.

See also COGNITIVE FUNCTION AND DYSFUNCTION; MEMORY AND MEMORY IMPAIRMENT; MENINGITIS.

Epstein-Barr virus A member of the herpesvirus family best known for causing the illness infectious mononucleosis. INFECTION with the Epstein-Barr VIRUS, also called human herpesvirus-4 (HHV-4), causes other disease as well and was the first virus researchers linked with cancer (notably Burkitt's lymphoma). Epstein-Barr virus is ubiquitous; it infects more than 90 percent of Americans by age 25.

As is characteristic of herpesvirus infections, Epstein-Barr virus causes first an acute illness (infectious mononucleosis), then retreats into a state of dormancy and remains in the body as a latent infection that does not cause illness or symptoms. B-cell lymphocytes, white BLOOD cells key to ANTIBODY-MEDIATED IMMUNITY, harbor the latent Epstein-Barr virus. Though the virus does not change the ability of its host B-cell lymphocytes to function within the IMMUNE RESPONSE, it does alter their DNA such that they become immortalized—they lose their genetic encoding for APOPTOSIS, the natural process for cell death.

Only a small percentage of B-cell lymphocytes contain the virus, so for the most part immune function continues as normal. A healthy IMMUNE SYSTEM maintains a balance between B-cell lymphocytes and T-cell lymphocytes (white blood cells key to CELL-MEDIATED IMMUNITY) that prevents B-

cell lymphocytes containing the latent Epstein-Barr virus from endlessly proliferating. As a result of this balance, in most people the virus never regains enough presence to again cause illness.

Circumstances that challenge the immune system allow the Epstein-Barr virus to reactivate. The most notable of these circumstances are HIV/AIDS and IMMUNOSUPPRESSIVE THERAPY after ORGAN TRANSPLANTATION. The reactivated Epstein-Barr virus may cause symptoms similar to infectious mononucleosis (chronic infectious mononucleosis) during which the person may spread the virus to others. It may also cause lymphoproliferative disorders: abnormal growth (tumors) of lymphatic structures such as lymph nodes and MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT). Though research is under way to develop a VACCINE to prevent infection with Epstein-Barr virus, at present there are no effective measures to prevent infection with the virus and no treatments to eradicate the virus once it establishes infection.

DISEASES ASSOCIATED WITH EPSTEIN-BARR VIRUS

acute infectious mononucleosis	AIDS-associated lymphoma
chronic infectious mononucleosis	Burkitt's lymphoma
nasopharyngeal CARCINOMA	generalized lymphoproliferative disease
	post-transplant lymphoproliferative disorder (PTLD)

See also B-CELL LYMPHOCYTE; CELL STRUCTURE AND FUNCTION; HERPES SIMPLEX; HERPES ZOSTER; KAPOSI'S SARCOMA; LYMPH NODE; LYMPHOCYTE; MONONUCLEOSIS, INFECTIOUS; OPPORTUNISTIC INFECTION; T-CELL LYMPHOCYTE.

***Escherichia coli* infection** Illness that results from INFECTION with any of the numerous strains of *Escherichia coli* BACTERIA, some of which are NORMAL FLORA in the human gastrointestinal tract and others that are normal flora in the gastrointestinal tracts of animals consumed as food (such as cattle and poultry). Most strains of *E. coli* cause mild to moderate illness. Illness from *E. coli* infection results from the toxins the *E. coli* release through their normal metabolic functions. The strain *E. coli* O157:H7, found in beef contaminated with fecal matter, can cause particularly severe illness.

Symptoms and Diagnostic Path

The symptoms of common *E. coli* infection are generally mild to moderate in severity and include

- abdominal cramping
- DIARRHEA
- occasionally NAUSEA and VOMITING

The symptoms of *E. coli* O157:H7 infection are often more severe and include ABDOMINAL PAIN with profuse, sometimes bloody diarrhea. Though most people recover fully after the illness runs its course in 5 to 10 days, in some people the toxins the *E. coli* O157:H7 release cause the massive destruction of red BLOOD cells (erythrocytes), a process called HEMOLYSIS. The enormous volume of dead erythrocytes creates proteins in the blood that are damaging to the KIDNEYS, resulting in RENAL FAILURE. The combination of these circumstances is HEMOLYTIC UREMIC SYNDROME (HUS), which occurs as a complication of *E. coli* O157:H7 infection in about 5 percent of people (mostly children under age 5). HUS nearly always results in END-STAGE RENAL DISEASE (ESRD), requiring dialysis or KIDNEY TRANSPLANTATION.

The diagnostic path for *E. coli* infection may include culture of stool samples to determine the causative PATHOGEN, though most often doctors do this only when the illness continues beyond about two weeks or has severe symptoms. The doctor must specifically request culture for *E. coli* O157:H7 as most laboratories do not routinely include this in their testing.

Treatment Options and Outlook

E. coli diarrheal illnesses are very common and nearly all people who acquire them fully recover in three to five days without treatment, except fluid replacement to prevent DEHYDRATION. ANTIBIOTIC MEDICATIONS are seldom appropriate because the cause of symptoms is the toxins the *E. coli* bacteria release, and killing the bacteria causes them to release even more toxins. It is sometimes helpful to avoid dairy products until bowel activity returns to normal. People who become seriously ill with *E. coli* O157:H7 may require care in the hospital. Though *E. coli* O157:H7 infection has gained substantial notoriety, more than 95 percent

of people who become ill with it recover without complications.

Risk Factors and Preventive Measures

E. coli infections result from contaminated water or food, especially meats. Swimming in lakes and rivers often exposes people to *E. coli* contamination; swallowing the water allows the bacteria to enter the gastrointestinal system. Most *E. coli* infections are FOODBORNE ILLNESSES.

Preventive measures include

- diligent HAND WASHING
- following FOOD SAFETY guidelines for handling and preparing meats and other foods
- thoroughly cooking meats, especially ground beef

Most *E. coli* infections are preventable.

See also ERYTHROCYTE; WATERBORNE ILLNESSES.

F–G

fever An elevation of body temperature above the normal range. Body temperature varies over the course of a circadian cycle, roughly equivalent to 24 hours, to accommodate the body's metabolic needs. Body temperature is lowest just before waking in the morning and highest in the late afternoon or early evening, times that typically correlate with the body's lowest and highest expenditures of energy. The normal range of body temperature is 97.6°F to 99.6°F, with the mean of 98.6°F generally perceived as the standard normal temperature. Health-care providers generally view a body temperature of 100°F or higher as a fever.

The body's IMMUNE RESPONSE raises body temperature as a mechanism for fighting INFECTION. Elevated body temperature increases the body's METABOLISM, which enhances the IMMUNE SYSTEM's ability to contain and eradicate the pathogens responsible for infection. Each degree of elevation in body temperature accelerates metabolism by 10 to 15 percent. The various types of white BLOOD cells (leukocytes) release INTERLEUKINS, PROSTAGLANDINS, TUMOR NECROSIS FACTORS (TNFS), and other biochemicals (CHEMOKINES) that temporarily reset the body's thermoregulatory mechanisms.

Though common practice is to attempt to lower a fever through measures such as cool baths and acetaminophen or other medications, doctors now believe fever does not ordinarily require treatment. To the contrary, recent research shows that the immune response and most ANTIBIOTIC MEDICATIONS work more effectively when body temperature is elevated. Doctors recommend treating fever only when there is risk for febrile seizures, when the person cannot eat or drink enough to meet the body's metabolic needs, or when the fever creates discomfort. Medications to treat other symptoms due to the infection, such as HEADACHE, also reduce fever.

See also ANALGESIC MEDICATIONS; HEAT EXHAUSTION; HEAT STROKE; LEUKOCYTE; NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS); PATHOGEN.

foodborne illnesses Diseases resulting from consumption of foods contaminated with pathogenic BACTERIA, fungi, parasites, or viruses. Foodborne illnesses, also called food poisoning, are common, affecting 76 million Americans each year. There are several hundred known foodborne illnesses, most of which cause mild to moderate gastrointestinal symptoms including abdominal cramping, NAUSEA, VOMITING, and DIARRHEA. Illness results from consuming a food contaminated with pathogens. Common sources include undercooked meats and cooked foods that remain at room temperature for longer than two hours. Most often, it is not possible to tell from taste, smell, or appearance that a food contains pathogens.

Prevention is the primary focus when it comes to foodborne illnesses. The simple measure of washing the hands before and after preparing foods, eating meals, changing diapers, and using the bathroom could eliminate many foodborne illnesses by preventing bacteria and other pathogens from contact with foods. Other FOOD SAFETY measures to reduce the risk for infection from foodborne pathogens include

- using separate utensils and surfaces for meats and for other foods
- washing fruits and vegetables, including "rind" fruits such as oranges and watermelon, in running water before eating or preparing them

- thoroughly cooking all animal-based foods (including eggs), to 160ºF for most meats and poultry (no pink in the flesh)
- prompt refrigeration of leftover foods

Most foodborne illnesses are self-limiting; the infection runs its course (usually within three to five days) and the person fully recovers without medical treatment. Supportive treatment such as adequate fluid intake is important to prevent DEHYDRATION; soups and juices also help maintain nutrition. Doctors often discourage people from taking ANTIDIARRHEAL MEDICATIONS that work by slowing gastrointestinal motility, such as loperamide or diphenoxylate, because these drugs may prolong the illness by prolonging the presence of the PATHOGEN in the gastrointestinal tract.

Some foodborne illnesses need prompt medical treatment, such as BOTULISM. Some parasitic and bacterial infections require appropriate medications. Some foodborne illnesses may spread from one person to another, such as HEPATITIS and *ESCHERICHIA COLI* INFECTION. A doctor should evaluate symptoms that are severe or persist longer than five days.

FOODBORNE ILLNESSES

AMEBIASIS	BOTULISM
CAMPYLOBACTERIOSIS	*Escherichia coli* INFECTION
GIARDIASIS	HEPATITIS
LISTERIOSIS	Norwalk-like virus
SALMONELLOSIS	SHIGELLOSIS
TOXOPLASMOSIS	

See also FUNGUS; PARASITE; VIRUS; WATERBORNE ILLNESSES.

fungus Any of the 200,000 or so of single or multiple cell organisms (living structures), microscopic (visible only using a microscope for magnification) and macroscopic (visible to the unaided EYE), that are abundant in the natural environment. Yeasts are single-cell fungi that live in colonies; molds are multiple-cell fungi that form structures. Like BACTERIA, fungi are among the oldest life forms to inhabit the Earth; fossils of yeasts date back more than 2 billion years.

Most fungi are harmless to humans and many are NORMAL FLORA (present in body and on the SKIN). Fungi break down organic waste; yeasts, for example, populate the gastrointestinal tract where they aid in digestion. Many ANTIBIOTIC MEDICATIONS derive from fungi, notably penicillin (first cultivated from the mold *Penicillium chrysogenum*).

Some fungi are pathogenic (disease causing) in people under any circumstances and others cause OPPORTUNISTIC INFECTION in people who are IMMUNOCOMPROMISED. Fungal diseases may be localized, such as ONYCHOMYCOSIS (fungal INFECTION of the nail beds), or systemic, such as HISTOPLASMOSIS. Doctors use ANTIFUNGAL MEDICATIONS to treat fungal infections that cause disease.

FUNGAL DISEASES

ASPERGILLOSIS	blastomycosis
CANDIDIASIS	COCCIDIOIDOMYCOSIS
CRYPTOCOCCOSIS	HISTOPLASMOSIS
mucormycosis	ONYCHOMYCOSIS
sporotrichosis	tinea barbae (ringworm)
tinea capitis (ringworm)	tinea corporis (ringworm)
tinea cruris (jock itch)	tinea pedis (athlete's foot)

Fungi may also be a source of poisoning. *Aspergillus* molds on grains produce aflatoxins, for example, which cause LIVER damage and are associated with LIVER CANCER. Many types of mushrooms produce toxins (mycotoxins) that cause illness or death when eaten, such as the highly toxic "death cap" mushroom, *Amanita phalloides*. Molds may grow in buildings where humidity and darkness converge to provide the ideal environment for their growth, such as inside walls and floors where there have been water leaks. The spores of these fungi cause respiratory illnesses and other health problems when breathed in with the air, particularly for people who have ASTHMA or other chronic pulmonary conditions.

See also BUILDING-RELATED ILLNESS; INDOOR AIR QUALITY; MICROBE; OCCUPATIONAL HEALTH AND SAFETY; PARASITE; PATHOGEN; PROTOZOA; TINEA INFECTIONS; VIRUS.

genital herpes A sexually transmitted disease (STD) resulting from INFECTION with herpesvirus, usually HERPES SIMPLEX VIRUS 2 (HSV-2). Herpes

simplex virus 1 (HSV-1), which causes cold sores, may also cause sores in the genital area. Genital herpes is one of the most prevalent STDs in the United States, infecting about 25 percent of teens and adults—more than 45 million people. About 1 million new infections occur each year.

As is characteristic of the herpesviruses, HSV-2 remains in the body for life after the initial infection, retreating to NERVE roots within the areas of infection. Periodically the virus travels along the nerves to the surface of the SKIN, causing outbreaks of blisters that become crusted sores. During these outbreaks the virus both replicates and sheds, and the infected person is highly contagious. Such a pattern of REMISSION and RECURRENCE continues through life; there currently is no cure for genital herpes.

Direct contact with SEMEN, vaginal fluids, and saliva spreads genital herpes from one person to another during vaginal intercourse, anal intercourse, or oral sex. The infection does not spread via contact with objects such as toilet seats or in water (such as swimming pools and hot tubs). Genital herpes is contagious even when no sores are present. Because symptoms may be mild, or in women occur within the VAGINA, many people do not know they have genital herpes. The first outbreak of symptoms tends to be the most severe. Over time outbreaks tend to become less frequent with fewer and smaller sores.

Symptoms and Diagnostic Path

Symptoms, when they occur, begin about two weeks after sexual contact with an infected person who is shedding the virus. Initial symptoms may include

- tingling, burning, or pain at the site of infection (PENIS, vagina, CERVIX, ANUS, RECTUM, MOUTH, and sometimes on skin surfaces)
- FEVER
- HEADACHE
- swollen LYMPH nodes near the site of the infection
- vaginal discharge in women
- painful URINATION in men

The hallmark symptom of genital herpes is painful sores that begin as red bumps that BLISTER and then crust. The sores appear at the sites where the virus entered the body and are usually most severe with the first outbreak. Symptoms of subsequent outbreaks tend to be more mild, though sores may appear in new locations as the virus spreads along nerve paths. The sores are present for three to four weeks and then heal without scarring. Periods of remission during which there are no sores or other symptoms may last several weeks to several months.

Health-care providers generally presume a diagnosis of genital herpes when the characteristic sores are present in a person who is sexually active. BLOOD tests can detect the presence of HSV antibodies but this is not especially useful information from a diagnostic perspective because more than 90 percent of people have some sort of herpesvirus infection—herpes simplex, HERPES ZOSTER, varicella (CHICKENPOX)—that activates the ANTIBODY response and blood tests cannot distinguish among the type of herpesvirus present. Cultures of the sores may produce HSV-2, which confirms the diagnosis. However, cultures of the sores may sometimes be negative even when HSV-2 infection is present.

Treatment Options and Outlook

The sores that erupt during a genital herpes outbreak will heal without treatment within two or three weeks. ANTIVIRAL MEDICATIONS can shorten the length of the outbreak and reduce the number and severity of the sores. Some people benefit from taking an antiviral medication daily, which may lessen the frequency of outbreaks. Valacyclovir is the medication doctors most commonly prescribe for regular use. Antiviral medications do not cure genital herpes, however.

ANTIVIRAL MEDICATIONS TO TREAT GENITAL HERPES

acyclovir	famciclovir	valacyclovir

Most people who have genital herpes experience outbreaks of symptoms several times a year. Stress, MENSTRUATION, and other viral infections such as COLDS seem to trigger outbreaks though symptoms may erupt without apparent cause. The open sores of genital herpes create increased risk for infection with HIV. A pregnant woman can pass genital herpes to her unborn child; doctors

may recommend CESAREAN SECTION (surgical delivery) for women whose infections are active (symptomatic) near the time of delivery to prevent this.

Risk Factors and Preventive Measures

Because HSV-2 infection is so prevalent, all sexually active people are at risk for genital herpes. Uninfected people who are in monogamous relationships with uninfected sexual partners have the lowest risk for infection; uninfected people who have multiple sexual partners or who are in relationships with sexual partners who have genital herpes have the highest risk for infection. At present the most effective means of prevention among sexually active adults is abstinence during outbreaks and barrier protection such as latex condoms during all sexual activity. Barrier protection is not absolute, however, as the HSV-2 virus may infect nerve cells at the skin's surface that the condom does not cover.

The antiviral medication valacyclovir significantly reduces viral shedding, slowing but not entirely preventing transmission of genital herpes. This preventive measure is most effective in monogamous relationships in which one person has HSV-2 and the other does not. Clinical studies are under way to evaluate a vaccine for genital herpes.

See also CHLAMYDIA; COLD SORE; CONTRACEPTION; GONORRHEA; HUMAN PAPILLOMAVIRUS (HPV); LYMPH NODE; OCULAR HERPES; SEXUAL HEALTH; SEXUALLY TRANSMITTED DISEASE (STD) PREVENTION; SEXUALLY TRANSMITTED DISEASES (STDS); SYPHILIS.

giardiasis An illness resulting from INFECTION with the protozoan *Giardia lamblia* (also called *Giardia intestinalis*). *Giardia* are abundant in fresh water throughout the United States; infection occurs through drinking contaminated water. The PROTOZOA infect the SMALL INTESTINE of humans and animals and can survive for extended periods without a host. The most common means of infection is through swallowing water in recreational settings, such as lakes, rivers, and streams. Fountains, swimming pools, and hot tubs that lack proper chlorination also may harbor *Giardia*. Giardiasis also spreads through fecal contamination by direct contact, such as by changing diapers, and can occur as a FOODBORNE ILLNESS spread through poor FOOD SAFETY practices.

Symptoms develop after an incubation period of 7 to 10 days and include DIARRHEA, excessive FLATULENCE (gas), abdominal discomfort, and NAUSEA. The diarrhea is watery and has a greasy appearance. Some people also experience fatigue, loss of APPETITE, and rapid weight loss. It is also possible to have giardiasis and have no symptoms. Stool samples examined under the microscope typically contain both cysts and trophozoites, the immature and mature forms, respectively, of the *Giardia*. Treatment is ANTIBIOTIC MEDICATIONS and ANTIFUNGAL MEDICATIONS. The course of illness runs four to six weeks with treatment, after which most people recover without complications or residual consequences. Without treatment giardiasis may persist for six to eight weeks, with gradual though complete recovery.

MEDICATIONS TO TREAT GIARDIASIS

albendazole	furazolidone
metronidazole	nitazoxanide
paromomycin	tinidazole

See also AMEBIASIS; BABESIOSIS; DRINKING WATER STANDARDS.

gonorrhea A sexually transmitted disease (STD) resulting from INFECTION with the bacterium *Neisseria gonorrhoeae*. *N. gonorrhoeae* infects 350,000 Americans each year, though public health officials believe another 350,000 people have gonorrhea that goes undiagnosed because they do not know they are infected. Gonorrhea is highly contagious and passes among sexual partners through vaginal intercourse, anal intercourse, or oral sex. People who have multiple sex partners have increased risk for gonorrhea as well as other STDs. Gonorrhea is a public health concern of great magnitude worldwide because a number of strains of *N. gonorrhoeae* have become resistant to the ANTIBIOTIC MEDICATIONS used to treat the infection.

Symptoms and Diagnostic Path

Gonorrhea has a 2- to 10-day INCUBATION PERIOD (time from exposure to symptoms) though often causes no symptoms, especially in women. Symptoms that do occur tend to be generalized and

vague, such as lower abdominal discomfort, and go away in a few days to a week. When symptoms are present they typically include

- a thick, discolored (yellowish or greenish), or bloody discharge from the PENIS in men and the VAGINA in women
- burning or PAIN with URINATION (more common in men)
- pain or bleeding during SEXUAL INTERCOURSE (more common in women)

Early symptoms will go away without treatment, though the infection remains. As the *N. gonorrhoeae* BACTERIA multiply in the body, they cause increasing irritation to the tissues, resulting in INFLAMMATION and the formation of SCAR tissue. In men the next level of infection with untreated gonorrhea is EPIDIDYMITIS, which causes swelling and pain in the TESTICLES, and URETHRITIS, which causes intense pain with urination. In women the next level of infection with untreated gonorrhea is PELVIC INFLAMMATORY DISEASE (PID), which involves the UTERUS and FALLOPIAN TUBES. PID often causes severe ABDOMINAL PAIN. Scarring from the infection blocks the fallopian tubes, putting a woman at high risk for ECTOPIC PREGNANCY.

Diagnosis is laboratory examination of a sample of the discharge taken from the penis (men) or the CERVIX (women). A fast test done in the doctor's office is highly accurate for men but not for women; for women, a conventional culture is the most reliable diagnostic procedure. The doctor likely will conduct diagnostic tests for other STDs as well, notably CHLAMYDIA and SYPHILIS. All sex partners should also undergo testing and receive treatment if they have gonorrhea, even if they do not have symptoms.

Treatment Options and Outlook

The current standard of treatment for gonorrhea is a single DOSE of a fluoroquinolone antibiotic, which cures the infection in most people. However, new strains of *N. gonorrhoeae* are showing resistance to these antibiotics, causing doctors to look to combinations of antibiotics and to stronger antibiotics to cure the infection.

ANTIBIOTIC MEDICATIONS TO TREAT GONORRHEA

azithromycin	cefixime
ceftriaxone	ciprofloxacin
levofloxacin	ofloxacin

The debut of penicillin in the 1940s provided the first cure for gonorrhea. However, 30 years later, most strains of *N. gonorrhoeae* were resistant to penicillin and to tetracycline, the second-choice antibiotic. Doctors can no longer prescribe these antibiotics to treat gonorrhea. Though antibiotic medications remain the standard of treatment for gonorrhea, doctors and public health officials worry that the ability of *N. gonorrhoeae* to adapt will soon put gonorrhea out of reach for treatment. Researchers have recently unraveled the GENETIC CODE (DNA sequence) of the *N. gonorrhoeae* and are hopeful this advance will lead to new kinds of treatments.

Risk Factors and Preventive Measures

Those who are at highest risk for gonorrhea and other STDs are

- women between the ages of 15 and 19
- men between the ages of 20 and 24
- men who have sex with men
- men or women who have multiple sex partners

Monogamy (having only one sex partner) and consistent use of latex condoms are measures that can prevent *N. gonorrhoeae* infection. People who are sexually active should undergo regular testing for STDs. Reinfection can occur.

See also ANTIBIOTIC RESISTANCE; GENITAL HERPES; HIV/AIDS; HUMAN PAPILLOMAVIRUS (HPV); SEXUAL HEALTH; SEXUALLY TRANSMITTED DISEASE (STD) PREVENTION; SEXUALLY TRANSMITTED DISEASES (STDS).

hantavirus pulmonary syndrome An illness resulting from INFECTION with hantavirus. Certain species of deer mice carry the hantavirus, which they shed in their droppings, URINE, and saliva. People who come into contact with these excretions, which may be through direct touch or inhalation, may then acquire infection with the VIRUS. Deer mice live primarily in wooded areas. Most often a person acquires the infection after cleaning in barns and outbuildings where mouse droppings can accumulate; the cleaning stirs up dust that carries the virus into the respiratory tract. People who go camping in areas where there are large populations of deer mice also are at risk for infection.

The INCUBATION PERIOD (time between exposure and illness) is one to three weeks. Symptoms emerge abruptly and include FEVER, severe MUSCLE aches (particularly in the large muscles of the legs and back), and shortness of breath (DYSPNEA) that rapidly progresses to respiratory failure. A BLOOD test can show the presence of antibodies to confirm the diagnosis. Treatment is hospitalization, usually in an intensive care unit, to provide support for BREATHING while the virus runs its course. Hantavirus pulmonary syndrome is a very serious infection with a high fatality rate. Early, aggressive medical support offers the best potential for successful recovery.

See also ANTIBODY; HEMORRHAGIC FEVERS; MECHANICAL VENTILATION.

hemorrhagic fevers Life-threatening illness resulting from INFECTION with various viruses, spread by the bites of mosquitoes and ticks, the hallmark of which is the collapse of multiple organ systems because damage to the BLOOD vessels impairs their ability to contain and transport blood. The dozen or so viruses that cause hemorrhagic fevers belong to four viral families: arenaviruses, bunyaviruses, filoviruses, and flaviviruses. These viral families also contain viruses that cause infection other than hemorrhagic FEVER. For example HANTAVIRUS belongs to the bunyavirus family and the yellow fever VIRUS belongs to the flavivirus family. Viral hemorrhagic fever infections occur in tropical regions, notably Africa and South America.

HEMORRHAGIC FEVER VIRUSES

Arenaviruses	
Guanarito VIRUS	Junin virus
Lassa virus	Machupo virus
Sabia virus	
Bunyaviruses	
Crimean-Congo virus	Rift Valley virus
Filoviruses	
Ebola virus	Marburg virus
Flaviviruses	
Dengue virus	Omsk virus

Rodents, primarily certain species of rats and mice, harbor the viruses. Mosquitoes and ticks that feed on the rodents continue to spread the virus among rodent populations. Rodent droppings and other excretions, such as saliva and URINE, contain the viruses. The viruses can then infect people who come into contact with the excretions. Contact with body fluids from an infected person further spread the virus. Symptoms of illness arise suddenly and are severe, typically including high fever, fatigue, evidence of internal bleeding, and weakness. Subsequent

symptoms develop as organs fail. The only treatment for viral hemorrhagic fevers is supportive; the illnesses are usually fatal. Outbreaks of viral hemorrhagic fevers occur periodically. Global efforts are under way to find medical treatments that can halt the course of disease as well as to contain rodent, mosquito, and tick populations.

See also COMMUNITY SANITATION.

herpes simplex INFECTION with the herpes simplex VIRUS 1 (HSV-1) or HSV-2. HSV-1 primarily causes cold sores on the lips and in the MOUTH, transmitted through saliva. HSV-2 primarily causes GENITAL HERPES, a sexually transmitted disease (STD) that causes ulcerative sores on the genitals. However, either form of the virus can cause infection anywhere in the body. HSV-1 and HSV-2, like other herpes viruses, are highly contagious through contact with the sores and may also spread from one person to another even when no sores are present. Herpes simplex infection is lifelong, though symptoms characteristically wax and wane. About 90 percent of Americans have HSV-1 and about 30 percent have HSV-2.

The typical course of an outbreak begins with itching or tingling, called the prodrome, which gives way to the eruption of a BLISTER within 48 hours. Cold sores typically form as single blisters though may occur as multiple blisters in several locations; genital herpes sores tend to erupt in clusters. After two or three days the blisters rupture and form crusted sores that subsequently heal. The cycle from prodrome to HEALING lasts about 10 days. Because the course of illness is so characteristic, the doctor can usually make the diagnosis on the appearance of the sores. Laboratory culture of the fluid within a blister or sore can provide a definitive diagnosis.

After an outbreak of symptoms the virus retreats to the local NERVE roots where it remains dormant until the next outbreak. Researchers are not certain what factors initiate outbreaks though stress and exposure to sunlight appear to play key roles. Doctors sometimes prescribe ANTIVIRAL MEDICATIONS such as acyclovir for people who have six or more outbreaks of herpes simplex infection in a year or who have severe symptoms during outbreaks. Herpes infections may involve the eyes or the BRAIN, where they can cause permanent damage.

See also CANKER SORE; CHICKENPOX; COLD SORE; HERPES ZOSTER; SEXUALLY TRANSMITTED DISEASE (STD) PREVENTION; SEXUALLY TRANSMITTED DISEASES (STDS).

herpes zoster An INFECTION that results from reactivation of the varicella-zoster VIRUS, which lies dormant in the spinal NERVE roots after causing CHICKENPOX. The virus can remain dormant for decades; doctors do not know what reactivates it though suspect a combination of aging and stress to the IMMUNE SYSTEM. The infection travels the tract of a spinal nerve to the SKIN, causing burning or PAIN as it makes its way to the body's surface. Called the prodrome, this discomfort yields in about two days to a rash of painful blisters that erupts along the nerve's pathway, called a DERMATOME. The blisters rupture in three to five days and crusted sores form at the sites of the blisters.

Herpes zoster, also called shingles, occurs only on one side of the body, most commonly on the chest though may affect dermatomes anywhere on the body. The blisters of the herpes zoster outbreak can spread the virus, which can cause chickenpox in people who have not had it or have not received the varicella VACCINE. An uncomplicated outbreak of herpes zoster runs its course in three to four weeks, after which the virus again goes dormant. Treatment with an antiviral medication taken at the onset of pain but before blisters emerge (the prodrome) can significantly shorten the course of illness and decrease the severity of symptoms.

ANTIVIRAL MEDICATIONS TO TREAT HERPES ZOSTER

acyclovir	desciclovir
famciclovir	penciclovir
valacyclovir	

Complications after the outbreak abates may include damage to the eyes, loss of taste, and partial PARALYSIS of the face when the outbreak involves the trigeminal nerve. Post-herpetic NEURALGIA is pain that persists along the dermatome after the sores have completely healed, and may be debilitating. Unlike its predecessor infection, chickenpox, herpes zoster can recur though usually does not.

See also AGING, EFFECTS ON IMMUNE RESPONSE; BLISTER; GENITAL HERPES; HERPES SIMPLEX; SPINAL NERVES.

histoplasmosis An illness resulting from INFECTION with the FUNGUS *Histoplasma capsulatum*. This fungus, commonly called a mold, thrives in soils where bird droppings are abundant, such as chicken farms, barns where pigeons and starlings nest, and caves where bats roost. Histoplasmosis is endemic (continuously present) in the river valley areas of the central United States, where the rich and acidic soil provides an especially supportive environment for fungi to grow.

When inhaled, the *H. capsulatum* spores cause lesions in the LUNGS. An acute infection causes symptoms only in about 10 percent of people, though nonetheless can do considerable damage to lung tissue. Permanent scarring (granulomas and cavitations) often occurs in untreated histoplasmosis. Chronic histoplasmosis may develop in people who have underlying pulmonary disease or repeated exposure to *H. capsulatum* spores. The most significant risk of histoplasmosis is disseminated disease, in which the spores enter the BLOOD circulation and migrate to other organs throughout the body. Disseminated histoplasmosis, often an OPPORTUNISTIC INFECTION in people who have HIV/AIDS or are otherwise IMMUNOCOMPROMISED, has a high rate of fatality.

Symptoms and Diagnostic Path

Symptoms in acute histoplasmosis generally appear within two weeks of exposure and include

- FEVER
- HEADACHE
- JOINT PAIN
- MUSCLE aches
- nonproductive (dry) COUGH

People who inhale a large quantity of the spores may have extensive lung involvement that causes shortness of breath (DYSPNEA). The diagnostic path begins with a detailed personal health history with emphasis on exposure to bird droppings, blood tests, and a SKIN ANTIGEN test. Chest X-RAY reveals the characteristic histoplasmosis lesions, and may also show enlarged LYMPH nodes in the chest (hilar and mediastinal LYMPHADENOPATHY).

Treatment Options and Outlook

Acute histoplasmosis usually resolves without treatment, running a course much like that of a common upper respiratory infection. Bacterial PNEUMONIA may occur as a complication of acute histoplasmosis, requiring treatment with ANTIBIOTIC MEDICATIONS. Doctors prescribe ANTIFUNGAL MEDICATIONS to treat moderate to severe acute symptoms, chronic histoplasmosis, and disseminated histoplasmosis. With appropriate treatment, most people who have normal immunocompetence recover though residual lung damage is possible. Chronic and disseminated forms of infection often require long-term or lifelong treatment with antifungal medications.

ANTIFUNGAL MEDICATIONS TO TREAT HISTOPLASMOSIS

amphotericin B	itraconazole	ketoconazole

Risk Factors and Preventive Measures

People who work with live poultry or in outdoor areas that have large bird populations have increased risk for infection with *H. capsulatum*. Minimizing disturbance of the soil helps reduce the release of spores into the air. People who work in areas where exposure is a risk should wear respirators. Recreational activities in areas where birds or bats are common may also be a risk for exposure.

See also HANTAVIRUS; LESION.

HIV/AIDS An INFECTION with the human immunodeficiency virus (HIV) that ultimately results in the illness acquired immunodeficiency syndrome (AIDS). Though new HIV/AIDS infections are on the decline in the United States and other industrialized nations, HIV/AIDS remains endemic on the African continent.

HIV/AIDS spreads through contact with body fluids such as occurs with sexual contact (vaginal intercourse, anal intercourse, and oral sex) or through shared needles among intravenous DRUG users. Though previously infection through transfused BLOOD or blood products was a key means of infection, screening for HIV antibodies in donated

blood supplies has significantly reduced this risk and infection through blood products is now uncommon.

Though there are numerous treatments for HIV/AIDS, there is no cure. HIV, the infection, nearly always progresses to AIDS, the illness, over the course of 5 to 20 years. Aggressive treatment can further manage the symptoms and complications of AIDS for years to sometimes decades. However, AIDS is ultimately fatal. AIDS does not itself cause death but instead so extensively damages the IMMUNE SYSTEM, the infection's target, that the body cannot protect itself from infections or conditions such as cancer, which become the causes of death.

The Virus: HIV

The human immunodeficiency virus, HIV, is a retrovirus that exists in two known types, HIV-1 and HIV-2. Each infects the body in the same way and etches the same pathway to AIDS. HIV-1 is predominant in North America and Europe; HIV-2 is predominant in Africa, Southeast Asia, and China. HIV enters the body by attaching itself to a type of T-CELL LYMPHOCYTE called a CD4 cell (helper T-cell). CD4 cells direct the immune system's response to infection and are integral to CELL-MEDIATED IMMUNITY. Once attached, the HIV virion, the essential structure of the VIRUS before it acquires a host cell, can infiltrate the cell without the immune system detecting its presence.

As a retrovirus, HIV uses reverse transcriptase, an enzyme, to instruct the CD4 cell's RNA to replicate the virus's RNA in place of the cell's DNA. The cell then supports and replicates the virus, releasing new virions to infect additional CD4 cells. The entire process is quite stealthy. Therapeutic interventions are not quite of comparable stealth, though are getting closer to the mark. For example, ANTIVIRAL MEDICATIONS called nucleoside analogs can interject themselves into the process of reverse transcription, with the result that the cell produces "blank" DNA that fails to replicate the virus.

The Illness: AIDS

The ultimate outcome, at present, of HIV infection is the collapse of the immune system. Eventually the number of CD4 cells under HIV control is significantly greater than the number of CD4 cells under control of the immune system. Critical mass shifts and the immune system becomes deficient: It lacks the resources to rally against even the most minor of infections. Illness ranging from CANDIDIASIS (yeast infection) to AIDS-related lymphoma (a type of cancer) takes over. It is these illnesses, not HIV/AIDS, that causes death.

Symptoms and Diagnostic Path

About two weeks after infection with HIV, mild flulike symptoms appear that last 10 to 14 days. Most people do not recognize these symptoms as HIV infection. After these initial symptoms resolve, there are no further symptoms until AIDS emerges. However, HIV antibodies become present in the body three to six months after infection (called seroconversion). Various tests are available to detect the presence of HIV antibodies, which confirm that a person has HIV infection (is HIV-positive). HIV infection is not the same as AIDS. AIDS is the end-stage outcome of HIV infection. At present the diagnostic criteria for the transition from HIV infection to AIDS is a CD4 count below 200 cells per cubic millimeter (mm^3) and/or the development of an AIDS-defining clinical conditions (an illness that a healthy immune system would block from occurring).

AIDS-DEFINING CLINICAL CONDITIONS

AIDS-associated lymphoma	Burkitt's lymphoma
CANDIDIASIS	chronic HERPES SIMPLEX
COCCIDIOIDOMYCOSIS	CRYPTOCOCCOSIS
CRYPTOSPORIDIOSIS	CYTOMEGALOVIRUS (CMV) disease or retinitis
HISTOPLASMOSIS	invasive CERVICAL CANCER
HIV-related ENCEPHALOPATHY	KAPOSI'S SARCOMA
isosporiasis	*Pneumocystis carinii* PNEUMONIA
Mycobacterium avium complex	*Salmonella* SEPTICEMIA, recurrent
progressive multifocal leukoencephalopathy	TUBERCULOSIS
TOXOPLASMOSIS of brain	
wasting syndrome due to HIV	

Treatment Options and Outlook

There are numerous treatment protocols for HIV/AIDS that extend both life expectancy and QUALITY OF LIFE. Early HIV infection does not require treatment beyond lifestyle measures to stay as healthy as possible. As the HIV begins to

compromise the immune system, aggressive treatment with a regimen called HAART (highly active antiretroviral therapy), which combines three or more medications taken daily, can delay the progression of infection. Three factors influence the decision to begin HAART:

- CD4 count (the number of CD4 T-lymphocytes in the blood circulation) below 350 cells per cubic millimeter (mm^3)
- viral load (the number of copies of HIV in the blood circulation) above 100,000 per milliliter (ml)
- presence of symptoms or an AIDS-defining clinical condition

Doctors wait to start HAART until these conditions exist because the antiretroviral drugs have potentially serious side effects, necessitating a careful balance between benefit and risk, and because once started, treatment is lifelong.

ANTIRETROVIRAL DRUGS TO TREAT HIV/AIDS (HAART)

Nonnucleoside Reverse Transcriptase Inhibitors (NNRTIs)		
delavirdine	efavirenz	nevirapine
Nucleoside Reverse Transcriptase Inhibitors (NRTIs)		
abacavir	didanosine	emtricitabine
lamivudine	stavudine	tenofovir
zalcitabine	zidovudine	
Protease Inhibitors (PIs)		
amprenavir	atazanavir	fosamprenavir
indinavir	lopinavir	nelfinavir
ritonavir	saquinavir	tipranavir
Fusion Inhibitors		
enfuvirtide		

Regular blood tests to monitor CD4 counts and viral load determine how well a particular drug combination is working. Because drug toxicity and resistance are both problems with long-term HAART, it is sometimes necessary to change regimens.

Risk Factors and Preventive Measures

Numerous risk factors exist for HIV/AIDS. Key among them are

- unprotected vaginal intercourse, anal intercourse, or oral sex
- multiple sexual partners
- intravenous drug use with shared needles
- infection with SEXUALLY TRANSMITTED DISEASES (STDS) that have open sores, such as SYPHILIS and GENITAL HERPES
- vaginal intercourse during MENSTRUATION

Use of condoms with all sexual activity reduces the risk for spreading the virus but does entirely prevent infection. Pregnant women who are HIV-positive should discuss prophylactic treatment during PREGNANCY and for the infant after birth.

See also ANTIBODY; ANTIBODY-MEDIATED IMMUNITY; HIV/AIDS PREVENTION; SEXUAL HEALTH; SEXUALLY TRANSMITTED DISEASE (STD) PREVENTION.

human ehrlichiosis Any of several illnesses resulting from INFECTION with various species of *Ehrlichia* BACTERIA. Human ehrlichiosis infection spreads via tick bites. The tick species and the *Ehrlichia* species vary by geographic region. *Ehrlichia* bacteria infect white BLOOD cells. The two main forms of human ehrlichiosis in the United States are human granulocytic ehrlichiosis (hGE), in which the infection involves granulocytes (primarily neutrophils), and human monocytic ehrlichiosis (hME), in which the bacteria infect monocytes and macrophages. hME is about twice as common as hGE.

The INCUBATION PERIOD for human ehrlichiosis is 5 to 10 days, after which symptoms appear that are flulike in nature. Symptoms may include

- FEVER
- HEADACHE and general sense of not feeling well (malaise)
- JOINT PAIN and MUSCLE aches
- NAUSEA, VOMITING, and DIARRHEA

The diagnostic path includes blood tests to evaluate blood cell counts. The bacteria are also apparent with microscopic examination of a blood sample. *Ehrlichia* bacteria are highly sensitive to doxycycline, an antibiotic in the tetracycline family of ANTIBIOTIC MEDICATIONS. Because blood test results may take a week or longer, responsiveness

to antibiotic therapy is often a diagnostic measure. People who have human ehrlichiosis show marked improvement in symptoms within 24 to 36 hours of beginning doxycycline treatment. Most people recover fully with appropriate treatment. Though some people develop mild illness with few symptoms and fully recover without treatment, untreated human ehrlichiosis can become very serious very quickly because the attack on the white blood cells compromises immune function.

The risk for *Ehrlichia* infection in the United States is highest during the summer months (May through October) when people are hiking and camping in areas where ticks thrive. Measures to prevent tick bites include wearing protective clothing (such as long pants tucked into socks) or using an appropriate insect repellent and checking the SKIN carefully for ticks or signs of bites after being in wooded areas.

See also GRANULOCYTE; MACROPHAGE; MONOCYTE; ROCKY MOUNTAIN SPOTTED FEVER.

human papillomavirus (HPV) A family of more than 100 strains of VIRUS, various strains of which cause common WARTS, genital HPV infection, and CERVICAL CANCER.

HPV and Common Warts

The strains of HPV that cause common warts are mildly contagious and are more likely to spread to different locations on a person's body rather than to other people. These strains include

- HPV-2, HPV-4, and HPV-7, which cause the raised, rounded warts commonly found on the hands and fingers
- HPV-3 and HPV-7 cause flat, round warts that typically grow on the face and backs of the hands
- HPV-1, which causes plantar warts on the plantar surfaces, or soles, of the feet

Common warts typically do not cause symptoms other than their appearance, which people tend to find cosmetically displeasing. Numerous products and methods are available to remove them. Over time, most warts left on their own gradually recede and disappear as the IMMUNE SYSTEM dispenses with the virus that causes them. Plantar warts, because they are on the walking surface of the foot, often become painful. Plantar warts are also more commonly spread among people, typically via exposure in locker rooms and shower rooms where people walk barefoot.

Genital HPV Infection

Genital HPV INFECTION is the most common of the SEXUALLY TRANSMITTED DISEASES (STDS) in the United States, causing new infection in over 5 million people each year. More than 20 million people currently have HPV infections. More than 40 strains of HPV cause genital HPV infection. These strains are contagious among people and spread via sexual contact (vaginal intercourse, anal intercourse, and oral sex). Some strains produce no symptoms.

HPV-6 and HPV-11 produce fleshy growths, often called genital warts, at the sites where the virus enters the body. Commonly genital warts grow on the tip of the PENIS, on the VULVA and at the opening of the VAGINA, and around the ANUS. Genital warts may also grow within the vagina and on the CERVIX in women and on the SCROTUM in men. Genital HPV may infect the MOUTH and THROAT through oral sex, though this is much less common than genital infection.

Women may first learn they have genital HPV infection during a ROUTINE MEDICAL EXAMINATION when the health-care provider detects genital warts inside the vagina and on the cervix. The gynecologist may perform COLPOSCOPY, an examination of the interior vagina with a specialized microscope, for further diagnostic assessment and to remove tissue samples (biopsy). Genital warts turn white after a few minutes when dabbed with a mild acetic acid solution (vinegar), providing the doctor with a quick diagnostic assessment. Laboratory examination of tissue samples from the growths can confirm the diagnosis.

Because genital warts continue to grow, which both cultivates and sheds the virus, doctors recommend treatment to remove them. Treatment options include medications, cryosurgery (freezing), electrocautery (burning), and laser therapy. Genital warts tend to recur, however, as long as the HPV infection remains present in the body.

TOPICAL MEDICATIONS TO TREAT HPV GENITAL WARTS

bichloracetic acid (BCA)	5-fluorouracil cream
imiquimod cream	podofilox solution
podophyllin solution	trichloroacetic acid (TCA)

Most HPV strains that cause genital infection do not produce symptoms. Many of these asymptomatic infections are benign (harmless) and go away in two or three years. Other genital HPV infections cause molecular changes in the cells of tissues. The tissues most commonly affected are the walls of the vagina and the cervix. These changes, called DYSPLASIA, are detectable only through microscopic examination of cells such as the doctor collects for a routine PAP TEST. Though often dysplasia resolves over time without treatment, it may progress to cancer. Doctors generally treat dysplasia to remove the risk for such progression.

Genital HPV Infection and Cancer

In recent years researchers have discovered that nearly all primary cervical cancer tumors contain one or more of 13 strains of HPV. Further, primary cervical cancer rarely occurs in women who have never had HPV infection. Cancer experts now believe HPV infection is the cause of primary cervical cancer. HPV types 16, 18, 31, 33, 39, 45, 51, 52, 56, 58, 59, 68, and 69 are the causative strains; HPV-16 and HPV-18 together account for about 85 percent of cervical cancers. Though these strains of HPV cause cervical cancer, only a small percentage of women infected with them develop cervical cancer. Routine Pap tests are a woman's best defense against HPV infection leading to cervical cancer because the changes in cells takes place slowly over years. Detecting and treating cervical or vaginal dysplasia eliminates the risk for the cells to continue a transition to cancer.

Preventing HPV Infection

Because human papillomaviruses are so prevalent, avoiding infection is difficult. Minimizing touch with common warts and treating them while they are small reduces the risk for spreading them to other parts of the body. Wearing shower sandals in locker rooms and public showers reduces the risk for contracting HPV-1 infection, which causes plantar warts.

Because of the risk for infection with one of the HPV strains linked with cancer, prevention measures are particularly important for genital HPV infection. Using latex condoms during all sexual activity greatly reduces the likelihood of contact with genital warts as well as with infected tissues that do not show symptoms. Annual Pap tests are essential for sexually active women. Men and women who have multiple sex partners have increased risk for genital HPV infection.

In 2006 the US Food and Drug Adminstration (FDA) approved the first vaccine to prevent infection with HPV types 6, 11, 16, and 18 in women. Administered as three injectons over 6 months, the vaccine appears to be highly effective with minimal side effects. However, the vaccine does not benefit women who already have HPV infection. Health experts recommend women through age 26 receive the HPV vaccine and girls receive HPV vaccine at age 11 or 12.

I

immunization The mechanism through which the body protects itself from subsequent INFECTION with the same PATHOGEN. Immunization may occur as a natural consequence of infection or through vaccination (also called inoculation). The IMMUNE SYSTEM creates unique antibodies, specialized proteins that attach to B-cell lymphocytes that circulate in the BLOOD and the LYMPH, in response to antigens present on the cell surfaces of the pathogen. The antibodies then respond to the presence of the ANTIGEN within the body, activating a rapid IMMUNE RESPONSE to contain and neutralize the pathogen before it establishes sufficiently to cause illness. A VACCINE contains a nonpathogenic preparation of an antigen to stimulate the same immune response without causing illness. Natural immunization is usually lifelong. Immunization acquired through vaccination may require a series of vaccinations or periodic booster vaccines to maintain adequate protection against infection.

See also ANTIBODY; ANTIBODY-MEDIATED IMMUNITY; B-CELL LYMPHOCYTE; CHILDHOOD DISEASES; LYMPHOCYTE; PREVENTIVE HEALTH CARE AND IMMUNIZATION.

incubation period The length of time between the exposure to a PATHOGEN and the appearance of symptoms or illness. Incubation periods vary from a few hours (illnesses such as CHOLERA and SHIGELLOSIS) to months (illnesses such as HEPATITIS C, TUBERCULOSIS, and AMEBIASIS). Some diseases, such as AIDS (acquired immunodeficiency syndrome) and HUMAN PAPILLOMAVIRUS (HPV), may have incubation periods of years. During the incubation period the pathogen replicates until its presence reaches a level that can overcome the immune system's efforts to contain it. Viral infections in particular may be contagious during the incubation period.

See also BACTERIA; FUNGUS; HIV/AIDS; INFECTION; PARASITE; VIRUS.

infection The invasion of the body by a PATHOGEN (microorganism capable of causing disease), sometimes called an infectious agent, that enters cells and attempts to reproduce or replicate itself. The pathogen may be a bacterium, FUNGUS (yeast or mold), VIRUS, PARASITE, or prion. Not all infections cause symptoms or illness, and some infections may be present in the body for an extended time before they cause disease. The length of time between the entrance of a pathogen into the body and the appearance of symptoms is the illness's INCUBATION PERIOD.

The IMMUNE SYSTEM detects and in some way contains most pathogens. INFLAMMATION and FEVER, for example, are ways in which the immune response creates an unfavorable environment for many pathogens. Though the common perception that symptoms such as fever and MUSCLE aches are the effects of the infection, they are often instead the immune system's methods for eliminating the pathogen before its presence can cause illness.

Sometimes an infection is able to evade the immune system's efforts to eliminate it, such as HIV (human immunodeficiency virus), the infection that ultimately results in AIDS (acquired immunodeficiency syndrome). HIV actually infects the cells of the immune system that would fight its presence, restructuring their functions so they are no longer effective.

See also ANTIBODY-MEDIATED IMMUNITY; BACTERIA; CELL-MEDIATED IMMUNITY; IMMUNIZATION.

influenza A common and potentially serious viral INFECTION, commonly called the flu, that

causes upper respiratory symptoms. Influenza viruses rapidly adapt and mutate, which gives them the perpetual ability to cause illness. There are three types of human influenza VIRUS—influenza A, influenza B, and influenza C. Influenza A viruses are primarily responsible for annual outbreaks of the flu, though influenza B viruses also cause illness.

Some strains of influenza A infect humans and some strains infect animals such as pigs (swine influenza virus) and poultry (avian influenza virus). Strains of influenza A that infect animals can sometimes mutate in ways that permit them to cross over to infect people, as happened in 1918 with the world's most severe influenza pandemic, known as the Spanish flu (because the first cases occurred in Spain), which researchers today believe mutated from a variety of swine influenza virus.

Symptoms and Diagnostic Path

Influenza is an illness of the upper respiratory tract, the symptoms of which tend to emerge rapidly and full-force. Symptoms of influenza include

- high FEVER (102°F or higher)
- severe HEADACHE
- muscle aches and JOINT PAIN
- nonproductive COUGH
- sore THROAT
- nasal and sinus congestion

Some people, especially young children, may experience NAUSEA and VOMITING. However, gastrointestinal symptoms are not characteristic of influenza, and their prominent presence suggests a different infection. There are several tests available for influenza, including rapid tests that the doctor can use in the office as well as blood tests.

Treatment Options and Outlook

Most often, the flu simply runs its course and treatment targets relieving symptoms such as fever and aches. Rest, fluids, and nutritious foods are important for helping the body to fight the virus. Secondary bacterial infections and other complications can occur and require appropriate treatment. ANTIBIOTIC MEDICATIONS are not effective for treating viruses, though the doctor may prescribe an antibiotic to treat a secondary bacterial infection that develops, such as PNEUMONIA or STREP THROAT. The most common complication of influenza is PNEUMOCOCCAL PNEUMONIA, a bacterial infection for which there is a one-time vaccine (though people who have lung disorders or respiratory compromise may need a second vaccine 10 years after the first vaccine).

The flu vaccine IMMUNIZATION remains the frontline of treatment for influenza. Each year researchers determine the two strains of influenza A and one strain of influenza B most likely to cause infection (based on complex algorithms of historic and projected viral cycles). Manufacturers then cultivate the three strains to create the year's VACCINE. This is a somewhat speculative approach, however, and the actual strains of influenza that surface may be entirely different. When the strains are similar to those in the vaccine the vaccine is highly effective in preventing or moderating influenza infection. When the strains are not at all close, the vaccine offers no protection from influenza infection. Because the influenza virus so rapidly mutates, each vaccine is effective only for a single flu season.

Antiviral medications ANTIVIRAL MEDICATIONS may shorten the course of illness and lessen the severity of symptoms when taken within 48 hours of the first symptoms and may prevent infection with influenza after exposure to someone who has the viral infection. Antiviral medications work by interfering with the mechanisms viruses use to alter the functions of their host cells, typically by blocking the action of key enzymes or proteins that the virus uses to instruct RNA to take over the host cell. Some antiviral medications are effective against influenza A (amantadine and rimantadine) and others against influenza B (zanamivir and oseltamivir). Further testament to the influenza virus's ability to mutate is the emergence of influenza virus strains that are resistant to amantadine and rimantadine.

Risk Factors and Preventive Measures

People at highest risk for influenza are the very young, the very old, and those who have compro-

mised immune function, such as people who have HIV/AIDS or CANCER or who take IMMUNOSUPPRESSIVE THERAPY after ORGAN TRANSPLANTATION. People who have DIABETES and other chronic health conditions also have increased risk for infection. Preventive measures to reduce the risk for influenza infection include

- frequent HAND WASHING with warm water and soap
- disinfecting common use surfaces such as doorknobs
- minimizing exposure to enclosed crowds of people during peak flu season (November through March in the United States)

Annual flu vaccines are currently the most effective method for preventing influenza.

See also BACTERIA; INFLUENZA PREVENTION; SNEEZE/COUGH ETIQUETTE.

L–M

listeriosis An illness that results from INFECTION with the bacterium *Listeria monocytogenes*. Listeriosis most often occurs as a foodborne illness and has the potential to cause serious symptoms. *L. monocytogenes* are normally present in soil and can contaminate milking equipment. Animals also can carry *L. monocytogenes* without illness. The most common sources of listeriosis are unpasteurized milk and cheeses and processed foods that become contaminated after processing, such as lunch meats served in delis and restaurants. Thorough cooking and pasteurization kill *L. monocytogenes* BACTERIA.

Symptoms and Diagnostic Path

Symptoms of listeriosis are often fairly severe and many people who develop the illness require hospitalization for treatment. Symptoms may include

- FEVER
- difficulty BREATHING (DYSPNEA)
- NAUSEA and VOMITING
- MUSCLE aches and JOINT PAIN

Symptoms may also be specific to the type of infection, such as MENINGITIS or PNEUMONIA. The diagnostic path includes BLOOD cultures and, when neurologic symptoms are present, LUMBAR PUNCTURE to examine and culture the spinal fluid. The presence of *L. monocytogenes* confirms the diagnosis.

Treatment Options and Outlook

Treatment is antibiotic therapy, intravenous when symptoms are serious and oral when symptoms are moderate. Ampicillin, erythromycin, and sulfamethoxazole/trimethoprim (SMZ-TMP) are the antibiotics most effective; the usual course of antibiotic therapy may be four to six weeks. Most people fully recover with appropriate ANTIBIOTIC MEDICATIONS.

Risk Factors and Preventive Measures

People most at risk for listeriosis are those who are IMMUNOCOMPROMISED, particularly people who have HIV/AIDS. Pregnant women are also more vulnerable to infection and can pass the infection to their unborn babies; researchers believe this is due to the changes that take place in a woman's body under the influence of the hormones of PREGNANCY. Some pregnant women can harbor *L. monocytogenes* bacteria without becoming ill, though pass the infection to their babies. Listeriosis can cause STILLBIRTH (fetal death) and serious neurologic problems in newborns after birth. Health experts caution pregnant women (and other people at increased risk for listeriosis) to eat lunch meats and hot dogs only that are thoroughly reheated, to eat only pasteurized cheeses, to drink only pasteurized milk, and to wash all vegetables and fruits before eating them including lettuce) as methods for reducing their exposure to *L. monocytogenes* infection.

See also FOODBORNE ILLNESSES; FOOD SAFETY; HORMONE; WATERBORNE ILLNESSES.

Lyme disease An illness that results from INFECTION with the bacterium *Borrelia burgdorferi* in North America and other *Borrelia* species in Europe. The bite of the *Ixodes scapularis* tick, common in wooded areas throughout the northern United States, spreads the infection. *B. burgdorferi* infection primarily causes flulike symptoms though may also affect the CENTRAL NERVOUS SYSTEM, cardiovascular system, and the joints.

Symptoms of Lyme disease begin 5 to 30 days after a tick bite, typically with a characteristic RASH

called erythema migrans. The rash starts at the site of the bite and looks somewhat like a bull's eye around the bite. The rash expands over five to seven days, becoming large and raised, and may burn or hurt. The rash may also spread to other parts of the body.

Other symptoms may include

- FEVER
- HEADACHE
- MUSCLE aches and JOINT PAIN
- LYMPHADENOPATHY (swollen LYMPH nodes)

Though these symptoms, including the rash, will go away without treatment, the infection remains in the body and extends its involvement. Untreated Lyme disease may cause

- NEUROPATHY (tingling and numbness in PERIPHERAL NERVES), ENCEPHALOPATHY (disturbances of BRAIN function), and MENINGITIS (INFLAMMATION of the membranes that surround the brain and SPINAL CORD)
- BELL'S PALSY (PARALYSIS of the facial muscles)
- arthritis (inflammation of the joints), particularly in the knees and hips
- PALPITATIONS, dizziness, and changes in BLOOD PRESSURE resulting from cardiovascular involvement

BLOOD tests confirm the diagnosis. Treatment with ANTIBIOTIC MEDICATIONS eliminates the infection. People who receive early diagnosis and treatment nearly always recover quickly and fully. When the infection has spread to multiple body systems, residual effects may continue for several months.

ANTIBIOTIC MEDICATIONS TO TREAT LYME DISEASE

amoxicillin	ampicillin
azithromycin	cefuroxime
doxycycline	

Tick precautions when hiking or camping in tick-infested areas are the most effective means of preventing Lyme disease. Such precautions include wearing long pants tucked into high boots or socks to prevent ticks from attaching to the lower legs, examining the entire body for ticks after activities of possible exposure, and immediately removing any attached ticks. Because early treatment can avert serious complications, anyone bitten by a tick who develops rash or flulike symptoms should receive a medical evaluation for the possibility of Lyme disease or for ANTIBIOTIC PROPHYLAXIS (preventive antibiotic therapy).

See also ROCKY MOUNTAIN SPOTTED FEVER.

malaria An illness that results from INFECTION with one of four *Plasmodium* parasites: *Plasmodium malariae, P. ovale, P. vivax,* and *P. falciparum*. Bites from the female *Anopheles* mosquito spread the infection from one person to another. Though malaria has not occurred naturally in the United States since the 1950s, travel to or immigration from regions of the world where malaria is endemic results in about 1300 cases of malaria in the United States each year.

Malaria can be serious or fatal without treatment and is a major cause of death worldwide, particularly in developing nations with limited access to medical resources. Malaria is particularly devastating in the Sahara and sub-Sahara regions of the African continent, where it claims the life of one child every 30 seconds. Extreme poverty, lack of medical resources, and environmental conditions in which mosquito populations flourish converge in these regions, maintaining an endemic presence of malaria that is the most extensive in the world.

Plasmodium parasites initially infect LIVER cells, where they reproduce. They then migrate into erythrocytes (red BLOOD cells), entering the blood circulation. The INCUBATION PERIOD ranges from 8 days to several months, after which flulike symptoms emerge that include

- FEVER and chills
- HEADACHE
- MUSCLE aches
- NAUSEA, VOMITING, and DIARRHEA
- JAUNDICE (yellow discoloration of the SKIN)
- tiredness or fatigue

Microscopic examination of a blood sample shows the parasites, confirming the diagnosis.

Early treatment with medications to kill the *Plasmodium* parasites is essential, particularly when the infective PARASITE is *P. falciparum,* which causes life-threatening illness. Because antimalarial medications are effective against the parasites in the blood, it is essential to continue treatment through several life cycles of the parasites to kill those emerging from the liver. Only one antimalarial medication, primaquine, can kill liver-based *Plasmodium*. The specific medications and length of treatment depend on the type of infection, region of the world where the person acquired the infection, and the person's age and other health circumstances.

MEDICATIONS TO TREAT MALARIA

atovaquone-proguanil	chloroquine
doxycycline	mefloquine
primaquine	quinine
sulfadoxine-pyrimethamine	

Aggressive mosquito-control measures are the most successful preventive approach. These measures include public health efforts to eradicate mosquito populations, such as through insecticide application and eliminating standing water that serves as mosquito breeding grounds, and personal prevention efforts, such as wearing clothing that protects against mosquito bites. People planning travel to regions where *Plasmodium* infection is possible should take prophylactic medications.

See also ERYTHROCYTE; TOXOPLASMOSIS; TYPHOID FEVER.

measles An illness resulting from INFECTION with the measles VIRUS. Once among the most common childhood diseases worldwide, measles (also called rubeola) now primarily exists in developing nations where it remains a leading cause of childhood blindness and death. Routine measles IMMUNIZATION, the standard of care since becoming available in the early 1960s, has eradicated measles from much of the industrialized world. In the United States children generally receive measles VACCINE through the combination MMR (measles-mumps-rubella) vaccine.

Measles is one of the most highly contagious infections and spreads through droplet contamination via airborne transmission (sneezing and coughing) as well as direct contact. The virus invades the lining of the THROAT and the LUNGS, where it replicates. The virus then uses the lymphatic system to enter the BLOOD circulation, after which prodrome symptoms emerge that include

- FEVER
- sensitivity to light (PHOTOPHOBIA)
- congestion of the nasal passages and profuse nasal discharge
- nonproductive COUGH

Within two days the characteristic measles RASH emerges. This red, itchy rash starts at the hairline on the scalp and spreads to cover the entire body, including the palms of the hands and soles of the feet. The course of illness runs about 10 days after the rash begins. The infection is most contagious during the prodrome stage, though contagiousness continues through the rash stage. Diagnosis is clinical based on the characteristic nature of symptoms and history of exposure.

The risk for complications from measles is high, primarily because the measles virus's use of the IMMUNE SYSTEM to distribute itself compromises the IMMUNE RESPONSE, lowering resistance to infection from other pathogens. As a consequence secondary bacterial infections, notably OTITIS media (middle EAR infection) and PNEUMONIA, are common. Such bacterial infections require treatment with ANTIBIOTIC MEDICATIONS, though antibiotics do not treat measles. The measles virus may also cause viral pneumonia and MENINGITIS. IMMUNOGLOBULIN may prevent or moderate illness in people exposed to measles. However, ANTIVIRAL MEDICATIONS are not effective. Complications are more common in people who have vitamin A deficiency, though doctors do not know whether vitamin A supplementation during illness with measles decreases this risk.

See also BACTERIA; CHICKENPOX; MUMPS; PATHOGEN; PREVENTIVE HEALTH CARE AND IMMUNIZATION; SNEEZE/COUGH ETIQUETTE; VITAMINS AND HEALTH.

meningitis INFLAMMATION of the MENINGES, the membranes that surround the BRAIN and SPINAL CORD. Meningitis may result from bacterial, viral, or fungal INFECTION. Viruses are the most common causes of meningitis and can be highly contagious.

Enteroviruses and *Haemophilus influenzae* type B (Hib) VIRUS are the common viral causes, though many viruses can cause meningitis. Bacterial meningitis may be life threatening and requires immediate treatment with intravenous ANTIBIOTIC MEDICATIONS. The contagiousness of bacterial meningitis depends on the BACTERIA.

Symptoms and Diagnostic Path

Symptoms of meningitis tend to be milder with viral meningitis. They may appear gradually and include

- FEVER
- severe HEADACHE
- NAUSEA and VOMITING
- sore or stiff neck, or inability to touch the chin to the shoulder or chest
- agitation and confusion
- inability to remain alert or awake

LUMBAR PUNCTURE, which may reveal elevated cerebrospinal pressure and evidence of infection such as white BLOOD cells or the presence of bacteria, is the definitive diagnostic procedure.

Treatment Options and Outlook

Bacterial meningitis requires immediate treatment with antibiotic medications. Viral meningitis is self-limiting and usually improves on its own as the illness runs its course. Supportive treatment for viral meningitis may include intravenous fluids to maintain adequate HYDRATION. Complications that may occur with meningitis regardless of the causative PATHOGEN include swelling of the brain tissue, seizures, and diminished CONSCIOUSNESS. With appropriate treatment many people recover fully; some people have residual complications such as cognitive dysfunction, VISION IMPAIRMENT, or HEARING LOSS.

Risk Factors and Preventive Measures

The primary risk for meningitis is infection with any virus that can involve the meninges. Meningitis sometimes occurs in clusters of cases in settings where people live in close contact, such as college dormitories. People who are IMMUNOCOMPROMISED have increased risk for meningitis and many other kinds of infections. The most effective prevention measures are those that reduce the risk for acquiring viral infections—frequent HAND WASHING and diligent PERSONAL HYGIENE—and early treatment for symptoms of bacterial meningitis.

See also COGNITIVE FUNCTION AND DYSFUNCTION; ENCEPHALITIS; FUNGUS; VIRUS.

microbe A living organism, also called a microorganism, that is too small to see with the unaided EYE. Most microbes are single-cell or simple multiple cell organisms. Common microbes include BACTERIA, fungi (yeasts and molds), viruses, PROTOZOA, and algae. Microbes are abundant in the natural environment as well as the environment of the human body. Many microbes can cause INFECTION and illness in humans. Dutch scientist Antonie van Leeuwenhoek (1632–1723) identified many microbes using microscopes he constructed himself, paving the way for what would become the foundation of understanding for many disease processes.

See also FUNGUS; VIRUS.

mononucleosis, infectious An illness that results from INFECTION with the EPSTEIN-BARR VIRUS. Infectious mononucleosis is most prevalent among adolescents and young adults though may occur at any age. The infection spreads through contact with saliva; among young people and within families, sharing drinks and food are common means of contracting the illness. The Epstein-Barr VIRUS infects B-cell lymphocytes, also called mononuclear (single nucleus) lymphocytes, which is what gives the illness its name.

Symptoms and Diagnostic Path

The symptoms of infectious mononucleosis are flulike and generally mild to moderate in severity. Many people do not realize they have the illness. Symptoms include

- low-grade FEVER
- HEADACHE
- sore THROAT (PHARYNGITIS)
- fatigue
- cervical and axillary LYMPHADENOPATHY (swollen LYMPH nodes in the neck and underarms)

- abdominal tenderness
- slight JAUNDICE (yellow discoloration of the SKIN)

The diagnostic path includes BLOOD tests; the presence of abnormal lymphocytes and antibodies for Epstein-Barr virus confirms the diagnosis. Some people have mild HEPATITIS (INFLAMMATION of the LIVER), which blood tests also confirm, and mild to moderate SPLENOMEGALY (enlarged SPLEEN), which the doctor can detect with palpation (by feeling the abdomen).

Treatment Options and Outlook

Treatment is supportive, with rest and plenty of fluids. The course of illness may run three to six weeks, during which time the person is contagious and can spread the infection to other people. Most people recover fully, though it may take several months to feel back to normal. Though infectious mononucleosis is generally a benign, self-limiting viral infection, the Epstein-Barr virus remains in the body for life and is linked to certain kinds of cancer (notably Burkitt's lymphoma). A person can have infectious mononucleosis only once; the body develops IMMUNITY with infection.

Risk Factors and Preventive Measures

The Epstein-Barr virus is ubiquitous in the world; avoiding infection is nearly impossible. Measures such as frequent HAND WASHING and appropriate SNEEZE/COUGH ETIQUETTE reduce the risk for passing the infection to others. Adequate rest during the active illness reduces the risk for complications.

See also ANTIBODY; ANTIBODY-MEDIATED IMMUNITY; B-CELL LYMPHOCYTE; LYMPHOCYTE.

mumps An illness resulting from the mumps VIRUS, which primarily infects the SALIVARY GLANDS and may also involve the PANCREAS, TESTICLES (men), OVARIES (women), and sometimes the KIDNEYS. The mumps virus may also invade the CENTRAL NERVOUS SYSTEM, causing NEURITIS and ENCEPHALITIS. Since the advent of the mumps VACCINE in the early 1980s, mumps infections have become uncommon in the United States and now tend to occur in adults who did not have the INFECTION as children. Infection with mumps confers lifelong IMMUNITY, as does vaccination.

The mumps virus is contagious through contact with saliva, either direct or via airborne droplets. After an INCUBATION PERIOD of 14 to 21 days, symptoms emerge that include

- painful swelling of the parotid salivary glands at the base of the EAR
- HEADACHE
- sore THROAT
- FEVER

Swollen testicles are common in boys and lower abdominal PAIN, reflecting ovarian swelling, is common in girls. The classic "eat a pickle" test for mumps has some merit in that eating sour foods greatly intensifies the pain. However, the doctor usually makes the diagnosis on the basis of the symptoms and history of exposure or lack of IMMUNIZATION. Treatment targets symptom relief. Most people recover fully. A small percentage of people, usually adults, who acquire mumps infection develop neurosensory HEARING LOSS that is usually temporary. Mumps infection in both testicles (bilateral testicular mumps) can cause sterility, though this is uncommon. Though mumps encephalitis and MENINGITIS are serious complications, they are seldom fatal and most people recover without long-term consequences.

See also CHICKENPOX; CHILDHOOD DISEASES; MEASLES.

N–O

necrotizing fasciitis A rare but serious bacterial INFECTION of the fascia, the layer of connective tissue that covers, separates, and connects the muscles and other musculoskeletal structures. In necrotizing fasciitis a combination of aerobic and anaerobic bacterial activity produces an abundance of nitrogen, hydrogen, and methane gases. These gases act to suppress the activity of white BLOOD cells that ordinarily would move in to fight the infection. Necrotizing fasciitis is most commonly an OPPORTUNISTIC INFECTION that develops in people who have DIABETES, HIV/AIDS, and other circumstances of immunocompromise.

Nearly always the infection arises at or near the site of a wound, either accidental (more common) or surgical. Symptoms include sudden, severe PAIN at the site along with redness and slight swelling. The person generally feels and looks well in the early stages of the infection, then suddenly becomes critically ill. The redness of the RASH becomes purple, and the SKIN is odd to the touch. Often there is loss of sensation (traumatic ANESTHESIA) in the area. Necrotizing fasciitis moves very rapidly along the fascia into the deep tissues; the farther into the body it goes, the faster its progression because the anaerobic conditions (lack of oxygen) support its growth. Diagnosis is difficult in the early stages but unmistakable in the later stages. Blood cultures and cultures of tissue samples from the innermost edges of the infection generally reveal the causative BACTERIA, which allows doctors to choose effective ANTIBIOTIC MEDICATIONS.

Treatment is multifocused and includes intravenous antibiotics, usually multiple drugs, to attack the various types of bacteria involved in the infection as well as surgery to expose the infection to air (which reduces the ability of anaerobic bacteria to flourish) and remove dead and infected tissue so only healthy tissue remains. The surgical wounds are often significantly larger than the surface appearance of the infection would suggest because so much of the infection is deep within the body. Multiple operations are often necessary. Treatment with hyperbaric oxygen speeds improvement in some people.

With early detection and aggressive treatment that keeps necrotizing fasciitis fairly localized, the likelihood for recovery is good. When infection is extensive and other health conditions exist that challenge the IMMUNE RESPONSE, about 20 percent of people survive necrotizing fasciitis. Because researchers do not understand the complexity of circumstances that allows necrotizing fasciitis to develop, there are no methods for preventing infection. People who have any degree of immunocompromise should carefully monitor any wounds and seek prompt medical care for those that do not seem to follow a normal path of HEALING.

See also ANTIBIOTIC RESISTANCE; BOTULISM; GANGRENE; IMMUNOCOMPROMISED.

normal flora The BACTERIA, fungi, and other microorganisms naturally present within the environment of the healthy body. Normal flora exist on the surface of the SKIN, within natural cavities such as the NOSE and MOUTH, in the gastrointestinal tract, and in the reproductive tract. These beneficial microbes participate in the body's IMMUNE RESPONSE, digestive functions, and reproductive functions, among others.

Normal flora microbes exist in a balance that prevents one type of MICROBE from overpowering another. Circumstances that change this balance may allow illness to develop. Antibiotic therapy targets bacteria, for example, though antibiotics

cannot distinguish between normal flora and pathogenic bacteria. So ANTIBIOTIC MEDICATIONS, particularly broad-spectrum antibiotics, kill bacteria in the gastrointestinal tract and the reproductive tract at the same time they kill pathogenic bacteria. The result may be DIARRHEA or yeast VAGINITIS.

See also FUNGUS; INFECTION.

nosocomial infections Illnesses that result from INFECTION acquired in a hospital, skilled nursing facility, or other health-care facility. The PATHOGEN is typically bacterial, viral, or fungal. Many pathogens that cause nosocomial infections are resistant to common methods of treatment. The most common causes of nosocomial infections are

- invasive procedures ranging from intravenous (IV) lines and urinary catheters to surgery
- environmental factors such as air-conditioning and heating systems that harbor and distribute pathogens
- poor hygiene practices by staff (inadequate HAND WASHING, improper disposal of contaminated items)
- inappropriate separation of patients (such as medical patients roomed with surgical patients)

The risk for acquiring a nosocomial infection correlates directly to the length of time the person remains in the hospital or care facility—the longer the stay, the greater the risk. About 2 million people acquire nosocomial infections in the United States each year. Prevention efforts include improved infection control procedures and education for hospital and care facility staff.

See also ANTIBIOTIC RESISTANCE; BACTERIA; FUNGUS; LEGIONNAIRES' DISEASE; OPPORTUNISTIC INFECTION; VIRUS.

opportunistic infection Illness that develops in a person who is IMMUNOCOMPROMISED as a result of exposure to an otherwise benign MICROBE or a PATHOGEN a healthy IMMUNE SYSTEM could contain or eradicate. Opportunistic infections commonly occur in people who have HIV/AIDS, are receiving IMMUNOSUPPRESSIVE THERAPY after ORGAN TRANSPLANTATION, or are undergoing certain kinds of treatment for cancer. The weakened state of the IMMUNE SYSTEM allows infections to take hold as well as makes fighting the INFECTION more difficult.

COMMON OPPORTUNISTIC INFECTIONS

CANDIDIASIS	CYTOMEGALOVIRUS (CMV) INFECTION
HERPES SIMPLEX infection	COCCIDIOIDOMYCOSIS
CRYPTOCOCCOSIS	*Pneumocystis carinii* PNEUMONIA
TOXOPLASMOSIS	TUBERCULOSIS

See also NOSOCOMIAL INFECTION.

P–R

parasite An organism that requires coexistence with another organism for its survival. The parasite typically draws nourishment and other needs from its host organism without contributing in return to the host's survival. Some parasites can survive away from their hosts for limited periods of time or defined portions of their life cycles. Some parasites are host-specific whereas others can adapt to various hosts.

Pathogenic parasites are those that cause INFECTION and disease. Common pathogenic parasites include flukes, worms, and PROTOZOA (amebas). They may infect the SKIN or migrate to internal organs such as the LUNGS, LIVER, or BRAIN, where they often form cysts. Treatment for parasitic infections and illnesses depends on the parasite and the illness.

People who travel to tropical regions or areas where community sanitation is substandard may acquire parasitic infections otherwise uncommon in their home regions. Many systemic parasitic infections cause gastrointestinal symptoms such as DIARRHEA. These infections are usually contagious, spread through fecal–oral contact (contact with surfaces and substances such as food or water that are contaminated with particles of feces). Diligent PERSONAL HYGIENE, especially HAND WASHING, and appropriate FOOD SAFETY practices are key preventive measures.

COMMON PARASITIC INFECTIONS

AMEBIASIS	BABESIOSIS
CRYPTOSPORIDIOSIS	CYCLOSPORIASIS
GIARDIASIS	MALARIA
microsporidiosis	PEDICULOSIS
SCABIES	TRICHOMONIASIS

See also BACTERIA; FUNGI; MICROBE; VIRUS.

pathogen A MICROBE capable of causing illness. The most common pathogens are BACTERIA, fungi, parasites, and viruses. The process through which a pathogen, also called an infectious agent, causes illness is pathogenesis. The body attempts to protect itself from pathogens through numerous mechanisms, key among them being ANTIBODY-MEDIATED IMMUNITY and CELL-MEDIATED IMMUNITY. Vaccines and treatments with ANTIBIOTIC MEDICATIONS, ANTIVIRAL MEDICATIONS, and ANTIFUNGAL MEDICATIONS are among the methods available to contain and eradicate pathogens once they establish infection in the body.

See also FUNGUS; PARASITE; PROTOZOA; VACCINE; VIRUS.

pertussis An illness resulting from INFECTION with the VIRUS *Bordetella pertussis*. Pertussis is among the childhood diseases for which routine IMMUNIZATION is the standard of care in the United States. The hallmark of the illness is a rapid, violent cough that causes the person to make a "whooping" sound when trying to breathe through the coughing, hence the common term whooping cough. The cough can be severe enough to prevent BREATHING. Pertussis was once a leading cause of death among children under age 5. Though immunization has dramatically reduced infection, pertussis may still be fatal in very young children and very old adults. IMMUNITY, either natural (following infection and illness) or via VACCINE, lasts about 12 years.

The unmistakable cough is the primary symptom and begins about seven days after exposure. In untreated pertussis, the cough worsens rapidly and may continue for as long as eight weeks. Many people also experience VOMITING with the coughing. The doctor often makes the diagnosis on the basis

of the cough, though cultures taken from the MOUTH and NOSE may provide confirmation. Cultures are positive in about 80 percent of people.

Treatment in the early stages of pertussis is ANTIBIOTIC MEDICATIONS, typically erythromycin or trimethoprim and sulfamethoxazole (TMP-SMZ). The further into the course of illness, the less effective antibiotics become, however. The infection causes the nasal passages, THROAT, bronchi, and bronchioles to ooze fluid that clogs the airways; the cough is the body's attempt to remove the fluid to permit free breathing. A profusely runny nose (rhinorrhea) is the earliest symptom of pertussis though often is perceived as a cold until the cough begins. Antibiotic therapy can substantially shorten the course and lessen the severity of illness. Most people recover fully with appropriate treatment, particularly when treatment begins early.

See also CHILDHOOD DISEASES; DIPHTHERIA; PREVENTIVE HEALTH CARE AND IMMUNIZATION.

pneumococcal pneumonia An illness resulting from INFECTION with the bacterium *Streptococcus pneumoniae*, which is normally present in the mucous membranes of the NOSE and sinuses. Researchers do not know what processes occur in the body that allow *S. pneumoniae* to shift from NORMAL FLORA to causing infection in its native environment. Pneumococcal pneumonia is a serious upper respiratory illness that can invade the LUNGS and spread to the BRAIN (causing MENINGITIS) and middle EAR (causing OTITIS media). Pneumococcal pneumonia can also cause SEPTICEMIA, a life-threatening illness of widespread bacterial infection that involves multiple organ systems.

Symptoms and Diagnostic Path

Symptoms begin suddenly and are usually severe. They include

- a shaking chill followed immediately by sudden high FEVER
- nonproductive COUGH
- difficulty BREATHING (DYSPNEA) and CHEST PAIN
- HEADACHE
- NAUSEA and VOMITING
- fatigue

The diagnostic path includes chest X-RAY and BLOOD or fluid tests to determine the presence of *S. pneumoniae*. Because symptoms are severe and the risk for complications is high, doctors typically begin immediate treatment with ANTIBIOTIC MEDICATIONS. Symptoms that dramatically improve with the first 24 hours of treatment further confirm the diagnosis.

Treatment Options and Outlook

Penicillin is the antibiotic of first choice for treatment, though about 25 percent of *S. pneumococcal* strains are now resistant to it. Most resistant strains are sensitive to other antibiotic medications. The antibiotic of last resort is vancomycin, which doctors reserve for pneumonia that does not respond to treatment with any other antibiotics. With appropriate antibiotic therapy many people fully recover from pneumococcal pneumonia, though it is important to take the full course of antibiotics even after symptoms are gone. Pneumococcal pneumonia can be fatal.

ANTIBIOTIC MEDICATIONS TO TREAT PNEUMOCOCCAL PNEUMONIA

cefotaxime	ceftizoxime
ceftriaxone	clindamycin
erythromycin	gatifloxacin
grepafloxacin	levofloxacin
penicillin	moxifloxacin
sparfloxacin	vancomycin

Risk Factors and Preventive Measures

People most vulnerable to pneumococcal pneumonia are the very young, the very old, and those who are IMMUNOCOMPROMISED. The pneumococcal VACCINE, administered each year, can prevent *S. pneumoniae* infection.

See also ANTIBIOTIC RESISTANCE; INFLUENZA; INFLUENZA PREVENTION.

prion A protein fragment that becomes a PATHOGEN. Prion illnesses affect the BRAIN and cause extensive damage to brain tissue, causing it to become spongy in appearance. Though prion illnesses are not contagious in typical fashion, introduction of infectious prions into healthy brain tissue transmits the INFECTION. Because of these characteristics, researchers call prion illnesses

transmittable spongiform encephalopathies (TSEs). Some prion diseases are inherited and others are acquired. The most notorious prion illness is variant Creutzfeldt-Jakob disease (vCJD), acquired through the consumption of beef from cattle that have bovine spongiform encephalopathy (BSE), commonly called mad cow disease. Prions are highly resistant to disinfectants and sterilization procedures. Many hospitals now use disposable instruments for brain surgery to reduce the risk for transmitting a prion disease through an OPERATION.

See also CREUTZFELDT-JAKOB DISEASE (CJD); FOOD SAFETY.

prodrome The stage of illness immediately before the emergence of full symptoms. Prodrome is particularly prominent in herpesvirus INFECTION, which features tingling and irritation at the sites where herpes blisters are about to erupt. Prodrome occurs with many viral infections, such as MEASLES and CHICKENPOX. Often these infections are most contagious during the prodrome.

See also BLISTER; HERPES SIMPLEX; HERPES ZOSTER; GENITAL HERPES.

protozoa Single-celled organisms such as amebas. Many protozoa are parasitic and require host organisms for survival. Some protozoa are pathogenic, notably those that cause MALARIA and infections such as AMEBIASIS, BABESIOSIS, and GIARDIASIS. Some protozoal infections are self-limiting and others require treatment with medications such as antibiotics.

See also ANTIBIOTIC MEDICATIONS; BACTERIA; FUNGUS; PARASITE; VIRUS.

rabies A potentially fatal illness resulting from INFECTION with the rabies VIRUS, which belongs to the *Lyssavirus* viral family. Rabies is very rare in people though a common infection in wild animals who can transmit the infection to unvaccinated pets such as dogs and cats or to people through bites. Raccoons, skunks, coyotes, and bats are reservoirs for the rabies virus; though infected with the rabies virus, these animals do not themselves become ill with rabies. Nearly any animal may acquire rabies infection as a result of contact with saliva or other secretions from an infected animal, usually a bite.

In animals and humans the rabies virus infects the CENTRAL NERVOUS SYSTEM. It travels via the PERIPHERAL NERVES to the BRAIN, where it replicates within brain neurons (NERVE cells). Symptoms of illness generally appear one to three months after exposure, though the INCUBATION PERIOD may be as short as a few days or as long as several years. Once symptoms appear rabies is fatal. The illness of rabies is ENCEPHALITIS.

The most effective treatment for rabies infection in people is postexposure prophylaxis, which consists of one injection of human rabies IMMUNOGLOBULIN and five injections of rabies VACCINE administered at regular intervals after a bite from a potentially infected animal. The vaccine injections are given in the upper arm and are similar in discomfort to receiving a tetanus shot. The course of postexposure prophylaxis covers 28 days and appears to be 100 percent effective. People at high risk for rabies exposure, such as those who work with animals, can receive rabies vaccinations to prevent infection, though they also need postexposure prophylaxis if bitten.

See also IMMUNIZATION.

retroviruses See VIRUS.

Rocky Mountain spotted fever An illness resulting from INFECTION with the bacterium *Rickettsia rickettsii*. Tick bites spread Rocky Mountain spotted FEVER, so-named because of the characteristic RASH the illness causes. Symptoms generally appear within five days of a tick bite and include

- fever
- slight RASH
- NAUSEA and VOMITING
- severe HEADACHE
- MUSCLE PAIN

Symptoms become rapidly more severe as the illness progresses. Diagnosis is primarily clinical, based on the presentation of symptoms in combination with a history of tick bite or exposure to settings where tick bites are possible (such as hiking or camping in wooded areas). Treatment is prompt administration of doxycycline or tetracycline, ANTIBIOTIC MEDICATIONS that are especially

effective against *R. rickettsii*. Rapid improvement of symptoms confirms the diagnosis before BLOOD tests are able to do the same.

Most people fully recover with appropriate antibiotic treatment. However, Rocky Mountain spotted fever is life threatening for people who have G6PD DEFICIENCY, an inherited condition in which there is a lack of an enzyme important for maintaining red blood cells (erythrocytes). Age extremes (very young or very old) and chronic ALCOHOLISM are other factors that increase the severity of illness. Delayed treatment of Rocky Mountain spotted fever often results in multiple organ failure, requiring intensive medical treatment and a long recovery.

See also BACTERIA; ERYTHROCYTE; GENETIC DISORDERS; HUMAN EHRLICHIOSIS.

rubella An illness resulting from INFECTION with the rubella virus, a member of the *Rubivirus* viral family. Rubella, also called three-day MEASLES or German measles (because German researchers were the first to identify rubella as an illness separate from measles), is a mild course of illness in most people. However, the infection can cause serious BIRTH DEFECTS, collectively called congenital rubella syndrome, in a developing FETUS when a pregnant woman becomes infected during the first trimester of PREGNANCY.

Rubella is fairly contagious and spreads primarily through droplet inhalation (airborne transmission). The INCUBATION PERIOD is 14 to 21 days, after which most people experience low-grade FEVER; LYMPHADENOPATHY (swollen LYMPH nodes); and a red, slightly bumpy RASH that begins on the face and spreads to cover the entire body. Adults who get rubella often have PAIN and inflammation in the joints that continues for up to six weeks after other symptoms abate. Infection conveys lifelong IMMUNITY.

Rubella is among the diseases for which children in the United States receive routine IMMUNIZATION. This is particularly important because of the risk rubella infection presents to the unborn fetus. Congenital rubella syndrome affects about 90 percent of babies born to women who contract rubella during the first trimester of pregnancy. The syndrome's key features are

- HEARING LOSS, often profound (deafness)
- cataracts, GLAUCOMA, and RETINOPATHY
- pulmonary artery stenosis, ventral septal defect (VSD), patent ductus arteriosus (PDA), and other HEART anomalies
- impaired immune function
- early childhood development of type 1 DIABETES

Congenital rubella syndrome often causes lifelong health problems for affected children.

See also CATARACT; CATARACT EXTRACTION AND LENS REPLACEMENT; CHILDHOOD DISEASES; CONGENITAL HEART DISEASE; MEASLES; MUMPS; PREVENTIVE HEALTH CARE AND IMMUNIZATIONS; SCARLET FEVER.

S

salmonellosis An illness resulting from INFECTION with any of the numerous strains of *Salmonella* BACTERIA. *Salmonella* are common in the feces of birds and animals. Salmonellosis is most often a foodborne illness acquired through eating raw eggs, unpasteurized dairy products, and undercooked poultry. Reptiles kept as pets, such as turtles and iguanas, also carry *Salmonella*. Once salmonellosis develops, the infected person can spread it to other people.

The INCUBATION PERIOD (time between exposure and illness) is often less than 12 hours. The most common symptom of salmonellosis is DIARRHEA, which may be bloody or profuse. Other symptoms include abdominal discomfort, NAUSEA, VOMITING, and FEVER. The course of illness is self-limiting and runs four to seven days in otherwise healthy people. In people who are IMMUNOCOMPROMISED salmonellosis may occur as an OPPORTUNISTIC INFECTION that causes significant illness. Because salmonellosis is self-limiting, doctors do not usually prescribe ANTIBIOTIC MEDICATIONS to treat it even though the cause is bacterial. Researchers have discovered that the *Salmonella* bacteria remain longer in the bodies of people who receive antibiotics for salmonellosis, extending the possibility of spreading the infection to other people.

The most effective approach is prevention through proper food handling and diligent PERSONAL HYGIENE. Thorough cooking kills *Salmonella*. FOOD SAFETY procedures include

- washing the hands with soap and warm water before and after handling food
- thoroughly rinsing fresh fruits and vegetables in running water before eating or preparing them for meals
- using separate food preparation surfaces, such as cutting boards, and utensils for poultry and meats
- thoroughly cooking eggs, poultry, and other animal-based foods

See also FOODBORNE ILLNESSES; WATERBORNE ILLNESSES.

scarlet fever An illness resulting from INFECTION with group A beta-hemolytic streptococcal BACTERIA that occurs as a complication of STREP THROAT. Scarlet FEVER begins with the same symptoms as strep THROAT—sudden onset of fever and often severe throat PAIN. Within two days a RASH erupts, starting on the chest and back and spreading to cover the entire body. The key characteristic of the rash is that it feels like sandpaper to the touch. Other symptoms of scarlet fever include

- bright red, inflamed ("strawberry") tongue
- bright red color to the natural creases in the SKIN (under the arms and in the groin)
- HEADACHE
- peeling of the skin on the fingertips, on the tips of the toes, and in the creases of the groin

Scarlet fever, like strep throat, is contagious and spreads among people through airborne transmission or direct contact with saliva (such as through shared food or eating utensils). The diagnostic path includes culture of the throat to detect the presence of group A strep bacteria, though the symptoms are so characteristic the doctor can usually make the diagnosis on the basis of their presence (clinical diagnosis).

Treatment is with ANTIBIOTIC MEDICATIONS, typically penicillins or erythromycin. Most people rapidly and fully recover with appropriate antibiotic therapy. Though the infection may resolve without treatment, the risk is very high for the strep bacteria to migrate to other locations in the body, notably the HEART valves where it causes RHEUMATIC HEART DISEASE. The infection may also spread to the joints, causing INFECTIOUS ARTHRITIS.

See also PHARYNGITIS; SNEEZE/COUGH ETIQUETTE; TONSILLITIS.

septicemia A life-threatening bacterial INFECTION that invades the BLOOD circulation, resulting in spreading the infection throughout the body. Septicemia, also called bacteremia, typically arises as a complication of localized bacterial infection. The onset and progression of septicemia are rapid and can result in septic SHOCK, ACUTE RESPIRATORY DISTRESS SYNDROME (ARDS), and death within hours. Treatment requires hospitalization, usually in an intensive care unit, with administration of intravenous ANTIBIOTIC MEDICATIONS as well as other medications to sustain vital functions such as HEART RATE and BLOOD PRESSURE. People who recover from septicemia tend to have a long path of recuperation before they are able to return to regular activities.

See also DISSEMINATED INTRAVASCULAR COAGULOPATHY (DIC); NECROTIZING FASCIITIS; TOXIC EPIDERMAL NECROLYSIS; TOXIC MEGACOLON; TOXIC SHOCK SYNDROME.

severe acute respiratory syndrome (SARS) A life-threatening illness resulting from INFECTION with the VIRUS SARS-associated coronavirus (SARS-CoV). The first outbreak of SARS occurred in 2003 and sickened more than 8,000 people in Asia, Europe, and South America. The handful of people infected in the United States acquired SARS during travel to countries experiencing outbreaks.

Infection occurs through close contact; SARS-CoV spreads through airborne droplets as well as direct touch with saliva and other bodily secretions that shed the virus. Symptoms appear 2 to 10 days after infection and begin with HEADACHE, general MUSCLE aches and JOINT PAIN, sore THROAT, and moderate FEVER. Within a few days shortness of breath (DYSPNEA) develops and may result in HYPOXIA (insufficient oxygen entering the BLOOD circulation for distribution to organs and tissues. Blood tests confirm the presence of SARS-CoV.

Treatment is primarily supportive; ANTIVIRAL MEDICATIONS may lessen the severity of symptoms. Some people require hospitalization in an intensive care unit with MECHANICAL VENTILATION and other medical care to support respiration and other vital functions while the illness runs its course. PNEUMONIA is the most common complication. The course of illness may run several weeks. Most people recover, though may require several months of recuperation before feeling well enough to return to their normal activities.

See also INCUBATION PERIOD.

shigellosis An illness resulting from INFECTION with any of numerous strains of *Shigella* BACTERIA. Shigellosis most commonly occurs as a foodborne illness, producing symptoms of FEVER, abdominal cramping, and bloody DIARRHEA within about 12 hours of infection with the bacteria. The illness is generally self-limiting, running its course in five to seven days. Most people recover fully, though for a small percentage the bacteria infect other areas of the body such as the joints, causing the chronic condition REITER'S SYNDROME.

Doctors may prescribe ANTIBIOTIC MEDICATIONS for the very young, the very old, and people who are IMMUNOCOMPROMISED or who have unusually severe and extended symptoms. Ampicillin, trimethoprim/sulfamethoxazole (TMP-STZ) combination, and ciprofloxacin are among the antibiotics doctors more commonly prescribe. Diligent PERSONAL HYGIENE and frequent HAND WASHING are the most effective means to curtail the spread of shigellosis from one person to another.

See also ANTIBIOTIC RESISTANCE; FOODBORNE ILLNESSES; FOOD SAFETY; WATERBORNE ILLNESSES.

smallpox An illness resulting from INFECTION with the *Variola* VIRUS. Though smallpox was once a much-feared and leading cause of death worldwide, aggressive vaccination efforts resulted in the World Health Organization's determination of its eradication as a naturally occurring disease in

1980. The last smallpox infection to occur in the United States was in 1949; the last smallpox infection in the world was in 1977 (Somalia).

The name derives from the characteristic appearance of small sores that BLISTER and then crust, or pox, on the body when illness emerges. The sores, along with FEVER, are the primary symptom. They are also the means by which the virus sheds; contact with the sores or the fluids they contain spreads the virus and the infection. Throughout history until its eradication in the 20th century, smallpox claimed the lives of a third of those infected and often left disfiguring scars on those who survived.

Because the risk for complications is relatively high with the smallpox VACCINE and there are no smallpox infections worldwide, routine vaccination for smallpox no longer occurs. Smallpox reemerged as a potential public health concern in the early 2000s with worries that it, along with other infectious pathogens such as ANTHRAX, could be used as a biologic weapon or bioterrorism agent. Governments around the world have prepared emergency response plans to cope with such potential actions. Though when smallpox occurred naturally as a disease there were no known treatments, researchers believe modern ANTIVIRAL MEDICATIONS would be effective against smallpox infection today.

See also IMMUNIZATION; PATHOGEN.

sneeze/cough etiquette A method of PERSONAL HYGIENE to help prevent the spread of INFECTION. Sneezing and coughing are among the mechanisms the body uses to expel bacterial and viral particles in illnesses such as COLDS and INFLUENZA. However, these particles spread the infection to others who breathe them in with the air or touch surfaces on which they land. Health experts recommend these procedures to reduce the risk of spreading infection through sneezing and coughing:

- SNEEZE or COUGH into a tissue that covers the NOSE and MOUTH, then discard the tissue and wash the hands with soap and warm water.
- Sneeze or cough into the crook of the arm, which is less likely to be a point of contact with surfaces and other people.
- Avoid shaking hands with other people during illnesses that cause sneezing or coughing.

See also BACTERIA; VIRUS.

strep throat An INFECTION of the pharynx (throat), also called streptococcal PHARYNGITIS, with various strains of group A beta-hemolytic streptococcal BACTERIA. Strep throat is highly contagious through contact with saliva and requires treatment with ANTIBIOTIC MEDICATIONS to prevent potentially serious complications such as RHEUMATIC HEART DISEASE.

Symptoms and Diagnostic Path

The symptoms of strep throat come on suddenly, usually within five days of exposure to the infection. A characteristic indication of strep throat is the appearance of symptoms without other cold-like symptoms. Only about 5 percent of sore throats (pharyngitis) are strep throat; most sore throats are viral infections. Key symptoms of strep throat include

- FEVER
- moderate to severe throat PAIN
- difficulty swallowing
- HEADACHE
- ABDOMINAL PAIN and VOMITING
- enlarged, painful LYMPH nodes in the neck
- MUSCLE aches and JOINT pain

Symptoms generally peak 48 hours after they first appear. The throat looks very red and may have pockets of pus (white patches or streaks), particularly on the tonsils. However, the throat's appearance is not diagnostically conclusive. A rapid ANTIGEN test, which produces results in minutes from a swab of the throat, is fairly accurate when positive but inaccurate when negative. A culture of the throat provides definitive diagnosis.

Treatment Options and Outlook

Antibiotic medications are necessary to treat strep throat. Because antibiotics do not help viral infections of the throat and because antibiotic-resistant strains of strep are beginning to appear, doctors

tend to wait for the throat culture results before prescribing antibiotic medications unless the person has a history of strep throat.

ANTIBIOTIC MEDICATIONS TO TREAT STREP THROAT	
ampicillin	azithromycin
cefaclor	cefazolin
cefuroxime	cephalexin
clarithromycin	penicillin VK

Most people recover fully with appropriate antibiotic therapy, with symptoms dramatically improved within 48 hours of starting the antibiotic. It is important to take the full course of antibiotic therapy even when symptoms are gone to make sure the antibiotic completely eliminates the strep bacteria. Possible complications of strep throat, which are more likely to occur with delayed treatment or in untreated strep throat, are serious and include PERITONSILLAR ABSCESS, GLOMERULONEPHRITIS (strep infection involving the KIDNEYS), and rheumatic heart disease (strep infection involving the HEART valves).

Risk Factors and Preventive Measures

Strep throat is most common in children between the ages of 5 and 15, though people of any age may acquire the infection. People who have their tonsils have greater risk. Diligent PERSONAL HYGIENE; frequent HAND WASHING; and avoiding the sharing of drinks, foods, and eating utensils among family members or friends are measures that can reduce the risk for exposure to the strep bacteria.

See also ANTIBIOTIC RESISTANCE; MENINGITIS; SCARLET FEVER; TOXIC SHOCK SYNDROME.

syphilis A sexually transmitted disease (STD) that results from INFECTION with the bacterium *Treponema pallidum*. Syphilis spreads through vaginal intercourse, anal intercourse, and oral sex. It is not possible to acquire syphilis from objects such as toilet seats or in hot tubs. Syphilis is curable with appropriate antibiotic therapy. Untreated syphilis can cause widespread damage in the body. Congenital syphilis, which a pregnant woman who has syphilis can pass to her unborn child, can cause numerous abnormalities or STILLBIRTH.

Symptoms and Diagnostic Path

Untreated syphilis has four stages: primary, secondary, latent, and tertiary. Symptoms are specific to the stage of illness. Diagnosis typically occurs through BLOOD tests that confirm the presence of antibodies or examination of cell samples (such as from body fluids) under a microscope that reveal the presence of *T. pallidum* BACTERIA.

Primary syphilis Primary syphilis is the first manifestation of illness and occurs two to six weeks after infection with *T. pallidum*. Its symptom is the formation of a painless, ulcerlike sore (chancre) at the site where the infection entered the body. Because this site may be inside the VAGINA in a woman or within the URETHRA in a man, the chancre often goes undetected and heals.

Secondary syphilis Though the chancre heals the *T. pallidum* bacteria continue to multiply and invade the blood circulation, which carries them throughout the body. The characteristic symptoms of secondary syphilis emerge about two months after the chancre and include

- skin RASH of brown spots or sores that involves the palms of the hands and soles of the feet as well as other locations on the body
- mucous patches in the vagina or MOUTH and on the PENIS
- condylomata lata, which are spongy, wartlike patches that often appear on the labia (women) or SCROTUM (men)
- low-grade FEVER (around 100°F)
- sore THROAT and HEADACHE

Secondary syphilis lasts up to three months, during which the person can spread the infection to others through nonsexual as well as sexual contact because the sores of the rash contain *T. pallidum* bacteria. Some people experience outbreaks of secondary syphilis symptoms for a year or longer.

Latent syphilis In latent syphilis the bacteria remain in the body but cause no symptoms. During this stage the person cannot pass the infection to other people. Latent syphilis may last for decades, during which the bacteria silently attack the NERVOUS SYSTEM, joints, HEART, and other structures.

Tertiary syphilis The last stage of syphilis, the tertiary stage, is the emergence of symptoms resulting from the damage that occurred during the latent stage. Damage is often widespread and significant, producing symptoms of cognitive dysfunction, blindness, heart disease, kidney disease, and NEUROPATHY (sometimes called neurosyphilis).

Treatment Options and Outlook

Treatment for syphilis at any stage is penicillin by injection (or doxycycline for people who are allergic to penicillin). Most people who receive treatment for primary or secondary syphilis recover completely. Treatment can still cure tertiary syphilis but the damage the infection has already caused is permanent. Reinfection is possible; there is no IMMUNITY for syphilis. All sexual partners should be tested so they can receive treatment if they have syphilis. Primary syphilis carries increased risk for HIV infection because the chancre gives an easy pathway for the VIRUS to enter the body.

Risk Factors and Preventive Measures

People who have multiple sexual partners and men who have sex with men have the greatest risk for contracting syphilis and other STDs. Precautions such as condom use with all sexual activity reduce the risk for infection. Early diagnosis and treatment are essential to prevent complications and to prevent spreading the infection to other people.

See also CHLAMYDIA; GENITAL HERPES; GONORRHEA; HUMAN PAPILLOMAVIRUS (HPV); SEXUAL HEALTH; SEXUALLY TRANSMITTED DISEASE (STD) PREVENTION; SEXUALLY TRANSMITTED DISEASES (STDS).

T

toxic shock syndrome A systemic IMMUNE RESPONSE to the endotoxins many BACTERIA produce during infections. The immune response produces widespread, significant INFLAMMATION involving multiple organ systems. Staphylococcal toxic shock syndrome, resulting from *Staphylococcus aureus* INFECTION, is more common and causes milder illness. Streptococcal toxic shock syndrome, which results from group A beta-hemolytic streptococcal bacteria, produces severe illness and causes death in about 60 percent of people who develop it.

Symptoms are those of acute bacterial infection such as FEVER and PAIN, with HYPOTENSION (low BLOOD PRESSURE) and RASH that involves the entire body, including the palms of the hands and soles of the feet. Illness is severe enough to require hospitalization, often in an intensive care unit, for supportive medical care (including fluid replacement, cardiovascular stabilization, and MECHANICAL VENTILATION as necessary) and treatment with intravenous IMMUNOGLOBULIN and ANTIBIOTIC MEDICATIONS. Complications of toxic shock syndrome are potentially life-threatening and include DISSEMINATED INTRAVASCULAR COAGULATION (DIC), ACUTE RESPIRATORY DISTRESS SYNDROME (ARDS), and NECROTIZING FASCIITIS. People who recover from toxic shock syndrome may have lingering health problems and are at risk for RECURRENCE.

Toxic shock syndrome first emerged as a significant health issue in the 1980s when superabsorbent tampons new on the market caused an outbreak of toxic shock syndrome among otherwise healthy women. The superabsorbency of the tampons meant women could change them less frequently, an unexpected SIDE EFFECT of which was a spike in bacterial infections. Changes in tampon materials and widespread education efforts have significantly reduced toxic shock syndrome due to tampon use, although tampon use remains a risk factor. Other risks for toxic shock syndrome include surgical packing (such as after an OPERATION on the NOSE) and illness due to common bacterial infections.

See also SCARLET FEVER; STREP THROAT; SEPTICEMIA.

toxoplasmosis An illness that results from INFECTION with the PARASITE *Toxoplasma gondii*. Health experts in the United States estimate that about 60 million Americans are infected with *T. gondii,* though only a small percentage of them become ill. *T. gondii* may migrate into body tissues, forming cysts.

Domestic cats carry *T. gondii*; cat feces in litter boxes and outdoors in garden areas are the most common source of infection. Outdoor cats are more likely to have *T. gondii*. Other sources of *T. gondii* include undercooked or raw meats, especially pork and lamb. People acquire the infection through touching contaminated objects and then transmitting the parasites to food or drink. Children may acquire *T. gondii* infection through playing in outdoor sandboxes.

Toxoplasmosis is often an OPPORTUNISTIC INFECTION that causes illness in people who are IMMUNOCOMPROMISED, such as people who have HIV/AIDS or who are taking IMMUNOSUPPRESSIVE THERAPY after ORGAN TRANSPLANTATION. Toxoplasmosis, whether or not it produces symptoms, is a particular risk for a pregnant woman because she can pass the infection to her unborn child. The cysts that *T. gondii* form in the tissues can cause serious BIRTH DEFECTS in the developing fetus, including damage to the eyes that results in permanent loss of vision. HEARING LOSS and neurologic injuries are also common.

Symptoms, when they occur, are similar to those of influenza and may include

- FEVER
- MUSCLE aches and JOINT PAIN
- upper respiratory congestion
- tiredness or fatigue

A BLOOD test that shows the presence of antibodies confirms the diagnosis. Anyone who has ever had toxoplasmosis will have a positive blood test; infection confers lifelong IMMUNITY. Toxoplasmosis is self-limiting; once the illness runs its course any symptoms subside. Though the *T. gondii* remain in the body, the IMMUNE SYSTEM can contain them so they do not cause illness. Doctors may recommend treatment with sulfadoxine and pyrimethamine, two medications used to prevent MALARIA, for pregnant women who acquire *T. gondii* infection or develop toxoplasmosis and for people who are immunocompromised. These medications are effective because *T. gondii* is similar to the parasite that causes malaria. The antibiotic clindamycin is also effective in people who are immunocompromised.

Washing the hands with warm water and soap after handling cats, cleaning litter boxes, gardening, and preparing pork or lamb removes *T. gondii*, preventing infection. Pregnant women should also wear gloves when gardening or cleaning litter boxes.

See also ANTIBIOTIC MEDICATIONS; HAND WASHING; INVESTIGATIONAL NEW DRUG (IND).

transmission modes The methods by which pathogens spread to cause INFECTION. Common transmission modes include

- airborne, in which pathogens enter the respiratory tract as particles suspended in the air
- sexual, in which pathogens enter the body through sexual contact
- direct contact, in which pathogens enter the body via touch
- foodborne, in which consumed foods contain pathogens
- waterborne, in which consumed water and foods prepared in that water contain pathogens
- bloodborne, in which pathogens enter the blood circulation through BLOOD TRANSFUSION or contaminated needles

Many infectious agents have multiple transmission modes. The common cold, for example, spreads through direct contact with nasal secretions as well as via airborne droplets.

See also COLDS; FOODBORNE ILLNESSES; PATHOGEN; SNEEZE/COUGH ETIQUETTE; WATERBORNE ILLNESSES.

trichomoniasis A sexually transmitted disease (STD) resulting from INFECTION with the protozoan *Trichomonas vaginalis*. Though trichomoniasis affects men and women equally, women are more likely to show symptoms. About two thirds of men and half of women who have trichomoniasis do not have symptoms, though they are nonetheless able to spread the infection through sexual contact.

Symptoms of trichomoniasis include

- greenish or yellowish, often foul-smelling, discharge
- lower abdominal discomfort
- in men, burning with URINATION
- in women, vaginal or vulvar itching or burning

The diagnostic path includes examination under the microscope of a sample of the discharge, which usually contains *T. vaginalis* though a third of people who have the infection may have negative findings with this test. Culture of discharge samples can provide definitive diagnosis. Treatment is oral therapy with the medication metronidazole. It is important to also treat all sexual partners, as the likelihood that they also have the infection is very high. Appropriate treatment cures trichomoniasis, though infection may recur with reexposure. Without treatment the infection remains active. Complications of untreated trichomoniasis include EPIDIDYMITIS and PROSTATITIS in men and chronic vaginitis and vaginal ulcerations in women.

See also CANDIDIASIS; CHLAMYDIA; GENITAL HERPES; GONORRHEA; HUMAN PAPILLOMAVIRUS (HPV); SEXUAL HEALTH; SEXUALLY TRANSMITTED DISEASE (STD) PREVENTION; SEXUALLY TRANSMITTED DISEASES (STDS); SYPHILIS; URETHRITIS.

tuberculosis An illness resulting from INFECTION with the MICROBE *Mycobacterium tuberculosis*. Though tuberculosis most commonly infects the LUNGS, the disease may involve other organs as well, notably the KIDNEYS. Health experts estimate more than 2 billion people worldwide have active (symptoms are present) or latent (symptoms are not present) tuberculosis. An important characteristic of mycobacteria is their ability to rapidly develop resistance to ANTIBIOTIC MEDICATIONS.

Untreated tuberculosis is debilitating and progressive, giving the appearance that it consumes the body. This characteristic accounts for the archaic common name of the disease, "consumption." Tuberculosis was a leading cause of death throughout the world until the discovery of the FUNGUS-derived antibiotic streptomycin in 1944. Today's treatment regimens seldom incorporate streptomycin, however, because of its high likelihood for causing HEARING LOSS (OTOTOXICITY) and because many strains of *M. tuberculosis* have developed resistance to it.

When breathed into the lungs, *M. tuberculosis* BACTERIA infect macrophages, white BLOOD cells responsible for consuming invading pathogens, in the alveoli. Rather than the MACROPHAGE consuming the *M. tuberculosis* bacterium, however, the bacterium takes over the macrophage. Other cells of the IMMUNE RESPONSE surround the infected macrophage, enclosing it within a GRANULOMA. The bacteria may remain dormant within the granuloma. When enough granulomas accumulate, they interfere with the normal function of the organ—typically the lungs, though also the kidneys, bones, and BRAIN when *M. tuberculosis* bacteria migrate to those structures.

Symptoms and Diagnostic Path

Many people who have tuberculosis do not have symptoms and do not know they have the infection. Chest X-RAY for other diagnostic reasons may detect lesions in the lungs; other people learn they have tuberculosis through routine tuberculin SKIN testing such as many states in the United States require for people who work with the public, such as health-care workers and food service workers. When symptoms are present they include

- prolonged, productive COUGH that may include blood (HEMOPTYSIS)
- unintended weight loss
- FEVER
- night sweats
- fatigue
- wheezing or feeling of tightness in chest

The diagnostic path includes chest X-ray, tuberculin skin test, and cultures of sputum samples. When the findings of these diagnostic procedures are inconclusive, the doctor may conduct additional tests, including BRONCHOSCOPY or COMPUTED TOMOGRAPHY (CT) SCAN.

Treatment Options and Outlook

Current treatment regimens use multiple medications in a rotating pattern over 9 to 12 months. The first phase of treatment—the initial phase, which lasts two months—generally involves taking four medications. The second phase of treatment—the continuation phase, which lasts four to seven months—generally incorporates a combination of two medications. The specific drugs depend on numerous clinical factors, including the person's HIV status and the sensitivities of the causative strain of *M. tuberculosis* from sputum cultures.

MEDICATIONS TO TREAT TUBERCULOSIS

Standard Infection	
ethambutol	isoniazid
pyrazinamid	rifabutin
rifampin	rifapentine
Resistant Infection	
amikacin	capreomycin
cycloserine	ethionamide
gatifloxacin	kanamycin
levofloxacin	moxifloxacin
p-aminosalicylic acid	protionamide
pyrazinamide	viomycin

Symptoms in most people improve dramatically within three weeks of starting medication, though clinical changes (X-ray) often do not become apparent for several months. Treatment regimens are complex, and the medications can cause unpleasant side effects, the combination of which tempts people to stop taking the medications.

Doing so is hazardous both for the person, who then remains infected with tuberculosis, and in the context of public health because it fosters DRUG resistance. It is essential to take the medications as directed for the full course of treatment. When compliance is a significant concern, doctors may use a protocol called directly observed treatment (DOT), in which the person comes to a clinic and takes his or her medication under direct observation of a health-care provider. Such treatment cures the tuberculosis. Any damage to the lungs or the kidneys (granulomas) remains, however, and is permanent.

Risk Factors and Preventive Measures

Crowded, unsanitary living conditions present the greatest risk for tuberculosis infection. Active tuberculosis is contagious through contact with sputum (material coughed up from the lungs), which contains *M. tuberculosis*. Latent tuberculosis is not contagious, though may emerge as active disease and become contagious. Tuberculosis is a common OPPORTUNISTIC INFECTION in people who have HIV/AIDS. Prevention efforts focus on routine testing of people at risk for exposure. In the United States, such testing takes place through public health programs, school-based programs, institutional programs (such as in the military and in prisons), and employer-based programs. People who have positive skin tuberculin tests should receive further evaluation from a doctor and may require a course of prophylactic treatment with anti-tuberculosis medications.

See also BONE; COMMUNITY SANITATION; PATHOGEN.

typhoid fever An illness resulting from INFECTION with the bacterium *Salmonella typhi*. Typhoid FEVER is rare in the United States, and most people who have the illness acquire the infection while traveling in regions of the world where typhoid fever is endemic. Substandard COMMUNITY SANITATION is the key risk for the spread of typhoid fever. The BACTERIA infect the SMALL INTESTINE. Infection spreads through fecal–oral contamination, primarily through consumption of contaminated water and foods. Some people are carriers of typhoid fever; they are infected with *S. typhi* but do not develop symptoms or illness.

Symptoms of typhoid fever include

- high fever
- NAUSEA, VOMITING, and DIARRHEA
- RASH
- ABDOMINAL PAIN
- extreme fatigue and weakness

Cultures of BLOOD and stool samples reveal the presence of *S. typhi*, which is conclusive for diagnosis. Treatment is ANTIBIOTIC MEDICATIONS, commonly ampicillin, trimethoprim-sulfamethoxazole (TMP-SMZ), or ciprofloxacin. Most people feel much improved within three days of starting antibiotic therapy, though the bacteria may remain in their bodies for six weeks or longer, during which time they remain contagious (capable of passing the infection to others). People who work in food service, health care, and other public contact jobs may require a doctor's statement of health, verifying negative blood and stool cultures, before they can return to work. People who are planning to travel to regions of the world where typhoid fever is common should receive typhoid fever VACCINE to prevent infection.

See also FOODBORNE ILLNESSES; WATERBORNE ILLNESSES.

V–W

virus An infectious PATHOGEN that must invade a host cell to replicate, technically called an obligate intracellular PARASITE. A virus is a particle of living material that contains an inner core of nucleic acid (DNA or RNA), called the genome, encased in an outer shell of protein, called a capsid. Some viruses contain a third layer composed of lipids, called an envelope, that further protects and nourishes the virus. These components, collectively called a virion, cannot themselves support a full life cycle, which obligates the virus to find a host to maintain its survival. A virus can attach only to the type of cell capable of supporting it, binding to specific protein molecules on the surface of the cell membrane.

ANTIBIOTIC MEDICATIONS are not effective in treating illnesses that result from viral infections, such as COLDS and INFLUENZA.

After invading a host cell, a virus hijacks the cell's structures and functions to serve its own needs and to replicate itself. DNA viruses produce

COMMON VIRUSES AND THE ILLNESSES THEY CAUSE

Virus or Viral Family	Genetic Configuration	Illness
ADENOVIRUS	DNA	PHARYNGITIS, PNEUMONIA, acute respiratory disease, cervicitis, URETHRITIS, CYSTITIS, GASTROENTERITIS
CYTOMEGALOVIRUS (CMV)	DNA	CMV INFECTION
EPSTEIN-BARR VIRUS	DNA	infectious mononucleosis, Burkitt's lymphoma, Hodgkin's lymphoma
HEPATITIS A virus (HAV), hepatitis C virus (HBV)	RNA	HEPATITIS
HERPES SIMPLEX virus 1 (HSV-1)	DNA	COLD SORE
herpes simplex virus 2 (HSV-2)	DNA	GENITAL HERPES
human herpesvirus 8 (HHV-8)	DNA	KAPOSI'S SARCOMA
human immunodeficiency virus 1 (HIV-1), human immunodeficiency virus 2 (HIV-2)	RNA retrovirus	AIDS

Virus or Viral Family	Genetic Configuration	Illness
human papillomavirus (HPV)	DNA	genital WARTS, CERVICAL CANCER, vaginal cancer
human parainfluenza viruses	RNA	acute upper respiratory disease, CROUP, bronchiolitis, BRONCHITIS, pneumonia
INFLUENZA viruses	RNA	influenza (flu)
MEASLES virus	RNA	measles
MUMPS virus	RNA	mumps
Norwalk-like viruses	RNA	acute gastroenteritis
poliovirus	RNA	POLIOMYELITIS
RABIES virus	RNA	rabies
respiratory syncytial virus	RNA	bronchiolitis, pneumonia, acute upper respiratory disease
rhinoviruses	RNA	COLDS
RUBELLA virus	RNA	rubella (German or three-day measles)
varicella-zoster	DNA	CHICKENPOX, HERPES ZOSTER (shingles)
variola	DNA	SMALLPOX

proteins that the host cell's RNA transcribe as instructions to replicate the virus's DNA, which the cell does. DNA contains the instructions for the cell's functions; RNA forms the messenger proteins that carry out the directives of the DNA. Eventually the virus's copies of DNA crowd out the cell's copies of DNA, and the cell becomes the agent of the virus. The cell either divides or ruptures, spreading the virus. RNA viruses achieve a similar result by causing the host cell to replicate their RNA, which then replaces the cell's RNA. Retroviruses are RNA viruses that contain the enzyme reverse transcriptase, which allows RNA to instruct DNA (the reverse of normal).

Viruses are highly adaptable and have numerous mechanisms to hide from the IMMUNE SYSTEM, allowing them to become well established infections before the immune system detects their presence. Once the immune system does detect a virus, it develops antibodies that protect against subsequent infection by the same virus. Many common viruses—such as those that are responsible for COLDS (rhinoviruses), GASTROENTERITIS (enteroviruses), and the flu (INFLUENZA viruses)—frequently alter their structures, evolving into different strains that can cause the same illnesses. Some viruses, such as human T-lymphotropic virus (HTLV) and HUMAN PAPILLOMAVIRUS (HPV), cause cancer (oncoviruses). The human immunodeficiency virus (HIV) is a retrovirus that attacks the immune system, causing AIDS (acquired immunodeficiency syndrome).

See also ANTIBODY; ANTIBODY-MEDIATED IMMUNITY; CELL-MEDIATED IMMUNITY; HIV/AIDS.

waterborne illnesses Diseases that result from pathogens transmitted by drinking or otherwise consuming contaminated water. Heavy metals and

industrial chemicals may also contaminate water supplies, causing poisoning. People may acquire waterborne infections through drinking water supplies or by swallowing water during recreational activities in lakes, rivers, pools, hot tubs, and similar sources.

Drinking water supplies in the United States must meet established DRINKING WATER STANDARDS for purity, which state and local health departments monitor through regular and spontaneous testing. Water that does not come from a community water supply or properly maintained and disinfected private well should be boiled for one minute, then cooled, before drinking or using to prepare food.

Environmental water sources such as lakes and rivers contain numerous BACTERIA and parasites that can cause illness with contact or consumption. Contamination is higher after steady or heavy rain, as runoff water that drains into streams, rivers, and lakes is likely to contain animal excrement as well as soil-based microbes. Recreational activities such as boating, swimming, water-skiing, and fishing hold increased risk for exposure to such pathogens. It is important to avoid swallowing environmental water and to shower to rinse the SKIN after being in the water. People who hike and camp in back-country areas should use appropriate decontamination or filtration methods to draw drinking water from natural sources. A rapidly moving stream or river does not necessarily contain fewer microbes, and the clearness of water's appearance does not mean it is safe to drink.

COMMON WATERBORNE ILLNESSES

CRYPTOSPORIDIOSIS	*Escherichia coli* INFECTION
GIARDIASIS	HEPATITIS A
AMEBIASIS	CYCLOSPORIASIS
CAMPYLOBACTERIOSIS	SALMONELLOSIS
SHIGELLOSIS	viral GASTROENTERITIS

See also COMMUNITY SANITATION; ENVIRONMENTAL HAZARD EXPOSURE; FOODBORNE ILLNESSES; FOOD SAFETY; HEAVY-METAL POISONING; HEPATITIS PREVENTION; PARASITE; POISON PREVENTION.

CANCER

The area of health care concerned with cancer prevention and treatment is oncology. Doctors who specialize in cancer treatment are oncologists. This section, "Cancer," presents an overview discussion of current understanding about cancer and entries about cancer concepts and treatments. Entries in other sections of The Facts On File Encyclopedia of Health and Medicine *provide detailed content about specific types of cancer.*

For example, this section, "Cancer," contains the entry HORMONE-DRIVEN CANCERS, whereas while the section "The Reproductive System" contains entries for BREAST CANCER, PROSTATE CANCER, and TESTICULAR CANCER. Cross-references connect entries with one another.

Cancer: Uncontrolled Cell Proliferation

Cancer is the uncontrolled growth and division (proliferation) of cells. Cancer cells lack the proper mechanisms for APOPTOSIS, the natural process that establishes the end of a cell's life cycle. In this regard, cancer cells have an endless open throttle: they can divide forever. Cancer cells also lack the proper mechanisms for self-regulation that shut down cell division in abnormal cells; they never stop growing and dividing.

Ordinarily the IMMUNE SYSTEM detects cells that present a threat to the body and mobilizes an IMMUNE RESPONSE to neutralize them before they can do much damage. Cancer cells appear able to evade such detection by the immune system because they arise from cells that belong to the body (self cells). Even as they mutate cancer cells retain enough essence of their self-cell origin to fool the immune system into continuing to perceive them as self cells. This deception allows cancer cells to congregate, forming the tumors that characterize the disease process of cancer.

Cancer may develop in any cell, with the potential to affect any kind of body tissue. The cells form tumors that invade healthy tissues and can spread to parts of the body beyond the site of origin. Cancer is a threat to health because its presence within tissues and organs disrupts their structure and functions. Cancer tumors take space, NUTRIENTS, and structure that tissues and organs need.

Heredity, Environment, and Aging

Researchers believe cancer is the result of genetic damage within individual cells that allows uncontrolled cell division and growth. This damage may occur as a consequence of heredity or environment or may develop through the process of aging.

Heredity and cancer The tendency toward cancer appears to run in families, providing much anecdotal evidence of genetic mutations that contribute to the risk for cancer. Researchers also have isolated specific genes for certain types of cancer, providing objective evidence that cancer can have a hereditary component. When this is the case, a person inherits mutated genes that do not properly regulate specific functions. This lack of regulation results in abnormal cell growth and division that can result in cancer. The BRCA-1/BRCA-2 GENE mutations are among the best known; these mutations are prominent in women who have some types of OVARIAN CANCER or breast cancer. However, only a small percentage of women who have these gene mutations develop cancer, evidence that many factors converge when cancer occurs.

Environmental influences and cancer More than a thousand substances found in the environment, natural and synthetic, may cause cancer.

Most are chemicals or sources of radiation, both of which alter the molecular structure of cells in ways that change their functions. The most common natural CARCINOGEN is the ultraviolet radiation of sunlight, which is responsible for nearly all SKIN CANCER. Other carcinogens are manmade, notably industrial chemicals such as formaldehyde and vinyl chloride. Many manufacturing processes use these and other carcinogenic chemicals; it is nearly impossible to avoid exposure to them.

Aging and cancer Genetic damage to cells may also occur as a consequence of natural deterioration within cells that takes place with aging. Cells become less able to repair themselves and exposure to carcinogens leaves them more vulnerable, allowing errant growth and division. Some cancers that are more common in advanced age are also less harmful to health overall. For example, researchers estimate that 90 percent of men over age 85 have prostate cancer, yet in most of them the cancer is so slow growing that it does not require treatment.

Traditions in Medical History

Surgery was the first treatment for cancer. Even ancient documents record procedures for removal of tumors. However, the development of ANESTHESIA gave surgery its big boost as treatment for cancer, allowing surgeons to more selectively remove cancerous tumors. Though the operations were often extensive and traumatic, they were able to save lives.

RADIATION THERAPY was the next treatment developed for cancer. Though doctors began using X-rays on tumors shortly after the discovery of X-rays in the late 19th century, the treatment was often more dangerous than the cancer. Radiation BURNS and radiation sickness were common as doctors struggled to find a balance between enough radiation to kill the tumor and not enough radiation to kill the patient. Finally, in the middle of the 20th century advances in technology and understanding made it possible for radiation to achieve this balance.

For centuries folk medicine contained various substances purported to treat cancer, some of which have become the basis for contemporary CHEMOTHERAPY (such as the camptothecins, vinca alkyloids, and taxanes). During the first half of the 20th century doctors realized that one SIDE EFFECT of poisonous mustard gas, used as a weapon of war, was that it eradicated certain types of cancer. Further exploration resulted in the first class of therapeutic chemotherapy agents, the alkylating agents.

In the later decades of the 20th century, researchers made significant breakthroughs in understanding the functions of the immune system and were able to develop methods to take advantage of the body's own mechanisms for fighting cancer. IMMUNOTHERAPY is now at the forefront of cancer research.

Breakthrough Research and Treatment Advances

Cancer treatment focuses on removing or disabling cancer cells so they can no longer grow and divide. Though cancer remains the second-leading cause of death in the United States, successes in treatments since the 1990s have improved the outlook significantly. Nearly 10 million Americans live with their cancer under control, in REMISSION, or cured. Treatment is so often curative for basal cell carcinoma (BCC) and squamous cell carcinoma (SCC), the two most common types of SKIN cancer, that cancer statistics do not include these cancers among them.

As researchers learn more about cancer, they are discovering ways to bolster the immune system's ability to detect and eradicate cancer cells before they gain enough momentum to establish themselves as tumors. Cancer vaccines currently in investigational trials show great promise for preventing the development of CERVICAL CANCER, prostate cancer, and lymphoma, and for preventing the RECURRENCE of other types cancer. New treatments specifically target molecular functions, either in cancer cells or within the immune response. These therapies reduce the unpleasant side effects traditionally characteristic of cancer treatment as well as improve the ability to eradicate the cancer. Other therapies establish boundaries around the cancer, containing it so it cannot spread and interfere with structures and functions. Many types of cancer may soon be as manageable (and perhaps preventable) through therapeutic interventions and lifestyle modifications as other chronic health conditions such as CARDIOVASCULAR DISEASE (CVD) and DIABETES.

A–B

adenocarcinoma A type of cancer that arises from the endothelial cells of glandular structures. Adenocarcinoma is the most common type of cancer to occur in the PROSTATE GLAND (PROSTATE CANCER), gastrointestinal tract (ESOPHAGEAL CANCER, STOMACH CANCER, PANCREATIC CANCER, LIVER CANCER, COLORECTAL CANCER), and endocrine glands (TESTICULAR CANCER, OVARIAN CANCER, THYROID CANCER). Adenocarcinoma begins as a benign (noncancerous) tumor, an adenoma. Over time, GENE mutations in the cells of the adenoma may cause the tumor to transition to an adenocarcinoma. Adenocarcinomas can involve numerous organs and tissues.

See also BLASTOMA; CARCINOMA; ENDOCRINE GLAND; FAMILIAL ADENOMATOUS POLYPOSIS (FAP); HEREDITARY NONPOLYPOSIS COLORECTAL CANCER (HNPCC); INTESTINAL POLYP; LEUKEMIA; MUTATION; SARCOMA.

adenoma-to-carcinoma transition The changes that take place in an ADENOMA, a benign (noncancerous) tumor, as it transforms into an ADENOCARCINOMA, a malignant (cancerous) tumor. The transition to cancer can occur with any adenoma though is most common with adenomas of the colon (intestinal polyps, also called adenomatous polyps). Only a small percentage of adenomas become cancerous. The sequence of events that transform an adenoma to an adenocarcinoma begins with multiple mutations in the genes that regulate cell division and APOPTOSIS (planned cell death). Over a series of cell divisions the mutations become increasingly prevalent among the cells, resulting in DYSPLASIA and ultimately cancer. Because of the risk for an adenoma to become adenocarcinoma, doctors often surgically remove adenomas when feasible.

See also CANCER PREVENTION; COLORECTAL CANCER; FAMILIAL ADENOMATOUS POLYPOSIS (FAP); GENE; HEREDITARY NONPOLYPOSIS COLORECTAL CANCER (HNPCC); INTESTINAL POLYP; MUTATION.

adult survivors of childhood cancer The current generation of adults is the first to grow up in the era of successful treatment for many childhood cancers. Nearly 300,000 American adults who are now in their 20s, 30s, and 40s enjoy CANCER-free, healthy lives. Doctors consider treatments for most types of LEUKEMIA, the most common childhood cancer, to be curative. Treatments for many types of BONE CANCER, BRAIN cancer, Hodgkin's LYMPHOMA, and kidney cancer (WILMS'S TUMOR) are also curative. Some health concerns may linger or occur, however, as a result of the cancer itself or the therapies used to treat the cancer.

Complications of Cancer Treatment

Complications of cancer treatment are the most significant cause of later health concerns for adults who had cancer as children. Some therapies for cancer that were the standard of care 20 or 30 years ago presented significant health risks that survivors are now beginning to experience. For example, doctors now know the CHEMOTHERAPY drugs, notably anthracyclines such as doxorubicin, can cause HEART FAILURE that tends to show up 10 to 30 years after treatment. Chemotherapy drugs affect all rapidly dividing cells in the body and can have a significant effect on healthy cells notably in the endocrine system, affecting THYROID GLAND function, growth, PUBERTY, and FERTILITY. Radiation to the chest, such as to treat lymphoma, can damage the HEART, manifesting in adulthood as CARDIOMYOPATHY or heart failure. Radiation to the head

or EYE can result in vision and hearing problems. Surgery, particularly AMPUTATION, may result in lifelong health issues that require regular medical attention.

Increased Risk for Another Cancer

Having had cancer increases the risk for developing another cancer later in life. For this reason, regular health screening for cancer is especially important for adults who had cancer as children. Radiation therapy and chemotherapy both increase the risk for leukemia and lymphoma, likely as a consequence of damage to the bone marrow during cancer treatment and especially chemotherapy. Radiation therapy to the upper body raises the risk for lung cancer, particularly when other risk factors for lung cancer exist such as cigarette smoking, and for breast cancer in women.

Emotional Health

The emotional consequences of successful cancer treatment in childhood may be pervasive, with numerous effects people do not recognize as related to the cancer experience. Some studies show that adults who had cancer as children reexperience the range of emotions and fears that accompanied their cancer when as adults they enter medical environments for health care of any kind, often as a presentation of POST-TRAUMATIC STRESS DISORDER (PTSD). The reaction to the current situation may be out of proportion to the situation itself. Having survived a health crisis as serious as cancer as a child may have a profound effect on a person's ability to engage in activities of life, manifesting as withdrawal in some people and in high-risk behaviors in others.

Maintaining a Balanced Perspective

It is important for adults who had cancer as children to maintain a balance between diligence and confidence when it comes to health matters. More often than not, subsequent health concerns arising from childhood cancer or its treatment are treatable and manageable, particularly with early detection. Many cancer treatment centers now offer follow-up services, including counseling, for adult survivors of childhood cancer.

See also CANCER PREVENTION; CANCER RISK FACTORS; LIFESTYLE AND CANCER.

alternative and complementary remedies for cancer Therapies outside the realm of conventional medical methods that are promoted to relieve cancer symptoms. Alternative practices are used instead of conventional treatments and methods; complementary practices are used in conjunction with conventional treatments and methods. Some therapies and remedies may be either alternative or complementary, depending on how they are used. Because some cancer treatment protocols are very precise, it is important to discuss alternative and complementary approaches with the oncologist before using them.

Complementary Therapies

Complementary therapies are often effective for treating symptoms related to cancer and discomforts related to conventional cancer treatment. ACUPUNCTURE, BIOFEEDBACK, and HYPNOSIS can provide relief from PAIN and NAUSEA. YOGA, TAI CHI, and MEDITATION provide relaxation and stress relief. Some therapies, such as acupuncture and biofeedback, have undergone clinical research studies that support their effectiveness and usefulness. Most complementary therapies integrate well with conventional treatments. Some herbal remedies, such as products for nausea or relaxation, may interact with chemotherapy drugs.

Alternative Remedies

Alternative remedies for cancer are approaches to treat cancer that have not been proven effective through conventional research studies; some have been proven ineffective. Alternative therapies may include health-care systems that differ in philosophy and practice from conventional Western medicine, such as AYURVEDA, HOMEOPATHY, and TRADITIONAL CHINESE MEDICINE (TCM). Alternative remedies may also consist of conventional treatments used in unproven or disproven ways; most have either not been subjected to conventional research study or have been disproved. Some alternative remedies are potentially harmful in themselves as well as for the delay they may cause

in receiving conventional treatments that could have health benefits.

Making Choices and Decisions

Choices and decisions in regard to treatment for cancer are not easy to make, particularly when the diagnosis comes after the cancer is fairly advanced or has metastasized. Emotions are high, and sometimes the route of conventional treatment has little to offer beyond palliative care. Alternative remedies may make claims that sound too good to pass up. Cancer experts urge people to fully explore the remedy and the evidence that surrounds its usefulness. These key questions can help put the claims of the therapy or remedy in perspective:

- What does the remedy do—specifically? How does it affect the cancer?
- Does the remedy claim to be able to replace or support medical treatments?
- Who administers or provides the remedy?
- What are the remedy's possible side effects?
- What kinds of research have tested the remedy?
- What is the cost of the remedy?
- Is the remedy available in the United States?

Unfortunately, many purported cancer remedies are ineffective at best and potentially harmful. In some circumstances those who are marketing the remedy sincerely believe in its ability to treat or even cure cancer. However, the market for alternative remedies also offers abundant opportunity for fraud. Complementary therapies that supplement conventional treatment can provide comfort and relief from many symptoms related to cancer and cancer treatment. Choosing an ineffective alternative remedy in lieu of conventional treatment may have irreversible consequences for health and for QUALITY OF LIFE.

An oncologist or credentialed cancer care center can provide information and guidance for choosing complementary therapies that are helpful. The Web sites for the American Cancer Society (www.cancer.org), the US National Cancer Institute's Office of Cancer Complementary and Alternative Medicine (www.cancer.gov/cam), and the US National Center for Complementary and Alternative Medicine (nccam.nih.gov) provide current information about alternative remedies and complementary therapies for cancer.

See also CHEMOTHERAPY; COPING WITH CANCER; DIAGNOSING CANCER; RADIATION THERAPY; SURGERY FOR CANCER.

angiogenesis inhibitor drugs Substances that stop tumors from developing new BLOOD vessels to support their survival. Numerous proteins and enzymes in the body function to encourage or suppress the growth of new blood vessels. Cancerous tumors are among the tissues that produce proteins that foster new blood vessel growth; these blood vessels then deliver to the tumor the nourishment it needs to grow. Cutting off the blood supply starves the tumor, causing its cells to die.

Among the natural angiogenesis inhibitors in the body are the INTERFERONS, which doctors have used in therapeutic forms with some success to slow tumor-related blood vessel growth. Some CHEMOTHERAPY drugs also have a secondary antiangiogenesis effect. In 2004 the US Food and Drug Administration (FDA) approved the first DRUG specifically developed to block angiogenesis, a monoclonal antibody that is called bevacizumab (Avastin).

Angiogenesis inhibition is of therapeutic interest in health conditions other than cancer that result from overgrowth of blood vessels, such as AGE-RELATED MACULAR DEGENERATION (ARMD) and RETINOPATHY of DIABETES. Research into drugs to encourage angiogenesis to restore blood flow to the HEART after HEART ATTACK or in severe ISCHEMIC HEART DISEASE led to many advances in angiogenesis inhibition as well.

See also CELL STRUCTURE AND FUNCTION; MOLECULARLY TARGETED THERAPIES; MONOCLONAL ANTIBODIES (MABS); TRANSMYOCARDIAL LASER REVASCULARIZATION (TMLR).

blastoma A cancerous tumor that arises from the immature cells that form the basis for an organ's structure. The cells are undifferentiated, which means they have not yet developed a specific role within the body. Researchers believe these are embryonic cells. Blastomas grow as the

type of tissue where the embryonic cells remain after organ development. Blastomas nearly always occur in childhood, though occasionally may occur in early adulthood. Most blastomas are malignant (cancerous), though osteoblastoma (blastoma of the BONE) is a benign (noncancerous) tumor. Treatment for blastoma typically combines surgery to remove the tumor with CHEMOTHERAPY, RADIATION THERAPY, or both to shrink the tumor before surgery and destroy any lingering cancer cells after surgery. The precise combination depends on the tumor's location and size at the time of diagnosis.

TYPES OF BLASTOMA

Tumor	Location
medulloblastoma	BRAIN
nephroblastoma	kidney
RETINOBLASTOMA	RETINA of the EYE
osteoblastoma	BONE
neuroblastoma	NERVOUS SYSTEM tissue
glioblastoma multiforme (GBM)	brain

See also ADENOCARCINOMA; CARCINOMA; LEUKEMIA; SARCOMA; SURGERY FOR CANCER; SURGERY BENEFIT AND RISK ASSESSMENT; WILMS'S TUMOR.

BRCA-1/BRCA-2 BREAST CANCER GENE 1 and breast cancer gene 2, the first genes in which researchers identified mutations that correlate to increased susceptibility to BREAST cancer and OVARIAN CANCER. About one in six women who have either of these cancers have mutations in either or both of the genes. Many are women who have a known family history of breast cancer or ovarian cancer. The presence of mutations in either of these genes means a woman has an increased risk for developing breast or ovarian cancer but it does not mean cancer is inevitable. Researchers do not yet know the extent to which BRCA-1/BRCA-2 gene mutations affect a woman's risk for cancer, though believe they are responsible for about 5 percent of breast and ovarian cancers. Many factors influence the development of cancer; genetics remains only one among them.

Testing for BRCA-1/BRCA-2 is controversial because there are few preventive or therapeutic actions women or doctors can take as a result of knowing a positive result. Under current practice guidelines, doctors may choose to offer such testing to women who have first-degree relatives (mother, daughter, sister, grandmother) who have breast cancer or ovarian cancer or who are themselves under age 50 at the time of being diagnosed with either type of cancer. A positive result (mutations are present) may be a factor in prophylaxis or treatment decisions, though is by itself not a strong enough indicator to be the basis for such decisions. Nor is a negative result any indication that a woman will not develop breast or ovarian cancer. Because doctors can detect breast and ovarian cancers early through regular examinations, most health experts believe such examinations remain the most effective means for early diagnosis and treatment regardless of genetic influences.

See also CA-125; GENETIC TESTING; MUTATION; PROSTATE-SPECIFIC ANTIGEN (PSA).

C

cancer risk factors The circumstances that may increase an individual's chance for developing cancer. Cancer risk is a combination of hereditary, environmental, viral, bacterial, immunologic, and lifestyle factors that alter CELL STRUCTURE AND FUNCTION. Age is the most significant single risk factor for cancer, with most cancer developing in people age 50 and older. This reflects current thinking that most cancer results from cumulative damage to cellular DNA, which causes changes in cells as they divide.

Gender is a significant risk factor for specific cancers. For example, BLADDER CANCER is three times more common in men than women, and only about 1 percent of BREAST CANCER occurs in men. Ovarian and endometrial cancers are uniquely women's cancers, and TESTICULAR CANCER and PROSTATE CANCER are uniquely men's cancers. LIVER CANCER and PANCREATIC CANCER are also more common in men. Hereditary genetic factors influence the risk for breast cancer, ovarian cancer, and COLORECTAL CANCER.

The most significant mutable (changeable) risk factor for cancer is cigarette smoking, which accounts for 85 percent of LUNG CANCER, 60 percent of bladder cancer, and about 30 percent of other cancers collectively. Excessive ALCOHOL consumption and exposure to environmental carcinogens (substances that cause cancer) are also preventable risks for cancer.

Infectious agents are emerging as major risk factors for certain cancers. Researchers have already linked certain cancers with specific infections. More than 90 percent of women who have CERVICAL CANCER also have HUMAN PAPILLOMAVIRUS (HPV) INFECTION. About 80 percent of people who have STOMACH CANCER test positive for the presence of *HELICOBACTER PYLORI*, which causes a low-grade bacterial infection in the stomach. In Western cultures, KAPOSI'S SARCOMA occurs nearly exclusively in people who have HIV/AIDS.

cancer treatment options and decisions The methods and protocols available to treat cancer and its symptoms. Most cancer treatment involves a combination of methods. There are a number of conventional treatment options for cancer:

- SURGERY FOR CANCER, in which the doctor performs an OPERATION to remove the cancer, is the treatment of first choice for most solid tumors (cancer that develops in organs and tissues other than the BLOOD, LYMPH, or BONE MARROW). The surgery generally removes the tumor and a safe margin of healthy tissue surrounding the tumor in the attempt to prevent stray cells at the tumor's periphery from migrating into other tissues. Sometimes the operation to remove the cancer involves removing an entire structure or organ to obtain such a margin.
- RADIATION THERAPY may precede or follow surgery or may be the sole or an adjuvant treatment. Radiation therapy targets high-energy particles at the cancer cells. The energy—radiation—disrupts the ability of the cancer cells to grow and divide. The cells die, and the body's natural mechanisms (such as PHAGOCYTOSIS) eliminate their debris. Radiation before surgery shrinks the tumor. The main purpose of radiation therapy after surgery is to kill any lingering or stray cancer cells. The oncologist may also combine radiation therapy with CHEMOTHERAPY

CANCER RISK FACTORS

Risk Factor	Type of Cancer
age 50 years and older	all cancers
ALCOHOL consumption	STOMACH CANCER, LIVER CANCER, PANCREATIC CANCER
cigarette smoking	cancers of the lung, BLADDER, kidney, STOMACH, BREAST, prostate, COLON, PANCREAS; acute myeloid LEUKEMIA (AML)
EPSTEIN-BARR VIRUS	Burkitt's lymphoma
gender: female	BREAST CANCER, ENDOMETRIAL CANCER, CERVICAL CANCER
gender: male	BLADDER CANCER, PROSTATE CANCER, pancreatic cancer, stomach cancer, CANCER OF THE PENIS, TESTICULAR CANCER, liver cancer
HELICOBACTER PYLORI INFECTION	stomach cancer, gastric lymphoma
HEPATITIS B VIRUS/hepatitis C virus	liver cancer
HIV/AIDS	KAPOSI'S SARCOMA, lymphoma
human herpes virus-8 (HHV-8)	Kaposi's sarcoma
HUMAN PAPILLOMAVIRUS (HPV) infection	cervical cancer, cancer of the PENIS, vaginal cancer, anal cancer, cancer of the VULVA
human T-lymphotropic virus-1 (HTLV-1)	adult T-cell leukemia/lymphoma (ATL)
INFLAMMATORY BOWEL DISEASE (IBD)	COLORECTAL CANCER
INTESTINAL POLYP	colorectal cancer
personal or family history of cancer	all, though notably breast, ovarian, and colorectal cancers
Schistosoma haematobium parasitic infection	bladder cancer
sun exposure	SKIN CANCER: basal cell CARCINOMA, squamous cell carcinoma, malignant melanoma
TOBACCO USE OTHER THAN SMOKING	oral cancer (lips, tongue, other structures of the MOUTH)

or IMMUNOTHERAPY for an additive effect. Adverse side effects generally stay localized (remain in the area exposed to the radiation).

- Chemotherapy uses drugs to kill cancer cells. Like radiation therapy, chemotherapy may precede or follow surgery to shrink tumors or kill residual cancer cells, serve as the sole treatment, or function as an adjuvant treatment in combination with other treatment methods for optimal effectiveness against certain types of cancer. Because chemotherapy affects the entire body, it can have significant side effects.
- Immunotherapy, also called biological response modification, uses methods to enhance the ability of the body's natural IMMUNE SYSTEM functions to target cancer cells for containment and destruction. Genetically engineered substances such as MONOCLONAL ANTIBODIES (MABS), INTERFERONS, and INTERLEUKINS are among the immunotherapy agents oncologists may administer to boost the IMMUNE RESPONSE.
- HORMONE THERAPY targets HORMONE-driven cancers such as PROSTATE CANCER, OVARIAN CANCER, ENDOMETRIAL CANCER, and BREAST CANCER. These cancers require hormones, typically ESTROGENS or TESTOSTERONE, to grow. Treatment either suppresses or boosts the presence of these hormones in the body. HORMONE THERAPY for breast cancer, for example, deprives the woman's body of estrogen or the ability to use it, and hormone therapy for prostate cancer deprives the man's body of testosterone or the ability to use it. Hormone therapy for prostate cancer may also include administration of estrogen in a further effort to shut down the tumor's hormone sources.
- BONE MARROW TRANSPLANTATION is a treatment option for LEUKEMIA, MULTIPLE MYELOMA, and lymphoma. BONE marrow transplantation replaces cancerous bone marrow with healthy marrow from a genetically matched donor called an allogeneic transplants (a syngeneic transplant when the donor is an identical twin). An autologous transplant uses the patient's own bone marrow, which is an option only when the cancer is in remission or when it does not involve the bone marrow. Bone marrow transplantation may sometimes be a treatment option for other types of cancer though has not proven to be as effective as originally hoped.
- Stem cell transplantation may be a treatment option in cancers that do not involve the bone marrow. The person's stem cells (precursors for red blood cells, white blood cells, and platelets) are gathered from the person's blood, then reinfused into the person after CHEMOTHERAPY.

Though there are established approaches, called treatment protocols, for most types of cancer, cancer treatment is highly individualized and treatment decisions evolve as a collaboration between the person who has cancer and the health-care team providing care for the person. The treatment decision process begins with consideration of the cancer's type, stage, and grade—the characteristics of the cancer cells, how widespread within the body the cancer is, and how aggressive the cancer cells are in their growth pattern. Other important factors include the person's age and overall health status, any other health conditions, and the person's preferences or goals for treatment.

INFORMATION MANAGEMENT

Because there is so much information to absorb and sort through when it comes to CANCER TREATMENT OPTIONS AND DECISIONS, it is a good idea to have a trusted family member or friend go along for key doctor visits to take notes. This lets the patient focus on the discussion with the doctor during the visit with the opportunity to later go over the notes and consider the options.

Sometimes there are clear "best" choices for treatment. Other times there are several treatment options that are likely to produce similar results. A person whose cancer is widespread (metastatic) by the time of diagnosis may choose only palliative treatment—treatments to relieve PAIN and other symptoms—or may choose to enter a clinical trial, a research study evaluating a new treatment that shows promise for the person's particular type or stage of cancer. Each treatment method has benefits and risks, which are important to consider when evaluating the various options.

A second opinion consultation from another oncologist (cancer specialist) is often helpful when there are numerous treatment options or when

treatment options appear slim. Different oncologists may view the same person's situation differently based on their level of experience and knowledge of specific cancers or treatments. Oncologists who practice through medical centers affiliated with research facilities, such as are common at large universities that have medical schools, often know of the newest drugs and therapies under evaluation in current or upcoming clinical trials.

There is an abundance of information about cancer available on the Internet and in publications; sorting through it all to determine what is reliable and what is potentially useful for an individual is confusing and often overwhelming. Because there are no controls over the content of Web sites in particular, a large amount of information is, unfortunately, inaccurate or potentially harmful; with the emotional factors that surround a cancer diagnosis, it is important to make treatment decisions based on sound principles. Many cancer treatment centers have staff and resources to help people put such information into contexts that are relevant for their personal situations. The American Cancer Society (www.cancer.org) and the US National Institutes of Health's (NIH's) National Cancer Institute (www.cancer.gov) provide numerous resources to help people sort through treatment claims and methods.

See also ALTERNATIVE AND COMPLEMENTARY REMEDIES FOR CANCER; BLOOD STEM CELLS; CANCER PREVENTION; COPING WITH CANCER; DIAGNOSING CANCER; END OF LIFE CONCERNS; QUALITY OF LIFE; STEM CELL; SURGERY BENEFIT AND RISK ASSESSMENT.

cancer vaccines Preventive therapies to keep cancer from developing in people who do not have it or to keep cancer from growing or recurring in people who have it. Most cancer vaccines remain in clinical trials. Two approved by the US Food and Drug Administration (FDA) are those for HEPATITIS B VIRUS (HBV), the virus primarily responsible for LIVER CANCER, and for some types of HUMAN PAPILLOMAVIRUS (HPV), the virus primarily responsible for CERVICAL CANCER. Preventing the viral infection nearly eliminates the risk for developing the cancer.

The HBV vaccine is among the recommended childhood vaccines in the United States, given as a series of three shots in infancy. Adults may also receive the HBV vaccine. Health experts recommend routine HPV vaccination for girls between ages 11 and 12, and for all young women to age 26. The HPV vaccine is a series of three injections given over 6 months. The vaccine protects against infection with HPV types 6 and 11, which cause genital warts, and types 16 and 18, which can cause cervical cancer. Both vaccines are effective indefinitely. However, the HPV vaccine is not effective in women who already have HPV infection.

Therapeutic cancer vaccines target an individual's cancer specifically, using antigens from the cancer cells to stimulate an IMMUNE RESPONSE against those cells. The laboratory makes a vaccine using cancer cells from the person. These cells contain the antigens for which the vaccine will stimulate the IMMUNE SYSTEM to produce antibodies. Therapeutic vaccines showing promise in clinical trials target PROSTATE CANCER, some types of BREAST CANCER, some types of LYMPHOMA, and some types of LUNG CANCER.

See also ANTIBODY; ANTIGEN; CANCER TREATMENT OPTIONS AND DECISIONS.

CA-125 Cancer ANTIGEN 125, a protein often elevated in the BLOOD circulation when certain cancers are growing in the body. The cells of the OVARIES, UTERUS, and FALLOPIAN TUBES produce CA-125; consequently CA-125 levels rise in OVARIAN CANCER, ENDOMETRIAL CANCER (cancer of the uterus), and CERVICAL CANCER. The most pronounced elevation occurs with ovarian cancer. However, numerous factors other than cancer can produce elevated CA-125 levels, including benign OVARIAN CYST and UTERINE FIBROIDS. Though an elevated CA-125 level may be one of numerous diagnostic factors the doctor considers when evaluating the possibility of a cancer diagnosis, this tumor marker by itself is not a reliable indicator of cancer. A blood test measures CA-125.

See also CARCINOEMBRYONIC ANTIGEN (CEA); GENETIC TESTING; ONCOGENES; PROSTATE SPECIFIC ANTIGEN (PSA); TUMOR MARKERS.

carcinoembryonic antigen (CEA) A protein present in the BLOOD circulation with certain types of cancer. In this regard, CEA serves as a tumor

marker. The cancers associated with elevated blood CEA levels are carcinomas of the COLON and RECTUM (COLORECTAL CANCER), PANCREAS, STOMACH, BREAST, and lung. The developing fetus also produces CEA, as do benign (noncancerous) tumors of the gastrointestinal tract. In these circumstances the presence of CEA in the blood circulation is normal and not an indication of cancer. Cigarette SMOKING AND CANCER treatment with CHEMOTHERAPY or RADIATION THERAPY also can produce elevated blood levels of CEA.

See also BREAST CANCER; CA-125; CARCINOMA; LUNG CANCER; PANCREATIC CANCER; STOMACH CANCER; TUMOR MARKERS.

carcinogen A substance that can cause cancer. The most common carcinogen is cigarette smoke, which is implicated in nearly all types of cancer and most specifically LUNG CANCER, BREAST CANCER, PROSTATE CANCER, pharyngeal cancer, STOMACH CANCER, and COLORECTAL CANCER. Other significant carcinogens include

- radon, a naturally occurring gas that results from the deterioration of naturally occurring uranium ubiquitously present in rocks and soil
- radiation, such as from overexposure to sunlight (ultraviolet) or ionizing radiation such as X-RAY and gamma-ray
- industrial chemicals such as benzene, vinyl chloride, and arsenic
- pharmaceutical agents such as hormones (oral contraceptives, estrogen supplements)

Some substances are beneficial in small amounts and carcinogenic in large amounts or in cumulative exposure over time, such as sunlight. Certain medications, notably IMMUNOSUPPRESSIVE MEDICATIONS and estrogen-containing drugs, may cause cancer. Others are hazardous at nearly any exposure level. CHEMOTHERAPY drugs, which effectively treat and cure many types of cancer, are themselves carcinogenic for certain types of LEUKEMIA and LYMPHOMA. RADIATION THERAPY as well increases the risk for subsequent cancers, depending on the site of irradiation. Pathogens such as viruses and BACTERIA cause certain kinds of cancer.

Limiting exposure to carcinogens reduces the likelihood that they will have adverse health effects. In the United States, federal and state regulations provide guidelines for occupational exposure to carcinogens. Other public health measures attempt to reduce carcinogen exposure through educational efforts.

COMMON CARCINOGENS

aflatoxins	arsenic
asbestos	benzene
beryllium	cadmium
chromium	cigarette smoke
cyclosporine	diethylstilbestrol (DES)
EPSTEIN-BARR VIRUS	ESTROGENS
ethylene oxide	formaldehyde
HELICOBACTER PYLORI	HEPATITIS B VIRUS
HUMAN PAPILLOMAVIRUS (HPV)	iodine-131
ionizing radiation	methyl chloride
radon	sunlight
tobacco	vinyl chloride

See also ASBESTOSIS; BERYLLIOSIS; CANCER PREVENTION; CANCER RISK FACTORS; ENVIRONMENTAL CIGARETTE SMOKE; ENVIRONMENTAL HAZARD EXPOSURE; LIFESTYLE AND CANCER; OCCUPATIONAL HEALTH AND SAFETY; PATHOGEN; RADON EXPOSURE; SMOKING AND CANCER.

carcinoma A cancerous tumor that arises from epithelial cells. Epithelial cells form the surface layer of tissue throughout the body: the SKIN, mucous membranes, and serous membranes (lining of the internal body cavities). Carcinoma is the most common form of cancer. A carcinoma generally carries the name of the tissue or site of its origin; for example, basal cell carcinoma originates in the basal cells of the skin and ADENOCARCINOMA originates in a glandular structure. Treatment depends on the nature, location, and size of the carcinoma and may incorporate surgery, CHEMOTHERAPY, RADIATION THERAPY, and IMMUNOTHERAPY.

TYPES OF CARCINOMA

Tumor	Location
ADENOCARCINOMA	glandular tissue
basal cell carcinoma	SKIN
intraductal carcinoma	BREAST
large-cell carcinoma	lung
lobular carcinoma	BREAST
small-cell carcinoma	lung
squamous cell carcinoma	skin, mucous membranes

See also ADENOMA; ADENOMA-TO-CARCINOMA TRANSITION; BLASTOMA; SARCOMA; SKIN CANCER.

chemotherapy Treatment for cancer that uses cytotoxic drugs (drugs that destroy cells) to kill cancer cells. About half of people who have cancer receive chemotherapy. Chemotherapy is commonly the treatment of first choice for LEUKEMIA, lymphoma, MULTIPLE MYELOMA, metastatic cancers, inoperable cancers, and as adjuvant therapy following or accompanying another method, such as surgery, that is the primary treatment. Sometimes chemotherapy is an appropriate choice for palliative treatment that shrinks cancer tumors to relieve symptoms such as PAIN. The goal of chemotherapy may be to eradicate the cancer or to keep the cancer in check to eliminate its symptoms and keep it from spreading.

How Chemotherapy Works to Treat Cancer

Chemotherapy drugs, also called chemotherapeutics or antineoplastic ("against new growth") drugs, work by interfering with cell growth, activity, or division. Many of them directly damage DNA, the cell's GENETIC CODE that directs the cell's processes for growth and replication. Chemotherapy drugs are toxic to all cells in the body. However, they have the most significant action on cells that are rapidly dividing, such as cancer cells. Most chemotherapy drugs have a NARROW THERAPEUTIC INDEX (NTI); there is a fine margin between their helpful and harmful actions. This narrow margin often causes unpleasant but predictable side effects that subside at the end of treatment.

Chemotherapy Agents

More than 600 chemotherapy drugs are currently available to oncologists, who often combine them in dozens of treatment protocols to treat various types of cancer. Chemotherapy drugs may be administered by MOUTH (oral), injection (intravenous, intramuscular, or subcutaneous), local application (topical or via instilled solution such as into the BLADDER), and intrathecal catheter (into the spinal canal).

Alkylating agents The alkylating agents are the oldest type of chemotherapy drugs and derive from nitrogen mustards, the chemical family to which poisonous mustard gas belongs. These chemotherapy drugs interfere with at least four stages of cell division, making them highly effective against many types of cancer. Consequently many chemotherapy protocols include an alkylating agent. Some of the alkylating agents require METABOLISM by CYTOCHROME P450 (CYP450) ENZYMES, a large group of enzymes in the LIVER that metabolize many kinds of drugs, to be effective. Many factors, including genetic encoding and diet, affect the function and efficiency of CYP450 enzymes.

COMMON ALKYLATING AGENTS

busulfan	carmustine
chlorambucil	cyclophosphamide
dacarbazine	iphosphamide
lomustine	mechlorethamine
melphalan	procarbazine
thiotepa	

Antimetabolites The antimetabolites derive from chemical structures similar to vitamins and amino acids (called metabolites) though are useless to cells. The chemical similarity is so close, however, that cells mistake antimetabolites for substances they need to carry out their metabolic processes. However, the antimetabolites cannot complete those metabolic processes, interfering with the ability of cells to synthesize (make) nucleic acid, an essential component of DNA. Without new DNA, cells cannot divide. Though each antimetabolite agent has specific cancers against which it is most effective, as a group the antimetabolites are particularly effective in treating leukemia, lymphoma, COLORECTAL CANCER, BREAST CANCER, BLADDER CANCER, PANCREATIC CANCER, and osteosarcoma. Antimetabolites have numerous side effects, including NAUSEA, HAIR loss, and tubular nephritis (damage to the KIDNEYS). Oncologists may give leucovorin along with the antimetabolite to counter these side effects.

COMMON ANTIMETABOLITES

6-mercaptopurine	6-thioguanine
arabinosylcytosine	capecitabine
cladiribine	cytarabine
dacarbazine	fludarabine
fluorouracil (5-FU)	gemcitabine
methotrexate	

Antibiotic chemotherapy agents The anthracyclines and the related DRUG bleomycin are antibiotics that come from the FUNGUS *Streptomyces verticillus*, which naturally occurs in soils primarily in Japan though also can be cultivated. These chemotherapy drugs work by forming free radicals that disrupt the structure of cellular DNA. They are particularly effective against leukemia, lymphoma, and many types of CARCINOMA, notably breast cancer. Bleomycin is similar to the anthracyclines, derived also from the *S. verticillus* fungus, but a different chemical composition and action in cells. It is most effective in combination with other chemotherapy agents for treating lymphoma and TESTICULAR CANCER. The most significant SIDE EFFECT of the anthracyclines is damage to the HEART, and of bleomycin damage to the LUNGS, as a result of free radical activity.

COMMON ANTIBIOTIC CHEMOTHERAPY AGENTS

bleomycin	dactinomycin
daunorubicin	doxorubicin
epirubicin	idarubicin
mitoxantrone	

Camptothecins, etoposide, and vinca alkaloids The camptothecins block the function of topoisomerase, an enzyme cells need to synthesize DNA. Their original source was the bark of the *Camptotheca acuminata* tree native to China. Etoposide has the same action but comes from the bark of the mandrake tree. Vinca alkaloids derive from the leaves of the *Vinca rosea* plant, a type of periwinkle. The vinca alkaloids disrupt cell division. Like the alkylating agents, the camptothecins, etoposide, and vinca alkaloids are effective in treating a broad spectrum of cancers from leukemia and lymphoma to carcinomas and some sarcomas.

COMMON CAMPTOTHECINS, ETOPOSIDE, AND VINCA ALKALOIDS

etoposide	vincristine
vinblastine	vinorelbine
irinotecan	topotecan

Taxanes The taxanes come from the bark of the *Taxus brevifolia*—the Pacific yew tree. They work as chemotherapy agents by blocking the ability of cells to form the structures necessary to divide. They also appear to enhance a number of immune functions and are particularly effective in treating some types of metastatic breast cancer. Currently there are two taxanes, each of which is often more effective in combination with other chemotherapy agents than alone. As well, each taxane has specific side effects: docetaxel can cause severe EDEMA (fluid retention) and paclitaxel can cause MUSCLE pain. Both drugs can cause NEUROPATHY (dysfunction of the nerves) and severe depletion of neutrophils (NEUTROPENIA), white BLOOD cells (leukocytes) important for fighting INFECTION. Neutropenia raises the risk for infection.

TAXANES

docetaxel
paclitaxel

Platinum compounds Platinum compounds disrupt cellular DNA function as well as the ability of cells to synthesize DNA. These chemotherapy agents are particularly effective in treating LUNG CANCER, testicular cancer, and colorectal cancer. They can cause kidney damage and neuropathy.

PLATINUM COMPOUNDS

carboplatin	cisplatin	oxaliplatin

Risks, Side Effects, and Complications of Chemotherapy

Because chemotherapy is a systemic treatment, it affects all cells in the body. Those most severely affected are those that grow and divide rapidly. Though cancer cells are at the head of that list, some healthy cells in the body also grow and divide rapidly. Among them are the cells of hair follicles (which produce hair), blood, and gastrointestinal tract, accounting for the most significant side effects of chemotherapy: hair loss, ANEMIA, increased susceptibility to infection, nausea, VOMITING, and DIARRHEA. However, the extent to which these side effects occur varies across the spectrum of chemotherapy drugs, and many people receiving chemotherapy do not experience them.

Medications and complementary remedies such as GINGER may help with chemotherapy-related nausea. ACUPUNCTURE also provides relief from nausea and other discomforts. Antinausea medica-

tions in the 5-HT3 receptor antagonist family (dolasetron, granisetron, ondansetron, and palonosetron) are especially effective. The long-term risks of chemotherapy include increased likelihood of developing another cancer, notably lymphoma or leukemia (especially acute myeloid leukemia with alkylating agents). Repeated chemotherapy, such as with chronic cancers or multiple recurrences, damages and may destroy the BONE MARROW.

HAIR LOSS DURING CHEMOTHERAPY

The cells of the HAIR follicles divide rapidly and thus are highly susceptible to the effects of chemotherapy. Because of this, people lose their hair after undergoing chemotherapy. However, because hair follicle cells are healthy and normal in their structure and function, most of them are able to resume growth and division—and hair production—when chemotherapy ends.

coping with cancer Methods for handling the physical, emotional, financial, and other stresses of a cancer diagnosis. The diagnosis of cancer is a life-altering event, no matter the type of cancer and its prognosis. Few other health conditions evoke such intense emotions. Though each individual responds uniquely, cancer evokes in everyone a recognition of vulnerability and mortality. It is important for each individual to be able to express his or her feelings, fears, anger, worries, and hopes. Some people want to talk about their cancer and their feelings, some people deny their diagnosis or its seriousness, and some people retreat to introspection.

The time of treatment is often very intense, with most of the focus in the person's life shifting to the treatment and its myriad details. Many people find themselves suddenly and completely immersed in an existence that revolves around doctors, hospitals, tests, and procedures. There may be concerns about health insurance coverage or payment for doctor bills, hospital services, treatment, and medications. Hospitals have financial counselors and social workers who can help work through details such as preauthorizations, coverage requirements, and private and government programs that subsidize or pay for care for people who lack the resources.

Many people are able to return to full, active lives after cancer treatment, and their outward appearance may seem the same as before the diagnosis. However, coping with cancer is a lifelong process for most people. Even when treatment concludes, residual effects may remain as reminders of the cancer. People who had surgery have visible scars and may have deformities, NERVE damage, BLOOD vessel or circulatory disruptions, LYMPHEDEMA, or alterations such as COLOSTOMY or reconstruction. As well, there often are ongoing health-care needs, such as doctor visits, medications, blood tests, and imaging procedures. Most people worry, no matter how healthy they are or how many years go by after treatment, about the possibility that the cancer could come back.

No one expects a diagnosis of cancer; when it strikes, it completely disrupts the fabric of everyday life. The cancer diagnosis also affects family members, friends, and co-workers. The person who has cancer must decide who, and how much, to tell about the cancer. Often, treatment requires time away from work and the person may not be able to return to full work activities for quite some time. People who have young children at home are likely to need extended help from family and friends during treatment and recovery. Older people who live alone may also need support with transportation, housekeeping, and cooking.

Despite the all-consuming nature of cancer diagnosis and treatment, it is important for the person to remain engaged in activities of life that bring relaxation, comfort, and joy, such as spending time with family and friends, participating in favorite recreations and hobbies, or traveling. Many people find peace and calm in YOGA, MEDITATION, or prayer. Because there are dimensions to having cancer that only other people who have cancer can fully understand, SUPPORT GROUPS provide a way for the person who has cancer to share their feelings and experiences.

See also LIFESTYLE AND HEALTH; QUALITY OF LIFE.

D

diagnosing cancer The procedures and tests that determine whether cancer is present. The diagnostic journey often begins with an unusual finding on a screening procedure, such as a MAMMOGRAM or PROSTATE SPECIFIC ANTIGEN (PSA) BLOOD test, or diagnostic procedure done for another purpose such as an X-RAY or a complete blood count (CBC). Sometimes the person identifies symptoms, such as the presence of a lump or rectal bleeding.

The initial doctor's evaluation includes a thorough ROUTINE MEDICAL EXAMINATION with specific focus on the abnormal findings; comprehensive PERSONAL HEALTH HISTORY; and appropriate diagnostic tests, which may include any combination of blood tests, X-rays, COMPUTED TOMOGRAPHY (CT) SCAN, POSITRON EMISSION TOMOGRAPHY (PET) SCAN, MAGNETIC RESONANCE IMAGING (MRI), ULTRASOUND, and biopsy.

Biopsy provides the definitive diagnosis for cancer, giving the pathologist the opportunity to examine tissue structure and cell composition. Depending on the location, size, and characteristics of a tumor, the doctor may remove a small sample of tissue or remove the entire tumor. Common methods for sampling tumors include

- fine-needle aspiration, in which the doctor inserts a small needle into the tumor to withdraw a sample of fluid and cells
- core-needle biopsy, in which the doctor inserts a larger needle into the tumor to extract a core of solid tissue
- ENDOSCOPY, in which the doctor inserts an endoscope into the body through a natural opening to examine suspicious tissues and remove samples
- incisional biopsy, in which the surgeon removes a portion of the tumor to obtain a representative tissue sample
- excisional biopsy, in which the surgeon removes the entire tumor

The pathologist then determines, from the diagnostic tests, imaging procedures, and biopsy findings, the cancer's stage and grade—assessments of how extensive the presence of the cancer in the body and how aggressive the growth of the cancer cells. Though most cancers fit within the standard parameters of STAGING AND GRADING OF CANCER, some do not. The doctor may then present the circumstances and diagnostic findings to a review panel of physician specialists, often called the "tumor board," for additional input and assessment. All of these evaluations then help guide the CANCER TREATMENT OPTIONS AND DECISIONS.

diet and cancer The ways in which foods and NUTRIENTS influence the risk for cancer, cancer development, and the effectiveness of cancer treatment. A number of foods have emerged that appear to contain substances that have cancer-fighting capabilities. Substances found in foods that appear able to help the IMMUNE SYSTEM suppress the development and growth of cancer cells include calcium, folate (folic acid), carotenoids, vitamin C, flavonoids, lignans, lycopenes, catechins, indoles, and SOY isoflavones. Numerous foods provide these substances. Conversely, foods that are high in saturated fat, highly salted foods,

FOODS THAT SUPPLY CANCER-FIGHTING SUBSTANCES

Cancer-Fighting Substance	Cancer-Fighting Actions	Food Sources
calcium	reduces the irritation bile and fatty acids cause in the gastrointestinal tract particular benefit to reduce risk for COLORECTAL CANCER	broccoli, bok choy, kale, milk, yogurt, cheese, salmon, legumes
carotenoids (beta-carotene, lutein, zeaxanthin)	block growth of cancer cells particular benefit to reduce risk for LUNG CANCER and CERVICAL CANCER	carrots, sweet potatoes, yellow squash, apricots, bell peppers, corn, spinach
catechins	neutralize free radicals	GREEN TEA, grapes, wine, chocolate
flavonoids	protect DNA, neutralize free radicals	carrots, citrus fruits, onions, apples, tomatoes, blueberries, broccoli, soybeans and soybean products
folate (folic acid)	essential for DNA synthesis and repair	beets, broccoli, cabbage, legumes, spinach, avocados, turkey, asparagus
indoles	block the actions of carcinogens to cause cells to mutate particular benefit to reduce risk for BREAST CANCER and PROSTATE CANCER	cauliflower, Brussels sprouts, bok choy, cabbage, broccoli
lignans	maintain cell health particular benefit to reduce risk for breast cancer, colorectal cancer, and prostate cancer	flaxseed oil, flaxseeds, whole grains, pumpkin seeds, cranberries, green tea, black tea
lycopenes	particular benefit to reduce risk for prostate cancer	tomatoes, tomato sauce, pink grapefruit, guava, watermelon
soy isoflavones	block tyrosine kinase, an enzyme that promotes cancer cell proliferation particular benefit to reduce risk for HORMONE-DRIVEN CANCERS (breast cancer, prostate cancer, OVARIAN CANCER, and ENDOMETRIAL CANCER)	fresh soybeans, tofu, soy flour, soy-based foods
vitamin C	ANTIOXIDANT that neutralizes free radicals blocks conversion of nitrates blocks cancer cells from dividing and proliferating particular benefit to reduce risk for ESOPHAGEAL CANCER and STOMACH CANCER	citrus fruits, strawberries, red cabbage, bell peppers, kiwi fruit, mangoes

and preserved foods appear to increase the risk for cancer overall and particularly for cancers of the gastrointestinal tract.

The extent to which nutrients can inhibit tumor growth remains an area of intensive study in CANCER PREVENTION research. Though foods and nutrients are not the sole factors that prevent or cause cancer, they clearly play significant roles in immune function.

See also CANCER RISK FACTORS; DIET AND HEALTH; EXERCISE AND HEALTH; LIFESTYLE AND CANCER; LYCOPENE.

dysplasia Abnormal changes that are occurring in cells. In dysplasia, rapidly dividing cells form tissue that has an anomalous structure. This structure has the potential of transitioning to cancer. Dysplasia is an early stage of development for all cancers but not all dysplasia becomes cancer. Because there is no way to know which direction dysplasia will go, doctors closely monitor and often surgically remove or otherwise treat dysplasia. ROUTINE MEDICAL EXAMINATION or health screening commonly detects dysplasia, which seldom produces symptoms. Frequently identified dysplasias include cervical dysplasia, which affects a woman's CERVIX, and oral dysplasia, which affects the mucous membranes in the MOUTH.

Doctors classify dysplasia according to the extent of disruption within the tissue. The earliest stage of dysplasia is hyperplasia, in which cells are growing more rapidly than normal but the structural integrity of the tissue remains normal. In mild dysplasia, the excessive cell growth produces erratic and abnormal tissue structure. In severe dysplasia, also called cancer in situ, cell growth and tissue structure are significantly abnormal but the irregularity remains confined to a single site. The risk for cancer in situ to evolve into a full cancer is high.

Treatment for dysplasia depends on the severity and location of the dysplasia as well as other health factors—such as smoking, which increases risk for all types of cancer—or a condition such as INFECTION with HUMAN PAPILLOMAVIRUS (HPV), which increases risk for cervical cancer. Mild dysplasia may revert to normal growth; often the doctor will recommend diligent observation with examination every three to six months to monitor cell activity at the site. Electrocautery (burning), cryotherapy (freezing), laser ablation, and surgical excision are among methods for eradicating dysplasia. Dysplasia may recur, depending on its cause, though in most circumstances does not return after treatment.

See also CELL STRUCTURE AND FUNCTION; LASER SURGERY; PAP TEST.

hormone-driven cancers Types of cancer that thrive on or require hormones for their survival. In men, ANDROGENS (notably TESTOSTERONE) sustain PROSTATE CANCER. In women, ESTROGENS and PROGESTERONE feed many types of BREAST CANCER, OVARIAN CANCER, and ENDOMETRIAL CANCER (cancer of the UTERUS).

Hormone-driven cancers arise in cells that are HORMONE dependent. However, researchers do not know whether hormones cause these cancers to develop or simply fuel them after they form. Researchers do know that breast cancer and ovarian cancer occur more often in women who have extended exposure to estrogen, such as with early onset of MENSTRUATION (MENARCHE before age 12) or late MENOPAUSE (after age 55). The use of oral contraceptives (birth control pills) or hormone replacement therapy (HRT) for menopause may also increase a woman's risk for these cancers, though research continues to investigate these connections.

The correlation between hormones and cancer becomes even less distinct with prostate cancer. Researchers know that testosterone fuels the growth of prostate cancer cells once the cancer develops. But the role of testosterone in the development of prostate cancer is unknown. Unlike estrogen and progesterone levels in women, testosterone levels in men are fairly constant though do decline gradually after age 30. Some researchers believe it is lower testosterone levels that allow prostate cells to mutate, becoming cancerous. Other researchers believe the changing balance between estrogen and testosterone in a man's body as he ages plays a contributing role. Hormone-driven cancers in men and women are more likely after age 50.

HORMONE THERAPY as adjuvant therapy is the standard of care for most hormone-driven cancers. Primary treatment may be surgery to remove the tumor, RADIATION THERAPY, or CHEMOTHERAPY, or a mix of any or all of these treatment options. Oncologists use luteinizing hormone–releasing hormone (LHRH) agonists, which suppress the body's production of androgens and estrogens, to treat prostate cancer in men and breast, ovarian, and endometrial cancers in women. Aromatase inhibitors, which block the body's ability to convert androgens to estrogen, and tamoxifen, which binds with estrogen receptors to block estrogen, are among the hormone therapies oncologists use to treat hormone-driven breast cancers in women.

See also CANCER TREATMENT OPTIONS AND DECISIONS; IMMUNOTHERAPY.

hyperplasia Overgrowth of cells. Hyperplasia, also called hypertrophy, may occur for various reasons. Though the overgrowth of tissue may cause symptoms it is not necessarily cancerous. For example, BENIGN PROSTATIC HYPERPLASIA (BPH) is common in men over age 65 and commonly causes symptoms such as difficult URINATION. Endometrial hyperplasia is similarly common in women approaching MENOPAUSE, causing symptoms such as abnormal uterine bleeding. Typically the structure of cells and tissue in hyperplasia is normal; there is simply an overgrowth. The risk is that hyperplasia will progress to abnormal cells and tissue structure, a precancerous condition called DYSPLASIA. Unless it causes symptoms, hyperplasia does not require treatment other than diligent monitoring.

See also CANCER RISK FACTORS; CELL STRUCTURE AND FUNCTION.

lifestyle and cancer Personal factors that may contribute to the prevention or the development of cancer. The most significant lifestyle factors related to cancer are smoking, diet, OBESITY, and exposure to environmental carcinogens.

Smoking and Other Tobacco Use

Cigarette smoking accounts for 87 percent of LUNG CANCER in the United States, making lung cancer one of the most preventable types of cancer. Cigarette smoking also raises the risk for numerous other types of cancer, including oral cancer, laryngeal cancer, ESOPHAGEAL CANCER, STOMACH CANCER, LIVER CANCER, COLORECTAL CANCER, PANCREATIC CANCER, kidney cancer, BLADDER CANCER, PROSTATE CANCER, BREAST CANCER, and CERVICAL CANCER. Cigar smoking increases the risk for oral cancers (cancers of the MOUTH and lips) as well as lung cancer, pharyngeal cancer, and stomach cancer. Other tobacco use, such as chewing tobacco and snuff, is the primary cause of oral cancers. Not using any form of tobacco removes its risk as a cause of cancer.

Diet and Nutrition

Numerous studies indicate a diet high in fruits, vegetables, and whole grains and whole grain products reduces the risk for most cancers overall and specifically for esophageal cancer, stomach cancer, and colorectal cancer. Researchers believe the NUTRIENTS, antioxidants, and fiber are the key substances that lower cancer risk. Nutrients and antioxidants boost the IMMUNE SYSTEM, improving its ability to detect and eliminate abnormal cells early in their development. Fiber helps absorb toxins in the gastrointestinal tract and move them more rapidly through the digestive process.

Conversely, research demonstrates that a diet high in red meat increases the risk for cancer overall and specifically HORMONE-DRIVEN CANCERS and cancers of the gastrointestinal tract. Red meat is the primary dietary source of saturated fats, which the body uses to synthesize (make) steroid hormones (androgens and estrogens). These hormones fuel the growth of some types of cancer cells in breast cancer, OVARIAN CANCER, ENDOMETRIAL CANCER, and prostate cancer. Whether they may also encourage the development of these cancers remains under investigation.

Some research has established a connection between the length of time food remains in the gastrointestinal tract with the risk for colorectal cancer. A diet high in plant-based, high-fiber foods moves through the digestive process more quickly than a diet high in fat. Some studies show a primarily plant-based diet may move through the body in 6 to 8 hours, while a high-fat, low-fiber diet may take as long as 26 hours to make the digestive journey.

Obesity

The risk for numerous cancers rises with OBESITY. The reasons for this are difficult to separate out. Researchers know that regular physical activity and nutritious EATING HABITS support the health of cells throughout the body as well as foster efficient immune function. These factors are generally lacking in obesity. Further, the increase in adipose tissue prevalent in obesity appears to be a contributing factor to hormone-driven cancers such as prostate cancer and breast cancer, the risks for which are higher in people who have obesity than in people who are of healthy weight.

Exposure to Environmental Carcinogens

Researchers have identified more than a thousand chemicals and other substances that have the ability to cause cancer. Some become hazardous only with repeated excessive exposure over time, and some have a fairly immediate consequence. Chemical exposures are common causes of THYROID CANCER, LEUKEMIA, and LYMPHOMA. The ultraviolet rays of sunlight are perhaps the most common long-term environmental CARCINOGEN, responsible for nearly all SKIN CANCER. Radon, which is present in the soil as a byproduct of deteriorating uranium and other radioactive minerals that occur naturally, is the second-leading cause of lung cancer. RADIATION THERAPY as treatment for cancer is also a carcinogen, raising the risk for lymphoma as well as solid tumors.

Lifestyle Modifications to Decrease Cancer Risk

Nutritious eating habits, daily physical exercise, and avoidance of tobacco products are key ways in which people can modify their lifestyles to reduce the risk for cancer as well as other significant health conditions such as CARDIOVASCULAR DISEASE

(CVD) and DIABETES. Health experts recommend that all homes be tested for radon levels, as basements and foundations can trap radon that emerges from the underlying soil. There are ways to release trapped radon so it does not present a cancer risk. ROUTINE MEDICAL EXAMINATION helps detect precancerous conditions and cancer when it is in its early, treatable stages.

See also CANCER PREVENTION; CANCER RISK FACTORS; DIET AND CANCER; HEALTH RISK FACTORS; RADON EXPOSURE; SMOKING AND CANCER; WEIGHT LOSS AND WEIGHT MANAGEMENT.

M–O

metastasis Cancer that spreads beyond its site of its origin. Metastasis may be local (extend outside the original tumor but remain near the original site), regional (remain in the general vicinity of the original site), or distant (in organs or tissues elsewhere in the body from the original site). It may occur as a result of direct invasion of adjacent tissues and organs or when cancer cells enter the LYMPH or BLOOD circulation. A metastasized cancer retains the characteristics of the tumor of origin. For example, PROSTATE CANCER that metastasizes to the BONE is metastatic prostate cancer, not BONE CANCER. The type of cancer is an important factor in determining the most effective treatment. The LUNGS, LIVER, and bone are the most common sites for metastasis. Cancer that comes back after treatment is a RECURRENCE. Metastasis may be evident at the time of diagnosis or may occur after treatment.

See also CANCER TREATMENT OPTIONS AND DECISIONS; REMISSION.

molecularly targeted therapies Treatment approaches for cancer that interfere with specific molecular functions within cancer cells to prevent them from dividing. The most significant benefit of molecularly targeted therapies is that they can selectively alter the function of specific cancer cells without affecting the function of normal cells. They do so primarily by targeting the protein signals cancer cells use that regulate their growth and division. These signals may be ones that promote growth or regulate APOPTOSIS (natural cell death). The drugs that target them may be signal-transduction inhibitors (also called small-molecule drugs), apoptosis-inducing drugs, and MONOCLONAL ANTIBODIES (MABS).

Current molecularly targeted therapies are especially promising for cancers that have a widespread presence in a vital organ or throughout the body, such as small-cell LUNG CANCER (SCLC) and MULTIPLE MYELOMA, which makes them difficult to treat through other approaches. Because molecularly targeted therapies are so new, doctors do not know their risks or long-term consequences or the extent to which they may be effective in treating cancers in general.

DRUGS USED IN MOLECULARLY TARGETED THERAPIES

bortezomib (Velcade)	gefitinib (Iressa)
imatinib mesylate (Gleevec)	oblimersen (Genasense)
rituximab (Rituxan)	trastuzumab (Herceptin)

See also CANCER TREATMENT OPTIONS AND DECISIONS; CELL STRUCTURE AND FUNCTION; CHEMOTHERAPY; IMMUNOTHERAPY; ONCOGENES; TUMOR SUPPRESSOR GENES.

oncogenes Mutated proto-oncognes that abnormally infuence the rate of growth of cells. Researchers believe oncogenes play a role in the development of cancer by altering cellular growth through one or more mechanisms. Oncogenes may accelerate cell division, block APOPTOSIS (planned cell death), or in other ways allow cells to grow beyond the boundaries of the body's normal controls. MOLECULARLY TARGETED THERAPIES and MONOCLONAL ANTIBODIES (MABS) show significant promise for altering oncogenes to reduce their role in the development of cancer.

Proto-oncogenes are the normal genes which contain the genetic code that tells cells which proteins, and how much of them, to produce to direct the cell's own growth. These proteins, called sig-

naling proteins, act as messengers within the cell. When proto-oncogenes mutate, their genetic instructions become garbled. The protein production they regulate changes. The cell may produce too many proteins that instruct it to grow, or not enough proteins that instruct it to stop growing. In either circumstance the cell's growth becomes excessive.

Oncogenes do not alone cause cancer, though researchers remain uncertain about the extent to which they influence the development of cancer. Other genetic and environmental factors come into play, affecting various aspects of cellular growth. Mutations may occur in the genes that regulate DNA repair, for example, allowing damaged cells to replicate. Researchers believe it is the convergence of factors, the emergence of oncogenes among them that permits cancer to develop.

IDENTIFIED ONCOGENES

Gene	Cancer Connection
bcl-2	B-cell lymphoma and numerous other cancers
c-erb	BREAST CANCER
c-myc	small-cell LUNG CANCER (SCLA), Burkitt's lymphoma
HER-2/neu	breast cancer
hTERT	numerous cancers
ras	numerous cancers
src	breast cancer, colon cancer, SCLA, neuroblastoma, rhabdomyosarcoma

See also CELL STRUCTURE AND FUNCTION; TUMOR SUPPRESSOR GENES.

P

pain management in cancer The ability to improve comfort and provide relief from PAIN and related symptoms that cancer and cancer treatment may cause. Many people worry about the potential for their cancer to cause pain. However, the broad spectrum of available ANALGESIC MEDICATIONS and other methods provide numerous options to manage, and often entirely relieve, pain due to cancer.

Causes of Pain in Cancer

Pain in cancer arises from either the cancer or from treatments for the cancer. Cancerous tumors can cause pain when they invade tissues and disrupt the nerves. Sometimes cancer can also invade NERVE tissue, also causing pain. Damage to structures, such as may occur when cancer invades and destroys tissues and organs, causes the cells of those structures to release numerous CYTOKINES (biochemicals that activate various components of the IMMUNE RESPONSE). Among these cytokines are substances that stimulate nociceptors, specialized molecules in peripheral neurons that send pain signals to the CENTRAL NERVOUS SYSTEM. RADIATION THERAPY is often effective for pain relief in such situations, as it can shrink the tumor so it no longer pressures nerves and other structures. Sometimes surgery to remove part of the tumor also provides relief.

SURGERY FOR CANCER is most often the cause of treatment-related pain. Sometimes surgery for cancer is extensive, and the recovery period can be lengthy and challenging. Most people are eager to recuperate and return to their normal activities as quickly as possible. They may feel taking analgesic medications prolongs their recovery or may fear that taking narcotic medications, the strongest pain relievers, will result in ADDICTION. Neither is true. It may be necessary to take analgesic medications regularly and for an extended time after major cancer surgery to effectively manage the pain. This is important because adequate pain relief not only provides comfort but also allows the body to heal. Protracted pain is emotionally and physically stressful in ways that interfere with HEALING and QUALITY OF LIFE.

Analgesic Medications for Pain Relief

Over-the-counter analgesic medications such as NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) and acetaminophen often provide relief from mild to moderate discomfort and pain. Prescription NSAIDs and narcotic medications may be necessary for moderate to significant pain. Dependence and addiction are very seldom concerns in people who are taking narcotic pain relievers for such levels of pain. As well, there is little risk for overdose, another major concern.

Though there is a ceiling effect with NSAIDs (a point beyond which increasing the dose does not provide any greater pain relief), this is not the case with opioid analgesics. The body seems able to accommodate the effects narcotics have on the respiratory cycle when the narcotics are necessary to relieve high levels of pain. However, opioid pain relievers do impair judgment and thought processes enough to make activities such as driving hazardous and ill-advised.

Palliative Treatments for Pain Relief

Radiation therapy and surgery are often options for palliative treatment for pain resulting from cancer. These treatments reduce the size of tumors, relieving their pressure on surrounding tissues. The relief may extend months to years, depending on the cancer. There is no discomfort

associated with palliative radiation therapy. Palliative surgery does entail recovery from the surgery, though this typically follows a predictable and fairly rapid course after which relief from the cancer pain is often pronounced or complete.

Other Methods of Pain Management

Other methods that may help a person cope with pain include ACUPUNCTURE, BIOFEEDBACK, HYPNOSIS, YOGA, and MEDITATION. These methods incorporate MIND–BODY INTERACTIONS that provide physical, mental, and emotional changes to lessen the effects of pain. Acupuncture is also effective for relieving NAUSEA and other discomforts associated with CHEMOTHERAPY. These methods may be alternatives to medication that allow management of pain and return to normal activities.

See also CHRONIC PAIN; NEURON; TERMINAL PAIN.

R

radiation therapy The use of ionizing electromagnetic energy particles or waves to destroy cancer cells. Radiation is the emission of energy in a pattern of rays, such as visible light. Ionizing radiation is a form of energy of sufficient intensity to alter the electronic charge of atoms and the structure of molecules, such as ultraviolet light. At high exposure, such alteration changes the structures of cells. The effects of ionizing radiation on cellular structure can cause as well as treat cancer.

The substances that contain the ionizing energy particles are radioactive isotopes, also called radionuclides or radioisotopes, most of which occur in the natural environment though scientists can cultivate them in the laboratory for consistency and ready availability. As the radioisotope disintegrates it releases radiation at a known rate, which allows the radiation oncologist to determine the appropriate exposure times and frequencies.

RADIOISOTOPES USED IN RADIATION THERAPY

cesium-137 (^{137}Cs)	cobalt-60 (^{60}Co)
gold-198 (^{198}Au)	iodine-125 (^{125}I)
iodine-131 (^{131}I)	iridium-192 (^{192}Ir)
palladium-103 (^{103}Pd)	phosphorus-32 (^{32}P)
radium-226 (^{226}Ra)	yttrium-90 (^{90}Y)

The radiation oncologist determines which radioisotope or type of radiation to use based on the type of cancer, its location in the body, and how extensively the tumor has spread. Some types of radiation are more effective for penetration to tumors deep within the body and others are more effective for treating tumors close beneath the surface of the SKIN. How rapidly the radioisotope dissipates is important for internal radiation therapy in which the radiation oncologist implants radioactive pellets into the body to directly expose the cancer tumor to the radiation.

How Radiation Therapy Works to Treat Cancer

A key characteristic of cancer cells is that they divide rapidly and without much organization. Radiation therapy works by damaging the DNA within the cells, which prevents them from dividing. Though all cells in the body are vulnerable to such damage, radiation therapy selectively targets the tumor, limiting the exposure of healthy cells to the radiation. Because normal cells do not divide as rapidly as cancer cells and they divide in an organized process, they are able to recover from the radiation exposure. The exceptions are the cells of fast-growing tissues such as skin and HAIR, which may experience some damage as a result of radiation therapy. The radiation oncologist structures shields and blocks to protect healthy tissue from the radiation as much as possible.

A fundamental premise of radiation therapy is fractionation—dividing a lethal DOSE of radiation into numerous sublethal doses administered over a period time. The standard protocol for radiation therapy in the United States delivers the fractionated dosage of radiation daily five days a week for two to nine weeks. Depending on the cancer and the capabilities of the treatment facility, some radiation therapy protocols use radioisotopes and delivery methods that allow fewer doses administered over a shorter time and that vary the intensity of radiation according to the type and location of the cancer.

Types of Radiation Therapy

There are two basic types of radiation therapy, external beam and internal radiation. Some people receive both external beam and internal radiation therapy, depending on the type and location

of their cancer. In external beam radiation therapy, the source of radiation is outside the body, directed toward the tumor using a machine. The radiation oncologist determines the precise point at which the radiation needs to enter the body, called the treatment portal, and places small tattoo dots to mark its boundaries. These tattoos are permanent and serve as the template for aligning the radiation delivery path.

The machine that delivers the radiation therapy is either a linear accelerator (which is most common) or a cobalt machine. These are similar in appearance to a large X-RAY machine. When receiving radiation therapy the person lies on a table beneath the machine, often positioned with supports and blocks to maintain the proper alignment for the radiation to hit the tumor. Each treatment session may take 15 to 30 minutes, though the actual delivery of radiation takes only a few minutes.

Radiation therapy does not hurt or cause any discomfort, though the experience can be somewhat stressful for people who are claustrophobic (become uncomfortable in closed spaces) because the machine is very large and often very close during treatment. Because the source of the radiation is outside the body, the person receives only the directed energy and does not become radioactive. External radiation therapy is often among the treatments for LUNG CANCER, BREAST CANCER, PROSTATE CANCER, COLORECTAL CANCER, Hodgkin's lymphoma, THYROID CANCER, pharyngeal cancer, and some types of brain cancer.

INTRAOPERATIVE RADIATION THERAPY

Another form of external beam radiation therapy is intraoperative radiation, in which the person receives radiation to the surgical bed (site where the surgeon removed the tumor). Intraoperative radiation takes advantage of direct exposure to the site of the cancer to destroy any cancer cells that may have penetrated the tissue surrounding the tumor.

Internal radiation therapy, also called radiation seeding or brachytherapy, more directly targets the tumor with radioactive pellets (radioisotopes encased in thin wire containers) about the size of grains of rice, implanted in the body into or very near the tumor. Internal radiation therapy delivers a higher dose of radiation more directly to the tumor site, and often for a shorter duration, than would be possible with external beam radiation therapy. Internal radiation may be among the treatments for breast cancer, ENDOMETRIAL CANCER, thyroid cancer, CERVICAL CANCER, prostate cancer, and some cancers of the head and neck.

Internal radiation therapy may be

- interstitial, in which the radiation oncologist implants the radioactive pellets into the tumor or the tissue surrounding the tumor
- intracavitary, in which the radiation oncologist inserts the radioactive pellets into a natural body cavity such as the UTERUS or RECTUM
- intraluminal, in which the radiation oncologist inserts the radioactive pellets into a natural body passage such as the ESOPHAGUS or VAGINA

The implantation generally takes place with the person under general, regional, or local ANESTHESIA. After implantation the person is radioactive—that is, he or she emits ionizing radiation that can expose other people to its effects. Sometimes it is necessary to restrict contact with other people until the end of the course of treatment when the radioisotope dissipates enough to emit a level of ionizing radiation that is within safe limits. Sometimes the surgeon implants the pellets after an OPERATION to remove the tumor. An internal radiation implant remains in place for a few days to several weeks in most circumstances, though may remain for a few minutes to a few hours when the dose of radiation is very high and indefinitely when the optimal therapy is low-dose radiation over an extended time.

Risks, Side Effects, and Complications of Radiation Therapy

About half of people who have cancer receive radiation therapy during the course of their treatment. The general short-term side effects of radiation therapy include

- damage to the skin in the treatment area, similar to SUNBURN
- damage to hair follicles in the treatment area, resulting in local thinning or loss of hair

- mild NAUSEA
- tiredness and fatigue

Short-term side effects generally go away after the course of radiation therapy ends. Short-term risks, which are uncommon, include radiation BURNS to the skin and damage to tissues and organs in the treatment area that impairs their function. Long-term risks and complications of radiation therapy include destruction of the BONE MARROW, development of other types of cancer (notably LYMPHOMA and MULTIPLE MYELOMA), and permanent damage to tissues in the treatment area such as skin and MUSCLE. Specific types of radiation therapy have additional risks.

See also CANCER TREATMENT OPTIONS AND DECISIONS; CHEMOTHERAPY; SURGERY FOR CANCER.

recurrence Cancer that returns after treatment. The cancer may come back to its original site or appear in another part of the body. Recurrent cancer that spreads to multiple sites is metastatic. Treatment for recurrent cancer depends on the type of cancer, its location, and the treatment for the original cancer. Recurrent cancer occurs because cancer cells remain in the body after treatment and are able to reestablish themselves. Some cancers recur because their cells are particularly aggressive. Such cancers require increasingly aggressive treatment that may hold the cancer in check for periods of time, though these periods of REMISSION tend to become shorter and the cancer progresses. Other types of cancer persistently recur, such chronic lymphoma. Treatment can effectively manage such cancers for decades.

See also CELL STRUCTURE AND FUNCTION; METASTASIS.

remission The period of time during which a person in treatment for cancer is free from symptoms though the cancer may still be in the body. In complete remission all symptoms disappear; in partial remission some or most symptoms go away. Remission is generally the result, or may be the goal, of RADIATION THERAPY or CHEMOTHERAPY. Remission may last months to years, depending on the type of cancer. Alternating periods of remission and RECURRENCE (return of the cancer and its symptoms) characterize some cancers, such as chronic LYMPHOMA, chronic LEUKEMIA, KAPOSI'S SARCOMA, and SKIN CANCER.

See also METASTASIS.

S

sarcoma Cancer that arises from connective tissue such as BONE, TENDON, CARTILAGE, fat, MUSCLE, and other soft tissues. Sarcomas may also develop within the walls of BLOOD vessels, which contain connective tissue. Treatment generally combines surgery to remove the tumor with RADIATION THERAPY or, less commonly, CHEMOTHERAPY. Radiation exposure, such as occurs with radiation therapy for other cancers or with accidental or industrial exposure, increases the risk for sarcoma.

TYPES OF SARCOMA

Tumor	Location
chondrosarcoma	CARTILAGE
dermatofibrosarcoma	SKIN
fibrosarcoma	fibrous connective tissue (fibroblast proliferation)
hemangiosarcoma	BLOOD vessel
KAPOSI'S SARCOMA	connective tissue of skin, mucous membranes, organs
leiomyoma	smooth MUSCLE, such as the UTERUS
liposarcoma	fatty tissue
neurofibrosarcoma	nerves
osteosarcoma	BONE
synovial sarcoma	synovial membrane of a JOINT

screening for cancer See CANCER PREVENTION.

sentinel lymph node dissection Surgery to remove and biopsy the first LYMPH NODE in the LYMPH network that drains lymph from the location of a cancerous tumor. The sentinel node is important in determining the course of treatment for the cancer because it would be the first lymph structure to which cancer cells would migrate in METASTASIS. During the OPERATION to remove the tumor, the surgeon injects a dye into the tissues at the tumor's location. The first lymph node to show the presence of the dye is the sentinel node, which the surgeon then removes. If cancer cells are in the sentinel node, then the surgeon removes additional lymph nodes and possibly more tissue surrounding the tumor. If there are no cancer cells in the sentinel node, then the surgeon does not need to remove any further tissue. Sentinel lymph node dissection is increasingly common in surgery for BREAST CANCER, malignant melanoma, and other cancers that may remain localized.

See also LYMPHEDEMA; STAGING AND GRADING OF CANCER; SURGERY FOR CANCER.

signs and symptoms of cancer Though each type of cancer has specific signs and symptoms, some symptoms are universal to nearly all types of cancer. Such symptoms include

- unintended weight loss, often rapid
- general sense of not feeling well (malaise)
- fatigue that does not improve with sleep and rest
- unexplained FEVER or night sweats
- swollen though painless LYMPH nodes
- unexplained loss of APPETITE

Early symptoms are general and may indicate numerous health conditions other than cancer. However, early detection and diagnosis of cancer presents the best opportunity for successful treatment. Possible cancer symptoms in combination with risk factors such as age over 50 years, cigarette smoking, or OBESITY are more suspicious.

Specific symptoms of certain cancers that are worthy of a doctor's assessment include

- prolonged COUGH, which may suggest laryngeal cancer or LUNG CANCER
- a wound or sore that does not heal, which may suggest SKIN CANCER
- a change in bowel habits or rectal bleeding, which may suggest COLORECTAL CANCER
- a lump in the BREAST or testicle, which may suggest BREAST CANCER or TESTICULAR CANCER
- extended NAUSEA, VOMITING, or DIARRHEA may suggest ESOPHAGEAL CANCER, STOMACH CANCER, PANCREATIC CANCER, or colorectal cancer

See also BREAST SELF-EXAMINATION; CANCER PREVENTION; DIAGNOSING CANCER; LYMPH NODE; TESTICULAR SELF-EXAMINATION.

smoking and cancer Cigarette smoking is the leading cause of numerous types of cancer. Cigarette smoke contains more than 4,000 chemicals, none of which is beneficial to health and about 60 of which are known carcinogens (cancer-causing substances). Among the key carcinogens in cigarette smoke are formaldehyde, aromatic amines, arsenic, chromium, phenols, tar, and vinyl chloride.

Though LUNG CANCER is currently the leading cause of death from cancer in the United States, health experts believe it is also the most preventable cancer because of smoking's role in its development. Cigarette smoking accounts for 85 percent of the 172,500 people in whom doctors diagnose lung cancer each year. It also accounts for significant percentages of BREAST CANCER, BLADDER CANCER, PROSTATE CANCER, STOMACH CANCER, PANCREATIC CANCER, ENDOMETRIAL CANCER (cancer of the UTERUS), ESOPHAGEAL CANCER, oral cancer (cancer of the MOUTH and lips), laryngeal cancer (cancer of the THROAT), and acute myeloid LEUKEMIA (AML).

Cigarette smoking continues to decline among Americans, with only one in four men and one in five women now being regular smokers. Half of all Americans who ever smoked now no longer smoke. Health experts anticipate a corresponding decline in smoking-related cancers over the coming decades.

See also ANTISMOKING EFFORTS; CANCER PREVENTION; SMOKING AND CARDIOVASCULAR DISEASE (CVD); SMOKING CESSATION; SMOKING AND HEALTH.

staging and grading of cancer The standardized processes and guidelines for assessing the severity of cancer after diagnosis. A cancer's stage and grade help determine the most effective treatment options. Though each type of cancer has its own specific staging and grading protocol, general methodologies apply to nearly all types of cancer, except LEUKEMIA.

Cancer Staging

The stage of a cancer identifies how contained or widespread the cancer is. The traditional method of staging assigns a number to the level of the cancer's severity based on the tumor's location, penetration into lymph nodes, and spread to adjacent or distant tissues. The higher the number, the more extensive the cancer. A stage 0 cancer is small and completely contained, often in situ (confined to the cells in which the cancer started). A stage 4 cancer is widespread with multiple tumors distant from the primary tumor (site where the cancer first started). Staging criteria vary somewhat among the different types of cancer.

GENERAL CANCER STAGING: TRADITIONAL METHOD

Stage	Extent of Cancer
Stage 0	in situ; tumor confined to the cells of its origin
Stage 1	tumor remains localized though has spread beyond the cells of its origin
Stage 2	tumor has spread to adjacent tissues *or* lymph nodes
Stage 3	tumor has spread to adjacent tissues *and* lymph nodes or is locally recurrent
Stage 4	multiple tumors distant from the primary tumor; cancer is recurrent

Another method of tumor staging is the TNM system in which *T* represents the tumor size, *N* represents the involvement of local and regional lymph nodes, and *M* represents METASTASIS to distant sites. The TNM system is internationally standardized and provides more detail about the cancer's characteristics than the traditional, or stage grouping, method. It also allows for more precise characterization of the cancer. As is the

case with traditional staging, criteria vary somewhat among the different types of cancer.

GENERAL CANCER STAGING: TNM METHOD

Stage	Extent of Cancer
Tumor (T)	
T0	no evidence of cancer
Tis	in situ; tumor confined to cells of origin
T1	localized tumor less than 3 centimeters (cm) in size
T2	tumor is larger than 3 cm *or* has invaded adjacent tissues
T3	tumor is larger than 3 cm and has invaded adjacent tissues
T4	large tumor has invaded adjacent tissues or is inoperable
Lymph Nodes (N)	
N0	no cancer in regional lymph nodes
N1	cancer in local lymph nodes
N2	cancer in regional lymph nodes
N3	cancer in lymph nodes beyond the region of the primary tumor
Metastasis (M)	
M0	cancer remains local or regional (no METASTASIS)
M1	cancer has spread to distant sites (metastasis)

Cancer Grading

The grade of a cancer identifies the characteristics of its cells and their growth patterns. Grade is relevant only for cancers that can have varying aggressiveness, such as sarcomas and some types of brain cancer. The pathologist determines the tumor's grade from tissue samples and assigns a numeric value that indicates the tumor's aggressiveness and likelihood for metastasis. As with cancer staging, the criteria differ among the types of cancer, though in general a higher grade value indicates a more extensive or serious cancer. Some tumors have a mix of different cancer cells, in which case the pathologist usually assigns the higher grade to the tumor overall.

Stage, Grade, and Outlook

Oncologists use cancer staging and grading as the general framework for making treatment decisions and assessing prognosis (expected outcome). Though many types of cancer are treatable, controllable, or curable with today's range of treatment options, the individual variation in cancer diagnosis is significant. Each person who has cancer has a unique response based on numerous and sometimes intangible factors. Staging, grading, and other diagnostic parameters represent only a best attempt to characterize a cancer so as to structure an optimal treatment approach; they do not define the outcome.

See also CANCER TREATMENT OPTIONS AND DECISIONS; DIAGNOSING CANCER; LYMPH NODE; TUMOR MARKERS.

surgery for cancer An OPERATION to remove a cancerous tumor. Surgery is the first line of treatment for cancer that a surgeon can readily reach without endangering the person, and when there is a single defined tumor. Multiple tumors may also be appropriate for surgery, depending on the type of cancer, the location of the tumors, and how clearly contained the tumors are. Surgery is typically the primary therapy for treating cancer, with adjuvant (accompanying or follow-up) treatment with RADIATION THERAPY, CHEMOTHERAPY, IMMUNOTHERAPY, or HORMONE THERAPY for a comprehensive approach. A person might undergo chemotherapy or radiation therapy before surgery to shrink the tumor, and also may undergo such treatment after surgery to eradicate any remaining cancer cells.

How Surgery Works to Treat Cancer

Surgery may be therapeutic (attempt to remove the cancer) or palliative (remove enough of the tumor to relieve PAIN or other symptoms). As oncologic surgeons have learned more about how cancer grows and spreads in the body, surgery methods

GENERAL TUMOR GRADING

Grade	Cancer Cell Characteristics	Cancer Aggressiveness
G1	good differentiation, nearly normal cells	low
G2	moderate differentiation, somewhat abnormal cells	intermediate
G3	poor differentiation, abnormal cells	high
G4	no differentiation, unstructured cells	very high

have become more precise. As well, pathology analysis of the tumor has become more efficient and accurate. The surgeon sends samples of the tumor and surrounding tissue to the pathology laboratory during the operation for immediate examination by a pathologist. The pathologist's initial report helps the surgeon determine whether there is a need to remove additional tissue.

In therapeutic surgery the surgeon excises (cuts out) the tumor with a margin of healthy tissue to capture stray cancer cells at the tumor's edges. The goal of such surgery is to eliminate the cancer so the person makes a full recovery and remains cancer free (with or without adjuvant therapies). For large tumors that are difficult to remove, the surgeon may perform cytoreduction (also called tumor debulking) to reduce the size and presence of the cancer as much as possible with the goal of improving the effectiveness of other treatments such as chemotherapy or radiation therapy. In advanced cancer, inoperable tumors may create obstructions or grow into the space an organ ordinarily occupies. The surgeon may perform palliative surgery to remove enough of the tumor to relieve pressure on nerves, BLOOD vessels, and other structures that may be causing pain or interfering with an organ's function.

Types of Surgery

Until the 1990s the standard practice in therapeutic cancer surgery was to remove substantial tissue to ensure removal of the cancer, often resulting in radical surgery such as MASTECTOMY (removal of a BREAST to treat BREAST CANCER) or bowel resection (removal of the COLON to treat COLORECTAL CANCER). Improvements in the understanding of how cancer functions in the body in combination with advances in other treatments for cancer have shifted the approach in cancer surgery toward sparing tissue, organs, and limbs to preserve body structures and functions, relying on a combination of therapies to treat the cancer. When the stage and grade of cancer still requires radical surgery, advances in reconstructive surgery (often performed at the same time as the cancer surgery) have improved QUALITY OF LIFE after surgery.

MINIMALLY INVASIVE SURGERY may be an option for stage 0 cancers, which are small and narrowly confined to the site of origin. OPEN SURGERY is generally the preference for stage 1 and 2 cancers, so the surgeon is able to remove all of the cancer and obtain an acceptable margin of healthy tissue. The length of hospitalization and recovery from the surgery depends on the operation and the person's overall health status. Many people who undergo surgery as primary treatment for cancer are otherwise healthy and typically experience a prompt and uneventful course of recovery.

Risks, Side Effects, and Complications of Surgery to Treat Cancer

Though cancer surgery methods are very advanced, risks and complications are possible. Diagnostic imaging procedures provide the surgeon with a good understanding of where the cancer is and how it involves tissues and organs. However, the surgeon cannot know for certain the nature and extent of the tumor until the surgery exposes it for full examination. Though most surgeries go exactly as anticipated, unexpected findings can shift the operation in a different direction. The surgeon typically recognizes the potential for the unexpected and includes discussion of such possibilities in the informed consent process. It is important to talk with the surgeon the anticipated benefits and potential risks of the planned operation. A second opinion consultation with another surgeon or with a medical oncologist for a discussion of nonsurgical treatment options is often a good idea, particularly when the proposed surgery is extensive or complex.

See also CANCER TREATMENT OPTIONS AND DECISIONS; MOHS'S SURGERY; QUALITY OF LIFE; PLASTIC SURGERY; SURGERY BENEFIT AND RISK ASSESSMENT.

tumor markers Molecules, often proteins, cancer cells and some other cells produce. Tumor molecules appear in the BLOOD or in the URINE, which makes it possible to measure their concentrations. Elevated levels of certain tumor markers indicate the need for further evaluation to determine whether a cancer is present. However, most tumor markers are not in themselves conclusive for specific types of cancer, even though they may occur in certain cancers as they can occur in numerous benign (noncancerous) conditions. As well, different types of cancer may generate elevations in a particular tumor marker, so elevated concentrations of the marker do not provide information of specific diagnostic value. Oncologists must evaluate tumor marker levels in the context of other clinical findings. Because so many factors influence tumor markers, oncologists disagree as to their usefulness, especially for screening and diagnostic purposes.

Some tumor markers are more useful for monitoring the effectiveness of treatment, because the oncologist can track the fall and rise of the marker's level in the blood circulation. However, tumor markers may rise with successful CHEMOTHERAPY because the dying cancer cells release high quantities of proteins into the blood. After successful treatment, monitoring tumor marker levels may provide early evidence of RECURRENCE should it develop.

COMMON TUMOR MARKERS

Tumor Marker	Corresponding Cancer	Reliability
alpha-fetoprotein (AFP)	LIVER CANCER (hepatocellular cancer); some ovarian cancers; some testicular cancers	moderate for diagnosis
Bence Jones protein	MULTIPLE MYELOMA	effective for diagnosis effective for monitoring treatment
beta-2 microglobulin (B2M)	multiple myeloma; some lymphomas	questionable for diagnosis effective for monitoring treatment
bladder tumor antigen (BTA)	BLADDER CANCER	moderate for diagnosis effective for monitoring treatment
CA-27.29	BREAST CANCER	unreliable for diagnosis in early stages; moderate for diagnosis in metastatic disease effective for RECURRENCE elevation possible in women who do not have cancer

Tumor Marker	Corresponding Cancer	Reliability
CA-72-4	OVARIAN CANCER; STOMACH CANCER; PANCREATIC CANCER; COLORECTAL CANCER	unreliable for diagnosis
CA-125	ovarian cancer	unreliable for diagnosis may be elevated in women who have previously had cancer and are currently cancer free elevated in endometriosis and benign OVARIAN CYST
CA-5-3	breast cancer	unreliable for diagnosis in early stages; moderate for diagnosis in metastatic disease effective for recurrence elevation possible in women who do not have cancer
CA-9-9	pancreatic cancer	moderately reliable for diagnosis
CALCITONIN	medullary THYROID CANCER	effective for diagnosis
CARCINOEMBRYONIC ANTIGEN (CEA)	colorectal cancer; LUNG CANCER; breast cancer	unreliable for diagnosis effective for recurrence elevated in numerous noncancerous health conditions elevated in people who smoke
chromogranin A	neuroendocrine cancers	moderate for diagnosis
HER-2/neu	breast cancer	unreliable for diagnosis moderate for monitoring treatment
human chorionic gonadotropin (hCG)	gestational trophoblastic neoplasia (GTN); TESTICULAR CANCER; ovarian cancer	moderate for diagnosis effective for monitoring treatment
M-protein	multiple myeloma	effective for diagnosis effective for monitoring treatment
NEURON-specific enolase (NSE)	small-cell lung cancer (SCLC)	modest for diagnosis moderate for monitoring treatment
PROSTATE-SPECIFIC ANTIGEN (PSA)	prostate cancer	effective for diagnosis effective for monitoring treatment elevated in BENIGN PROSTATIC HYPERPLASIA (BPH)

See also CANCER PREVENTION; DIAGNOSING CANCER; ONCOGENES; TUMOR SUPPRESSOR GENES.

tumor suppressor genes Genes that stop cell growth, preventing tumor development. In health, tumor suppressor genes direct the production of proteins to block cell division when there are abnormalities in the cell, such as DNA damage. When mutated, tumor suppressor genes lose the ability to influence cell division. Cells may then proliferate without regulation, the foundation of cancer. MOLECULARLY TARGETED THERAPIES and MONOCLONAL ANTIBODIES (MABS) show significant promise for altering the function of mutated tumor suppressor genes to restore their ability to block cell growth.

IDENTIFIED TUMOR SUPPRESSOR GENES

Gene	Cancer Connection
APC	COLORECTAL CANCER
BRCA-1/BRCA-2	BREAST CANCER, OVARIAN CANCER
MEN-1/MEN-2	MULTIPLE ENDOCRINE NEOPLASIA (MEN)
NF1/NF2	NEUROFIBROMATOSIS
PTEN	THYROID CANCER
Rb	RETINOBLASTOMA, osteosarcoma, breast cancer, LUNG CANCER
TP53 (p53)	lung cancer, breast cancer, LIVER CANCER, CERVICAL CANCER, SKIN CANCER, PROSTATE CANCER, ovarian cancer
WT1	WILMS'S TUMOR

MEDICAL ADVISORY REVIEW PANEL

Kyra J. Becker, M.D., is codirector of the University of Washington Stroke Center in Seattle, Washington. She is also an associate professor of neurology and neurological surgery at the University of Washington School of Medicine. Dr. Becker provides patient care through her practice at Harborview Medical Center and is a primary investigator on several stroke-related research studies.

Dr. Becker received her bachelor of science (B.S.) degree in biology *summa cum laude* from Virginia Tech in Blacksburg, Virginia, and her doctor of medicine (M.D.) degree from Duke University School of Medicine in Durham, North Carolina. She completed her internship in internal medicine, residency in neurology, and clinical fellowship in critical care neurology all at Johns Hopkins Hospital in Baltimore, Maryland. Dr. Becker is board-certified in neurology and psychiatry with a special certification in vascular neurology.

James C. Blair, III, PA-C, is director of Madrona Hill Urgent Care Center in Port Townsend, Washington. Mr. Blair is a physician assistant certified with special recognition in primary care and surgery. He is an advanced cardiac life support (ACLS) instructor and has worked much of his career to provide emergency services in small hospitals and clinical care settings in rural communities.

Mr. Blair received his associate of science degree in nursing from Wenatchee Valley College in Wenatchee, Washington, and completed the MEDEX Northwest Physician Assistant Program at the University of Washington School of Medicine in Seattle, Washington.

Alexa Fleckenstein, M.D., writes books and conducts lectures and workshops about natural health topics. Educated in Germany and the United States, she has extensive experience in natural therapies and integrative medicine. Dr. Fleckenstein is board-certified in internal medicine.

Dr. Fleckenstein received her medical degree from Universität Hamburg, Germany. She completed her internship and residency in primary care medicine at Carney Hospital in Boston, Massachusetts, and a fellowship in ambulatory medicine at VA Brockton, Massachusetts. Her subspecialty certification in natural medicine is from Ärztekammer Hamburg (German Board).

Nancy A. Lewis, Pharm.D., is a clinical pharmacist and medical science liaison for MGI Pharma, Inc., a biopharmaceutical company specializing in oncology and acute care products. Dr. Lewis frequently conducts workshops and focused training presentations. She is an active member of the Washington-Alaska Cancer Pain Initiative.

Dr. Lewis received her bachelor of science (B.S.) in pharmacy and her doctor of pharmacy (Pharm.D.) degrees from the University of Washington in Seattle, Washington. She serves on the clinical faculty at the University of Washington in Seattle, Washington and on the adjunct faculty at Washington State University in Pullman, Washington.

Gary R. McClain, Ph.D., is a psychologist, counselor, and consultant in New York City. Dr. McClain has more than 25 years of experience as a mental health professional and in the business world. The focus of his practice is healthcare and wellness.

Dr. McClain's graduate studies were in clinical psychology and education, with a focus on adult personality development and learning. He received his doctor of philosophy (Ph.D.) from the

University of Michigan. Dr. McClain has coauthored or edited 14 books and frequently conducts workshops.

Maureen Ann Mooney, M.D., is a clinical, surgical, and cosmetic dermatologist in private practice in Puyallup, Washington, where she specializes in treating skin cancer. Dr. Mooney is trained to perform Mohs' Micrographic Surgery. Dr. Mooney is board-certified in dermatology and dermatopathology.

Dr. Mooney received her bachelor of science (B.S.) degree in biology *summa cum laude* from the University of Minnesota College of Biological Sciences in St. Paul, Minnesota, and her doctor of medicine (M.D.) degree from the University of Minnesota School of Medicine in Minneapolis, Minnesota. She completed her internship at Hennepin County Medical Center in Minneapolis, Minnesota, and her residency in dermatology at New Jersey Medical School in Newark, New Jersey. Dr. Mooney also completed fellowships in Dermatopathology at New Jersey Medical School and Mohs' Micrographic Surgery at Louisiana State University Healthcare network in New Orleans, Louisiana.

Margaret J. Neff, M.D., M.Sc., is attending physician, pulmonary and critical care medicine, at Harborview Medical Center in Seattle, Washington. Dr. Neff is a medical monitor for the Cystic Fibrosis Therapeutic Diagnostics Network, co-chair of one of the biomedical committees of the University of Washington Institutional Review Board, and a clinical investigator on several research studies. She is board-certified in internal medicine, pulmonary disease, and critical care medicine.

Dr. Neff earned her bachelor's degree in biological sciences (B.S.) and medical degree (M.D.) from Stanford University in Stanford, California, and her master of science (M.S.) degree in epidemiology from the University of Washington in Seattle, Washington. She completed her internship and residency in internal medicine and a fellowship in intensive care at Stanford University and a fellowship in pulmonary/critical care at the University of Washington. Dr. Neff is an assistant professor of medicine in the division of pulmonary and critical care medicine at the University of Washington School of Medicine, Seattle, Washington.

Maureen Pelletier, M.D., C.C.N., F.A.C.O.G., is board-certified in obstetrics and gynecology as well as in clinical nutrition. A former aviation medical examiner, Dr. Pelletier is also licensed as a medical acupuncturist and is a DAN! (Defeat Autism Now!) physician. She is in private practice in Cincinnati, Ohio, with an emphasis on integrative medicine.

Dr. Pelletier received her medical degree (M.D.) from Tufts University School of Medicine in Boston, Massachusetts, and completed her residency in obstetrics and gynecology at the University of Cincinnati. She received clinical training in mind-body medicine at the Mind-Body Institute at Harvard University and completed the integrative medicine program at the University of Arizona School of Medicine. Dr. Pelletier is a national and international lecturer.

Otelio S. Randall, M.D., F.A.C.C., is director of the preventive cardiology program, hypertension and clinical trials, and the Cardiovascular Disease Prevention and Rehabilitation Center at Howard University Hospital in Washington, D.C. Dr. Randall is widely published in peer-reviewed journals and has authored two books. He has received numerous awards during his career, including the 2004 Outstanding Faculty Research Award from Howard University School of Medicine.

Dr. Randall received his bachelor's degree (B.S.) in chemistry from Howard University and his medical degree (M.D.) from the University of Michigan Medical School in Ann Arbor, Michigan. He completed his internship at the State University of New York at Brooklyn, residencies in internal medicine at Baylor College of Medicine in Houston, Texas, and University of Michigan Hospital, and a fellowship in cardiology at the University of Michigan Hospital. Dr. Randall is designated a specialist in hypertension by the ASH specialists program in affiliation with the American Society of Hypertension (ASH).

Susan D. Reed, M.D., M.P.H., is program director for the Women's Reproductive Health Research Program at the University of Washington in Seattle, Washington. She is a clinician at Harborview

Medical Center and University of Washington Medical Center. Dr. Reed is also an affiliate investigator at the Center for Health Studies and Fred Hutchinson Cancer Research Center, and an associate professor of obstetrics and gynecology, and an adjunct professor in epidemiology at the University of Washington School of Medicine. Dr. Reed's areas of clinical and research interest are gynecologic issues for women with genetic diseases, cross-cultural medicine, and management of menopause.

Dr. Reed received her master's degree (M.S.) in human genetics from Sarah Lawrence College in Bronxville, New York, her medical degree (M.D.) from Stanford University Medical Center in Stanford, California, and her Master of Public Health (M.P.H.) degree from the University of Washington School of Public Health. Dr. Reed is a licensed genetic counselor and board-certified in obstetrics and gynecology.

Jerry Richard Shields, M.D., is an ophthalmologist in private practice in Tacoma, Washington. He sees general ophthalmology patients and performs laser correction and cataract surgery. Dr. Shields is board-certified in ophthalmology and VISIX-certified.

Dr. Shields received his bachelor of science (B.S.) degree in biology *cum laude* from Wake Forest University in Winston-Salem, North Carolina, and his medical degree (M.D.) from the Medical College of Georgia in Augusta, Georgia. He completed his internship in internal medicine and his residency in ophthalmology at the University of Washington in Seattle, Washington.

Christina M. Surawicz, M.D., is gastroenterology section chief of at Harborview Medical Center in Seattle, Washington. She is also professor of medicine and assistant dean for faculty development at the University of Washington School of Medicine in Seattle. Dr. Surawicz is widely published in peer-reviewed journals and has authored, edited, and contributed to dozens of books.

Dr. Surawicz received her undergraduate degree, a bachelor of arts (B.A.) in biology, from Barnard College in New York City and her medical degrees (M.D.), awarded with honors, from the University of Kentucky College of Medicine in Lexington, Kentucky. She completed her medical internship, medical residency, and gastroenterology fellowship at the University of Washington in Seattle. Dr. Surawicz is board-certified in internal medicine and gastroenterology.

Denise L. Wych, R.N. C.M., is a cardiac nurse case manager at Palmetto Health-Richland Heart Hospital in Columbia, South Carolina, where she integrates clinical and medical appropriateness criteria in discharge planning and resource utilization within the framework of an interdisciplinary health-care team. She has worked in medical-surgical, intensive care unit, newborn, school nursing, and home health.

Ms. Wych received her diploma in nursing from Providence School of Nursing in Sandusky, Ohio. She served 10 years as an officer in the US Navy Nurse Corps, during which she was twice awarded the Navy Achievement Medal.

CONTENTS

VOLUME 3

FOREWORD

A big part of my role as a physician is educating my patients about their health. I take as much time as each person needs to explain prevention measures, test results, and treatment options. I encourage questions. But in the moment, sitting there in my office, most people do not yet know what to ask me. By the time questions flood their thoughts, they may be back at work or at home.

Numerous events and circumstances can challenge health, and we all need to know what actions we can take to keep ourselves healthy as well as to obtain appropriate treatment for health conditions that do affect us. Knowledge empowers all of us to make informed and appropriate decisions about health care. Certainly there is no shortage of reference material. Yet there is *so* much information available today! Even for physicians, it is challenging to keep up. How can you get to the core of what you want to know, reliably and to the level of detail you need?

The Facts On File Encyclopedia of Health and Medicine is a great resource for up-to-date health information presented in a manner that is both comprehensive and easy to understand no matter what your level of medical knowledge. The encyclopedia organizes entries by body system. The progression of body systems—and entries—throughout the encyclopedia presents topics the way you think about them.

Going beyond this basic structure, however, is another layer of organization that particularly appeals to me, which is a comprehensive structure of cross references that integrates entries across body systems. After all, your body functions in an integrated way; so, too, should a reference series that discusses your body's health. Not very much that happens with your health affects one part of your body in isolation from other body structures and functions. Your body attempts to compensate and adjust, often without your awareness, until it can no longer accommodate the injury or illness. The symptoms you bring to your doctor may reflect this compensation, for example frequent headaches that point not to brain tumor (as many people fear but is very rare) but to eye strain or muscle tension or sometimes to hypertension (high blood pressure).

In my medical practice I emphasize integrative health care, embracing the philosophy that health exists as the intricate intertwining of the body's many systems, structures, and functions. So, too, does the care of health. I received my medical degree from Tufts University School of Medicine in Boston, an institution noted for remaining at the forefront of the medical profession. I also completed clinical programs in Mind-Body Medicine at Harvard University, Integrative Medicine at the University of Arizona School of Medicine, and Medical Acupuncture at the University of California-Los Angeles (UCLA). I am a board-certified obstetrician-gynecologist, a board-certified clinical nutritionist, and a licensed acupuncturist. I see patients in my practice in Cincinnati, Ohio; I teach, I lecture, and I frequently go on television and radio to talk about health topics. In each of these areas, I encourage people to think about their health and health concerns from an integrative perspective. When you understand your health from multiple dimensions, you can better understand what to do to keep yourself as healthy as possible.

I wish you the best of health for all of a long, satisfying life. But when the time comes that you must make decisions about medical care, I want you to have the knowledge to make informed

choices that are right for you. Whether you start here and move on to more specialized resources or locate all the information you need within these four volumes, you will find *The Facts On File Encyclopedia of Health and Medicine* to be a most valuable reference resource.

—Maureen M. Pelletier, M.D., C.C.N., F.A.C.O.G.

HOW TO USE
THE FACTS ON FILE ENCYCLOPEDIA OF HEALTH AND MEDICINE

Welcome to *The Facts On File Encyclopedia of Health and Medicine*, a four-volume reference set. This comprehensive resource is an indispensable reference for students, allied health professionals, physicians, caregivers, lay researchers, and people seeking information about health circumstances and conditions for themselves or others. Entries present the latest health concepts and medical knowledge in a clear, concise format. Readers may easily accumulate information and build a complete medical profile on just about any health or medical topic of interest or concern.

A New Paradigm for the Health and Medical Encyclopedia

As the art and science of health and medicine continues to evolve, with complex and elegant discoveries and new techniques, medications, and treatments emerging all the time, the need has arisen for a new paradigm for the encyclopedia of health and medicine—a rethinking of the old, and increasingly outmoded, presentations. Carefully researched and compiled, *The Facts On File Encyclopedia of Health and Medicine* offers many distinguishing features that present readers and researchers with an organization as up-to-date and compelling as the breakthrough information its entries contain.

Recognizing the current emphasis on presenting a truly integrative approach to both health and disease, *The Facts On File Encyclopedia of Health and Medicine* organizes content across volumes within a distinctive format that groups related entries by body system (for example, "The Cardiovascular System") or by general health topic (for example, "Genetics and Molecular Medicine"):

- **Volume 1** presents the sensory and structural body systems that allow the body to engage with its surroundings and the external environment.
- **Volume 2** presents the cell- and fluid-based body systems that transport nutrients, remove molecular wastes, and provide protection from infection.
- **Volume 3** presents the biochemical body systems that support cellular functions.
- **Volume 4** presents topics that apply across body systems (such as "Fitness: Exercise and Health") or that address broad areas within health care (such as "Preventive Medicine").
- The appendixes provide supportive or additional reference information (such as "Appendix X: Immunization and Routine Examination Schedules").

Following Research Pathways

The Facts On File Encyclopedia of Health and Medicine's organization and structure support the reader's and researcher's ease of use. Many encyclopedia users will find all the information they desire within one volume. Others may use several or all four of the encyclopedia's volumes to arrive at a comprehensive, multifaceted, in-depth understanding of related health and medical concepts and information. Researchers efficiently look up information in *The Facts On File Encyclopedia of Health and Medicine* in several ways.

Each section's entries appear in alphabetical order (except the entries in Volume 4's "Emergency and First Aid" section, which are grouped by type of emergency). The researcher finds a desired entry by looking in the relevant volume and section. For example, the entry for **acne** is in Volume 1 in the section "The Integumentary System" and the entry for **stomach** is in Volume 3 in

the section "The Gastrointestinal System." The researcher can also consult the index at the back of the volume to locate the entry, then turn to the appropriate page in the volume.

Terms that appear in SMALL CAPS within the text of an entry are themselves entries elsewhere in *The Facts On File Encyclopedia of Health and Medicine*. Encyclopedia users can look up the entries for those terms as well, for further information of potential interest. Such SMALL CAPS cross references typically provide related content that expands upon the primary topic, sometimes leading the user in new research directions he or she might otherwise not have explored.

For example, the entry **hypertension** is in the section "The Cardiovascular System." The entry presents a comprehensive discussion of the health condition hypertension (high blood pressure), covering symptoms, diagnosis, treatment options, risk factors, and prevention efforts. Among the numerous SMALL CAPS cross references within the hypertension entry are the entries for

- **retinopathy**, an entry in the section "The Eyes" in Volume 1, which discusses damage to the eye that may result from untreated or poorly managed hypertension
- **blood pressure**, an entry in the Volume 2 section "The Cardiovascular System," which discusses the body's mechanisms for maintaining appropriate pressure within the circulatory system
- **stroke** and **heart attack**, entries in Volume 2's "The Cardiovascular System" about significant health conditions that may result from hypertension
- **kidney,** an entry in the section "The Urinary System" in Volume 3, which discusses the kidney's role in regulating the body's electrolyte balances and fluid volume to control blood pressure
- **atherosclerosis, diabetes, hyperlipidemia,** and **obesity**, entries in the sections "The Cardiovascular System" in Volume 2, "The Endocrine System" in Volume 3, and "Lifestyle Variables: Smoking and Obesity" in Volume 4, and all of which are health conditions that contribute to hypertension

Following the path of an encyclopedic entry's internal cross references, as shown above, can illuminate connections between body systems; define and apply medical terminology; reveal a broad matrix of related health conditions, issues, and concerns; and more. The SMALL CAPS cross references indicated within the text of encyclopedic entries lead encyclopedia users on wide-ranging research pathways that branch and blossom.

At the end of the entry for **hypertension** a list of cross references gathered in alphabetical order links together groups of related entries in other sections and volumes, such as **smoking cessation** in Volume 4's "Lifestyle Variables: Smoking and Obesity," to provide specific, highly relevant research strings. These *see also* cross references also appear in SMALL CAPS, identifying them at a glance. Encyclopedia users are encouraged to look here for leads on honing research with precision to a direct pathway of connected entries.

So, extensive cross-references in *The Facts On File Encyclopedia of Health and Medicine* link related topics within and across sections and volumes, in both broad and narrow research pathways. This approach encourages researchers to investigate beyond the conventional level and focus of information, providing logical direction to relevant subjects. Each cross-referenced entry correspondingly has its own set of cross references, ever widening the web of knowledge.

Using the Facts On File Encyclopedia of Health and Medicine

Each section of the encyclopedia begins with an overview that introduces the section and its key concepts, connecting information to present a comprehensive view of the relevant system of the human body or health and medical subject area. For most body systems, this overview begins with a list and drawings of the system's structures and incorporates discussion of historic, current, and future contexts.

Entries present a spectrum of information from lifestyle factors and complementary methods to the most current technologic advances and approaches, as appropriate. Text that is set apart or bold within an entry gives an important health warning, or targets salient points of interest to add layers of meaning and context. Lists and tables

collect concise presentations of related information for easy reference.

Each type of entry (mid-length and longer) incorporates consistent elements, identified by standardized subheadings:

- ***Entries for health conditions and diseases*** begin with a general discussion of the condition and its known or possible causes and then incorporate content under the subheadings "Symptoms and Diagnostic Path," "Treatment Options and Outlook," and "Risk Factors and Preventive Measures."
- ***Entries for surgery operations*** begin with a general discussion of the procedure and then incorporate content under the subheadings "Surgical Procedure," "Risks and Complications," and "Outlook and Lifestyle Modifications."
- ***Entries for medication classifications*** begin with a general discussion of the type of medication and its common uses and then incorporate content under the subheadings "How These Medications Work," "Therapeutic Applications," and "Risks and Side Effects."
- ***Entries for diagnostic procedures*** begin with a general discussion of the test or procedure and then incorporate content under the subheadings "Reasons for Doing This Test," "Preparation, Procedure, and Recovery," and "Risks and Complications."

Entries in Volume 4's section "Emergency and First Aid" are unique within the orientation of *The Facts On File Encyclopedia of Health and Medicine* in that they feature instructional rather than informational content. **These entries do *not* replace appropriate training in emergency response and first aid methods.** Rather, these entries provide brief directives that are appropriate for guiding the actions of a person with little or no first aid training who is first on the scene of an emergency.

Each volume concludes with a complete, full index for the sections and entries within the volume. Volume 4 of *The Facts On File Encyclopedia of Medicine* contains a comprehensive index for all four encyclopedia volumes that researchers can use to quickly and easily determine which volumes contain desired sections or entries.

The Facts On File Encyclopedia of Health and Medicine in Four Volumes

PREFACE TO VOLUME 3

Volume 3 of the four-volume *The Facts On File Encyclopedia of Health and Medicine* presents the body systems that support the body through biochemical functions. From the breakdown of foods into nutrient forms the body can use to the intertwining of hormones with nearly every other body system, biochemistry is the basis of cellular function.

The Gastrointestinal System

Leading Volume 3 is "The Gastrointestinal System," presenting the organs, structures, and functions that deliver nutrients to cells throughout the body. Complex biochemical processes break down all consumed foods into their basic molecular structures, the biochemical forms the body's cells can use.

No matter what a food's original form—apple, steak, french fries—the gastrointestinal system reduces it to molecules. The body then uses the molecules for fuel to maintain cellular activity and metabolism. Among the nutrients essential to sustain life are vitamins, minerals, carbohydrates, proteins, and fats.

As efficient as these processes are for distilling foods into nutrients, there is of course material the body cannot digest or use. The gastrointestinal system takes care of that, too, carrying solid waste from the body.

The Endocrine System

The endocrine system is the body's network of glands and hormones. Glands produce hormones, the chemical messengers that direct myriad activities within the body. The hormones the endocrine system produces interact with every other body system and are responsible for key functions such as metabolic rate, blood pressure, and the sleep-wake (circadian) cycle.

Hormones also manage the processes of digestion. Fat molecules (lipids) are essential for the production of many hormones. Estrogen brings the process full circle through its role in how the body breaks down and uses lipids.

The most common association many people have with hormones is their role to regulate growth and to initiate and maintain secondary sexual characteristics and reproductive ability. Following a person's unique genetic blueprint, hormones determine how fast and how tall the person grows. Hormones also give a man his deep voice and regulate a woman's menstrual cycle.

The Urinary System

The urinary system contains the organs and structures that filter biochemical wastes from the blood and excrete them from the body. All blood passes through the kidneys, which filter from it the wastes of cellular metabolism. If allowed to accumulate in the blood circulation, these wastes rapidly become toxic. Through their filtration functions, the kidneys also maintain the body's fluid and electrolyte levels to help regulate blood pressure. These versatile organs also produce hormones essential for blood pressure regulation.

The kidney was the first organ to be successfully transplanted, and today kidney transplantation is the most commonly performed transplant operation. Thousands of people receive transplanted kidneys every year in the United States; kidney transplantation is the only successful treatment for end stage renal disease, a common complication of diabetes and hypertension (high blood pressure).

Some structures of the male urinary system—the penis, urethra, and prostate gland—do double duty as organs of the male reproductive system.

The Reproductive System

The organs, structures, and functions of the reproductive system make possible the continuation of human life. The reproductive system remains in a state of immaturity until puberty, when the endocrine system initiates hormonal changes to stimulate the development of secondary sexual characteristics. Hormones remain the foundation of reproductive function for all of adulthood.

Pregnancy, the key function associated with the reproductive system, represents an intricate physiologic choreography in which female and male gametes—ovum and sperm—unite to establish a new life. The woman's body carries the new life for nearly 10 months, changing and adapting, as a result of hormones, until it is capable of independent survival.

Psychiatric Disorders and Psychologic Conditions

Biochemical balance and imbalance are integral to the functions and conditions that involve the mind and emotions. The section "Psychiatric Disorders and Psychologic Conditions" brings Volume 3 to a close. Though much of the working of the mind remains a mystery, researchers have made much progress to understand the integrated functions of the endocrine and nervous systems as they relate to psychiatric disorders and psychologic conditions.

Pharmaceutical therapies (medications) to alter neurotransmitter balances in the brain are often the foundation of treatment approaches. Their effects on neurologic function and emotional processes can be profound, even when doctors do not entirely understand the mechanisms of action that produce such results.

THE FACTS ON FILE ENCYCLOPEDIA OF

HEALTH AND MEDICINE

IN FOUR VOLUMES:

VOLUME 3

THE GASTROINTESTINAL SYSTEM

The gastrointestinal system converts ingested foods to nutrients the body can absorb and use. Physician specialists who treat gastrointestinal conditions are gastroenterologists. This section, "The Gastrointestinal System," presents a discussion of gastrointestinal structures and their functions, an overview of gastrointestinal health and disorders, and entries about the health conditions that can affect the gastrointestinal system.

Structures of the Gastrointestinal System

- MOUTH
  - hard palate
  - soft palate
  - cheeks
  - SALIVARY GLANDS
  - TEETH
  - tongue
  - lips
- epiglottis
- ESOPHAGUS
- lower esophageal sphincter
- stomach
  - fundus
  - rugae
  - gastric glands
  - pylorus
  - pyloric sphincter
- LIVER
- GALLBLADDER
- common bile duct
- cystic duct
- hepatic duct
- PANCREAS
- pancreatic duct
- accessory pancreatic duct
- SMALL INTESTINE
  - DUODENUM
  - ampulla of Vater
  - ILEUM
  - JEJUNUM
- COLON
  - APPENDIX
  - CECUM
  - ascending colon
  - transverse colon
  - descending colon
  - sigmoid colon
  - RECTUM
- ANUS

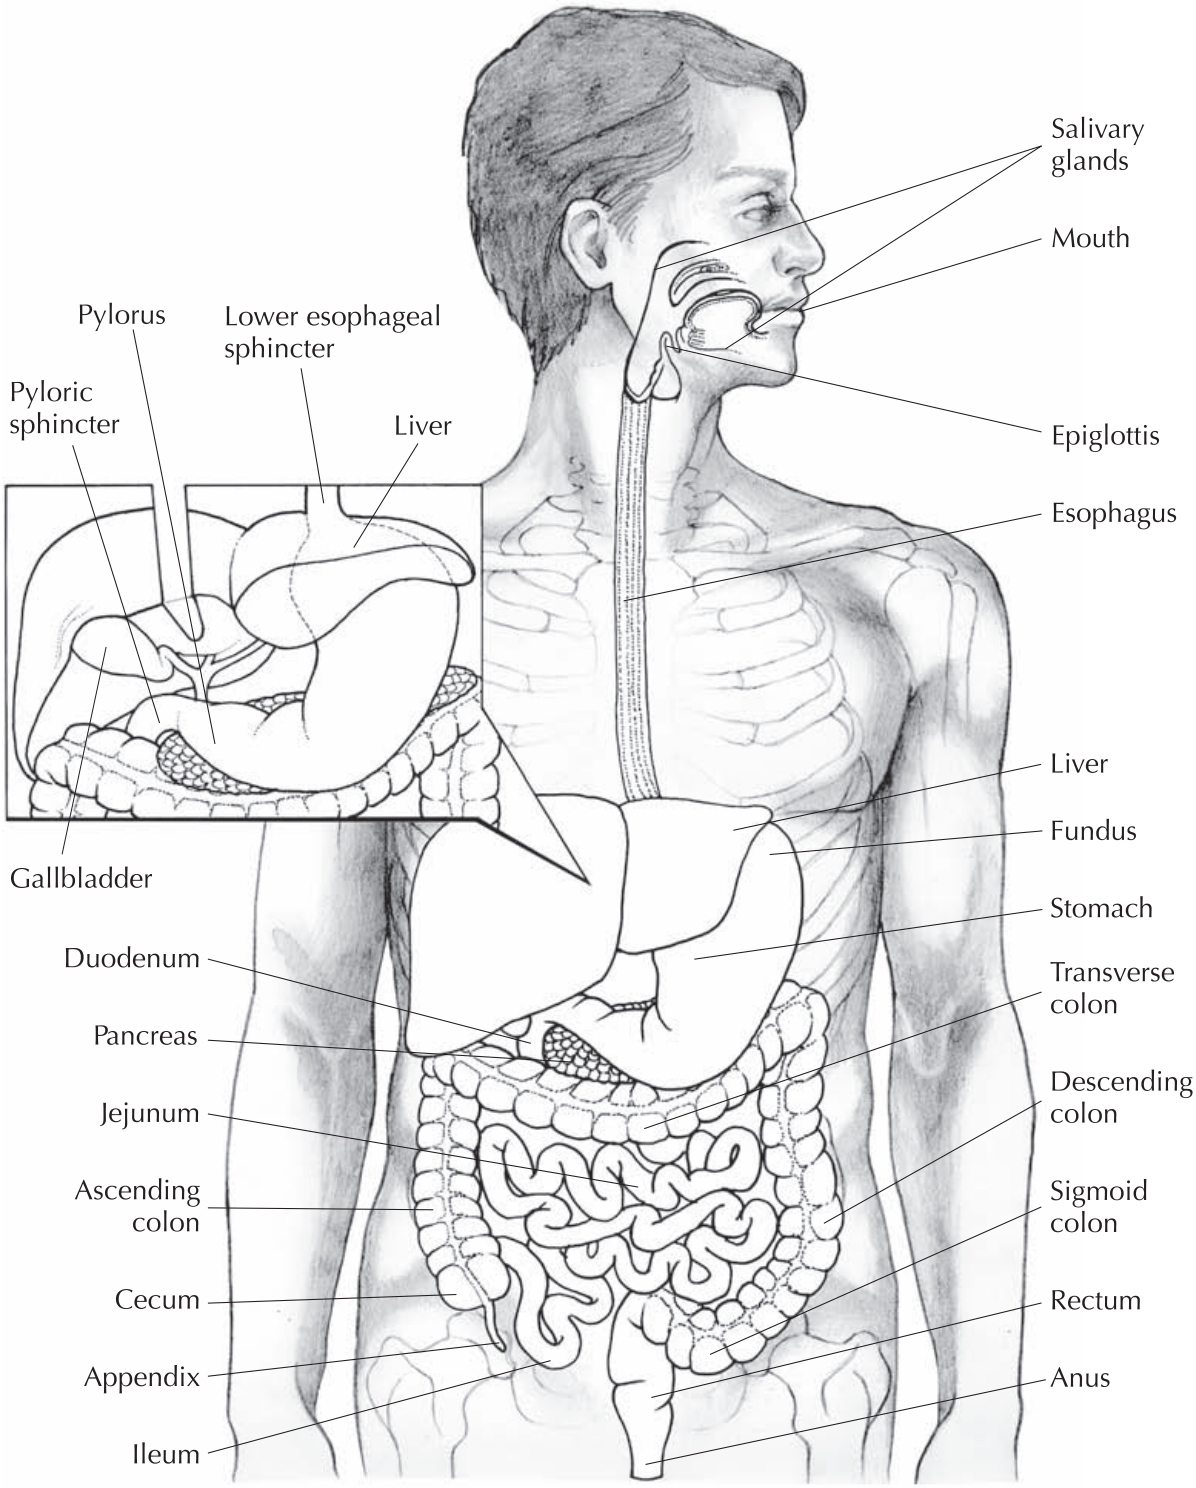
Functions of the Gastrointestinal System

TRADITIONAL CHINESE MEDICINE (TCM), a centuries-old philosophy of health centered on balance among the body's systems and functions, views the torso as the "triple burner" or "triple heater." Here the upper, middle, and lower segments of the body converge, becoming the core that distributes energy throughout the body much like a burner or heater. Western medicine shares a similar understanding, translated into the tangibility of physical structures and their functions.

The gastrointestinal system, also called the digestive or alimentary system, functions as the body's furnace. Fuel—food—enters the gastrointestinal tract in raw form at the MOUTH. Some 20 hours or so later, the compressed residue—feces, also called stool—exits at the other end of the gastrointestinal tract, from the ANUS. Along its passage, the food undergoes numerous transformations as the gastrointestinal organs and structures break it down, mechanically and chemically, into particles and eventually into molecules of energy (NUTRIENTS) that the bloodstream can transport to cells throughout the body. That the typical adult eats three to five times (or more) in 24 hours, yet the body often passes a single BOWEL MOVEMENT in the same period is testament to the gastrointestinal system's efficiency in extracting every molecule, literally, of useful matter from all that food.

The LIVER and PANCREAS produce numerous chemical substances to aid in breaking down the core nutrients of food—carbohydrate, protein, and fat—into molecules that can pass through the membrane of the small intestine to enter the bloodstream. The liver synthesizes BILE, a complex fluid containing water, electrolytes, cholesterol, biliary acids, and BILIRUBIN (400 to 800 milliliters per day). A network of channels, the BILE DUCTS, collect bile from the liver and transport it to the GALLBLADDER. The gallbladder extracts water from the bile to form a concentrated solution, which it stores until DIGESTIVE HORMONES signal the need to release bile for digestion. The bile flows through another duct, the common bile duct, mixes with

The Gastrointestinal System



pancreatic juices, and drains into the DUODENUM, the first part of the SMALL INTESTINE. INSULIN is the best known of the pancreatic products, though the pancreas synthesizes a number of other important hormones, DIGESTIVE ENZYMES, and juices essential for digestion. Digestive hormones orchestrate and synchronize the multitude of gastrointestinal functions.

Mechanical preparation: the mouth The digestive journey begins with the mouth. Each mouthful of food passes between the crushing force of the TEETH, which can exert up to 3,500 pounds per square inch, at least two dozen times. The taste, texture, and smell of the food induce the SALIVARY GLANDS to release saliva, a watery liquid that contains the digestive enzyme amylase. Amylase begins to break down carbohydrates in the food into the sugar molecules that form them, getting a head start on extracting from food the body's most significant fuel source. The lips and cheeks hold the food in the mouth while the tongue pushes the food under the teeth and against the palate (roof of the mouth). These actions grind the food and mix the particles with saliva to form a pastelike wad called a bolus. Finally the tongue pushes the bolus to the back of the THROAT for swallowing. A small projection of cartilaginous tissue that hangs at the back of the throat, the epiglottis, closes across the TRACHEA (windpipe) to direct the bolus of food down the ESOPHAGUS.

Wavelike contractions—PERISTALSIS—propel the bolus down the esophagus, a muscular tube about 12 inches long. The MUSCLE structure of the esophagus changes along its length, transitioning from striated muscle tissue that responds to voluntary control to smooth muscle tissue, completely under direction of the autonomic NERVOUS SYSTEM. Esophageal peristalsis thrusts the swallowed food bolus toward the STOMACH with such vigor that the food continues to its destination even if the person is upside down. A ring of muscle, the lower esophageal sphincter, opens to pass the bolus into the stomach then closes to keep it there.

Liquefication: the stomach The pouchlike stomach can expand to five or six times its empty size to accommodate the meals that come its way. This is where the process of digestion gets under way; the stomach digests more than half the carbohydrates and about 20 percent of the protein that a meal contains. The stomach resides below the DIAPHRAGM, its upper portion resting under the apex of the HEART and near the SPLEEN, just under the left ribs, and its lower portion beneath the liver.

The inside of the stomach is the gastric mucosa, a thick layer of mucous membrane. A network of deep folds, called rugae, gives the gastric mucosa a furrowed appearance. At the bottom of the folds of the rugae are the gastric glands, which produce hydrochloric acid and digestive enzymes (gastric juices). Near the top of the folds are the cells that produce the mucus that protects the stomach's lining from the gastric juices. When the stomach expands with food the rugae flatten, spreading the mucus and expanding the surface area of the stomach for thorough mixing of food with gastric juices. The gastric mucosa also secretes the digestive hormone gastrin.

Three layers of muscle give the stomach STRENGTH and FLEXIBILITY. The innermost layer wraps obliquely, or diagonally, around the gastric mucosa. The middle layer encircles the oblique muscle. The outer layer, the longitudinal muscle, envelopes the stomach lengthwise. Among them, these muscles give the stomach the ability to contract and convolute with considerable force as well as the ability to expand and contract for the volume of food it contains. These layers of muscle also give the stomach the ability to squeeze its contents downward into the small intestine for the rest of the digestive journey.

Food, in a semiliquid state after initial preparation in the mouth, enters at the top of the stomach, called the fundus, and flows downward across the rugae. Gastric juices immediately begin working to dissolve food particles, breaking them down into more basic compounds that the small intestine can digest. At the same time the stomach muscles contract, producing powerful contortions that further mix and liquefy the stomach's contents. The combined chemical and mechanical actions produce chyme, a somewhat soupy solution the stomach then sends to the small intestine. The lower portion of the stomach is the pylorus, from the Greek for "gatekeeper." Chyme exits the stomach through the pyloric sphincter, which relaxes to permit passage into the duodenum. Chyme trickles from the stomach over four to six hours.

Extracting nutrients: the small intestine The small intestine is where nutrients move from the gut to the blood. The nearly 18 feet of small intestine loop back and forth within the abdominal cavity, framed inside the COLON. Two layers of smooth muscle, the outer longitudinal and the inner circular, form the walls of the small intestine. These muscles rhythmically contract to move digestive matter through the gastrointestinal tract. The intestinal mucosa, a thin mucous membrane, forms the inner lining. It produces a number of digestive enzymes and digestive hormones.

In the first segment of the small intestine, the duodenum, the intestinal mucosa is fairly smooth. Only 10 inches long, the duodenum handles the majority of digestive activity. In addition to receiving chyme from the stomach, the duodenum receives bile and pancreatic juices via the common bile duct, which enters the duodenum at a small port called the ampulla of Vater. These solutions complete the breakdown of foods into end-product nutrients. Bile transforms fats into fatty acids. Pancreatic and intestinal enzymes convert proteins to amino acids and polysaccharides (compound sugars) to monosaccharides (simple sugars). Further chemical interactions separate out vitamins and minerals. Monosaccharides and some electrolytes (salts and minerals) enter the bloodstream through the duodenum, which is also the major site for absorption of iron and calcium.

The watery mixture containing the remaining nutrients moves on to the middle and end segments of the small intestine for absorption. In these segments, the JEJUNUM and the ILEUM, millions of tiny projections called villi extend from the intestinal mucosa to vastly expand the mucosal surface area. A network of capillaries (tiny blood vessels) weaves through the villi. Nutrients pass through the mucosal membrane and into the capillaries, which transport them into the bloodstream and throughout the body. The jejunum, about seven feet long, absorbs the remaining monosaccharides and many amino acids, additional electrolytes, water-soluble vitamins (the B vitamins and vitamin C), folic acid, and minerals such as iron. The final segment of the small intestine, the ileum, is about 10 feet long. It absorbs fatty acids and the remaining amino acids, as well as vitamin B_{12} and the fat-soluble vitamins (vitamins A, D, E, and K). The ileum also reabsorbs bile salts. The journey through the small intestine takes 8 to 10 hours.

Compacting waste: the colon The colon, also called the large intestine, collects and compacts the remnants of digestion for their elimination from the body, a process it accomplishes primarily by absorbing water. Like the small intestine, the colon's wall contains two layers of muscle, the outer running lengthwise and the inner circling around, that rhythmically contract. The inner lining is flat mucous membrane. The CECUM, the first segment of the colon, is a pouchlike structure that receives digestive material from the ileum, which enters near its floor. The ileocecal valve maintains the passage for one-way movement. The cecum absorbs about a third of the water from the digestive material it receives. Peristalsis then carries the intestinal content from the cecum through the rest of the colon.

The main colon loops around the outer edge of the abdominal cavity. It contains five segments. The ascending colon rises from the cecum and travels up the body's right side. At the gallbladder the colon takes a turn; the next segment is the transverse colon. The transverse colon extends across the top of the abdomen, with the liver and stomach above and the small intestine beneath. It takes a downward turn at the base of the stomach's fundus, becoming the descending colon. The descending colon drops along the left perimeter of the abdominal cavity. The descending colon makes a staggered turn inward toward the midline of the body, becoming the sigmoid colon. These four segments of the colon are functionally contiguous, progressively dehydrating and compacting the digestive residue that moves through them. The final segment of the colon is the RECTUM, by which point digestive waste has reached the solid form known as feces or stool. The rectum stores stool until its expulsion from the body via the anus (bowel movement). The journey through the colon generally takes four to six hours, though can take longer.

Health and Disorders of the Gastrointestinal System

The gastrointestinal system represents an intricate balance of mechanical and chemical functions.

Lifestyle and dietary habits can affect this balance. To help maintain this balance and preserve gastrointestinal health, gastroenterologists recommend

- Eating foods high in fiber such as fruits, vegetables, and whole grains and whole grain products. High-fiber foods move quickly through the gastrointestinal tract and result in residual bulk that helps keep stools soft, reducing the risk for conditions such as CONSTIPATION and HEMORRHOIDS.
- Reducing consumption of foods high in fats. Fats require more steps to digest, slowing movement through the gastrointestinal tract. Saturated (animal) fats are associated with an increased risk for COLORECTAL CANCER.
- Limiting consumption of products that contain CAFFEINE or ALCOHOL, which are frequent causes of DIARRHEA.
- Drinking plenty of noncaffeinated and nonalcoholic fluids throughout the day.
- Chewing food thoroughly before swallowing and remaining upright after eating.

Gastrointestinal symptoms are the second-leading reason for visits to the doctor, with diarrhea being the most common of these symptoms. Many gastrointestinal ailments are minor, such as INFECTION (GASTRITIS, GASTROENTERITIS, and COLITIS) and irritations such as DYSPEPSIA. The close proximity of the lower esophagus and the bottom of the heart gives rise to the term "heartburn," an apt descriptor for the burning sensation that occurs when gastric contents bubble back up into the esophagus. GASTROESOPHAGEAL REFLUX DISORDER (GERD) develops when such backwash becomes chronic.

Chronic gastrointestinal conditions such as CELIAC DISEASE, DIVERTICULAR DISEASE, IRRITABLE BOWEL SYNDROME (IBS), and INFLAMMATORY BOWEL DISEASE (IBD) can significantly interfere with QUALITY OF LIFE. People who have conditions such as these must work closely with their doctors to develop effective treatment approaches and manage their lifestyles in ways that minimize symptoms and support gastrointestinal health.

Cancers are among the most serious gastrointestinal conditions and can involve any organ or structure of the gastrointestinal system. Though colorectal cancer remains the second-leading cause of deaths due to cancer in the United States, it also offers great opportunity for prevention as well as early detection and treatment. Doctors now know that detecting and removing intestinal polyps, fleshy growths that develop in the colon's mucosa, via screening COLONOSCOPY eliminates the foundation for more than 90 percent of colorectal cancers.

HEALTH CONDITIONS OF THE GASTROINTESTINAL SYSTEM

ACHALASIA
ANAL FISSURE
BARRETT'S ESOPHAGUS
BILIARY ATRESIA
CELIAC DISEASE

Traditions in Medical History

Ancient doctors learned much about the inner structures and workings of the body from wounds that occurred on the battlefield. The writings of the Roman physician Celsus (14–37 C.E.) documented his recommendations to his students that they take advantage of such natural opportunities. One student who took the advice to heart was GALEN (130–200 C.E.), whose own teachings and writings would shape the understanding and practice of Western medicine for centuries. Galen learned much of the practice of medicine while treating soldiers and gladiators. Of the digestive process, Galen believed stomach liquefied food that then passed to the intestines. From the intestines the mixture traveled to the liver, where it mysteriously became blood that the veins carried around to the various tissues of the body. Though wrong in some fundamental ways, the extrapolation was not so far off from the reality.

In 1822, U.S. Army surgeon William Beaumont became the first physician to witness and explore the functions of the stomach in "real time." In June of that year French-Canadian trader Alexis St. Martin suffered a musket wound to his left side that opened a fist-size hole in his stomach. St. Martin's comrades brought him to Beaumont for treatment. Miraculously in an era of no antibiotics and limited surgical expertise, St. Martin survived. With great scientific curiosity, over several decades Beaumont observed the activities of St. Martin's stomach through this window. He conducted experiments with various items of food tied to string that he periodically withdrew to assess the extent of their demolition in the stomach. He measured the volume and temperature of stomach juices. And he watched the digestive process as much as his schedule and St. Martin's patience permitted.

Finally, in 1833 Beaumont published his findings in a book, *Experiments and Observations on the Gastric Juice and the Physiology of Digestion.* St. Martin lived 58 years with the hole in his stomach, outliving Beaumont by 27 years and dying at age 86. Beaumont's detailed observations and experiments gave modern medicine the most extensive understanding of digestion possible until the 1940s when ANESTHESIA and ANTIBIOTIC MEDICATIONS made surgery practical, and surgeons could more carefully explore the stomach and other gastrointestinal structures.

Breakthrough Research and Treatment Advances

The 21st century arrived on the heels of amazing advances in medical and surgical treatments for gastrointestinal conditions. Among the most significant advances have been those in ORGAN TRANSPLANTATION, which result from a blend of improved surgical techniques, organ harvesting procedures, and immunosuppressive methods. In 1984 LIVER TRANSPLANTATION became the standard treatment for end-stage LIVER FAILURE, a milestone in its progression from experiment to therapeutic solution. Within 15 years surgeons in the United States were performing more than 5,000 liver transplantations a year. Surgeons are now exploring applications for transplantation technology in other conditions, such as to replace the severely diseased small intestine, stomach, and even pancreas. Though these transplant operations remain largely investigational, they hold great promise for people who have disorders such as CYSTIC FIBROSIS, SHORT BOWEL SYNDROME, DIABETES, and severe diverticulosis.

Other advances in diagnostic and operative procedures take advantage of fiberoptic technology. Endoscopic surgery has transformed once-grueling operations, procedures such as open CHOLECYSTECTOMY, which often required up to 12 weeks of recuperation, to a few minor incisions and a third of the recovery time. Surgeons now can perform APPENDECTOMY, herniorrhaphy and hernioplasty, colon resection, and even operations on the stomach with minimally invasive techniques. COLOSTOMY (a surgically created opening through the abdominal wall for the passage of solid digestive waste), once nearly certain after most operations on the colon, now is often temporary or can be avoided altogether. Surgeons have developed methods for anastamosing, or connecting, the remaining segments of the bowel to restore near-normal function. Medications help soothe the bowel and control BACTERIA during HEALING.

The HUMAN GENOME PROJECT, the complete mapping of the human genetic structure, has led to discoveries that have altered the understanding, course of treatment, outlook, and prevention measures for a number of gastrointestinal disor-

ders, including PEPTIC ULCER DISEASE, IBD, and familial cancers of the gastrointestinal tract. GENETIC SCREENING and GENETIC COUNSELING make it possible for people to learn whether they are at risk for many familial or hereditary disorders and take appropriate measures to minimize their likelihood for acquiring the condition. Numerous clinical trials are exploring investigational GENE THERAPY methods to treat or thwart hereditary disorders such as celiac disease and cystic fibrosis.

COLONOSCOPY, visualization of the entire colon using a flexible, lighted endoscope inserted through the anus, has the potential to eliminate 70 percent or more of colorectal cancer through early detection and removal of the adenomatous polyps that are most often the source of cancerous growths in the colon. Research continues the quest for a less intrusive approach, with the current focus on virtual colonoscopy and other procedures that allow for the visualization of the gastrointestinal tract without entering it (though virtual colonoscopy does not offer the opportunity to remove polyps; conventional colonoscopy remains the therapeutic option of choice for most polypectomies). Researchers are also looking for ways to use ENDOSCOPY to screen for other cancers that often go undetected until they are too advanced for treatment, hoping technology may offer similar preventive benefits for a broader range of gastrointestinal malignancies.

A

abdominal distention Swelling of the abdomen, sometimes referred to as bloating. Doctors evaluate abdominal distention as a clinical indicator for a wide range of health conditions. The most common cause of transitory abdominal distention is excessive intestinal gas resulting from eating too fast, which results in swallowing of air along with the food. The BACTERIA in the COLON that ferment high-fiber carbohydrates such as vegetables, fruits, and legumes (beans) also produce intestinal gas during digestion. Infants often swallow air when nursing or bottle feeding, which can cause noticeable abdominal distention rather rapidly. "Burping" the infant relieves the distention. Abdominal distention due to EATING HABITS dissipates as the meal moves through the gastrointestinal system. Completely chewing food before swallowing, especially meats and high-fiber foods, helps slow eating, prepare food for digestion, and reduce the amount of air that enters the gastrointestinal system.

Menstruating women often experience transitory abdominal distention in the few days before and during MENSTRUATION, a result of fluid retention related to hormonal changes taking place in the body. Abdominal distention is a normal feature of PREGNANCY. In early pregnancy the distention and corresponding discomforts may mimic gastrointestinal causes, though as the pregnancy continues the characteristic abdominal enlargement becomes apparent. Extreme OBESITY may mask this presentation, however, resulting in the appearance of generalized abdominal distention rather than characteristic pregnancy. Abdominal distention often is an early sign of ECTOPIC PREGNANCY, a life-threatening condition in which the fertilized egg implants in the fallopian tube instead of the UTERUS. Doctors commonly test for pregnancy in women of childbearing age who seek treatment for abdominal distention.

Abdominal distention that develops gradually and persists may signal health conditions that require medical attention. The most common cause of prolonged abdominal distention is OBESITY, in which excessive body fat accumulates in the central abdomen. The resulting distention may cause the abdominal wall to protrude or cause generalized thickening through the midsection (the "spare tire" presentation of ABDOMINAL ADIPOSITY). Weight reduction results in the gradual recession of abdominal adiposity. ASCITES is a form of abdominal distention that results from fluid accumulating in the peritoneal cavity. Chronic LIVER disease, HEART FAILURE, and chronic KIDNEY disease are among the health conditions associated with ascites. Less commonly, abdominal distention may signal tumors, UTERINE FIBROIDS, OVARIAN CYST, and other growths affecting the abdominal organs. Abdominal distention is a symptom in numerous gastrointestinal conditions including IRRITABLE BOWEL SYNDROME (IBS), MALABSORPTION disorders, and intestinal obstruction.

The doctor should evaluate abdominal distention that persists or in which there is accompanying PAIN, FEVER, or GASTROINTESTINAL BLEEDING. Palpation (feeling the abdomen), BARIUM SWALLOW and BARIUM ENEMA, X-ray endoscopic procedures such as gastroscopy and COLONOSCOPY, ULTRASOUND, COMPUTED TOMOGRAPHY (CT) SCAN, MAGNETIC RESONANCE IMAGING (MRI), and paracentesis (withdrawing fluid from the abdominal cavity through the abdominal using a needle and syringe) are among the common diagnostic methods the doctor may use to identify the cause of abdominal distention. Treatment targets the underlying conditions.

abdominal pain Discomfort in the trunk region that can range from mild cramping to severe PAIN.

Abdominal pain requires emergency medical attention when:
- **PAIN is sudden, sharp, and unrelenting**
- **Pain radiates into the shoulder or jaw**
- **The abdomen is tense and tender to the touch**
- **There is bloody VOMITING or DIARRHEA**

Abdominal pain is one of the most common reasons people seek medical care. Numerous health conditions can cause abdominal pain, from DYSPEPSIA (indigestion) and FLATULENCE (gas) to APPENDICITIS and GALLBLADDER DISEASE. Advanced or metastatic CANCER, LIVER disease, and HEART ATTACK also can involve abdominal pain, among other symptoms.

COMMON CAUSES OF ABDOMINAL PAIN

APPENDICITIS	cholecystitis
cholelithiasis (gallstones)	CONSTIPATION
dissecting abdominal ANEURYSM	DYSPEPSIA (indigestion)
ECTOPIC PREGNANCY	FECAL IMPACTION
GASTROESOPHAGEAL REFLUX DISORDER (GERD)	HEART ATTACK
	HERNIA
ILEUS (intestinal obstruction)	INTUSSUSCEPTION
NEPHROLITHIASIS (KIDNEY stones)	PANCREATITIS
PELVIC INFLAMMATORY DISEASE (PID)	PERITONITIS
URETHRITIS	URINARY TRACT INFECTION (UTI)
viral GASTROENTERITIS	

It is difficult to gauge the severity of the underlying cause of pain on the basis of the pain's qualities. Intestinal gas can cause immobilizing pain, while heart attack may initially manifest as vague discomfort. FEVER (body temperature above 100° F) often accompanies bacterial infections, which require treatment with ANTIBIOTIC MEDICATIONS. Most abdominal discomfort is transitory and benign. Abdominal discomfort requires medical attention when pain is debilitating or continues for longer than five days without improvement, there is discharge from the PENIS or VAGINA, or there is accompanying VOMITING or DIARRHEA for longer than three days.

See also ABDOMINAL DISTENTION.

achalasia A disorder of the ESOPHAGUS in which the lower esophageal sphincter, the ring of MUSCLE at the entry to the STOMACH, remains constricted, failing to allow food to pass into the stomach. Researchers believe the cause is a reduced number of inhibitory nerve cells, the specialized neurons that direct involuntary muscle tissue to relax. The resulting imbalance allows excitory NERVE cells (neurons that direct involuntary MUSCLE tissue to contract) to dominate. Over time the peristaltic action of the esophagus, a structure of involuntary muscle tissue, slows as well. Symptoms of achalasia include

- painful or difficult swallowing
- regurgitation of swallowed food
- DYSPEPSIA (heartburn)
- PAIN in the central chest and beneath the sternum (breastbone) after eating
- unintended weight loss

BARIUM SWALLOW can suggest the diagnosis, with manometry (which measures the pressure within the esophagus) providing confirmation. The gastroenterologist may also perform esophagogastroduodenoscopy (EGD), an endoscopic examination of the upper gastrointestinal tract, to rule out cancers and to use balloon dilation to gently stretch the sphincter. Some people experience relief with medications, such as calcium channel blockers, which block the actions of excitory neurotransmitters to help relax the lower esophageal sphincter. BOTULINUM THERAPY, in which the gastroenterologist injects botulinum toxin into the sphincter to paralyze it, can provide temporary relief. The treatments of choice for short-term relief are disruption of the lower esophageal sphincter, in which the gastroenterologist uses special instruments to widen the sphincter, or esophagomyomotomy, a surgical OPERATION to cut a portion of the sphincter.

See also ENDOSCOPY; NERVOUS SYSTEM; NEURON; NEUROTRANSMITTER; PERISTALSIS; SWALLOWING DISORDERS.

aging, gastrointestinal changes that occur with The organs and structures of the gastrointestinal system undergo numerous changes as an individual grows older. At birth, the infant's MOUTH supports sucking and swallowing liquid nourishment. With the eruption of TEETH and the elongation of the head, developmental changes that occur in early childhood, the oral cavity shifts to support chewing and swallowing solid foods. By three years of age most children in the United States are eating fully solid foods, their gastrointestinal systems capable of digesting nearly any food an adult's body can accommodate.

The gastrointestinal system remains fairly stable until about the fourth decade of life, at which time changes in muscle tone, vasculature (blood vessel function and blood supply), and body composition begin to affect its structures and functions. Some of these changes are physiologic and others relate to lifestyle; combined they result in increased gastrointestinal problems such as GASTROESOPHAGEAL REFLUX DISORDER (GERD), GALLBLADDER DISEASE, DIABETES (altered functioning of the PANCREAS), and PEPTIC ULCER DISEASE. Changes such as weight gain or OBESITY may affect digestive functions as well, particularly with ABDOMINAL ADIPOSITY, a pattern of body fat distribution in which excess body fat accumulates in the abdomen. This accumulation can compress the intestines, slowing intestinal motility. In the fifth decade of life and beyond, there is increased risk for STOMACH CANCER, LIVER CANCER, PANCREATIC CANCER, and COLORECTAL CANCER.

Changes in vasculature, which often result from other health circumstances such as HYPERTENSION (high BLOOD PRESSURE) and ATHEROSCLEROSIS, affect gastrointestinal motility and absorption. A person age 50 absorbs about a third less calcium than a person age 25. Absorption of other vital nutrients slows as well; many older adults benefit from NUTRITIONAL SUPPLEMENTS. In the seventh decade of life and beyond, the SALIVARY GLANDS and digestive glands slow production of their respective secretions. Reduced saliva makes chewing and swallowing more difficult; reduced gastric juices further impede digestion and absorption. These changes increase the potential for gastrointestinal disturbances such as DIARRHEA and CONSTIPATION.

Measures to preserve gastrointestinal health can mitigate many of the age-related changes that occur in the gastrointestinal system. These include

- eating a high-fiber, low-fat diet
- drinking six to eight ounces of water every hour or two during waking hours
- maintaining healthy weight
- getting daily physical exercise
- having regular screening, such as COLONOSCOPY, for colorectal cancer
- managing other health conditions such as diabetes

anal atresia A CONGENITAL ANOMALY, also called imperforate ANUS, in which the anal opening that allows the elimination of feces is missing or misplaced. Diagnosis typically takes place within 24 to 48 hours following birth, with the passage of, or failure to have, the first BOWEL MOVEMENT. Complete anal atresia requires immediate surgery to create a means for the body to pass stool; often the surgeon creates a temporary COLOSTOMY (opening from the large intestine through the abdominal wall) until the infant can undergo any necessary reconstructive surgery. When partial anal atresia is present, the anus may open into another structure such as the VAGINA or URETHRA. Partial anal atresia also requires surgical repair. After surgical reconstruction of the anus many infants have normal bowel function. However some infants have damage to, or are missing, the nerves that regulate the anal sphincter, with resulting FECAL INCONTINENCE. Anal atresia often occurs in combination with other congenital anomalies, notably NEURAL TUBE DEFECTS.

See also BOWEL ATRESIA; CONGENITAL HEART DISEASE; ESOPHAGEAL ATRESIA; RECTAL FISTULA.

anal fissure Small tears in the tissue around the ANUS. Anal fissures can be internal or external. They typically are painful and may bleed with bowel movements, resulting in small amounts of bright red BLOOD on the toilet tissue or in the toilet bowl.

The most common cause of anal fissure is CONSTIPATION, in which the bowel movement is hard and often forced. PAIN can be intense with bowel movements. The doctor can diagnose anal fissure on the basis of the symptoms and by examining the anal area, though may perform an anoscopy to examine the inner anus. Most anal fissures heal with conservative treatment that includes frequent sitz baths, topical application of hydrocortisone preparations to reduce INFLAMMATION, high-fiber diet and stool softeners to pull more moisture into the stools, and daily physical exercise such as walking to improve intestinal motility (movement of food through the gastrointestinal tract) and encourage regular bowel movements.

The next level of treatment for anal fissure that persists is topical nitroglycerin or topical nifedipine (a calcium channel blocker), both of which increase blood flow to the anal sphincter and cause it to relax. Doctors prescribe these medications in oral form to relax the CORONARY ARTERIES as a treatment for CORONARY ARTERY DISEASE (CAD); the pharmacological action on the blood vessels in the anal area is similar. Nitroglycerin ointment, like other forms of nitroglycerin, can cause HEADACHE and dizziness. Another treatment option is BOTULINUM THERAPY, in which the doctor injects the anal sphincter near the fissure with botulinum toxin to temporarily paralyze the MUSCLE fibers, which relaxes the sphincter. The effect of the botulinum toxin lasts about three months. Extensive anal tears and fissures that do not heal with other treatments may require surgical repair. INFECTION may develop with persistent or extensive anal fissure, and requires appropriate antibiotic therapy.

See also ENDOSCOPY; HEMORRHOIDS; PROCTITIS; SITZ BATH.

antacids Products that neutralize gastric (STOMACH) acid to relieve DYSPEPSIA (heartburn and indigestion). Antacids work by increasing the pH (acid level) of the gastric juices, which reduces the irritation to the stomach tissues. Most antacids contain mineral salts, which are alkaline.

Because of their high salt and mineral content, many antacids can cause CONSTIPATION or DIARRHEA by drawing excessive fluid from the gastrointestinal tract. Sodium bicarbonate, which most people mix at home by dissolving baking soda in water, has such a high sodium level that it can affect BLOOD PRESSURE and the rhythm of the HEART. Anyone who has CARDIOVASCULAR DISEASE (CVD), especially HYPERTENSION or ARRHYTHMIA, should not use sodium bicarbonate as an antacid.

COMMON ANTACID PRODUCTS

Active Ingredient	Representative Products
aluminum hydroxide	ALternaGEL
aluminum/magnesium combination	Maalox, Mylanta
bismuth subsalicylate	Pepto-Bismol
calcium carbonate	Tums, Titralac
magnesium hydroxide	milk of magnesia
simethicone	Gas-X, Phazyme
sodium bicarbonate	baking soda

Aluminum hydroxide, though very effective at neutralizing stomach acid, is so likely to cause constipation that it nearly always is combined with magnesium, which has the opposite effect. Doctors may recommend magnesium-based antacids, such as milk of magnesia, as LAXATIVES to treat mild, occasional constipation. Many antacid products also contain simethicone, a surfactant that breaks up intestinal gas bubbles to relieve bloating and FLATULENCE.

Bismuth subsalicylate products such as Pepto-Bismol contain an aspirin-like ingredient that can cause the rare but serious SIDE EFFECT, REYE'S SYNDROME, in children who have viral infections. Children should not take these products.

Antacids are available over the counter, without a doctor's prescription. Occasional use of antacids can provide rapid relief of dyspepsia and other digestive discomforts. Antacids are most effective taken with food, which increases the time the antacid remains in the stomach, and liquid forms seem to be more effective than chewable forms. Chronic or regular use of antacids can result in numerous health problems, ranging from

"rebound" dyspepsia or gastric reflux (most common with calcium carbonate products) to OSTEOPOROSIS (with magnesium products, as magnesium binds with calcium) and aluminum TOXICITY. Indications of antacid overuse include

- dyspepsia symptoms that seem to surge when the antacid DOSE nears the end of its effectiveness
- the need to take higher or more frequent doses of the antacid to obtain relief
- mental CONFUSION (indicating possible aluminum toxicity)
- chronic diarrhea (typically with aluminum/magnesium combination products)

Antacids also interfere with the actions of numerous medications. Other products, such as H2 ANTAGONIST (BLOCKER) MEDICATIONS and PROTON PUMP INHIBITOR MEDICATIONS, are more effective for managing long-term gastric discomfort such as GASTROESOPHAGEAL REFLUX DISORDER (GERD). Antacids also interfere with H2 antagonist blockers. Children age 12 and under should not take antacids unless a doctor recommends them. A pharmacist can suggest an appropriate antacid for the circumstances and to avoid interfering with any medications a person is taking.

See also ANTIDIARRHEAL MEDICATIONS; ANTIEMETIC MEDICATIONS; PEPTIC ULCER DISEASE.

antidiarrheal medications Medications that relieve DIARRHEA. Antidiarrheal medications work by slowing the activity of the gastrointestinal tract or by absorbing more fluid in the COLON (large intestine). Though diarrhea is unpleasant, doctors recommend letting the body restore its balance without medications in most circumstances of acute diarrhea. Acute diarrhea (diarrhea that comes on suddenly) may result from simple gastrointestinal upset following unusual foods and beverages, (such as when traveling), excessive

COMMON ANTIDIARRHEAL MEDICATIONS

Active Ingredient	Representative Products	Availability
attapulgite	Kaopectate, Parepectolin	over the counter
belladonna	Donnatal	requires a doctor's prescription
bismuth subsalicylate	Pepto-Bismol	over the counter
codeine	codeine	requires a doctor's prescription
difenoxin and atropine	Motofen	requires a doctor's prescription
diphenoxylate	Lomotil	requires a doctor's prescription
kaolin and pectin	Kapectolin	over the counter
loperamide	Imodium	over the counter
methylcellulose	Citrucel	over the counter
octreotide	Sandostatin	requires a doctor's prescription
paregoric	camphorated tincture of opium	requires a doctor's prescription
psyllium	Metamucil	over the counter

CAFFEINE consumption, FOOD-BORNE ILLNESSES, or viral INFECTION (GASTROENTERITIS or ENTERITIS). These circumstances tend to resolve themselves within a few days, which may be briefer than the actions of many antidiarrheal medications.

Taking an antidiarrheal product may result in rebound CONSTIPATION. However, diarrhea more significantly interferes with daily activities than does constipation, and many people opt to take medications to slow or stop it. It is important to drink extra fluids when taking antidiarrheal medications, to replace fluids lost with the diarrhea as well as to maintain adequate hydration of the gastrointestinal tract to prevent rebound constipation from developing. Some antidiarrheal medications are available over the counter and others require a doctor's prescription.

Doctors sometimes prescribe anticholinergic medications, which act on the NERVOUS SYSTEM to slow gastrointestinal function, for severe diarrhea. However, these medications have numerous actions throughout the body, and doctors tend to reserve them for use when other antidiarrheal medications are ineffective. Opiate NARCOTICS such as paregoric and codeine are effective for slowing gastrointestinal motility. Attapulgite, pectin, and kaolin are natural substances that absorb fluid. Though typically perceived as LAXATIVES, bulking agents such as psyllium and methylcellulose also absorb water and can help restore normal bowel function.

Antidiarrheal medications are most effective for controlling outbreaks of diarrhea such as may occur with IRRITABLE BOWEL SYNDROME (IBS), INFLAMMATORY BOWEL DISEASE (IBD), and MALABSORPTION. Antidiarrheal medications are also effective for treating antibiotic-induced diarrhea that does not end when the antibiotic therapy ends. Remedies such as taking lactobacillus or eating plain yogurt may help restore normal BACTERIA to the gastrointestinal tract.

The most frequent complication of antidiarrheal medications is rebound constipation. A rare but serious complication that can occur when taking antidiarrheal medications that slow gastrointestinal motility is TOXIC MEGACOLON, in which the colon becomes vastly dilated and flaccid and the flow of the intestinal content stops. Antidiarrheal medications also can mask conditions that require medical attention. For most people, occasional use of over-the-counter antidiarrheal medications provides prompt relief of diarrhea with few complications.

See also ANTACIDS; ANTIEMETIC MEDICATIONS; FIBER AND GASTROINTESTINAL HEALTH.

antiemetic medications Medications that relieve NAUSEA and VOMITING (known clinically as emesis). The most commonly used are anticholinergic medications and antihistamine MEDICATIONS, which suppress the vestibular system mechanisms that cause vomiting. Many antihistamine products are available over the counter. Doctors may recommend or prescribe these medications to treat nausea related to VERTIGO, MÉNIÈRE'S DISEASE, LABYRINTHITIS, and other disorders of the inner EAR and vestibular system, and to help prevent motion sickness. Both anticholinergics and antihistamines can cause drowsiness and dry MOUTH.

A classification of powerful antiemetics, the 5-HT3 RECEPTOR ANTAGONIST MEDICATIONS, became available in the 1990s. Doctors prescribe these medications, such as dolasetron and ondansetron, primarily to treat nausea and vomiting resulting from RADIATION THERAPY, CHEMOTHERAPY, and surgery. These medications work by blocking serotonin from reaching receptors in the gastrointestinal system and may have neurologic side effects such as Parkinson-like symptoms.

Over-the-counter products to treat nausea include bismuth subsalicylate (Pepto-Bismol) and cola syrup, both of which are effective for relieving mild nausea and vomiting with viral INFECTION (such as GASTRITIS and GASTROENTERITIS). Pharmacies also sell a commercial preparation of phosphorated carbohydrate solution, similar to cola syrup, called Emetrol. Cola drinks allowed to go "flat" have the same antinausea effect. These substances act to soothe the inner lining of the stomach. GINGER also has a calming action on the stomach and can provide relief through drinking flat ginger ale (brands that contain ginger, not just ginger flavoring) or eating small pieces of fresh ginger root.

Treatment for nausea and vomiting also targets any underlying conditions or causative circumstances.

See also ACUPUNCTURE; MORNING SICKNESS; NEUROTRANSMITTER.

COMMON ANTIEMETIC MEDICATIONS

Active Ingredient	Representative Products	Availability
bismuth subsalicylate	Pepto-Bismol	over the counter
buclizine	Bucladin-S	requires a doctor's prescription
cyclizine	Marezine	requires a doctor's prescription
dimenhydrinate	Dramamine	over the counter
diphenhydramine	Benadryl	over the counter
dolasetron	Anzemet	requires a doctor's prescription
granisetron	Kytril	requires a doctor's prescription
meclizine	Antivert, Bonine	over the counter (prescription strength also available)
metoclopramide	Reglan	requires a doctor's prescription
ondansetron	Zofran	requires a doctor's prescription
prochlorperazine	Compazine	requires a doctor's prescription
promethazine	Phenergan	requires a doctor's prescription
scopolamine transdermal	Transderm-V	requires a doctor's prescription
trimethobenzamide	Tigan	requires a doctor's prescription

anus The opening through which the body passes solid waste (feces), below the final segment of the COLON and the terminus of the gastrointestinal system. The anal sphincter is a ring of MUSCLE that contracts to contain fecal matter and relaxes to expel it. Learning to control the contraction and relaxation of the anal sphincter begins to take place at age two or three; most children master this control by age four or five. NERVOUS SYSTEM damage, such as with PARKINSON'S DISEASE and sometimes as a consequence of aging, can cause loss of anal sphincter control with resulting FECAL INCONTINENCE.

For further discussion of the anus within the context of gastrointestinal structure and function, please see the overview section "The Gastrointestinal System."

See also ANAL ATRESIA; ANAL FISSURE; RECTUM; SPINAL CORD INJURY; STROKE; TRAUMATIC BRAIN INJURY (TBI).

appendectomy A surgical OPERATION to remove an inflamed or infected APPENDIX. The conventional open procedure involves making an incision two to three inches long in the lower right abdomen. Open appendectomy typically requires two or three days of hospitalization and four to six weeks for full recovery. A laparoscopy appendectomy requires a shorter hospital stay and is a more rapid recovery. For a laparoscopic appendectomy, the surgeon makes four or five small incisions (about ½ inch in length). Through one of the incisions the surgeon inserts the laparoscope, a flexible lighted tube. Through the other incisions the

surgeon inserts special instruments. LAPAROSCOPIC SURGERY often requires only an overnight stay in the hospital, with return to normal activities in three to four weeks. Laparoscopic appendectomy is the operation of choice for most circumstances of simple appendicitis in which INFLAMMATION and INFECTION remain confined to the appendix and the diagnosis is clear-cut. The surgeon may choose to convert a laparoscopic to an open procedure should there be any complicating factors once the surgery begins.

Risks of appendectomy, open or laparoscopic, include leakage of intestinal content into the peritoneal cavity, which can result in PERITONITIS, or postoperative ABSCESS (pocket of infection). To safeguard against these complications, postoperative care includes intravenous ANTIBIOTIC MEDICATIONS during the hospital stay and a course of oral antibiotics following hospital discharge. As with any surgery, reaction to ANESTHESIA and bleeding during or after the operation are also risks. Full recovery after appendectomy for simple appendicitis is the norm, with most people returning to their usual activities within six weeks (up to eight weeks for strenuous physical activity such as competitive sports).

See also ENDOSCOPY.

appendicitis INFLAMMATION of the APPENDIX. Because the appendix is so narrow, inflammation can rapidly cause it to swell closed, trapping BACTERIA-laden intestinal matter. This sets the stage for INFECTION that can spread to involve nearby structures.

Appendicitis is an emergency that requires immediate surgery.

The classic symptoms of appendicitis include

- PAIN in the lower right abdomen
- NAUSEA, VOMITING, and aversion to food
- tendency to lie in somewhat of a fetal position, often on the right side with the knees drawn toward the chest

However, more than a third of people who have appendicitis have atypical symptoms that may include diffuse (generalized) abdominal discomfort, pain referred to the back or shoulder area, or symptoms that mimic other health conditions ranging from DYSPEPSIA (indigestion) to URINARY TRACT INFECTION (UTI). Further, there are no definitive causes of appendicitis, though often the surgeon or pathologist detects particles of food or fecal matter lodged in the appendix. The key risk of appendicitis is that the inflamed appendix may perforate (rupture), spilling intestinal debris and infectious matter into the peritoneal cavity. The resulting widespread contamination evolves quickly to PERITONITIS, a life-threatening infection.

The diagnostic path begins with a physical examination to determine the quality of the pain. Key signs of appendicitis during examination include rebound tenderness (increased pain when the doctor presses slowly downward on the abdomen and then suddenly releases the pressure) and pain (often intense) with pressure applied directly over the location of the appendix. A DIGITAL RECTAL EXAMINATION (DRE) also often elicits a significant pain response. A complete blood count (CBC) may reveal the inflammatory process or an infection.

Surgical removal of an inflamed appendix (APPENDECTOMY) provides the only conclusive diagnosis of appendicitis. ANTIBIOTIC MEDICATIONS generally are not effective in treating appendicitis because the infection is generally well under way by the time of diagnosis and the risk of peritonitis or other complicating factors is very high.

See also GALLBLADDER DISEASE; PELVIC INFLAMMATORY DISEASE (PID).

appendix A small, fingerlike projection, sometimes called the vermiform appendix, extending from the bottom of the CECUM, the first segment of the large intestine (COLON). Historically health professionals have viewed the appendix as a vestigial structure with no functional purpose. However, recent research identifies clusters of GUT-ASSOCIATED LYMPHOID TISSUE (GALT), fragments of lymphoid tissue, within the lining of the appendix. Though researchers do not yet understand the role of GALT, they know it belongs to the IMMUNE SYSTEM and has functions related to the IMMUNE RESPONSE. It appears that the immune functions of the appendix, like those of the THYMUS, are most active early in life. Researchers are studying the relation-

ship between the appendix and INFLAMMATORY BOWEL DISEASE (IBD) as well as the role of GALT HYPERPLASIA (enlargement of the lymphoid tissue) in APPENDICITIS. Because of its location and narrow structure, the appendix is vulnerable to circumstances that cause it to become inflamed or infected. Appendicitis is the most common health condition involving the appendix.

For further discussion of the appendix within the context of gastrointestinal structure and function, please see the overview section "The Gastrointestinal System."

See also AGING, EFFECTS ON IMMUNE RESPONSE; APPENDECTOMY; MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT).

ascites The accumulation of fluid within the peritoneal cavity. Ascites is an abnormal condition that often accompanies chronic LIVER disease such as CIRRHOSIS and LIVER DISEASE OF ALCOHOLISM. Ascites sometimes also develops with HEART FAILURE, END-STAGE RENAL FAILURE (ESRF), OVARIAN CANCER, and metastatic cancer that infiltrates abdominal structures. Ascites typically causes little discomfort. Paracentesis, in which the doctor uses a needle and syringe to withdraw a sample of the fluid, can help to diagnose the cause of the ascites. The doctor also may use paracentesis to withdraw large amounts of fluid to relieve the ascites. Other treatments include a very low sodium diet and diuretic medications to encourage the kidneys to withdraw larger amounts of fluid from the blood. Untreated or persistent ascites invites PERITONITIS, a potentially life-threatening INFECTION.

See also HEPATITIS; PORTAL HYPERTENSION; STEATOHEPATITIS.

B

barium enema A diagnostic imaging procedure to examine the structures of the lower gastrointestinal tract including the RECTUM and COLON, sometimes called a lower GI (gastrointestinal) series. The gastroenterologist may request a barium ENEMA to help diagnose intestinal polyps, DIVERTICULAR DISEASE, INFLAMMATORY BOWEL DISEASE (IBS), HIRSCHSPRUNG'S DISEASE, intestinal obstruction, COLORECTAL CANCER, and RECTAL PROLAPSE. Preparation for barium enema typically includes a clear liquid diet for two days before the procedure, a laxative the night before the procedure, and an ENEMA the morning before the procedure to cleanse the colon.

The test consists of a barium mixture administered via enema, followed by a series of X-rays (FLUOROSCOPY). Body position and the heaviness of the barium help the barium mixture to flow upward into the lower gastrointestinal tract. For a single-contrast barium enema, the radiologist takes X-ray images of the barium-filled colon and rectum. For a double-contrast barium enema the person eliminates as much barium as possible after the first series of X-rays, then the radiologist injects a small amount of air into the lower bowel and takes another X-ray series. Double-contrast barium enema provides more detailed visualization. The heaviness and pressure of the barium make the procedure uncomfortable and some people experience cramping. The procedure takes 20 to 45 minutes, with the person placed in different positions to help move the barium through the colon. Light-colored stools are normal for several days after the procedure while the barium clears the body. A rare complication is bowel perforation.

See also BARIUM SWALLOW; COLONOSCOPY; INTESTINAL POLYP; LAXATIVES.

barium swallow A diagnostic imaging procedure to examine the structures of the upper gastrointestinal tract including the ESOPHAGUS, STOMACH, and DUODENUM (beginning of the SMALL INTESTINE), sometimes called an upper GI (gastrointestinal) series. The gastroenterologist may request a barium swallow to help diagnose HIATAL HERNIA, esophageal obstruction, ESOPHAGEAL SPASM, stomach dysfunction, and PEPTIC ULCER DISEASE. Preparation for barium swallow typically is nothing to eat or drink for 8 to 12 hours, before the procedure.

The test consists of swallowing a preparation of barium, a high-contrast medium, during a series of X-rays (FLUOROSCOPY). The barium lines the structures of the upper gastrointestinal tract, making them visible by X-ray. The barium preparation is about the consistency of a milkshake though chalky in texture. The procedure takes 30 to 60 minutes, with the person placed in different positions to help move the barium through the upper gastrointestinal tract. Some people experience mild CONSTIPATION after the procedure, and it is normal for the stools to be light-colored for several days after the procedure while the barium clears the body.

See also BARIUM ENEMA; ENDOSCOPY.

Barrett's esophagus Changes to the lining of the ESOPHAGUS in which the tissue becomes similar to that of the intestine. The altered tissue is Barrett's esophagus does not itself cause symptoms, though the condition often appears in association with GASTROESOPHAGEAL REFLUX DISORDER (GERD), which does cause symptoms. The key clinical significance of Barrett's esophagus is its association with a rare and deadly form of CANCER, esophageal ADENOCARCINOMA. Though few people who have Barrett's esophagus will develop esophageal adenocarcinoma, nearly everyone who does develop

esophageal adenocarcinoma also has Barrett's esophagus.

Diagnosis of Barrett's esophagus requires endoscopic biopsy of the esophageal lining. Altered tissue often appears reddened in endoscopic visualization, though appearance cannot make the diagnosis as GERD also can cause INFLAMMATION and irritation of the esophageal lining that causes it to appear reddened. A person who has confirmed Barrett's esophagus should undergo periodic endoscopic biopsy as a measure to detect further changes in the tissue (dysplasia) that could indicate a developing cancer. Esophageal adenocarcinoma appears to develop slowly, with a period of years during which the tissue changes are transitional. Dysplasia or cancer requires appropriate treatment, which varies according to individual health circumstances. There are no treatments for Barrett's esophagus or to prevent its conversion to esophageal adenocarcinoma.

See also CANCER RISK FACTORS; ENDOSCOPY; ESOPHAGEAL CANCER; ESOPHAGITIS.

bezoar A hardened mass of indigestible matter that forms in the STOMACH, such as HAIR (trichobezoar), insoluble plant fiber (phytobezoar), or a combination of hair and plant fiber (trichophytobezoar). Bezoars can develop in children who chew their hair or eat substances such as sand or grass and in adults who have slowed gastrointestinal motility, such as might occur with GASTROPARESIS or ACHALASIA. A bezoar can remain undetected in the stomach for months, until it becomes large enough to block the passage of food into the SMALL INTESTINE. Common symptoms include PAIN, NAUSEA, VOMITING, and occasionally a palpable lump. BARIUM SWALLOW or ENDOSCOPY can confirm the diagnosis. Surgery (endoscopic or open) to remove the bezoar is often the only treatment, as by the time a bezoar causes symptoms it is too large to pass through the gastrointestinal tract. Bezoars may recur when the behavior responsible for their development, such as hair chewing, persists.

See also ILEUS.

bile A liquid that the LIVER produces to carry some of its waste products into the digestive tract. Specialized cells called hepatocytes synthesize bile from water, cholesterol, bile acids, bile salts, BILIRUBIN and other bile pigments, and electrolytes. The hepatocytes break down cholesterol, a fatty acid, into bile acids. Other cells in the liver further convert bile acids into water-soluble forms called bile salts.

The SPLEEN is the body's scavenger and one of its jobs is to remove old erythrocytes (red BLOOD cells) from the blood and break them down. One of the byproducts of this process is heme, the iron compounds. After further metabolism one derivative of heme is bilirubin. Bilirubin is dark yellow and is the primary pigment in bile, giving bile its dominant yellow coloration. Other bile pigments come from substances the liver detoxifies from the blood, adding to the bile's color.

A network of BILE DUCTS collects bile from the liver and carries it to the GALLBLADDER. The walls of the gallbladder absorb about 90 percent of the water the bile contains, producing a greatly concentrated solution that the gallbladder ejects during digestion to aid in digesting fatty foods. Bile that enters the intestinal tract that the body does not need for digestion continues to travel through the intestines, eventually mixing with fecal matter for excretion from the body. The liver secretes about 750 milliliters (roughly a quart) of bile every day.

See also ERYTHROCYTE; CHOLESTEROL BLOOD LEVELS; GALLBLADDER DISEASE; PANCREATITIS.

bile ducts Channels that carry BILE from LIVER to the GALLBLADDER and from the gallbladder to the DUODENUM (first segment of the SMALL INTESTINE). The intrahepatic ducts are within the structure of the liver. They collect bile the liver secretes and transport it from the liver. The extrahepatic ducts are outside the liver and route bile to the gallbladder and duodenum. They are

- the hepatic duct, which carries bile out of the liver to the cystic duct
- the cystic duct, which carries bile from the hepatic duct to the gallbladder and from the gallbladder to the common duct
- the common duct, which carries bile into the duodenum

The health conditions most likely to involve the bile ducts are BILIARY ATRESIA, a CONGENITAL ANOMALY in which the bile ducts form incompletely or not at all, and ductal occlusion resulting from cholelithia-

sis, in which gallstones escape from the gallbladder and lodge in a bile duct, blocking the flow of bile and causing PAIN. CANCER of the bile ducts, called cholangiocarcinoma, occurs though is rare.

For further discussion of the bile ducts within the context of gastrointestinal structure and function, please see the overview section "The Gastrointestinal System."

See also GALLBLADDER DISEASE; PANCREAS; PRIMARY BILIARY CIRRHOSIS; PRIMARY SCLEROSING CHOLANGITIS.

biliary atresia Absence or malformation of the BILE DUCTS, also called neonatal CHOLESTASIS. Biliary atresia is nearly always congenital (present at birth). In some infants biliary atresia appears to develop as a consequence of an inflammatory process that occurs shortly after birth, destroying the bile ducts. Biliary atresia prevents the flow of BILE from the LIVER, causing toxins to accumulate in the liver. Symptoms depend on the extent of the atresia and may become apparent within days of birth or manifest slowly over the first six months of life. Symptoms include

- JAUNDICE, a yellowish discoloration of the SKIN resulting from the liver's inability to break down BILIRUBIN into components the body can excrete as waste
- stools that are pale in color, the consistency of clay, and unusually foul smelling
- dark URINE
- failure to grow or gain weight
- ABDOMINAL DISTENTION resulting from enlarged SPLEEN
- fussiness and irritability

NEONATAL JAUNDICE

NEONATAL JAUNDICE is fairly common, affecting about 50 percent of full-term and 80 percent of preterm (premature) newborns. It points to biliary atresia or other LIVER conditions only when it is apparent within the first 24 hours after birth or persists despite treatment.

The diagnostic path includes blood tests to measure the amounts of bilirubin in the blood and PERCUTANEOUS LIVER BIOPSY to determine whether the hepatocytes, the cells that process bilirubin, are normal. Normal hepatocytes strongly suggest biliary atresia. Other diagnostic procedures may include ULTRASOUND and intraoperative cholangiography (injecting dye into the bile ducts to visualize them using FLUOROSCOPY or other imaging technologies).

The only treatments for biliary atresia are surgical procedures to help restore the flow of bile. The first of these procedures is hepatic portoenterostomy, in which the surgeon creates an opening between the JEJUNUM (middle segment of the SMALL INTESTINE) and the bile duct structures that exist outside the liver. This procedure allows bile to drain directly from the liver into the small intestine and can achieve adequate liver function for up to several years. However, it does not correct the structural defects of the bile transport network within the liver, and damage to the liver (fibrosis and CIRRHOSIS) continues. Nearly all infants who have biliary atresia require LIVER TRANSPLANTATION, the second surgical procedure to treat the condition, before they are three years old. Long-term success of liver transplantation depends on numerous variables.

See also CONGENITAL ANOMALY; LIVER FAILURE.

bilirubin A metabolic product of ERYTHROCYTE (red BLOOD cell) heme that is a key component of HEMOGLOBIN. Bilirubin exists in two forms, conjugated (also called direct), which is water soluble, and unconjugated (also called indirect or free), which is fat soluble. The amounts and ratios of bilirubin present in the BLOOD help doctors assess LIVER and GALLBLADDER functions.

NORMAL BLOOD BILIRUBIN VALUES

unconjugated (indirect) bilirubin	0.1 to 1.0 milligrams per deciliter (mg/dL)
conjugated (direct) bilirubin	0.0 to 0.4 mg/dL
total bilirubin	0.3 to 1.9 mg/dL

The SPLEEN removes old erythrocytes (red blood cells), which contain high concentrations of hemoglobin, from the circulation and begins to break them down into their components. The bilirubin that results from this process is unconjugated, a form the body cannot eliminate. ALBUMIN, a protein in the blood, transports this unconjugated bilirubin to the liver. There, actions of an enzyme—glucuronyl transferase—help a chemical

reaction that converts the unconjugated bilirubin to conjugated bilirubin, which then becomes an ingredient of BILE.

Bilirubin is yellow and in turn colors the bile yellow; hence its designation as a bile pigment. Intestinal BACTERIA further metabolize bilirubin, the major component of which is urobilinogen. Urobilinogen gives the feces their characteristic dark color. Pale feces are a hallmark of disturbances of bilirubin METABOLISM. Increased bilirubin levels in the blood result in JAUNDICE, a yellowish discoloration of the SKIN most visible in the SCLERA ("white" of the EYE). Certain wavelengths of light on the skin help the body complete bilirubin metabolism.

See also CIRRHOSIS; HEPATITIS; PHOTOTHERAPY.

biliary dysfunction See GALLBLADDER DISEASE.

borborygmus The growling and rumbling sound of gas moving through the gastrointestinal tract during digestion. Borborygmus, sometimes referred to in the plural, *borborygmi,* indicates normal function of the gastrointestinal system. The sounds originate with the STOMACH and continue through the SMALL INTESTINE and large intestine. Excessive rumblings may indicate incomplete digestion such as may result from eating too rapidly or eating too much at one time. Some people experience an increase in borborygmus when they are hungry.

See also BOWEL SOUNDS; FLATULENCE.

bowel atresia A CONGENITAL ANOMALY in which there is incomplete development of the intestinal tract, typically with closures and "dead ends" that block flow through the intestines. The intestines may be entangled or intussuscepted (one segment of bowel telescopes into another), presenting grave risk for tissue death (necrosis). Nearly always the diagnosis is apparent within hours of birth because the infant is unable to eat and the abdomen quickly becomes distended. VOMITING BILE is a key indicator of intestinal obstruction of some sort. Bowel atresia is more common in premature infants. The most common locations for bowel atresia are the DUODENUM (duodenal atresia) and the JEJUNUM and ILEUM (jejunoileal atresia). Bowel atresia is life-threatening and requires emergency surgery to correct the defects.

See also ANAL ATRESIA; CONGENITAL HEART DISEASE; ESOPHAGEAL ATRESIA; INTUSSUSCEPTION.

bowel movement The passage of solid digestive waste (called feces or stool) from the body through the ANUS. The frequency, appearance, and nature of bowel movements are highly variable. Food typically travels through the gastrointestinal system in 18 to 36 hours, so most people have bowel movements daily or every other day. However, "normal" is an individual pattern that correlates to dietary habits, physical activity level, and lifestyle and can range from three bowel movements a day to one bowel movement every three days. What can become significant from a health standpoint are deviations from an individual's pattern of bowel movements. Short-term changes in bowel patterns may result from eating different foods, viral INFECTION (GASTROENTERITIS or ENTERITIS), inadequate fluid consumption, and medications. A shift in bowel patterns not due to intentional actions such as dietary or exercise change may indicate health conditions that require medical evaluation.

See also BOWEL SOUNDS; CONSTIPATION; DIARRHEA.

bowel sounds The noises of the gastrointestinal tract. Listening to bowel sounds through a stethoscope (AUSCULTATION) provides important clues about the function of the gastrointestinal tract. Normal bowel sounds vary in tone and loudness according to the activity of the bowel though follow characteristic patterns the doctor can identify. Excessive bowel sounds often accompany excessive bowel activity such as DIARRHEA, GASTROENTERITIS, and flare-ups of INFLAMMATORY BOWEL DISEASE (IBD). Reduced bowel sounds occur when bowel activity slows, such as between meals or when there is an intestinal obstruction. Narcotic medications and anesthetic agents also slow bowel function, and reduced bowel sounds may persist for several days after surgery. The absence of bowel sounds signals a nonfunctioning bowel, which can be due to intestinal obstruction or, in an infant, a gastrointestinal atresia. The absence of bowel sounds may be a sign of a medical emergency that requires surgical intervention.

See also BORBORYGMUS; BOWEL ATRESIA; ESOPHAGEAL ATRESIA.

C

cecum The first segment of the COLON (large intestine) into which the ILEUM, the final segment of the SMALL INTESTINE, empties digestive matter. The cecum is a pouchlike structure located in the lower right abdomen that absorbs water from the waste, returning fluid to the body and consolidating the waste for its journey through the end stage of digestion. The rhythmic contractions of PERISTALSIS move the remaining solid waste into the remainder of the colon. The APPENDIX extends from the bottom of the cecum.

For further discussion of the cecum and the colon within the context of gastrointestinal structure and function, please see the overview section "The Gastrointestinal System."

See also ANUS; RECTUM.

celiac disease A condition affecting the SMALL INTESTINE in which consuming foods that contain gluten, a plant protein prominent in wheat, triggers an inflammatory response that prevents the intestinal mucosa (lining) from absorbing NUTRIENTS. Gluten, and more specifically proteins it contains called gliadins, acts as an ANTIGEN to initiate a localized IMMUNE RESPONSE. Researchers believe celiac disease has a genetic foundation, though the specific GENE or genes responsible remain undetermined. Though severe celiac disease can cause significant NUTRITIONAL DEFICIENCIES that affect growth, FERTILITY, and overall health, most people who adopt a gluten-free diet are able to avert the inflammatory episodes and minimize damage to the intestinal mucosa. About 1 in 5,000 Americans has celiac disease.

Symptoms and Diagnostic Path

Symptoms appear in celiac disease with exposure to gluten, so usually do not become apparent until after the age of two years when children begin eating solid foods. People who have celiac disease experience a broad range of symptoms, with some people having virtually no indications they have celiac disease until nutritional deficiencies become problematic and other people suffering chronic DIARRHEA, cramping, ABDOMINAL DISTENTION, and other gastrointestinal disruptions. Some people have outbreaks of DERMATITIS herpetiformis, an itchy SKIN RASH. An early indication of celiac disease, especially in children, is the passing of large, loose, light-colored, foul-smelling stools, which suggests high fat excretion (STEATORRHEA) characteristic of MALABSORPTION.

Celiac disease may affect any or all of the segments of the small intestine, and the degree to which it affects them determines the symptoms. Many of the symptoms and signs of celiac disease arise from health problems due to nutritional deficiencies that correlate to the segment of small intestine affected, manifesting in conditions such as ANEMIA (deficiency of iron, suggesting involvement of the DUODENUM and upper JEJUNUM) and frequent nosebleeds (deficiency of VITAMIN K, suggesting involvement of the lower jejunum and the ILEUM). Children who have celiac disease may also appear malnourished, showing spindly limbs and protruding bellies, despite adequate food consumption.

Biopsy of the intestinal mucosa in people who have celiac disease tends to show marked structural differences from normal intestinal mucosa. Most significant is flattening of the mucosal tissue from its normal "pleated" appearance, which reduces the surface area available for nutrient absorption. Lymphocytes and leukocytes are also present within the mucosal tissue, evidence of the inflammatory process. However, there are no definitive tests to diagnose celiac disease. BLOOD

tests to measure ANTIBODY levels and biopsy of the intestinal mucosa provide strong, though not conclusive, evidence of celiac disease. Antibody levels become elevated only during active episodes of the disease, and biopsy samples may not represent the overall status of the small intestine.

The gastroenterologist considers these results in conjunction with the pattern of symptoms, FAMILY MEDICAL PEDIGREE, and response to a gluten-free diet. Symptoms that disappear with a gluten-free diet provide fairly conclusive diagnosis, though this marker is useful only in people who have obvious gastrointestinal or dermatologic symptoms.

Treatment Options and Outlook

The primary treatment for celiac disease is a gluten-free diet. This means eliminating all wheat and wheat products, as well as numerous processed foods that contain gluten as filler. Many foods that restaurants serve also contain gluten, requiring great diligence to determine food ingredients. Wheat-free products may still contain gluten. Some people also need to eliminate oats, barley, and rye and products made from them, as these grains contain small amounts of gluten. People who have severe celiac disease may require NUTRITIONAL SUPPLEMENTS or nutritional-replacement therapies. Most people who follow a gluten-free diet experience improvement within two weeks and an end to their symptoms within a few months. The longer there are no symptoms, the more the intestinal mucosa restores itself and often returns to normal in people who remain symptom-free for several years.

Risk Factors and Preventive Measures

Celiac disease appears to be genetic, and as yet researchers do not know what, if any, risk factors exist. Many people are able to control their symptoms and prevent disease flareups by avoiding foods that trigger them. The doctor also may recommend nutritional supplements to minimize or prevent nutritional deficiencies.

cholecystectomy A surgical OPERATION to remove the GALLBLADDER. Cholecystectomy is the most common treatment in the United States for GALLBLADDER DISEASE including gallstones (cholelithiasis), cholecystitis (INFLAMMATION or INFECTION of the gallbladder), and biliary dyskinesia (diminished ability of the gallbladder to eject BILE). About 500,000 Americans undergo cholecystectomy each year.

Surgical Procedure

There are two methods for performing cholecystectomy, laparoscopic and open. About 95 percent of cholecystectomies surgeons perform in the United States are laparoscopic. Surgeons perform open cholecystectomy, once the standard, only when there are contraindications for laparoscopic cholecystectomy (such as extreme OBESITY) or laparoscopic cholecystectomy cannot successfully remove the gallbladder (such as when there are many stones or there is extensive scarring from long-standing gallbladder disease or repeated infections). Both operations require general ANESTHESIA and an overnight stay in the hospital.

Laparoscopic cholecystectomy In laparoscopic cholecystectomy the surgeon makes four or five small incisions and inserts a laparoscope and tiny instruments through them. The surgeon operates by visualizing the gallbladder via closed-circuit television display. The operation takes 45 to 60 minutes. Most people then stay several hours in the recovery room and overnight in the hospital. After surgery, many people returning to regular daily activities (except strenuous physical exercise) within three weeks, though full recovery takes six to eight weeks.

Open cholecystectomy This procedure is major surgery. The surgeon makes an incision 5 to 8 inches long through the abdominal muscles to expose the LIVER and the gallbladder beneath it. The operation takes about two hours. Most people then stay five to seven days in the hospital. Many people can return to light activity in about four weeks. Full recovery after open cholecystectomy takes about 12 weeks.

Risks and Complications

The primary risks of either operation are bleeding, anesthesia reaction, damage to the bile ducts and other adjacent organs and structures, and postop-

erative infection. The surgeon often administers preoperative and postoperative doses of ANTIBIOTIC MEDICATIONS as a prophylactic measure for infection. Factors that can complicate or slow recovery include DIABETES, OBESITY, and bleeding or clotting disorders. For reasons doctors do not fully understand, 15 to 20 percent of people who undergo cholecystectomy (either laparoscopic or open) continue to experience symptoms similar to those of gallbladder disease even after surgery, called postcholecystectomy syndrome. Occasionally gallstones can escape from the gallbladder during surgery and become trapped in the common bile duct or cystic bile duct, requiring a follow-up procedure, typically ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY (ERCP), to remove them. Rarely, gallstones can form in the bile ducts months to years after cholecystectomy.

Postoperative infection is a significant risk with open cholecystectomy and in people who have diabetes or obesity, as these conditions can impair HEALING. Warning signs of infection include

- increased PAIN at the incision site
- pain elsewhere in the abdomen
- drainage from the incision site
- FEVER (temperature above 101°F)
- NAUSEA and VOMITING

Prompt antibiotic therapy successfully treats most postoperative infections. Persistent infection or delayed treatment may result in an ABSCESS that requires additional surgery to open and drain the infection.

BENEFITS AND RISKS OF CHOLECYSTECTOMY

Benefits	Risks
ends symptoms	intraoperative or postoperative bleeding
restores normal digestion	ANESTHESIA reaction
averts symptom-related complications	postoperative PAIN
	postoperative INFECTION
	inadvertent damage to LIVER and other structures
	scarring and adhesions
	postcholecystectomy syndrome

Outlook and Lifestyle Modifications

Cholecystectomy eliminates symptoms in about 80 percent of people who have gallbladder disease. Most people return to the same lifestyle habits as before surgery, including eating. The liver continues to manufacture bile, which flows directly into the small intestine. The body adapts to the weaker concentration of this bile within a few weeks of the cholecystectomy, and digestion returns to normal. Some people find that high-fat meals generate mild to moderate gastrointestinal distress or mimic gallbladder disease symptoms for several months after surgery. People who undergo open cholecystectomy may be unable to participate in strenuous physical activities for up to six months while the abdominal muscles regain STRENGTH.

See also HEPATIC ABSCESS; JAUNDICE; SURGERY BENEFIT AND RISK ASSESSMENT.

cholecystitis See GALLBLADDER DISEASE.

cholelithiasis See GALLBLADDER DISEASE.

cholestasis Inadequate or lack of BILE flow resulting from either obstruction of the BILE DUCTS or dysfunctions of the LIVER. Common symptoms of cholestasis include

- JAUNDICE (yellow discoloration of the SKIN)
- PRURITUS (generalized itching)
- easy bruising
- pale stools and dark URINE
- xanthomas (fatty deposits in the dermis layer of the skin)

CONDITIONS THAT CAN CAUSE CHOLESTASIS

BILIARY ATRESIA	gallstones
HEPATITIS	HEPATOXINS
LIVER DISEASE OF ALCOHOLISM	medication SIDE EFFECTS
obstructed BILE DUCTS	PANCREATIC CANCER
PANCREATITIS	PRIMARY BILIARY CIRRHOSIS

The diagnostic path includes blood tests to confirm the cholestasis, typically the levels of BILIRUBIN and the enzyme alkaline phosphatase, both of which become elevated with cholestasis. Other diagnostic procedures may include ULTRASOUND,

COMPUTED TOMOGRAPHY (CT) SCAN, and PERCUTANEOUS LIVER BIOPSY. Treatment targets the underlying cause or condition.

Longstanding cholestasis can result in deficiencies of fat-soluble vitamins, notably vitamin D and VITAMIN K, as the SMALL INTESTINE needs bile to digest fats.

See also ALCOHOLISM; LIVER FAILURE; XANTHOMA.

cholesterol, endogenous A sterol ALCOHOL molecule essential for many functions of cellular METABOLISM and the synthesis (production) of numerous hormones. The LIVER synthesizes the cholesterol that circulates within the body (endogenous) from dietary fats, particularly saturated fats, and the components of dietary cholesterol that enter the bloodstream from the gastrointestinal tract. The liver can continue to synthesize cholesterol as long as it receives the ingredients to do so, under genetically mediated regulation.

Because cholesterol is fat soluble it does not dissolve in the blood, so lipoproteins bind with cholesterol to transport it through the bloodstream. Excessive amounts of cholesterol in the bloodstream contribute to cardiovascular conditions such as ATHEROSCLEROSIS and CORONARY ARTERY DISEASE (CAD). Inadequate amounts of cholesterol in the body are uncommon though occur with conditions such as myelogenous LEUKEMIA and AIDS. Low cholesterol prevents cells from repairing themselves and also the body unable to produce "stress" hormones, such as CORTISOL that are essential for IMMUNE RESPONSE. The liver also uses cholesterol to synthesize BILE, which carries cholesterol into the gastrointestinal tract for reabsorption and recycling or elimination. Various endocrine glands use cholesterol to synthesize STEROID hormones, such as the ADRENAL GLANDS, which produce cortisol, and the gonads (sex glands), which produce TESTOSTERONE and ESTROGENS. Cells throughout the body use cholesterol for cell membrane repair.

See also CHOLESTEROL BLOOD LEVELS; CHOLESTEROL, DIETARY; HIV/AIDS; HYPERLIPIDEMIA; LIFESTYLE AND HEALTH; STRESS RESPONSE HORMONAL CASCADE.

cirrhosis A progressive condition in which fibrous tissue replaces damaged LIVER tissue, usually over an extended time and as a result of continued injury to the liver. The scarring is permanent and interferes with the liver's ability to function, eventually resulting in LIVER FAILURE. Numerous circumstances and health conditions can result in cirrhosis. The most common causes of cirrhosis are HEPATITIS, LIVER DISEASE OF ALCOHOLISM, chronic dysfunction of the BILE system, STEATOHEPATITIS, and HEPATOTOXINS. Cirrhosis is the leading reason for LIVER TRANSPLANTATION, the only treatment for end-stage cirrhosis and resulting liver failure.

Symptoms and Diagnostic Path

In its mild to moderate stages, cirrhosis often does not show symptoms or generates vague symptoms that suggest a variety of causes. Until cirrhosis becomes fairly advanced, even BLOOD tests that measure liver enzymes (a hallmark of liver function) and diagnostic imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN often show normal findings. When symptoms become apparent, the cirrhosis has significantly compromised liver function, and numerous changes occur throughout the body. Indications of these changes often include

- edema (swelling of the limbs) and ASCITES (fluid accumulation in the abdominal cavity) resulting from PORTAL HYPERTENSION (increased resistance to blood flow through the liver) and RENAL FAILURE (kidney dysfunction)
- JAUNDICE (yellow discoloration of the SKIN) and PRURITIS (extreme itching of the skin) resulting from the liver's inability to metabolize HEMOGLOBIN and synthesize bile, which allows BILIRUBIN concentrations in the blood to rise
- easy bruising and prolonged bleeding due to the liver's inability to synthesize CLOTTING FACTORS and produce enough bile to metabolize the dietary fats necessary for absorbing VITAMIN K
- lack of APPETITE, resulting from diminished bile production, and corresponding unintended weight loss
- INSULIN RESISTANCE or type 2 DIABETES resulting from the liver's inability to properly metabolize cholesterol and manage GLUCOSE (sugar) storage and retrieval

- GYNECOMASTIA (enlarged breasts) in men and AMENORRHEA (absence of menstrual periods) in women due to the diminished ability of the liver to metabolize ESTROGENS

The liver may feel enlarged or irregular when the gastroenterologist palpates the abdomen. By this stage, numerous blood chemistry tests show abnormal results. PERCUTANEOUS LIVER BIOPSY confirms the presence of fibrous tissue and the diagnosis of cirrhosis.

Treatment Options and Outlook

Treatment attempts to manage symptoms, address consequential health problems, and slow the progression of any underlying health conditions. Eliminating ALCOHOL consumption, medications, and environmental exposures that damage liver cells are among the measures essential to preserve remaining liver function. Numerous clinical studies show the ability of the herbal product MILK THISTLE or silymarin, its active ingredient, to help protect the liver from further damage. When cirrhosis progresses despite these interventions, liver transplantation becomes the treatment of final resort. Without liver transplantation, progressive cirrhosis is fatal. Liver transplantation permanently resolves cirrhosis, though at present there are far fewer donor livers available than people who need them. Live donor liver segment donation, in which a living person donates a portion of his or her healthy liver, is an option to full liver transplantation when a donor is available.

Risk Factors and Preventive Measures

Cirrhosis results from chronic, long-term damage to the liver. People who are at risk for developing cirrhosis have longstanding liver disease, such as chronic hepatitis, hepatitis of ALCOHOLISM, HEMOCHROMATOSIS, PRIMARY BILIARY CIRRHOSIS, PRIMARY SCLEROSING CHOLANGITIS, and WILSON'S DISEASE. Preventive measures include vaccination against hepatitis INFECTION (hepatitis A and hepatitis B) and minimizing behaviors that allow exposure to hepatitis. Consistent PERSONAL HYGIENE practices, such as HAND WASHING before handling food and after going to the bathroom, help control the spread of the hepatitis VIRUS.

See also HEPATITIS PREVENTION; LIFESTYLE AND HEALTH; ORGAN TRANSPLANTATION.

colitis INFLAMMATION of the COLON. Colitis can be acute (sudden) or chronic (long-term). Various circumstances can cause acute colitis. Among them are INFECTION, radiation, and ischemia. Chronic colitis is usually a form of INFLAMMATORY BOWEL DISEASE (IBD), an autoimmune disorder. The symptoms of colitis are abdominal discomfort, cramping, and DIARRHEA. The doctor makes the diagnosis primarily on the basis of symptoms; BLOOD tests often can confirm the presence of pathogens. Treatment may include medications that target the underlying cause of the inflammation or infection as well as antidiarrheal medications.

Infectious Colitis

Bacterial and protozoan infections of the colon are common. People who are already debilitated—such as the very old, the very young, and those with compromised immune function—face increased risk for complications, such as DEHYDRATION, that can be fatal. Fecal cultures can identify the causative agent, which then determines the appropriate treatment.

Bacterial colitis Numerous BACTERIA cause bacterial infections of the colon, which often are FOODBORNE ILLNESSES. Those most frequently detected include *Salmonella, Shigella, Campylobacter jejuni,* and *Listeria monocytogenes*. Treatment for bacterial colitis is the appropriate antibiotic medication, which helps contain symptoms within 48 to 72 hours and eliminate the infection in about 10 to 14 days. Bacterial infections, notably LISTERIOSIS, can be especially dangerous for pregnant women.

Parasites Parasitic infections can occur from drinking contaminated water, eating contaminated foods, and through contact with someone who has such an infection. It is possible to have a protozoan or parasitic infection and show no symptoms. The most common infective protozoan is *Entamoeba histolytica*, which causes AMEBIASIS (also called amoebic dysentery). Treatment is a course of antiparasitic medication such as metronidazole. Recovery is usually complete with appropriate treatment. Other protozoan infections include GIARDIASIS, CYCLOSPORIASIS, and CRYPTOSPORIDIASIS.

Radiation Colitis

RADIATION THERAPY to treat cancers, such as PROSTATE CANCER, in the lower abdominal region

(pelvic area) can damage the colon, causing symptoms such as diarrhea and cramping. Symptoms typically resolve as the damaged tissue regenerates. Treatment targets symptom relief. Radiation colitis typically resolves when radiation therapy ends.

Ischemic Colitis

Impaired blood flow to the intestinal tract, such as might occur with serious ATHEROSCLEROSIS, can impede intestinal function. Ischemic colitis is most common in people age 70 and older. Treatment focuses on restoring adequate circulation and minimizing symptoms, such as diarrhea, that can result in nutritional deficits and dehydration.

Inflammatory Bowel Disease (IBD)

Chronic inflammation of the colon takes the form of ulcerative colitis or Crohn's disease, collectively called IBD. Crohn's disease can affect the entire gastrointestinal tract but most commonly involves the terminal ileum and the ascending colon. Ulcerative colitis can affect the whole colon but usually starts in the rectum and left colon. IBD is an autoimmune disorder in which the IMMUNE SYSTEM attacks sections of the intestinal tract and destroys the mucus lining. This creates ulcerations that cause PAIN, diarrhea, and MALABSORPTION. Treatment for inflammatory colitis typically includes CORTICOSTEROID MEDICATIONS and sometimes immunosuppressive agents such as methotrexate or cyclosporine to suppress the IMMUNE RESPONSE. IBD is a serious and lifelong disorder that requires continuous management through medications and diet.

colon The large intestine, which extracts water from and consolidates the waste byproducts of digestion. The colon extends from the ILEUM, the final segment of the SMALL INTESTINE, to the ANUS, the exit from the body for solid digestive waste (feces or stool). The colon goes up the left side of the abdomen (the ascending colon), across the abdomen at the lower ribs (the transverse colon), and down the right side of the abdomen to about the level of the hip JOINT (the descending colon). The final segments of the colon are the sigmoid colon and the RECTUM. The colon is about five feet long in the average adult.

COMMON CONDITIONS AFFECTING THE COLON

COLITIS	COLORECTAL CANCER
CONSTIPATION	Crohn's disease
DIARRHEA	DIVERTICULAR DISEASE
FECAL IMPACTION	FECAL INCONTINENCE
HIRSCHSPRUNG'S DISEASE	ILEUS
INFLAMMATORY BOWEL DISEASE (IBD)	INTESTINAL POLYP
IRRITABLE BOWEL SYDROME (IBS)	PROCTITIS
RECTAL FISTULA	RECTAL PROLAPSE
TOXIC MEGACOLON	ulcerative colitis

For further discussion of the colon within the context of gastrointestinal structure and function, please see the overview section "The Gastrointestinal System."

See also ANAL ATRESIA; ANAL FISSURE; BORBORYGMUS; BOWEL ATRESIA; BOWEL SOUNDS; COLONOSCOPY; STOMACH.

colonoscopy An examination of the COLON (also called bowel or large intestine) to detect and remove INTESTINAL POLYPS, fleshy growths that may become cancerous, and to biopsy or remove small adenocarcinomas (cancerous polyps). Conventional colonoscopy is an endoscopic procedure in which the gastroenterologist inserts a flexible, lighted tube (endoscope or colonoscope) through the ANUS and into the large intestine.

Reasons for Doing This Test

Colonoscopy is a diagnostic procedure to detect intestinal polyps, COLORECTAL CANCER, and other conditions affecting the colon. Cancer experts believe screening colonoscopy, performed at age 50 (or earlier, when there is family history of colorectal cancer) and every 5 to 10 years thereafter, can prevent 80 to 90 percent of colorectal cancers.

Preparation, Procedure, and Recovery

The gastroenterologist performs conventional colonoscopy in an ENDOSCOPY center or hospital unit, with intravenous general sedation to mini-

mize discomfort and anxiety. The procedure takes 30 to 45 minutes, with another one to two hours to recover from the sedation.

Preparation Most people find the preparation for colonoscopy, which consists of cleansing the gastrointestinal tract, the most unpleasant aspect of the procedure. The preparation for virtual colonoscopy requires the same bowel-cleansing procedure as does conventional colonoscopy. Completing the preparation for colonoscopy is essential for optimal results, however. It typically includes

- no aspirin or aspirin products (to reduce the risk for bleeding) and no iron supplements or products (iron darkens tissue) for five days before the colonoscopy
- no nuts, seeds, grapes, peas, beans, or tomatoes for three days before the colonoscopy (particles from these foods lodge in the folds of the intestinal mucosa)
- no NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) for five to seven days before the colonoscopy (to reduce the risk for bleeding)
- only clear liquids for 24 hours before the colonoscopy
- at midday the day before the colonoscopy, the bowel-cleansing process begins with the drinking of a laxative solution consumed at the rate of eight ounces every 10 minutes for a total consumption of one gallon of the solution

The laxative prep results in bowel movements that start about an hour after beginning to drink the solution and continue for about eight hours. Drinking the solution often causes NAUSEA. Keeping the solution as cold as possible (even surrounding it with ice in the refrigerator) and chewing gum or sucking on hard candy between glasses can help. It is necessary to drink the entire gallon of the solution to completely clear the gastrointestinal tract. Fecal remnants in the colon can obscure the wall of the bowel, limiting the ability of the gastroenterologist to visualize the entire colon. Most gastroenterologists will not proceed with the colonoscopy if the preparation is incomplete.

Procedure The person lies on his or her left side on a narrow bed, with the knees flexed. After initiating intravenous sedation, the gastroenterologist gently inserts the lubricated colonoscope into the anus. A small pump injects air ahead of the scope, opening the colon so the gastroenterologist can advance it into the colon. The examination of the colon takes about 20 minutes, longer when there are polyps for the gastroenterologist to remove or biopsy. Some people feel pressure with the injection of air or when the scope rounds the corners of the colon. However, most people feel little discomfort and cannot recall the procedure when it is over.

Recovery Following conventional colonoscopy, the person rests in a recovery area until the sedative wears off, usually within an hour or two, and then may go home. Doctors recommend resting quietly for the remainder of the day, which is what most people feel like doing. There is usually no discomfort after the procedure, aside from an accumulation of intestinal gas until regular eating returns the gastrointestinal tract to normal function. The gastroenterologist receives the pathologist's analysis of any tissues removed within about a week. Following virtual colonoscopy, the person may go home immediately after the procedure.

Risks and Complications

Complications related to conventional colonoscopy are very rare but may include perforated bowel (which requires emergency surgery to repair), INFECTION, and bleeding from removed or biopsied polyps.

Virtual Colonoscopy

Virtual colonoscopy, a procedure that allows noninvasive visualization of the gastrointestinal tract, became available in the late 1990s. Virtual colonoscopy, correctly called computed tomography colonography or CT colonography, uses COMPUTED TOMOGRAPHY (CT) SCAN to examine the colon with nearly the same accuracy as conventional colonoscopy but without the need for sedation or to enter the body.

The significant drawback to CT colonography is that it allows only viewing of the colon, not biopsy or polypectomy. The gastroenterologist must still use conventional colonoscopy to remove detected intestinal polyps or to biopsy suspicious growths. The preparation for virtual colonoscopy

requires the same bowel cleansing procedure as does conventional colonoscopy.

Virtual colonoscopy does not require sedation. For the procedure, the radiologist inserts a small tube into the rectum for the injection of air to open the colon for improved visualization, which may cause discomfort that feels like intestinal gas. Over a period of 10 to 20 minutes the CT scanner takes sequential X-rays while the person lies on his or her back and then STOMACH. A computer compiles the X-rays to create three-dimensional images of the colon.

See also BARIUM ENEMA; CANCER PREVENTION; INTESTINAL POLYP.

colorectal cancer Malignant growths in the COLON, most commonly in the sigmoid colon and the RECTUM. Colorectal cancer is the second-leading cause of death due to CANCER in the United States. However, colorectal cancer is also one of the most preventable and, with early detection, among the most treatable kinds of cancer. More than 95 percent of primary colorectal cancer is ADENOCARCINOMA, a form of cancer in which abnormal but otherwise benign growths (adenomas) become cancerous. Intestinal polyps are adenomas that develop in the colon, growing from the mucous membrane that lines the colon. Intestinal polyps become more common with increasing age, and by age 50, about half of American adults are likely to have them.

TYPES OF POLYPS

There are two common types of colon polyps: adenomas, which are neoplastic (abnormal growths that have no useful function within the body) and have malignant potential, and hyperplastic, which are not neoplastic and have no malignant potential.

A polyp takes 5 to 10 years to grow from microscopic to detectable, and up to several decades to become cancerous, if that is its course. People who have no exceptional risk factors for colorectal cancer typically have a window of 5 to 10 years during which the polyp's cell structure is transitional. Doctors consider such a polyp precancerous. Though only a small percentage of intestinal polyps will become cancerous, there is no way to distinguish those that will from those that will remain benign. As a precaution doctors recommend removing all intestinal polyps, which eliminates any concerns about their potential malignancy.

Symptoms and Diagnostic Path

Early colorectal cancer has few, if any, symptoms, further emphasizing the importance of regular screening. When present, symptoms often indicate a cancer that is moderately to significantly advanced and include

- a change in bowel habits or the nature of bowel movements
- unexplained NAUSEA, VOMITING, DIARRHEA, or CONSTIPATION
- rectal bleeding (may be patches of dark discoloration or bright bleeding)
- sensations of abdominal fullness or bloating
- tiredness and fatigue
- unintended weight loss
- ABDOMINAL DISTENTION and pain

The most effective way to detect and diagnose colorectal cancer is through regular screening procedures, which may include

- DIGITAL RECTAL EXAMINATION (DRE), in which the doctor inserts a gloved, lubricated finger into the rectum via the ANUS to feel for abnormalities
- FECAL OCCULT BLOOD TEST (FOBT), in which a laboratory tests a stool sample for microscopic blood (home-testing kits are also available)
- double-contrast BARIUM ENEMA, in which the radiologist instills barium into the lower colon via an ENEMA, then takes X-rays as the barium fills the rectum and sigmoid colon
- sigmoidoscopy, in which the doctor inserts a lighted viewing tube (rigid or flexible) through the anus into the rectum and sigmoid colon, the two segments of the colon nearest the end of the intestinal tract and the sites where more than half of colorectal cancers originate
- COLONOSCOPY, in which the doctor inserts a lighted, flexible viewing tube through the anus and into the entire colon (done under sedation)
- virtual colonoscopy (CT colonography)

Sigmoidoscopy (for the lower colon) and colonoscopy (for the full length of the colon) allow the gastroenterologist to detect and remove intestinal polyps and to biopsy suspicious growths. The gastroenterologist may use colonoscopy to explore suspicious findings from other screening procedures. Further diagnostic procedures may include transrectal or abdominal ULTRASOUND, COMPUTED TOMOGRAPHY (CT) SCAN, and MAGNETIC RESONANCE IMAGING (MRI).

Pathology examination of the suspect tissue confirms the diagnosis and establishes the extent of the cancer, a clinical classification process called STAGING OF CANCER. Staging identifies how far the cancer has spread, determines treatment recommendations and protocols, and establishes expectations about how the cancer will respond to treatment (prognosis). The higher the stage number, the more advanced the cancer.

Treatment Options and Outlook

Surgery is the first course of treatment for nearly all colorectal cancers. In cancers detected early, surgery often cures the cancer. Depending on the location and extent of the cancer, the surgeon can usually remove the cancerous tissue (called a bowel resection) and reconnect the healthy ends of the colon so the colon continues to function normally. Sometimes the colon needs first to heal from the resection, in which case the surgeon performs a temporary COLOSTOMY that allows the colon to pass fecal matter through an opening created in the abdomen. When the colon heals, the surgeon reconnects the ends and closes the colostomy. Extensive cancer may make necessary a permanent colostomy.

The oncologist may recommend RADIATION THERAPY to shrink large tumors before surgery or to kill any cancerous cells remaining after surgery, primarily for cancer located in the rectum. CHEMOTHERAPY kills cancer cells that may have spread beyond the local tumor, and is the follow-up treatment of choice for cancers that involve LYMPH NODES. Often the oncologist will recommend a combination of therapies. Oncologists also typically offer people who have stage 2 through stage 4 colorectal cancer the opportunity to participate in clinical research studies of new treatments. It is important to fully understand the benefits and risks of the investigational treatment.

BASIC STAGING OF COLORECTAL CANCER

Stage	Meaning	Treatment Protocol
stage 0	cancer is in its earliest stages, completely confined to the polyp; also called CARCINOMA in situ or intramucosal carcinoma	surgery to remove the cancerous polyp (polypectomy), typically via COLONOSCOPY
stage 1	cancer involves but remains confined to the inner layers of the intestinal mucosa	surgery to remove the tumor and the involved segment of colon (local excision)
stage 2	cancer extends beyond the wall of the COLON but not into the LYMPH NODES	surgery to remove the tumor and involved segment of colon; occasionally RADIATION THERAPY or CHEMOTHERAPY
stage 3	cancer extends beyond the wall of the colon and into nearby lymph nodes	surgery to remove the tumor, the involved segment of colon, the surrounding tissue into which the cancer has spread, and the involved lymph nodes; radiation therapy or chemotherapy
stage 4	cancer has spread to other organs	surgery to remove tumors and involved tissues when possible; radiation therapy and/or chemotherapy
recurrent	a return of the cancer to the colon	surgery to remove the tumor and involved segment of colon; radiation therapy and/or chemotherapy

Treatments for cancer offer varying benefits and risks. Cancer experts often recommend obtaining a second opinion evaluation from another physician specialist before making treatment decisions. Treatment is highly successful for colorectal cancers detected before they spread beyond the wall of the bowel. Stage 0 colorectal cancer is nearly always curable, and more than 90 percent of people diagnosed with stage 1 colorectal cancer are cancer-free five years after treatment. The course of advanced and recurrent colorectal cancer is more challenging, and often results in moderate to significant lifestyle changes. Recovery from extensive surgery may take several months, and radiation therapy and chemotherapy typically cause numerous and varied side effects that often limit participation in regular activities. Though the outlook for colorectal cancer continues to improve with early detection and new treatment technologies, it remains a serious health condition that requires appropriate and

COLORECTAL CANCER SCREENING PROCEDURES

Procedure	Frequency	Benefits	Drawbacks or Risks
DIGITAL RECTAL EXAMINATION (DRE)	annually after age 45	can detect growths and abnormalities in the RECTUM	does not detect very small growths or growths beyond the rectum further procedures required to investigate positive results
FECAL OCCULT BLOOD TEST (FOBT)	annually after age 50	detects microscopic blood in the stool, often while the growth causing the bleeding is still very small; sample collected at home; home-testing kits available	the growth is large enough to cause bleeding by the time of detection compliance is low further procedures required to investigate positive results
sigmoidoscopy	every 5 years for those with average risk; every 3 years for those with increased risk	provides direct examination of the walls of the rectum and sigmoid COLON; doctor can remove or biopsy detected polyps or tumors	does not visualize full length of the colon unpleasant preparation some discomfort during the procedure minimal risk of INFECTION, bleeding, or perforation further procedures required to investigate positive results
double-contrast BARIUM ENEMA	every 10 years for those with average risk; every 5 years for those with increased risk	provides clear representation of the full colon	does not detect very small polyps or tumors less effective in detecting polyps or tumors in the rectum than in the colon unpleasant preparation some discomfort during the procedure further procedures required to investigate positive results
COLONOSCOPY	every 10 years for those with average risk; every 5 years for those with increased risk	allows direct examination of the full colon; doctor can remove or biopsy detected polyps or tumors	unpleasant preparation some discomfort during the procedure requires general sedation minimal risk of infection, bleeding, or perforation

diligent attention. Cancer SUPPORT GROUPS provide excellent opportunities to share experiences and feelings in a protected setting.

Risk Factors and Preventive Measures

The most significant risk factor for colorectal cancer, as for many kinds of cancer, is age. Doctors diagnose more than 90 percent of colorectal cancer in people who are age 50 and older. Health and medical factors that present increased risk include

- of early-onset (before age 50) colorectal cancer among first-degree family members, notably parents and siblings
- previous diagnosis of colorectal cancer
- previous diagnosis of BREAST CANCER, endometrial (uterine) cancer, or OVARIAN CANCER in women
- mutations of the adenomatous polyposis coli (APC) gene, which causes FAMILIAL ADENOMATOUS POLYPOSIS (FAP), or of the gene that causes HEREDITARY NONPOLYPOSIS COLORECTAL CANCER (HNPCC); both mutations are rare, together accounting for less than 3 percent of colorectal cancers
- INFLAMMATORY BOWEL DISEASE (IBD), which may feature Crohn's disease, ulcerative COLITIS, or both
- OBESITY, notably ABDOMINAL ADIPOSITY (excess body fat carried around the belly)

Lifestyle factors that appear to increase the risk for colorectal cancer include a diet high in saturated fats (animal-based fats) and low in fruits and vegetables, lack of daily physical exercise, and smoking.

Regular screening is the most effective preventive measure for colorectal cancer. Cancer experts recommend colonoscopy as the first line of screening for colorectal cancer in most people starting at age 50, though earlier in people with family members who have had colorectal cancer at an earlier age, every 10 years for people with average risk and every 5 years for people with additional risk factors. Research suggests such screening could eliminate 80 to 90 percent of colorectal cancer.

Though conclusive evidence of dietary correlations to risk for intestinal polyps and colorectal cancer remains elusive, cancer experts encourage a diet high in natural fiber (especially fresh fruits and vegetables) and low in saturated fat. Other lifestyle recommendations include daily physical exercise, SMOKING CESSATION, and weight management.

colostomy A surgically created opening (stoma) through the abdominal wall through which the COLON passes fecal matter, typically accompanying surgery to remove a diseased segment of the colon. Though there are numerous medical reasons for colostomy, among the most common are COLORECTAL CANCER, traumatic injury, and severe INFLAMMATORY BOWEL DISEASE (IBD). A colostomy may be temporary when a period of nonactivity will help the colon recover from INFECTION or inflammatory damage or during the stages of reconstructive surgery. A colostomy is likely to be permanent when the surgeon must remove large segments of bowel.

The OPERATION is a major surgery done under general anesthetic. Typically the person enters the hospital the night before the scheduled OPERATION to complete the preparations for surgery, which usually include LAXATIVES and enemas to thoroughly cleanse the colon. The length of the operation depends on the extent of the procedures. The surgeon attempts to locate the colostomy in the lower abdomen when possible, though may place a temporary colostomy in the upper abdomen to rest the lower segments of the colon. Most people remain in the hospital for five to seven days, during which time an ostomy-care specialist provides education and instruction about colostomy care. HEALING after surgery takes about six to eight weeks. Diligent WOUND CARE during this period is essential to reduce the risk for infection and irritation and to help the stoma heal properly.

A small plastic bag, sealed against the SKIN with adhesive around the opening (stoma), collects fecal matter that exits the colon through the

colostomy. It is important to empty or change the colostomy bag frequently and regularly and to cleanse the skin around the stoma with each changing to minimize irritation from the adhesive and from fecal matter. Frequent bag changes also reduce odor, as do deodorizing tablets that go into the ostomy bag. Over time, most people find that certain foods (such as meats and many processed foods) are more likely than others to cause odor or irritation and can avoid eating them to further reduce odor.

Concerns about how having a colostomy will change appearance and daily living activities are natural and common. A colostomy significantly alters the body's structure and excretory function, which many people find challenging. An ostomy-care specialist can provide information and suggestions to smooth the adjustment. Most people find they are able to return to their regular activities when the stoma fully heals. The colostomy should not interfere with clothing, exercise, lifting and carrying, and most other daily activities.

The effect of colostomy on SEXUALITY is a major concern for most people. A risk of surgery on the colon is damage to the nerves that supply the perineal area, which can result in altered sensations in men and women and ERECTILE DYSFUNCTION in men. Some people feel self-conscious or embarrassed about having a colostomy. However, many people who have colostomies can return to regular sexual activity as soon as they feel the desire to do so. A special cap can cover the stoma during sex. Having SEXUAL INTERCOURSE or ORGASM does not cause any harm to the colostomy or adversely affect the underlying condition in most circumstances. It is important for partners to discuss their concerns and feelings openly and honestly so they can maintain intimacy within their relationships.

See also ILEOANAL RESERVOIR; ILEOSTOMY.

constipation Difficult or delayed bowel movements. Constipation may occur as a delay in the frequency of bowel movements, an attempt to pass stools that are hard and compact, or a combination. Constipation tends to be chronic (long-term), though can occur as acute (sudden) episodes. Abdominal cramping and bloating may accompany constipation.

Any rectal bleeding that accompanies constipation or bowel movements requires medical evaluation.

Though constipation can signal serious health conditions such as intestinal obstruction or HYPOTHYROIDISM, most often constipation relates to lifestyle factors such as diet, physical exercise, and HYDRATION (fluid intake). Numerous medications, notably ANTIHISTAMINE MEDICATIONS, narcotic ANALGESIC MEDICATIONS (pain relievers) and ANTIDEPRESSANT MEDICATIONS, can cause constipation. Constipation becomes more common with increasing age, partly due to lifestyle factors and partly due to age-related changes in intestinal motility.

Stools become hardened when the COLON extracts too much water from the fecal matter that passes through it. This can occur because the body needs more fluid (inadequate fluid intake) or because the fecal matter spends too much time in the colon (a consequence of inactivity or decreased intestinal motility). Hardened stools are difficult to pass and may cause irritation and even ABRASIONS to the anal canal and ANUS. Straining with the effort of a difficult BOWEL MOVEMENT aggravates common conditions such as HEMORRHOIDS and can have cardiovascular consequences such as ARRHYTHMIA (irregular heartbeat). Long-term use of LAXATIVES causes the colon to become reliant on them to stimulate bowel movements; overuse of laxatives is a frequent cause of chronic constipation.

For occasional constipation, many doctors recommend home treatment for two to three weeks, consisting of:

- increased water consumption
- increased fiber in the diet (eating more vegetables, fruits, whole grains, and whole grain products)
- 45 minutes to an hour of daily physical exercise such as walking, which encourages PERISTALSIS (the rhythmic, wavelike contractions of the intestinal wall) and improves BLOOD flow
- no laxatives
- sitz baths and hemorrhoidal preparations to soothe irritated hemorrhoids

These measures facilitate a return to gastrointestinal regularity for most people. Constipation that extends beyond two or three weeks, occurs with rectal bleeding, or causes ABDOMINAL PAIN or ABDOMINAL DISTENTION requires prompt medical evaluation.

Crohn's disease See INFLAMMATORY BOWEL DISEASE (IBD).

cyclic vomiting syndrome Episodes of uncontrolled VOMITING and NAUSEA, sometimes called abdominal migraine, that occur in cycles of symptoms and relief. Each episode may last hours and often repeats over a period of time after which there is an extended period without symptoms. Many people experience prodrome, a short period of time during which they have nausea, ABDOMINAL PAIN, a sense of the impending episode, or other symptoms that consistently occur before an episode. During an active episode, the person has persistent nausea and repeated vomiting that can last for hours to days.

Researchers believe the physiologic mechanisms of cyclic vomiting syndrome are similar to those of migraine headaches. Episode triggers may include infections and other physiologic stress, emotional stress, and certain foods such as chocolate. There are no conclusive diagnostic markers or tests for cyclic vomiting syndrome, making diagnosis a challenge. Generally the gastroenterologist strives to rule out other conditions that could cause the symptoms, resulting in diagnosis by exclusion.

Treatment targets symptom relief to the extent possible, which for many people is minimal, and supportive measures such as drinking plenty of fluids to replace those lost through vomiting. Some people experience relief with medications intended to head off migraine HEADACHE. Though some people can avert active episodes with medications or by altering their activities during the prodrome stage, there are no certain methods for preventing episodes. There is no known cure for cyclic vomiting syndrome, though episodes often diminish with aging. Cyclic vomiting syndrome is more common in children than adults, and can manifest in children as young as two or three years old.

See also GASTROENTERITIS.

D

diarrhea Watery or frequent bowel movements. Diarrhea can have serious health consequences for the very young, the very old, and those who have debilitating illnesses. It is important to increase fluid consumption when diarrhea is present as DEHYDRATION can occur very quickly. Diarrhea in an infant under six months old requires immediate medical attention. For older children and adults, medical attention becomes necessary when diarrhea exists with:

- ABDOMINAL PAIN for longer than two hours
- FEVER above 101°F for longer than 24 hours
- profuse VOMITING
- reduced or lack of URINATION
- suspected ingestion of toxic or obstructive substance

Bloody diarrhea may signal a serious health condition and requires immediate medical evaluation.

Numerous causes exist for diarrhea. Foods containing table sugar (sucrose), sugars that occur in milk (lactose), fruits (fructose), and sweeteners in juices and soft drinks (sorbitol and mannitol) can cause or worsen diarrhea because they draw additional fluid into the large intestine. Viral, bacterial, and parasitic infections, often food-borne, are common causes of diarrhea. Diarrhea is also a common symptom with gastrointestinal disorders such as IRRITABLE BOWEL SYNDROME (IBS) and INFLAMMATORY BOWEL DISEASE (IBD). Extended periods (weeks to months) of loose or frequent bowel movements may suggest dysfunction of the SMALL INTESTINE or MALABSORPTION disorders. Frequent, small bowel movements that are a change from usual bowel patterns may indicate conditions of the large intestine such as intestinal polyps or COLORECTAL CANCER. Women may have mild diarrhea with their menstrual periods. Diarrhea may occur with changes in eating habits, such as when traveling.

COMMON CAUSES OF DIARRHEA

antibiotic therapy	CELIAC DISEASE
changes in EATING HABITS	COLORECTAL CANCER
DIVERTICULAR DISEASE	excessive ALCOHOL consumption
excessive CAFFEINE consumption	FOOD-BORNE ILLNESSES
foods and beverages	GALLBLADDER DISEASE
ILEUS	INFLAMMATORY BOWEL DISEASE (IBD)
ingested toxins	INTESTINAL POLYP
IRRITABLE BOWEL SYNDROME (IBS)	MALABSORPTION
medication SIDE EFFECTS	viral, bacterial, and parasitic INFECTION

Bland foods such as cooked rice, oatmeal, soda crackers, graham crackers, and bananas can help calm the gastrointestinal tract and restore normal bowel function. Doctors often recommend an oral rehydration solution (ORS) such as Pedialyte or Rehydralyte when diarrhea persists beyond a few days in children, and for adults who show indications of dehydration or have extensive diarrhea. Doctors may recommend ANTIDIARRHEAL MEDICATIONS such as loperamide (Imodium) that slow PERISTALSIS (intestinal movement) to help control symptoms. Most diarrhea, though disruptive, represents minor and temporary gastrointestinal disturbance that fully resolves within one to three weeks.

See also COLITIS; GASTROENTERITIS; FOOD SAFETY.

digestive enzymes Specialized protein structures that help break down (hydrolyze) foods in the

MOUTH, STOMACH, and SMALL INTESTINE to assist in absorbing NUTRIENTS from foods. Gastrointestinal structures produce dozens of digestive enzymes, which they secrete in various digestive juices. Amylase in saliva, for example, breaks down carbohydrates into their sugar components. Gastric juices combine acid and protease (pepsin) to further hydrolyze foods. Numerous enzymes in the small intestine—such as lactase, cellulase, lipase, maltase—facilitate the chemical changes necessary to convert food particles to nutrient molecules the intestinal mucosa can absorb and transport into the bloodstream. Shortages of enzymes may occur, naturally or due to health conditions, that result in gastrointestinal disorders. A shortage of lactase, for example, causes LACTOSE INTOLERANCE.

See also CARBOHYDRATE INTOLERANCE; DIGESTIVE HORMONES; NUTRITIONAL SUPPLEMENTS.

digestive hormones Chemical messengers that stimulate or inhibit gastrointestinal functions. Organs and structures of the gastrointestinal system synthesize and release digestive hormones in response to chemical and physiologic changes that take place with the ingestion of food and its passage through the gastrointestinal tract. The major digestive hormones are

- gastrin, which stimulates the STOMACH to release gastric juices and begin contracting
- cholecystokinin (CCK), which stimulates the GALLBLADDER to release BILE, the PANCREAS to release digestive juices, and the stomach to slow the release of chyme (the slushy mix of food and digestive secretions) into the DUODENUM (first segment of the SMALL INTESTINE)
- secretin, which accelerates bile release from the gallbladder, stimulates the pancreas to release bicarbonates to neutralize stomach acid, and slows the release of gastric juices as chyme advances from the stomach into the duodenum
- motilin, which stimulates PERISTALSIS (contractions of the gastrointestinal tract)
- gastric inhibitory polypeptide (GIP), which stimulates the pancreas to release INSULIN, slows (inhibits) the release of gastric juices, and slows stomach contractions
- enterogastrone, which stimulates the stomach to release chyme into the duodenum
- vasoactive intestinal peptide (VIP), which stops the production of gastric acid
- SOMATOSTATIN, which stops the release of insulin and further slows gastric motility (the stomach's contractions)

See also DIABETES; DIGESTIVE ENZYMES; HORMONE.

digital rectal examination (DRE) Direct palpation of the RECTUM in which the doctor inserts a gloved and lubricated finger into the rectum via the ANUS. DRE allows the doctor to feel for abnormal growths within the rectum and, in men, to palpate the PROSTATE GLAND for enlargement and possibly nodules that could suggest PROSTATE CANCER. The doctor can perform DRE as an office procedure; there is little discomfort. The person may lie on his or her side with knees drawn up. DRE may accompany a PELVIC EXAMINATION for a woman. DRE is also part of the examination to determine the cause of acute ABDOMINAL PAIN and other symptoms of health conditions affecting the lower gastrointestinal tract.

See also BENIGN PROSTATIC HYPERPLASIA (BPH); CANCER PREVENTION.

diverticular disease A chronic condition in which pockets of the gastrointestinal mucosa (inner lining of the intestines) bulge through weakened areas of the intestinal wall, forming HERNIA-like protrusions called diverticula. Diverticula may form anywhere along the gastrointestinal tract from the ESOPHAGUS to the RECTUM, though are most common in the sigmoid COLON. Most diverticular disease develops over decades and manifests symptoms after age 60. A congenital form of diverticular disease, Meckel's diverticulum, affects the SMALL INTESTINE, typically the ILEUM. Meckel's diverticulum is uncommon. Diverticulosis is the presence of multiple diverticula; diverticulitis occurs when diverticula become inflamed or infected. Doctors suspect diverticular disease results from changes in the gastrointestinal system that occur with aging. Though for some people the condition is debilitating, many people who have diverticular disease have few symp-

toms. Diverticular disease tends to have a more intense course in people who are under age 50 at the time of diagnosis.

Symptoms and Diagnostic Path

Diverticulosis often presents mild and vague symptoms such as intermittent lower abdominal discomfort or shows up incidentally on diagnostic testing for other reasons. Large or multiple diverticula may cause intestinal bleeding that may appear as darkened stools or obvious bleeding with bowel movements. Localized PAIN, especially REBOUND TENDERNESS, and FEVER suggest diverticulitis though also are symptoms of APPENDICITIS.

The diagnostic path may include DIGITAL RECTAL EXAMINATION (DRE), FECAL OCCULT BLOOD TEST (FOBT) to check for microscopic bleeding, abdominal X-ray, BARIUM ENEMA, and sigmoidoscopy or COLONOSCOPY. These procedures help distinguish between diverticulitis and appendicitis though sometimes the distinction is difficult. Diverticula often are apparent though barium enema and either sigmoidoscopy or colonoscopy provides definitive diagnosis. Occasionally the doctor may request COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) to obtain detailed information on the extent of the condition or to identify a surgical emergency such as ABSCESS or PERITONITIS.

SYMPTOMS OF DIVERTICULAR DISEASE

Diverticulosis	Diverticulitis
painless rectal bleeding	pronounced and localized ABDOMINAL PAIN
	ABDOMINAL DISTENTION or rigidity
	FEVER

Treatment Options and Outlook

Diverticulitis requires treatment with ANTIBIOTIC MEDICATIONS to eradicate the INFECTION and calm the INFLAMMATION. Oral antibiotics successfully treat many people; widespread or deep infection may require intravenous antibiotics or even surgical intervention to drain the infection and remove any portions of damaged bowel. Untreated diverticulitis can result in abscess or peritonitis, which are life-threatening complications. Other complications include intestinal obstructions and fistulas (areas where the bowel erodes and establishes an opening into another structure such as the BLADDER or the VAGINA. These complications require surgical repair; a complete intestinal obstruction is an emergency.

Diverticulosis with no symptoms does not require treatment. Because diverticulosis is so prevalent among people age 50 and older, many gastroenterologists consider it nonpathologic (not a threat to health). Dietary measures such as increased fiber consumption may be enough to relieve mild symptoms such as occasional abdominal discomfort. It is important to determine the source of any intestinal bleeding, and to undergo regular COLORECTAL CANCER screening such as FOBT, sigmoidoscopy, or COLONOSCOPY. The gastroenterologist should evaluate any changes in bowel habits, persistent abdominal distention, or other circumstances that could suggest a different diagnosis.

Risk Factors and Preventive Measures

The primary risk factor for diverticulosis appears to be aging. Doctors commonly detect diverticula that do not cause symptoms in people who have gastrointestinal imaging procedures done for other reasons. People who are aware they have diverticulosis should try to maintain eating habits that support good gastrointestinal health, making sure they consume enough dietary fiber and water.

duodenum The first segment of the SMALL INTESTINE, which receives partially digested and liquefied food (called chyme) from the STOMACH. The common BILE duct ends in the duodenum, channeling bile from the GALLBLADDER to the small intestine. Much of the activity of digestion takes place in the duodenum, where an abundance of DIGESTIVE ENZYMES combines with the bile to further break down food particles into their core nutrient molecules. Digestive content that leaves the duodenum for its journey through the remainder of the intestinal tract is almost watery because of the added digestive fluids. The remaining segments of the small intestine, the ILEUM and the JEJUNUM,

absorb the nutrient molecules that result from the duodenum's activity. The duodenum is the most common site of the ulcers that characterize PEPTIC ULCER DISEASE.

For further discussion of the duodenum and the small intestine within the context of gastrointestinal structure and function, please see the overview section "The Gastrointestinal System."

See also BILE DUCTS; LIVER; PANCREAS.

dyspepsia The clinical term for indigestion or heartburn. Most people experience dyspepsia as a burning PAIN in the upper abdomen. Some people also experience NAUSEA, VOMITING, and excessive belching. Certain foods or drinks, such as spicy foods or caffeinated beverages, often worsen the discomfort, as do medications such as aspirin and other NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) and numerous prescription medications. ANTACIDS sometimes bring temporary relief. PEPTIC ULCER DISEASE and GASTROESOPHAGEAL REFLUX DISORDER (GERD) are common causes of dyspepsia. Rarely, persistent dyspepsia indicates STOMACH CANCER.

The diagnostic path may include upper endoscopy, esophagogastroduodenoscopy (EGD) (examination of the ESOPHAGUS, STOMACH, and DUODENUM with a lighted, flexible tube), or BARIUM SWALLOW to rule out other causes of the symptoms. Treatment targets the underlying cause and usually includes a medication to suppress gastric acid production, such as H2 ANTAGONIST (BLOCKER) MEDICATIONS or PROTON PUMP INHIBITOR (PPI) MEDICATIONS. The doctor may also prescribe an ANTIBIOTIC MEDICATIONS to eradicate *HELICOBACTER PYLORI* BACTERIA, the typical cause of gastric and duodenal ulcers, when the underlying condition is peptic ulcer disease. Most dyspepsia dramatically improves within six to eight weeks of appropriate treatment.

See also ACHALASIA; BARRETT'S ESOPHAGUS; ENDOSCOPY; GALLBLADDER DISEASE; GASTRITIS.

E

endoscopic retrograde cholangiopancreatography (ERCP) An endoscopic procedure that allows diagnostic as well as therapeutic procedures involving the DUODENUM, pancreatic duct, and common BILE duct. After administering a sedative the gastroenterologist inserts the flexible, lighted endoscope through the MOUTH, passing it down the ESOPHAGUS and through the STOMACH to the duodenum. While advancing the endoscope the gastroenterologist examines these structures. Once the endoscope is in the duodenum, the gastroenterologist inserts a catheter through the ampulla of Vater and injects contrast into the common bile duct, pancreatic duct, and right and left intrahepatic ducts. X-rays taken after the injection of radiopaque dye into the ducts can show blockages and narrowing of the ducts. Through ERCP the gastroenterologist can take tissue samples for biopsy, remove small gallstones, and perform other treatments. ERCP takes about an hour, after which the person rests in a recovery area for another two to three hours until the sedative wears off. ERCP has few risks and can help a person avoid more invasive surgery.

See also BILE DUCTS; ENDOSCOPY; PANCREAS; PANCREATITIS; SURGERY BENEFIT AND RISK ASSESSMENT.

endoscopy The collective term for minimally invasive procedures that allow the doctor to view internal organs and structures using a lighted, flexible scope inserted through a natural body opening or through a small incision. Endoscopy can be diagnostic or therapeutic. Most endoscopic procedures require preparation before the procedure, sedation during the procedure, and supervised recovery after the procedure.

The primary risks of endoscopic procedures are minimal, consisting of primarily INFECTION or bleeding that results from unintended ABRASIONS to the tissues. A very rare but serious complication of endoscopic procedures of the bowel is perforation, in which the endoscope goes through the wall of

COMMON GASTROINTESTINAL ENDOSCOPY PROCEDURES

Procedure	Description and Purpose	Preparation
anoscopy	short, rigid scope for viewing the anal canal inserted through the ANUS diagnose HEMORRHOIDS, ANAL FISSURE, anal polyps, INFECTION	bowel evacuation (LAXATIVES or ENEMA before the procedure)
colonoscopy	flexible scope with a camera for viewing the full length of the COLON inserted through the anus detect and remove INTESTINAL POLYP diagnose inflammatory or infectious conditions evaluate bleeding or possible ILEUS (intestinal obstruction) biopsy suspicious growths or tumors	multiday bowel preparation, including dietary restrictions and a potent laxative to completely clear the colon intravenous sedation and pain medication during procedure

Procedure	Description and Purpose	Preparation
esophagoscopy	flexible scope with a camera for viewing the ESOPHAGUS inserted through the mouth diagnose esophagitis, BARRETT'S ESOPHAGUS, ESOPHAGEAL ATRESIA, HIATAL HERNIA, and ESOPHAGEAL CANCER evaluate SWALLOWING DISORDERS	fasting for 6 to 12 hours before the procedure intravenous sedation and pain medication during the procedure
esophagogastroduodenoscopy (EGD)	flexible scope with a camera for viewing the esophagus, stomach, and DUODENUM inserted through the mouth diagnose esophageal conditions, PEPTIC ULCER DISEASE evaluate upper GASTROINTESTINAL BLEEDING or PAIN, swallowing difficulties, or INFLAMMATION	fasting for 6 to 12 hours before the procedure intravenous sedation and pain medication during the procedure
gastroscopy	flexible scope with a camera for viewing the stomach inserted through the mouth take tissue samples to determine whether *HELICOBACTER PYLORI* is present cauterize bleeding ulcer	fasting for 6 to 12 hours before the procedure intravenous sedation and pain medication during the procedure
laparoscopy	flexible scope with a camera for viewing the structures of the internal abdominal cavity inserted through a small incision in the abdominal wall diagnose and treat numerous conditions (PERITONITIS, HEPATIC ABSCESS, diverticular disease, CELIAC DISEASE, gallstones, GALLBLADDER DISEASE, APPENDICITIS, PELVIC INFLAMMATORY DISEASE [PID]) numerous surgical procedures (APPENDECTOMY, CHOLECYSTECTOMY, HERNIA repair)	fasting for 6 to 12 hours before the procedure possible bowel cleansing (laxatives and enema) intravenous sedation and pain medication, epidural anesthetic, or general anesthetic
sigmoidoscopy	rigid scope or flexible scope with a camera for viewing the rectum and sigmoid colon inserted through the anus diagnose inflammation, infection, rectal polyps, rectal prolapse biopsy suspicious growths evaluate lower gastrointestinal tract bleeding	bowel evacuation (laxative or enema before the procedure)

the bowel. This requires surgical repair and ANTIBIOTIC MEDICATIONS to prevent PERITONITIS. Most people return to full and regular activities the day after diagnostic endoscopy and within a few weeks after endoscopic operations.

See also ANTIBIOTIC PROPHYLAXIS; ARTHROSCOPY; BRONCHOSCOPY; CANCER PREVENTION; CYSTOSCOPY; MINIMALLY INVASIVE SURGERY; SURGERY BENEFIT AND RISK ASSESSMENT.

enema The instillation of fluid into the RECTUM through the ANUS to stimulate a BOWEL MOVEMENT. An enema may relieve CONSTIPATION or be part of the preparation to cleanse the COLON for diagnostic procedures or surgery. Frequent enemas may result in dependence on them for bowel movements. Eating a diet high in fiber helps promote healthy bowel motility to prevent constipation. Doctors sometimes prescribe enemas containing hydrocortisone (a corticosteroid medication) to treat ulcerative COLITIS, a form of INFLAMMATORY BOWEL DISEASE (IBD), to deliver the medication directly to the sites of INFLAMMATION.

See also CORTICOSTEROID MEDICATIONS; LAXATIVES.

enteritis See GASTROENTERITIS.

esophageal atresia A CONGENITAL ANOMALY in which the ESOPHAGUS fails to form properly and does not connect to the STOMACH. The esophagus may stop short at any location from the back of the THROAT to the top of the stomach or may extend to the stomach but not connect. Often there is also a tracheal–esophageal fistula (opening between the TRACHEA and the esophagus) that allows excessive air to enter the stomach and can permit saliva as well as gastric secretions to enter the LUNGS. These anomalies require emergency intervention. The risk of ASPIRATION is especially serious, as fluids in the lungs can quickly lead to INFECTION and PNEUMONIA.

Treatment requires surgery, the nature and timing of which depend on where the esophagus ends. The doctor may surgically insert a feeding tube into the stomach to instill breast milk or formula for feeding, as well as a nasogastric tube into the portion of esophagus extending from the throat to suction saliva. Because the esophagus elongates as the child grows, doctors sometimes delay complete surgical reconstruction for 6 to 18 months. The feeding and suction tubes remain in place until the surgery, sometimes a series of operations over several months, is complete.

The esophagus forms very early in PREGNANCY, at about 30 gestational days. Nearly always esophageal atresia and any related anomalies show up on prenatal ULTRASOUND so both doctors and parents can make treatment decisions before the infant's birth. Esophageal atresia tends to occur as one of numerous congenital anomalies that may involve the spine, HEART, other parts of the gastrointestinal system, the kidneys, and the extremities, a constellation doctors refer to as VACTERL. Doctors often use MAGNETIC RESONANCE IMAGING (MRI) or COMPUTED TOMOGRAPHY (CT) SCAN to thoroughly examine the infant for these anomalies.

See also ANAL ATRESIA; BIRTH DEFECTS; BOWEL ATRESIA; CONGENITAL HEART DISEASE; VACTERL.

esophageal cancer Malignant growths in the ESOPHAGUS. CANCER of the esophagus takes one of two forms: ADENOCARCINOMA or squamous cell CARCINOMA. Adenocarcinoma is the more common form and nearly always originates near the esophageal entry to the STOMACH. Esophageal adenocarcinoma is nearly always a progression of BARRETT'S ESOPHAGUS, a condition in which the tissue structure of the esophagus changes to resemble that of the intestines. Adenocarcinoma can develop only in this altered tissue. Squamous cell carcinoma can develop anywhere along the esophagus and is more common in people who smoke. However, smoking, particularly in combination with excessive ALCOHOL consumption, is a major risk factor for either form of esophageal cancer. People who have untreated GASTROESOPHAGEAL REFLUX DISORDER (GERD) or ACHALASIA also face increased risk, as these conditions expose the esophagus to repeated irritation and INFLAMMATION. Though five-year survival rates have increased fourfold since the 1960s, esophageal cancer remains among the most deadly cancers because it shows few symptoms until the cancer is quite advanced.

Symptoms and Diagnostic Path

The most common symptom is difficulty swallowing (dysphagia), particularly the sensation of food

getting stuck when swallowing. Other symptoms include unintentional weight loss and sensations that are a combination of pressure and DYSPEPSIA (heartburn). Unfortunately these symptoms are vague enough that many people can ignore them or perceive them as insignificant, allowing the cancer to progress undetected.

The diagnostic path may include BARIUM SWALLOW, a series of X-rays to visualize the upper gastrointestinal tract, and ENDOSCOPY, in which the gastroenterologist directly views the esophagus using a flexible, lighted scope. Endoscopy allows biopsy of suspicious tissue. Procedures to help determine how far the cancer has spread include endoscopic ULTRASOUND, COMPUTED TOMOGRAPHY (CT) SCAN, MAGNETIC RESONANCE IMAGING (MRI), and POSITRON EMISSION TOMOGRAPHY (PET) SCAN.

Treatment Options and Outlook

The findings of the diagnostic procedures determine treatment options, which include

- Surgery to remove the cancerous portion of the esophagus and nearby tissue; this treatment is most effective when the cancer remains confined to the area of the esophagus where it originated. The surgeon then pulls the stomach up to connect it to the shortened esophagus, or uses a segment of intestine (called a graft) to construct a replacement for the removed section.
- RADIATION THERAPY to kill the cancerous cells; this treatment typically shrinks but does not eliminate the cancer, providing relief from swallowing difficulties.
- CHEMOTHERAPY attacks cancer cells throughout the body; this treatment is most effective when the cancer has spread to other locations in the body.

Treatment often combines these approaches. Each approach has significant risks and side effects. As with all cancers, early detection significantly improves the effectiveness of treatment.

Risk Factors and Preventive Measures

The key risk factors for esophageal cancer are Barrett's esophagus and a combination of smoking and excessive alcohol consumption. Preventive measures to reduce the risk factors for esophageal cancer include

- SMOKING CESSATION
- moderation in ALCOHOL consumption
- WEIGHT LOSS AND WEIGHT MANAGEMENT
- management of chronic conditions that irritate the esophagus, notably GERD
- regular esophageal endoscopy for people who have Barrett's esophagus

See also ADENOMA-TO-CARCINOMA TRANSITION; CANCER PREVENTION; CANCER RISK FACTORS; CANCER PREVENTION; CANCER TREATMENT OPTIONS AND DECISIONS; SMOKING AND HEALTH; STAGING AND GRADING OF CANCER.

esophageal spasm Nonfunctional and often painful contractions of the muscles that line the wall of the ESOPHAGUS. The main symptom of esophageal SPASM is difficult and painful swallowing. The spasms may involve only one portion of the esophagus or the entire length of the esophagus. Doctors do not know what causes esophageal spasm, though eating foods or drinking beverages that are extremely hot or extremely cold often triggers a spasm. The diagnostic path often includes manometry, a procedure that measures pressures within the esophagus. Treatment options include medications to relax smooth MUSCLE such as nitrates and calcium channel antagonist (blocker) medications. BOTULINUM THERAPY, in which botulinum toxin injected into portions of the esophagus to paralyze it, relieves symptoms in many people.

See also ESOPHAGITIS.

esophageal varices Enlarged and weakened veins in the walls of the ESOPHAGUS. Esophageal varices result from PORTAL HYPERTENSION, a condition of impaired BLOOD flow into the LIVER, and are potentially life-threatening should they rupture and HEMORRHAGE. Portal hypertension is a common complication of conditions such as CIRRHOSIS and chronic HEPATITIS that cause SCAR tissue to develop within the liver. Symptoms include GASTROINTESTINAL BLEEDING (VOMITING blood or passing blood in the stool), thirst that increased fluid consumption does not quench, lightheadedness, and mental

confusion (hepatic ENCEPHALOPATHY) resulting from toxins the damaged liver can no longer filter from the blood.

ENDOSCOPY (in which the gastroenterologist passes a lighted, flexible scope into the upper gastrointestinal tract) is the primary diagnostic procedure, allowing the gastroenterologist to see the ESOPHAGUS, STOMACH, and DUODENUM (first segment of the SMALL INTESTINE). The endoscopy reveals the swollen veins, which the gastroenterologist can ligate (band or tie off) or inject with a DRUG to clot the blood inside the VEIN. Bleeding esophageal varices require emergency treatment, nearly always endoscopic treatment to stop the bleeding. A radiologist can do an interventional procedure called TIPPS (transjugular intrahepatic portosystemic shunt) to decrease portal pressure and stop variceal bleeding. When other efforts are not successful a surgeon may place a shunt (tube that reroutes the flow of blood) to improve blood flow into the liver, relieving the pressure blood encounters when trying to enter the liver. Usually the end treatment for esophageal varices is LIVER TRANSPLANTATION.

See also HYPOTENSION; LIVER FAILURE.

esophagitis INFLAMMATION of the ESOPHAGUS. The most common cause of esophagitis is irritation from STOMACH contents that backflow into the esophagus, such as occurs with GASTROESOPHAGEAL REFLUX DISORDER (GERD) and ACHALASIA. INFECTION resulting from HERPES SIMPLEX, CYTOMEGALOVIRUS (CMV), or yeast (*Candida*) also can involve the esophagus to cause esophagitis. Symptoms include painful or difficult swallowing and DYSPEPSIA. The diagnostic path may include ENDOSCOPY to examine, biopsy, or culture the esophagus. Treatment targets the underlying cause and may include H2 ANTAGONIST (BLOCKER) MEDICATIONS or PROTON PUMP INHIBITOR MEDICATIONS to reduce the volume of gastric acid. ANTIBIOTIC MEDICATIONS or ANTIFUNGAL MEDICATIONS are necessary to treat INFECTION. Most people fully recover when the underlying condition resolves, though often esophagitis becomes chronic.

See also BARRETT'S ESOPHAGUS; GASTRITIS; GASTROENTERITIS; SWALLOWING DISORDERS.

esophagus The muscular tube that extends from the back of the THROAT to the top of the STOMACH. From 10 to 12 inches long, the esophagus carries ingested food and fluids to the stomach to begin the process of digestion. As the esophagus leaves the throat its MUSCLE tissue is primarily striated (voluntary); as the esophagus enters the stomach its muscle tissue is smooth (involuntary). Though a person can control the initiation of swallowing, the processes that propel food down the esophagus and into the stomach are involuntary.

COMMON CONDITIONS AFFECTING THE ESOPHAGUS

ACHALASIA	BARRETT'S ESOPHAGUS
DIVERTICULAR DISEASE	DYSPEPSIA
ESOPHAGEAL ATRESIA	ESOPHAGEAL CANCER
ESOPHAGEAL SPASM	ESOPHAGEAL VARICES
ESOPHAGITIS	GASTROESOPHAGEAL REFLUX DISORDER (GERD)

For further discussion of the esophagus within the context of gastrointestinal structure and function, please see the overview section "The Gastrointestinal System."

See also ANUS; CECUM; COLON; DUODENUM; ILEUM; JEJUNUM; RECTUM.

F

familial adenomatous polyposis (FAP) A genetic disorder in which hundreds of intestinal polyps grow in the RECTUM and COLON. FAP is an extreme risk for early-onset COLORECTAL CANCER. This autosomal dominant disorder results from a defective gene, inherited from one parent, in which there is a MUTATION of the adenomatous polyposis coli (APC) GENE. The ACP gene regulates the proteins that inhibit adenomas (abnormal growths arising from epithelial cells, the cells that form the surface layer of SKIN and membranes) in the intestinal mucosa. The mutation of the ACP gene blocks these proteins, allowing adenomas, called intestinal polyps when they occur in the colon, to flourish. In FAP polyps are generally abundant by late ADOLESCENCE, with COLORECTAL CANCER developing before age 40.

The rapid and prolific growth of FAP-associated intestinal polyps significantly favors their evolution to malignancies, manifesting primarily as colorectal adenocarcinomas though may also occur in other sections of the gastrointestinal tract, notably the DUODENUM. FAP polyps and malignancies seldom show early symptoms; family history is the most important diagnostic factor. Signs of FAP include specific dental anomalies and retinal changes that are apparent in childhood. CANCER experts recommend screening COLONOSCOPY annually beginning in early adolescence, and every three to six months when polyp growth becomes pronounced.

Colonoscopy allows the gastroenterologist to remove large intestinal polyps and polyps showing DYSPLASIA (cellular changes indicating that ADENOMA-TO-ADENOCARCINOMA TRANSITION is under way). Studies suggest some NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) may slow the growth of adenomas, reducing the number and size of the polyps. However, these medications do not alter the course of the disease, and surgery to remove the most heavily involved sections of intestine ultimately becomes the therapeutic solution.

Doctors often recommend prophylactic total bowel resection (removal of the colon and rectum) to eliminate the potential for colorectal cancer. Presently this is the only means to prevent FAP from developing into colorectal cancer. Advances in GENE THERAPY show the greatest potential for less invasive and more effective treatments in the future. Participation in clinical research studies that are evaluating investigational treatments may present other treatment opportunities.

fatty liver See STEATOHEPATITIS.

fecal impaction Hardened pieces of feces, also called stool, that lodge in the COLON or RECTUM. Fecal impaction typically occurs as a consequence of chronic CONSTIPATION or reduced bowel motility (movement of digestive waste through the colon) and is most common in people who are confined to bed for extended periods of time. Those who take narcotic PAIN medications or ANTIDIARRHEAL MEDICATIONS may also develop fecal impaction. Symptoms may include extended time without a BOWEL MOVEMENT, lower abdominal cramping or pain, and DIARRHEA from stool leaking around the impaction. DIGITAL RECTAL EXAMINATION (DRE) allows the doctor to make the diagnosis. Treatment may include manual removal of the impaction or ENEMA to soften the impaction and stimulate

bowel movements to expel it. Increased fiber in the diet, stool softeners (medications that help the stool retain fluid), increased fluid consumption, and daily physical activity such as walking when possible can help prevent constipation and fecal impaction.

See also DIET AND HEALTH; SPINAL CORD INJURY; TOXIC MEGACOLON.

fecal incontinence Loss of bowel control. Fecal incontinence occurs more frequently in young children and in elderly adults, though can occur at any age. FECAL IMPACTION, in which stool hardens in the RECTUM, is a common cause of fecal incontinence, particularly in children, as digestive waste that continues to move through the COLON forces its way around the impaction and leaks from the ANUS because the rectum has no capacity to store it. Fecal incontinence also may result from injury or damage to the nerves that provide sensation to the perineum and rectal area or that control the anal sphincter (MUSCLE that regulates the discharge of stool). Such injury may be congenital (such as may occur with SPINA BIFIDA and other congenital anomalies affecting the SPINAL CORD), the consequence of trauma to the perineal area during CHILDBIRTH (particularly EPISIOTOMY), a complication of surgery (such as to treat HEMORRHOIDS or ANAL FISSURE), or a SIDE EFFECT of RADIATION THERAPY to treat CANCER.

Though fecal incontinence is more common among those over age 70, it is not a natural consequence of aging. Treatment can improve or eliminate fecal incontinence in most circumstances. Treatment may include "retraining" the defecation response (BIOFEEDBACK), surgery to repair damaged muscle tissues or a weakened anal sphincter, or therapies to relieve INFLAMMATORY BOWEL DISEASE (IBD) and other conditions in which there is INFLAMMATION of the colon. Eating more fruits, vegetables, and whole grain products adds fiber to the diet, which improves gastrointestinal motility (the movement of digestive content through the gastrointestinal tract). Regular physical activity, such as daily walking, also improves gastrointestinal motility.

See also CONGENITAL ANOMALY; CONSTIPATION; DIARRHEA; DIVERTICULAR DISEASE; FIBER AND GASTROINTESTINAL HEALTH; RECTAL PROLAPSE.

fecal occult blood test (FOBT) A laboratory test to determine whether there is microscopic (occult) BLOOD in the stool, primarily to screen for COLORECTAL CANCER although other conditions, such as INFLAMMATORY BOWEL DISEASE (IBD) and diverticulosis, can also cause occult bleeding. Two kinds of FOBT kits are available for self-sampling at home, one that a laboratory tests and the other that shows immediate results.

For the conventional guaiac test, the person receives a kit from the doctor. The kit contains three cards onto which the person applies a small stool sample, one sample each day for three days. The cards go into a prepaid envelope for mailing to the laboratory (or may be returned to the doctor's office). The lab applies a chemical, guaiac, that reacts with heme, a component of the HEMOGLOBIN in blood. The reaction produces a blue coloration, a positive result. No color change indicates a negative result (no blood is present).

Any positive FECAL OCCULT BLOOD TEST (FOBT) result requires further medical evaluation to determine the source of the bleeding and to rule out serious conditions such as COLORECTAL CANCER.

Tests that show immediate results are available in most pharmacies and drugstores without a doctor's prescription. They contain reagent tissues that the person drops into the toilet following a BOWEL MOVEMENT (before flushing). The tissue turns blue-green if there is any heme present, indicating blood and remains colorless when no blood is present. As with the conventional test, the person tests three bowel movements over three days. The kit includes a card that the person can fill out and send to his or her doctor or keep for personal health records.

The FOBT is a good test for colorectal cancer because the intestinal polyps that are its starting points bleed easily, though the bleeding often is not apparent with visual examination of the stool. Many health conditions can cause positive results, such as ulcers, DIVERTICULAR DISEASE, HEMORRHOIDS, and ANAL FISSURE. Certain foods and other substances can cause false-positive or false-negative results with guaiac-based tests; test instructions may advise avoiding them for 48 hours before

performing the tests (seven days for aspirin and NONSTEROIDAL ANTI-INFLAMMATORY DRUGS [NSAIDS]). Women should do FOBT when they are not menstruating.

SUBSTANCES THAT MAY ALTER FOBT RESULTS

False-Positive Results	False-Negative Results
red meat	vitamin C supplements
cruciferous vegetables	citrus fruits and juices
cantaloupe	

Health-care professionals recommend FBOT annually starting at age 45 for both men and women as a screening for colorectal cancer. Doctors also may request FBOT when they suspect conditions that can cause GASTROINTESTINAL BLEEDING and when there is ANEMIA for no apparent reason.

See also CANCER PREVENTION; COLONOSCOPY.

fiber and gastrointestinal health Fiber, the indigestible residue of plant-based foods, adds bulk to the gastrointestinal contents. This bulk helps stimulate PERISTALSIS, the rhythmic MUSCLE contractions of the intestinal wall that move gastrointestinal contents through the digestive process. In the SMALL INTESTINE where digestive juices work to break down food particles into molecules of NUTRIENTS, the consistency fiber adds to the chyme (the thick, liquid mixture the STOMACH sends to the intestines) helps keep the food in the small intestine long enough for complete digestion to take place. In the COLON, fiber helps maintain more fluid in the stool, keeping this digestive waste soft enough to pass easily from the body during a BOWEL MOVEMENT.

A number of studies suggest a diet high in fiber and low in saturated fats measurably reduces the risk for intestinal polyps as well as for COLORECTAL CANCER. Good sources of dietary fiber include fruits, vegetables, and whole grains and whole grain products. Products such as methylcellulose (Citrucel) and psyllium (Metamucil) can supplement dietary fiber. Drinking plenty of water is also important to keep the body hydrated, which reduces the amount of water the colon extracts from digestive waste.

See also CONSTIPATION; DIARRHEA; INTESTINAL POLYP; NUTRITIONAL NEEDS.

flatulence The clinical term for intestinal gas. Flatulence indicates undigested food particles are present in the COLON. Consuming large quantities of indigestible fiber (such as with beans and other legumes), eating too fast to thoroughly chew food before swallowing, and eating a larger quantity of food than the gastrointestinal tract can accommodate are common reasons for excessive amounts of undigested food particles to make it to the colon. BACTERIA naturally present in the colon act on these food particles. In addition to breaking them down into nutrient molecules, the bacteria also produce gas as a byproduct. These gases eventually make their way through the colon and escape through the ANUS. The most common of these are methane and hydrogen sulfide, which give flatulence its characteristic odor. Excessive flatulence often causes lower abdominal discomfort and cramping. It may occur with LACTOSE INTOLERANCE, CARBOHYDRATE INTOLERANCE, and MALABSORPTION and as a SIDE EFFECT of numerous medications. The herbs peppermint, GINGER, and CHAMOMILE reduce intestinal gas, as do products containing simethicone, activated charcoal, or enzymes that help break down cellulose (residual fiber).

See also ANTACIDS.

G

gallbladder A small, muscular pouch on the underside of the LIVER that concentrates and stores BILE. The gallbladder absorbs about 90 percent of the water in the bile that arrives from the liver, creating concentrated, potent bile. Fats and proteins in the chyme (partly digested food) the STOMACH sends to the DUODENUM trigger the duodenum to release the digestive HORMONE cholecystokinin (CCK). CCK stimulates the gallbladder to contract, expelling bile into the duodenum to aid with digestion. The most common health conditions that affect the gallbladder are cholelithiasis (gallstones), cholecystitis (INFLAMMATION of the gallbladder), and biliary dyskinesia (inadequate contraction of the gallbladder). CANCER of the gallbladder occurs though is rare.

For further discussion of the gallbladder within the context of gastrointestinal structure and function, please see the overview section "The Gastrointestinal System."

See also CHOLECYSTECTOMY; DIGESTIVE HORMONES; GALLBLADDER DISEASE.

gallbladder disease Disorders and dysfunctions of the GALLBLADDER. Gallbladder disease becomes more common with increasing age. Though medical treatments can help some people with gallbladder disease, surgery to remove the gallbladder is the most common treatment and permanently resolves symptoms in about 90 percent of people who have primary gallbladder disease. Tumors and CANCER of the gallbladder occur, though are very rare. INFLAMMATION of the BILE DUCTS and HEPATITIS also can affect BILE production and gallbladder function. Gallbladder disease can be acute or chronic.

Biliary dyskinesia Dysfunction of the gallbladder prevents it from contracting to eject bile, reducing or stopping the flow of bile from the gallbladder to the DUODENUM (first segment of the small intestine). Biliary dyskinesia may occur as a result of injury to the nerves that supply the gallbladder, as a consequence of metabolic disorders affecting LIVER function, or for unknown reasons (most common).

Cholelithiasis Commonly called gallstones, cholelithiasis develops over years to decades in most people. Gallstones can range in size from a few millimeters to several centimeters. There can be one to a few to dozens. About 80 percent of gallstones contain mostly cholesterol; bile pigments such as BILIRUBIN make up the remainder. Many people have gallstones without symptoms. Gallstones become a health concern when they lodge in the bile ducts or when they cause irritation and inflammation of the gallbladder's mucosal lining. In a variation of cholelithiasis, called choledocholithiasis, the gallstones form in the bile ducts.

Cholecystitis Inflammation or INFECTION of the gallbladder most commonly occurs in conjunction with gallstones that block the flow of bile out of the gallbladder, though it can develop in biliary dyskinesia when the bile in the gallbladder stagnates. This stagnation irritates and inflames the lining of the gallbladder. Cholecystitis that occurs without gallstones is acalculus cholecystitis.

GALLBLADDER DISEASE AND WEIGHT LOSS

These weight-loss efforts increase the risk for gallbladder disease:

- rapid weight loss (3 pounds a week or greater)
- BARIATRIC SURGERY (gastric banding, stapling, bypass)
- weight loss cycling (cycles of loss and regaining weight, especially large amounts)

Symptoms and Diagnostic Path

PAIN is the primary symptom of gallbladder disease, and is characteristically:

- steady, sometimes intense pain between the right rib cage and shoulder blade felt in the front, back, or both
- brought on by eating fatty foods, often occurring several hours after eating
- common at night, waking one from sleep
- one to five hours in duration
- not relieved by changing positions or taking over-the-counter pain medications

Other symptoms of gallbladder disease include NAUSEA, VOMITING, gastrointestinal distress (gas, bloating, DIARRHEA) not relieved by ANTACIDS, and light-colored stools that contain noticeable mucus. When a gallstone blocks a bile duct there often is JAUNDICE (yellowish discoloration of the SKIN) and severe tenderness over the site of the blockage. FEVER, chills, and unrelenting pain may signal an infection in the gallbladder. These circumstances require immediate medical attention.

The doctor's physical examination includes a careful history of symptoms as well as palpation of the abdomen. The diagnostic path typically includes ULTRASOUND of the upper right abdomen, which can detect gallstones as small as 2 millimeters—about the size of a thick pencil lead. It also can show thickening of the gallbladder's wall, an indication of chronic inflammation and previous gallstone development. Because the liver shadows the gallbladder, ultrasound does not always detect inflammation related to acute cholecystitis or certain other gallbladder problems. Contrast dye X-RAY (oral or intravenous) and radioisotope imaging (cholescintigraphy) provide detailed information about gallbladder function.

Treatment Options and Outlook

Mild and infrequent symptoms may require no intervention beyond watchful waiting and lifestyle modifications such as eating a diet lower in fat, getting daily physical exercise, and WEIGHT LOSS AND WEIGHT MANAGEMENT. ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY (ERCP) often is successful in removing small gallstones from the bile ducts.

Surgery to remove the gallbladder (CHOLECYSTECTOMY) is the treatment of choice for acute, recurrent, or chronic cholecystitis and cholelithiasis in which gallstones cause pain and bile duct obstruction. There are two methods for performing cholecystectomy: laparoscopic surgery and OPEN SURGERY. About 95 percent of cholecystectomies performed in the United States are laparoscopic.

Medications to dissolve gallstones are not very successful and can cause significant side effects. Current treatment guidelines recommend these medications only when surgery is not a viable option. The two drugs doctors sometimes use are ursodiol (Actigall) and chenodiol (Chenix). Though EXTRACORPOREAL SHOCKWAVE LITHOTRIPSY (ESWL) is effective in breaking up KIDNEY stones, it so far has not proven to be successful in doing the same with gallstones.

About a third of people who have one gallbladder episode, such as a gallstone that causes pain, never have another. The gallbladder is an organ that, though useful, the body does not require. Most people make a full recovery from gallbladder surgery and can resume their normal activities without modification. No dietary restrictions or medications are necessary.

Risk Factors and Preventive Measures

Women are twice as likely as men to develop gallbladder disease. Researchers believe this increased risk correlates to the presence of ESTROGENS, which play an integral role in cholesterol METABOLISM. Women who are pregnant or taking oral contraceptives (birth control pills), which increase the body's level of estrogen, are at highest risk. Gallbladder disease seldom occurs in children.

These factors increase the risk for gallbladder disease in men and women alike:

- OBESITY
- rapid weight loss or weight cycling
- DIABETES
- taking lipid-lowering medications
- age 60 or older

Lifestyle habits such as nutritious diet and regular physical exercise minimize the likelihood of

gallbladder disease. Dietary fiber helps absorb cholesterol from consumed foods, reducing the amount of cholesterol that becomes available in the bloodstream and for the liver to process.

See also DIET AND HEALTH; ENDOSCOPY; HYPERLIPIDEMIA; LIFESTYLE AND HEALTH; MINIMALLY INVASIVE SURGERY; PRIMARY BILIARY CIRRHOSIS; PRIMARY SCLEROSING CHOLANGITIS.

gastrectomy Partial or complete surgical removal of the STOMACH, typically to treat STOMACH CANCER or uncontrollable bleeding resulting from PEPTIC ULCER DISEASE. Gastrectomy is a major OPERATION, typically an OPEN SURGERY, performed under general ANESTHESIA that requires several days to a week in the hospital and 8 to 12 weeks for total recovery and return to regular activities. An individual's course of recovery depends on the reasons for the surgery. The surgical operation takes two to three hours. After removing the diseased portion of the stomach through an abdominal incision at the lower edge of the left rib cage, the surgeon connects the remaining portion of the stomach (or the ESOPHAGUS, when the gastrectomy is total) to the DUODENUM. A partial (also called subtotal) gastrectomy leaves a gastric pouch that can carry on some of the digestive functions of the stomach. Total gastrectomy, which is less common, leaves no residual gastric pouch though the surgeon may construct one by expanding a portion of the duodenum.

Many people are able to return to normal eating habits after they recover from the surgery, though find that they need to eat frequent small meals to accommodate the smaller stomach and reduce gastrointestinal distress. Foods that are high in protein and low in simple sugars are easier for the small intestine to digest without the aid of the stomach. Some people have difficulty eating regular foods after gastrectomy and need to use NUTRITIONAL SUPPLEMENTS, typically liquid preparations, to meet their NUTRITIONAL NEEDS.

Risks and complications of gastrectomy include bleeding, INFECTION, dumping syndrome (RAPID GASTRIC EMPTYING), and damage to the vagus NERVE (which regulates gastric PERISTALSIS and other digestive functions). People who have total gastrectomies, and many people who have subtotal gastrectomies, need regular injections of vitamin B_{12} (cyanocobalamin) because the gastric mucosa is no longer able to produce intrinsic factor, a chemical substance that allows the SMALL INTESTINE to absorb this vital nutrient. Vitamin B_{12} deficiency causes pernicious ANEMIA.

See also BARIATRIC SURGERY; CANCER TREATMENT OPTIONS AND DECISIONS; CRANIAL NERVES; SURGERY BENEFIT AND RISK ASSESSMENT.

gastritis INFLAMMATION of the lining of the STOMACH. There are two broad classifications of gastritis: erosive and nonerosive. The most common cause of erosive gastritis is repeated irritation from ingested substances such as ALCOHOL, aspirin, and NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS). The most common cause of nonerosive gastritis is INFECTION with *HELICOBACTER PYLORI*, the strain of BACTERIA that causes PEPTIC ULCER DISEASE. Occasionally viral infections can cause acute gastritis, which resolves when the infection runs its course. Autoimmune gastritis, in which the IMMUNE SYSTEM attacks the cells that form the mucosal lining of the stomach, interferes with the absorption of certain NUTRIENTS, notably vitamin B_{12} (pernicious ANEMIA).

Symptoms include DYSPEPSIA (upset stomach), PAIN, NAUSEA, VOMITING, and a sensation of fullness. The diagnostic path may include BARIUM SWALLOW and endoscopic examination of the ESOPHAGUS, stomach, and DUODENUM (first segment of the SMALL INTESTINE and the site of peptic ulcer disease). The gastroenterologist may biopsy samples of stomach tissue. Treatment targets the underlying cause. Eliminating ingestion of the responsible substance often ends erosive gastritis. ANTIBIOTIC MEDICATIONS can eradicate *H. pylori*. Treatment for autoimmune gastritis focuses on countering any NUTRITIONAL DEFICIENCY that results as well as eliminating other sources of irritation to minimize gastric inflammation.

See also AUTOIMMUNE DISORDERS; COLITIS; ENDOSCOPY; GASTROENTERITIS; PANCREATITIS; STOMACH CANCER.

gastroenteritis INFLAMMATION of the SMALL INTESTINE. The most common cause of gastroenteritis is viral INFECTION, though sometimes BACTERIA or PARASITES are responsible. The inflammation of the intestinal mucosa (mucus lining of the intestinal

wall) reduces the small intestine's ability to absorb NUTRIENTS and fluid. People often refer to gastroenteritis as "stomach flu," though this is inaccurate; the "flu" or influenza is a viral infection of the pulmonary system.

Symptoms and Diagnostic Path

Symptoms of gastroenteritis include DIARRHEA, abdominal cramping, and occasionally ABDOMINAL DISTENTION. Depending on the cause of the infection, the diarrhea can be profuse or bloody; bloody diarrhea requires medical evaluation. There may also be FEVER and VOMITING.

Symptoms that extend beyond two or three days in children or the elderly, or in a person of any age who cannot keep any fluids down, require medical evaluation to prevent DEHYDRATION.

The diagnostic path may include laboratory tests to determine the presence of pathogens (agents of infection) in the stool and blood tests to help identify the extent and nature of infection. The doctor may take stool samples or a rectal swab to determine whether bacterial or parasitic pathogens are present, which would require treatment with the appropriate medications. Bacterial gastroenteritis most often results from consuming contaminated food or water. The doctor may recommend ANTIEMETIC MEDICATIONS to quell nausea and ANTIDIARRHEAL MEDICATIONS to reduce diarrhea, depending on the cause and extent of the symptoms.

Noninfectious forms of gastroenteritis include Crohn's disease and radiation gastroenteritis. Crohn's disease is a component of INFLAMMATORY BOWEL DISEASE (IBD), which many doctors believe is an autoimmune disorder with a genetic component in which the IMMUNE SYSTEM attacks the intestinal mucosa. The attacks result in small ulcerations that often bleed. The enteric symptoms are chronic; treatment targets the underlying disease. Radiation gastroenteritis results from damage to the intestinal mucosa that occurs with RADIATION THERAPY to the abdomen, and may be acute (limited to the course of radiation therapy) or chronic (signaling permanent changes in the intestinal mucosa).

COMMON ENTERIC PATHOGENS

Pathogen	Type	Route of Infection
astrovirus	VIRUS	contaminated food or water person-to-person
calicivirus	virus	contaminated food or water person-to-person
Cryptosporidium	PARASITE	contaminated water animal-to-person person-to-person
Cyclospora cayetanensis	parasite	contaminated food or water person-to-person
enteric adenovirus	virus	contaminated food or water person-to-person
Escherichia coli	BACTERIA	contaminated food or water person-to-person
Giardia lamblia	parasite	contaminated water person-to-person
Listeria	bacteria	contaminated food person-to-person
Microsporidia	parasite	unknown
rotavirus	virus	contaminated food or water person-to-person
Salmonella	bacteria	contaminated food reptile-to-person
Staphylococcus enterotoxin	bacteria	contaminated food person-to-person

Treatment Options and Outlook

Adequate fluid replacement and other supportive measures are the only treatment necessary for viral gastroenteritis, which typically runs its course in three to five days. Young children, older adults, and people who have serious chronic health care conditions are at greatest risk for complications from viral gastroenteritis, though most people recover fully. Bacterial and parasitic gastroenteritis require treatment with the appropriate medications to eliminate the causative PATHOGEN,

and sometimes have a longer course of illness than viral gastroenteritis. Treatment for radiation gastroenteritis focuses on dietary management (eating frequent small meals and foods high in fiber) with ANTIDIARRHEAL MEDICATIONS to help control diarrhea.

Risk Factors and Preventive Measures

Viral gastroenteritis is highly contagious and often occurs in outbreaks, particularly in group settings such as schools, day cares, nursing homes, camps, and contained environments such as cruise ships. These methods can significantly reduce infectious gastroenteritis:

- proper food handling and preparation
- frequent and thorough HAND WASHING
- drinking WATER PURIFICATION (boiling, filtration, chemical)

See also AMEBIASIS; COLITIS; CYCLOSPORIASIS; FOODBORNE ILLNESSES; FOOD SAFETY; GASTRITIS; GIARDIASIS; LISTERIOSIS; PARASITE; SALMONELLOSIS; SHIGELLOSIS; WHIPPLE'S DISEASE.

gastroesophageal reflux disorder (GERD) A chronic condition in which gastric contents leak back from the STOMACH into the ESOPHAGUS. Because stomach juices are highly acidic, this backwash creates chemical BURNS in the delicate tissues of the esophagus. The lining of the esophagus lacks the protective mucus that safeguards the stomach from gastric acid, making it vulnerable to injury. Up to 40 percent of adults in the United States have GERD. Though GERD can develop in people of any age, including children, the likelihood of it doing so increases with age. Treatments to manage GERD include medical, surgical, and lifestyle methods.

Symptoms and Diagnostic Path

The symptoms of GERD often appear or are more severe following meals, when lying on the back, when bending over, and when lifting or straining. Many people experience more severe symptoms at night that awaken them from sleep. Typical GERD symptoms are chronic (ongoing) and include

- PAIN, pressure, or burning sensation in the mid-chest
- NAUSEA, and less commonly VOMITING, after eating
- regurgitation (reflux) of stomach contents up to several hours after eating that causes a bitter taste in the MOUTH and a burning sensation in the THROAT
- a sense of fullness in the stomach even when hungry

Some people also experience chronic sore throat or hoarseness resulting from the persistent reflux, or HICCUPS, likely due to irritation of the DIAPHRAGM, where the esophagus and stomach join, which is the site of the irritation. The diagnostic path may include BARIUM SWALLOW, gastroesophagoscopy (endoscopic examination of the esophagus and stomach), and breath or BLOOD tests for the presence of *HELICOBACTER PYLORI*. Because GERD is so common and the diagnostic procedures are invasive, doctors often use a trial of medication, such as H2 ANTAGONIST (BLOCKER) MEDICATIONS or PROTON PUMP INHIBITOR MEDICATIONS (PPIs), to suppress gastric acid production and then assume a diagnosis of GERD if the medication relieves the symptoms.

Treatment and Outlook

Most people obtain full relief from their symptoms with a combination of medical treatments and lifestyle modifications. Many people find lifestyle modifications (diet, WEIGHT LOSS AND WEIGHT MANAGEMENT, SMOKING CESSATION) combined with ANTACIDS adequate, while other people require stronger medications such as H2 blockers or PPIs. Many H2 blockers are available in over-the-counter formulas. Reducing gastric acid significantly reduces the amount reflux that can backwash into the esophagus.

The most common surgical treatment for GERD that fails to improve with medication and lifestyle methods, fundoplication, reinforces the upper section of the stomach (the fundus) to increase tension on the lower esophageal sphincter. There are several fundoplication methods, some of which the surgeon can perform laparoscopically and others that require OPEN SURGERY. Another surgical option is endoscopic gastroplasty to repair or strengthen the lower esophageal sphincter. The

TREATMENTS FOR GERD

Medical Methods	Surgical Methods	Lifestyle Methods
H2 BLOCKERS	fundoplication	WEIGHT LOSS AND WEIGHT MANAGEMENT
PPIs	endoscopic gastroplasty	elevate head of bed
antibiotics for *H. PYLORI*		SMOKING CESSATION
ANTACIDS		avoid CAFFEINE and ALCOHOL
		reduce carbonated beverages
		stay upright for 2 hours after meals
		sleep lying on the left side
		avoid NSAIDs and aspirin

most common complications after surgery are INFECTION and difficulty swallowing.

Risk Factors and Preventive Measures

Doctors are uncertain what causes GERD to develop, though various factors appear to contribute. Among them are

- OBESITY
- cigarette smoking
- *H. pylori*
- ASTHMA
- eating within two hours of going to bed
- heavy ALCOHOL consumption

Preventive measures include avoiding or minimizing factors associated with GERD as well as eating smaller meals and getting regular physical exercise, which helps maintain effective PERISTALSIS and gastrointestinal motility (movement of food through the gastrointestinal tract).

See also ACHALASIA; BARRETT'S ESOPHAGUS; ENDOSCOPY; ESOPHAGITIS.

gastrointestinal bleeding Gross (obvious) or occult (microscopic) bleeding along any section of the gastrointestinal tract. Gross bleeding generally is obvious. Occult bleeding often occurs with intestinal polyps. FECAL OCCULT BLOOD TEST (FOBT) is one method used to detect microscopic BLOOD in the stool. Several kinds of FOBTs are available for home use, though it is imperative to follow up with the doctor when the results are questionable or positive.

Gastrointestinal bleeding can result from numerous conditions as well as excessive doses of anticoagulant medications or irritation from medications such as aspirin and NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS). The most common sites are the STOMACH, DUODENUM, sigmoid COLON, and RECTUM. There are three ways in which gastrointestinal bleeding presents:

- hematemesis is the VOMITING of bright red blood, signaling bleeding from the upper gastrointestinal tract (usually the ESOPHAGUS, stomach or duodenum)
- hematochezia is the passing of bright red blood rectally, indicating bleeding from the lower gastrointestinal tract (usually the sigmoid colon or rectum) or from HEMORRHOIDS
- melena is the passing of dark, tarry stools that signal bleeding from the upper gastrointestinal tract

All gastrointestinal bleeding requires medical evaluation to determine its cause. Persistent bleeding, even when the amounts of blood appear small, results in ANEMIA. The diagnostic path may include ENDOSCOPY of the upper and lower gastrointestinal tracts, esophagogastroduodenoscopy (EGD) and COLONOSCOPY respectively, as well as BARIUM SWALLOW and BARIUM ENEMA. Treatment targets the underlying condition, and may include BLOOD TRANSFUSION when the blood loss is significant.

CONDITIONS THAT CAN CAUSE GASTROINTESTINAL BLEEDING

ANAL FISSURE	BARRETT'S ESOPHAGUS
COLITIS	DIVERTICULAR DISEASE
ESOPHAGEAL CANCER	GASTRITIS
HEMORRHOIDS	INFLAMMATORY BOWEL DISEASE (IBD)
INTESTINAL POLYP	PEPTIC ULCER DISEASE
STOMACH CANCER	

See also ESOPHAGEAL VARICES; HEMORRHAGE.

gastroparesis Slowed function of the STOMACH that delays the travel of gastric contents into the DUODENUM. Gastroparesis results from disturbances of or damage to the vagus NERVE (the tenth cranial nerve), which carries the nerve impulses that accelerate PERISTALSIS (rhythmic contractions of the gastrointestinal tract). Gastroparesis most commonly occurs after a viral infection though also is a complication of DIABETES, which damages nerve structures throughout the body. Other causes include sclerotic conditions such as MULTIPLE SCLEROSIS or scleroderma, anticholinergic medications often prescribed to treat PARKINSON'S DISEASE, inadvertent damage to the vagus nerve as a complication of thoracic or HEART surgery, and intentional interruption of the vagus nerve (vagotomy) to treat conditions such as PEPTIC ULCER DISEASE. People who are on long-term PARENTERAL NUTRITION also often have gastroparesis.

The main symptom of gastroparesis is frequent VOMITING of undigested food hours after a meal. Other symptoms may include lack of APPETITE due to sense of fullness, NAUSEA, ABDOMINAL DISTENTION, and unintended weight loss. Gastroparesis can quickly result in DEHYDRATION, which can create significant disturbances of blood GLUCOSE and INSULIN levels in people who have diabetes. The first approach of treatment is to shift to eating numerous small meals throughout the day, attempting to slow the pace of ingestion to accommodate the stomach's slowed functioning.

Medications to stimulate gastrointestinal motility, such as metoclopramide (Reglan), may improve gastric emptying. Control of diabetes, which may require multiple insulin doses throughout the day, is crucial. If symptoms continue, the gastroenterologist may suggest a jejunostomy tube, or feeding tube, that bypasses the stomach. Most people, however, achieve an acceptable resolution of their symptoms, even when gastroparesis persists, through nonsurgical approaches.

H

heartburn See DYSPEPSIA.

Helicobacter pylori The BACTERIA responsible for much PEPTIC ULCER DISEASE and STOMACH CANCER. Researchers isolated *H. pylori* in 1982, a discovery that dramatically altered the treatment approach to ulcers. Though researchers do not know how *H. pylori* enter the gastrointestinal system, they believe INFECTION occurs early in life in most people. The bacteria establish themselves in the lining of the STOMACH in the area called the pylorus, and often in the DUODENUM (first segment of the SMALL INTESTINE) as well. The presence of *H. pylori* causes irritation, which the body counters with an inflammatory response in an attempt to buffer the gastric mucosa from the irritation. Over time this pattern of irritation and INFLAMMATION results in ulcerative erosions of the mucosa, commonly called stomach ulcers.

The urea breath test is a simple, accurate, and fast way for doctors to determine whether *H. pylori* are present. The person drinks a solution or swallows a capsule containing urea tagged with a carbon isotope. *H. pylori* metabolize the urea, releasing carbon dioxide containing the carbon isotope. A machine analyzes breath samples to detect the presence of carbon isotopes in the carbon dioxide. Endoscopic biopsy, blood tests to detect *H. pylori* antibodies, and stool tests that detect *H. pylori* antigens are other methods to diagnose *H. pylori* infection. As well, these tests show whether treatment with ANTIBIOTIC MEDICATIONS has successfully eradicated the bacteria.

H. pylori are sensitive to several antibiotics though have the ability to rapidly adapt and develop resistance. For this reason doctors prescribe two kinds of antibiotic medications in combination. Treatment also includes PROTON PUMP INHIBITOR (PPI) MEDICATIONS or H2 ANTAGONIST (BLOCKER) MEDICATIONS to suppress gastric acid production, which makes the stomach a more hostile environment for the *H. pylori* and reduces irritation to the inflamed tissues or ulcers. *H. pylori* are also sensitive to the common ANTIDIARRHEAL MEDICATION bismuth subsalicylate (Pepto-Bismol). There are numerous treatment protocols for eradicating *H. pylori* that use these medications in various combinations. Once eradicated, *H. pylori* seem not to recur.

See also ANTIBODY; ANTIGEN; CANCER RISK FACTORS; ENDOSCOPY; GASTRITIS.

hemorrhoids Veins and related structures in and around the ANUS that distend and swell. Hemorrhoids can be internal or external. An old term for hemorrhoids that remains in common use is piles, a reference to the appearance of external hemorrhoids. Hemorrhoids alone do not cause symptoms; about two thirds of adults in the United States have hemorrhoids. Hemorrhoids cause PAIN, itching, and bleeding when they become inflamed, develop BLOOD clots, or prolapse (protrude). Factors that contribute to symptomatic hemorrhoids include

- chronic CONSTIPATION and straining with BOWEL MOVEMENTS
- sitting on the toilet for extended periods of time, which reduces blood circulation
- low fiber diet, which results in small, hard stools that can be difficult to pass
- PREGNANCY, which pressures the pelvic floor and can affect perineal blood flow
- INFLAMMATORY BOWEL DISEASE (IBD)

The doctor can diagnose hemorrhoids via physical examination of the anal area, including DIGITAL RECTAL EXAMINATION (DRE) or anoscopy, when symptoms are mild. Treatment attempts to shrink and soothe the irritated tissues. Topical preparations containing an anesthetic agent and hydrocortisone can provide prompt, short-term relief. A SITZ BATH, or simply soaking in the bathtub, relaxes the anal sphincter enough to calm the spasms that prolapsed or thrombosed (clotted) hemorrhoids cause. Dietary changes (such as increased fiber and fluids) combined with frequent physical activity (such as walking) help to reduce constipation, which relieves straining and pressure on the anorectal area. The doctor can ligate (band off), cauterize, freeze, or excise (cut out) hemorrhoids that fail to respond to conservative treatment approaches. In the vast majority of people, appropriate treatment and lifestyle modifications end symptoms.

See also ANAL FISSURE; ENDOSCOPY.

hepatic abscess A pocket of INFECTION that develops within the LIVER, also called liver ABSCESS. Though not common, hepatic abscesses can develop as a complication of GALLBLADDER DISEASE in which infection spreads through the BILE DUCTS to the liver. Symptoms include ABDOMINAL PAIN (often focused in the upper left quadrant), tenderness and rigidity, and FEVER. A person with a hepatic abscess often appears very ill. Abdominal ULTRASOUND, COMPUTED TOMOGRAPHY (CT) SCAN, and MAGNETIC RESONANCE IMAGING (MRI) are among the diagnostic procedures that help detect hepatic abscess. Treatment is percutaneous aspiration (inserting a needle through the SKIN and into the abscess) or laparoscopic surgery to drain the collected pus, with intensive antibiotic therapy to eradicate the infection. An untreated hepatic abscess can quickly become life-threatening, as the liver's rich blood supply can carry the pathogenic bacteria throughout the body.

See also ANTIBIOTIC MEDICATIONS; MINIMALLY INVASIVE SURGERY; SEPTICEMIA.

hepatic cyst A noncancerous growth, often fluid-filled, that develops in the LIVER. Most simple hepatic cysts cause no symptoms; they become apparent during diagnostic procedures, such as abdominal ULTRASOUND, done for other reasons. When there are no symptoms, no treatment is necessary beyond regular monitoring (watchful waiting). A hydatid cyst contains the larvae of the PARASITE *Echinococcus granulosus,* acquired through contact with animal feces that contain the parasite's eggs, which migrate to the liver. A hydatid cyst grows slowly though can become large enough to hold a liter or more of fluid. Even when hydatid cysts show no symptoms, doctors remove them because they can cause life-threatening complications such as PERITONITIS or SEPTICEMIA if they rupture. Removal of a hepatic cyst is nearly always a laparoscopic surgery.

See also MINIMALLY INVASIVE SURGERY; PERCUTANEOUS LIVER BIOPSY.

hepatitis INFLAMMATION of the LIVER. There are numerous kinds and causes of hepatitis. Most hepatitis results from specific viruses that cause infections of the liver, ALCOHOL abuse, and hepatotoxic drugs. Hepatitis is the leading cause of LIVER FAILURE, and reason for LIVER TRANSPLANTATION, in the United States.

Infectious (viral) hepatitis The viruses that cause viral hepatitis belong to several virus families: the picornavirus family, which causes hepatitis A; the hepacivirus family, which causes hepatitis B; and the flavirus family, which causes hepatitis C.

Though these viruses are among the smallest researchers have yet detected, they cause a wide range of illnesses from COLDS to viral MENINGITIS to POLIO. Researchers refer to those that specifically target the liver as hepatotropic and label them alphabetically in the sequence of their discovery. Each individual VIRUS has unique characteristics that cause a particular pattern of disease. Researchers classify viral hepatitis according to the viral variant responsible for the disease response.

Five viruses identified as hepatotropic ("liver loving") cause 95 percent of the infectious hepatitis diagnosed in the United States: hepatitis A (HAV), hepatitis B (HBV), hepatitis C (HCV), hepatitis D (HDV), and hepatitis E (HEV). Hepatitis A and hepatitis E cause acute infection only and rarely cause permanent liver damage, though hepatitis A infection can cause serious illness and fatality. Hepatitis A accounts for more than 60

percent of hepatitis cases in the United States and hepatitis B for nearly 30 percent. Other identified hepatitis viruses (HFV and HGV) are rare in the United States. Hepatitis B and hepatitis C can be present without showing symptoms; about a third of people who have hepatitis B are carriers (the virus is present in their bodies and infects others, though does not cause illness in them). Though health agencies routinely test donated BLOOD, tissue, and organs for hepatitis (as well as numerous other infectious agents), people who receive donor substances face some risk of infection. Hepatitis C accounts for about 80 percent of such infections; new infections have become rare as a result of stringent donor substances screening. Hepatitis D can replicate only when hepatitis B is also present. It often causes "superinfection"—acute disease with chronic hepatitis B infection. Hepatitis E occurs in outbreaks related to water contamination, such as might follow widespread flooding, and tend to be more common among people who contract the virus during travel to developing countries where COMMUNITY SANITATION is inadequate.

Viral hepatitis begins with an acute illness that lasts from 2 to 10 months, though in most people the acute phase resolves in 4 to 6 months. Chronic forms of hepatitis often follow infection with HBV and HCV, resulting in recurring episodes of symptoms. The repeated inflammation is very harmful to the liver, causing scarring (fibrosis) that eventually becomes CIRRHOSIS (SCAR tissue replaces liver tissue). The damage tends to be progressive, culminating in liver failure in about 25 percent of

Hepatitis Virus	Mode of Infection	Preventive Measures
hepatitis A (HAV)	fecal-oral food-borne person-to-person occupational exposure	vaccination frequent HAND WASHING and conscientious PERSONAL HYGIENE postexposure prophylaxis
hepatitis B (HBV)	blood sexual contact shared needles among illicit injected DRUG users perinatal (to infant at birth) hemodialysis occupational exposure	vaccination safer sex practices avoid sharing needles barrier precautions to prevent occupational exposure postexposure prophylaxis
hepatitis C (HCV)	blood sexual contact shared needles among illicit injected drug users perinatal (to infant at birth) hemodialysis occupational exposure	safer sex practices avoid sharing needles barrier precautions to prevent occupational exposure postexposure prophylaxis
hepatitis D (HDV)	blood shared needles among illicit injected drug users occupational exposure	HBV vaccination (HDV can infect people only already infected with HBV) avoid sharing needles barrier precautions to prevent occupational exposure postexposure prophylaxis
hepatitis E (HEV)	fecal-oral water	boiling water when contamination is possible

people who have chronic hepatitis. About 10 percent of people who develop chronic hepatitis subsequently develop LIVER CANCER. People who have chronic forms of hepatitis may show no signs or symptoms of disease though are carriers who pass the virus to others with whom they have close contact (particularly sexual contact).

Alcoholic hepatitis Alcohol is highly toxic to the liver. Chronic alcohol abuse results in repeated inflammation of liver tissue, with resulting scarring (fibrosis) that ultimately limits the liver's ability to function (cirrhosis). Liver damage that occurs is permanent and may lead to liver failure.

Hepatotoxic hepatitis The most common hepatotoxins resulting in hepatitis are acetaminophen (Tylenol) and NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) such as ibuprofen (Motrin). Other hepatotoxins include cleaning solutions, industrial pollutants, and carbon tetrachloride. Hepatotoxic hepatitis can result in rapid liver failure or lead to chronic hepatitis.

Symptoms and Diagnostic Path

The general symptoms of hepatitis are the same regardless of the cause and occur in four distinct stages:

1. Infective asymptomatic, in which the virus has invaded the liver and is replicating. During this stage the person is most highly infective.
2. Prodromal, in which infection has not yet manifested symptoms but the person begins to feel generalized malaise, loss of APPETITE, and aversions to certain foods (and often to cigarette smoke).
3. Active disease response, with characteristic symptoms that include JAUNDICE, dark urine, pale stools, FEVER, fatigue, and abdominal tenderness.
4. Recovery, during which the person continues to feel fatigue and malaise but liver functions are returning to normal, or liver failure, indicating the disease process has overwhelmed the liver.

Viral hepatitis remains infectious for as long as the virus is active in the body. With chronic forms of viral hepatitis, symptoms recur periodically. Alcoholic hepatitis and hepatotoxic hepatitis remain in active disease state until the causative substance clears the body.

Treatment Options and Outlook

Treatment for hepatitis is largely supportive, consisting of fluid consumption, adequate nutrition, and rest. The course of acute disease may be mild and flulike or life-threatening, depending on numerous variables such as the cause and the individual's personal health status. People who have IMMUNE SYSTEM impairments, such as those who have HIV/AIDS, are very young, or are very old are at greatest risk for severe disease. ANTIVIRAL MEDICATIONS such as adefovir, ribavirin, interferon, amantadine, and lamivudine sometimes limit the course of active disease in chronic hepatitis (HBV and HDV). Liver damage due to hepatotoxic hepatitis may so overwhelming as to require immediate liver transplantation.

Chronic hepatitis remains a significant lifelong threat to health. Those who have chronic infectious hepatitis can pass the disease to others. Regardless of cause, chronic hepatitis limits the liver's ability to function. Physiologic stress, such as alcohol consumption or taking certain medications, can seriously strain the liver's capacity. People who have chronic hepatitis may experience frequent bouts of fatigue. Many people are able to enjoy relatively normal lifestyles, though must remain mindful of situations and substances that could challenge the liver.

Risk Factors and Preventive Measures

The primary risk factor for infectious hepatitis is exposure to others who have hepatitis infections. For hepatitis A, this includes consuming foods handled in an unsafe manner by a person who already has hepatitis A infection or handling contaminated fecal waste (such as diapers). Those at risk for blood-borne hepatitis infections (HBV, HCV, HDV) include

- people who have unprotected sex with multiple partners (hepatitis B is especially common among men who have sex with men)
- people who inject illicit drugs and share needles, paraphernalia, and drugs
- people who undergo long-term hemodialysis to treat renal (kidney) failure

- infants born to infected mothers
- people who received organ transplants before 1992 or blood transfusions before 1987 (before stringent screening practices became available)
- people who work in health care and public safety

The most effective measures for protecting against infectious hepatitis are diligent PERSONAL HYGIENE (especially HAND WASHING) and vaccination. Vaccines are available to prevent infection with hepatitis A and hepatitis B. The hepatitis B VACCINE also protects against hepatitis D, which requires the hepatitis B virus to replicate. Hepatitis A and hepatitis E infection confer lifelong immunity. Measures to reduce the risk for noninfectious hepatitis center on eliminating or limiting exposure to hepatotoxic substances including alcohol. The herb MILK THISTLE (silymarin) helps to protect the liver from damage and to recover from damage that occurs. Many health experts recommend that people who have hepatitis or have exposure to hepatotoxins take milk thistle.

See also FOOD SAFETY; HEPATITIS PREVENTION; LIVER CANCER; LIVER DISEASE OF ALCOHOLISM; SHORT BOWEL SYNDROME.

hepatomegaly An enlarged LIVER. Hepatomegaly is a symptom of numerous conditions involving the liver. Its presence or absence has no correlation to the seriousness of the underlying liver disease. Because hepatomegaly is a symptom rather than a condition, it often resolves when the underlying condition comes under control. Chronic liver conditions may result in long-term hepatomegaly.

CONDITIONS THAT CAN RESULT IN HEPATOMEGALY

AMYLOIDOSIS	ANEMIA
CIRRHOSIS	congestive HEART FAILURE
HEMATOCHROMATOSIS	HEPATITIS
INFECTION	infectious mononucleosis
LEUKEMIA	LIVER CANCER
LIVER DISEASE OF ALCOHOLISM	LIVER FAILURE
REYE'S SYNDROME	SARCOIDOSIS
sclerosing cholangitis	STEATOHEPATITIS

See also: HEPATOTOXINS; JAUNDICE; MONONUCLEOSIS, INFECTIOUS; PORTAL HYPERTENSION; SPLENOMEGALY.

hepatotoxins Substances that damage the LIVER. A key role of the liver is to metabolize chemicals that it filters from the BLOOD. In the case of medications, this releases the therapeutic components into the bloodstream and channels the waste byproducts for appropriate elimination. Often the chemical interactions of these metabolic processes generate substances that poison the cells of the liver. Most drugs affect liver function to some degree; hundreds of them have short-term toxic effects and dozens cause permanent liver damage. The most common are ALCOHOL, acetaminophen, and NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS). Recreational drugs such as hallucinogenic mushrooms are especially hazardous to the liver. Industrial chemicals such as carbon tetrachloride and numerous environmental pollutants also cause the death of liver cells (hepatonecrosis).

Elevated levels of key liver enzymes in the blood provide early indication of hepatotoxicity. These include aspartate aminotransferase (AST), alanine aminotransferase (ALT), and glutamate oxaloacetate transaminase (GOT). Hepatotoxicity may also result in symptoms similar to those of HEPATITIS, such as JAUNDICE, NAUSEA, vomiting, and occasionally FEVER. Damage can be fairly immediate (within days to weeks of ingestion) or manifest months later. Regular alcohol consumption reduces the capacity of the liver to handle toxins, lowering the threshold at which damage occurs. Liver function often returns to normal when ingestion of the toxic substance ends and the liver completes all metabolic functions related to it, though hepatotoxic consequences can cause irreversible loss of liver function and even LIVER FAILURE. Many substances that damage the liver also damage the KIDNEYS. The herb MILK THISTLE, which contains silymarin, helps protect the liver from toxins.

See also ANALGESIC MEDICATIONS; CIRRHOSIS; HALLUCINOGENS; LIVER DISEASE OF ALCOHOLISM; OVERDOSE; POISON PREVENTION; RENAL FAILURE.

hereditary nonpolyposis colorectal cancer (HNPCC) A form of COLORECTAL CANCER predisposed by a mutation in the *mlh1* and *msh1* genes. These genes direct DNA repair mechanisms, the processes cells follow to correct mistakes that occur when they replicate their DNA codes during

cell reproduction, for cells in the mucous membrane lining of the COLON and RECTUM. Having the GENE mutations for HNPCC increases the likelihood that a person will develop colorectal CANCER before the age of 50 years. HNPCC accounts for about 5 percent of colorectal cancer in the United States as well as increased risk for GASTRIC CANCER, ENDOMETRIAL CANCER, and OVARIAN CANCER.

Cancer experts recommend annual COLONOSCOPY (examination of the colon with a flexible, lighted scope) to screen for colorectal cancer when HNPCC mutations are present, beginning at age 20 or upon identification of the mutations. Such screening permits the early detection and removal of the intestinal polyps that are the preliminary foundation for colorectal cancer. Polyps tend to progress to malignancy much faster in people who have genetic predisposition to colorectal cancer. Such aggressive screening has good potential for preventing colorectal cancer. GENETIC TESTING is important as well.

See also ADENOMA-TO-ADENOCARCINOMA TRANSITION; CANCER PREVENTION; CANCER RISK FACTORS; CELL STRUCTURE AND FUNCTION; FAMILIAL ADENOMATOUS POLYPOSIS (FAP); GENETIC DISORDERS; GENETIC TESTING; INHERITANCE PATTERNS; INTESTINAL POLYP.

hiatal hernia A weakening in the DIAPHRAGM, the muscular wall that separates the thoracic cavity (chest) from the abdominal cavity, that allows part of the upper STOMACH to slide upward into the chest. The weakening develops in the natural lapse in the diaphragm's continuity, called the hiatus, that allows the ESOPHAGUS to join the stomach. Hiatal hernia becomes more common with increasing age and often coexists with GASTROESOPHAGEAL REFLUX DISORDER (GERD). Most hiatal hernias do not present symptoms, though the GERD does. The hiatal hernia can worsen the symptoms of GERD by forming a pocket that traps the refluxed gastric contents, intensifying the duration of exposure the esophageal mucosa experiences. Risk factors for hiatal hernia include PREGNANCY (which pressures the diaphragm) and OBESITY.

BARIUM SWALLOW or esophagoscopy (endoscopic examination of the esophagus) can detect the presence of hiatal hernia. Unless there is risk for gastric or esophageal strangulation, in which a portion of the esophagus or stomach becomes pinched off on the thoracic side of the diaphragm, lifestyle modifications such as weight loss and medications to treat associated GERD can successfully manage hiatal hernia. When there is a substantial risk for strangulation, such as with a large hernia, the gastroenterologist may recommend surgery to repair the hernia and prevent strangulation. Gastric or esophageal strangulation, though rare, requires emergency surgery.

See also ACHALASIA; BARRETT'S ESOPHAGUS; ENDOSCOPY; ESOPHAGITIS.

Hirschsprung's disease A CONGENITAL ANOMALY, also called congenital megacolon, in which the nerves that supply the lower COLON, typically the sigmoid colon and RECTUM, are missing. Nerves to the ANUS and anal sphincter are generally intact. The absence of nerves maintains the muscular wall of the lower colon in a state of perpetual contraction, bringing PERISTALSIS to a halt and causing digestive waste to accumulate. These events create pressure in the preceding segments of the colon, causing it to greatly dilate (megacolon). Untreated, this dilation results in TOXIC MEGACOLON, a massive dilation of the colon. Toxic megacolon is a life-threatening emergency that requires immediate surgery.

Symptoms include failure to pass MECONIUM (a newborn's first stool) within 48 hours of birth and ABDOMINAL DISTENTION. Hirschsprung's disease that involves only a short segment of the colon may remain undetected into childhood and even early adulthood, producing primarily symptoms of chronic CONSTIPATION and intermittent abdominal distress. The diagnostic path may include DIGITAL RECTAL EXAMINATION (DRE), abdominal X-rays, ULTRASOUND, or BARIUM ENEMA. Biopsy of the rectal wall confirms the absence of NERVE ganglia.

Treatment is surgery to remove the defective segments of bowel, connecting the ends of healthy bowel to maintain the integrity of the lower intestinal tract. The surgery restores normal bowel motility and function, allowing normal bowel movements. Sometimes the surgery takes place in two operations, the first to remove the defective bowel and the second to reconstruct the colon. A temporary COLOSTOMY allows digestive waste to leave the body during the interim HEALING phase. Most infants who undergo surgical repair before

toxic megacolon develops heal completely and without residual complications. Hirschsprung's disease often coexists with other congenital anomalies, notably DOWN SYNDROME.

See also GENE; INHERITANCE PATTERNS.

H2 antagonist (blocker) medications Medications that block molecular structures called histamine 2 receptors in the lining of the STOMACH. Histamines are chemicals called mediators that stimulate specific cells. Cells within the stomach's lining, called enterochromaffin-like (ECL) cells, release HISTAMINE in response to the digestive HORMONE gastrin. The histamine binds with H2 receptors on the parietal cells in the stomach. This binding stimulates the parietal cells to release hydrochloric acid into the stomach. H2 antagonists, or blockers, bind with the H2 receptors as well, blocking them from binding with endogenous histamine 2. The result is a decrease in acid production.

Other histamines are involved in different body functions. Histamine 1 (H1) stimulates smooth MUSCLE contraction and IMMUNE RESPONSE. H1 is familiar for its role in allergic response. Histamine 3 (H3) has NEUROTRANSMITTER activity. Histamine receptors are primarily unique; only H1 receptors accept histamine 1, only H2 receptors accept histamine 2, and only H3 receptors accept histamine 3. The ANTIHISTAMINE MEDICATIONS to relieve allergy symptoms have no effect on gastric acid production. Similarly, the H2 blockers have no effect on allergies.

Doctors may prescribe H2 blockers to treat GASTROESOPHAGEAL REFLUX DISORDER (GERD), PEPTIC ULCER DISEASE, chronic GASTRITIS, Crohn's disease that involves the stomach and ESOPHAGUS, HIATAL HERNIA, and other conditions in which excessive gastric acid causes symptoms or tissue damage. The four H2 blockers used in the United States are available in over-the-counter (OTC) and prescription strengths.

COMMON H2 BLOCKERS

H2 Blocker	Prescription Strength	OTC Strength
cimetidine (Tagamet)	200mg, 300mg, 400mg, 800mg	100mg
famotidine (Pepcid)	20mg, 40mg	10mg
nizatidine (Axid)	150mg, 300mg	75mg
ranitidine (Zantac)	150mg, 300mg	75mg

H2 blockers, most notably cimetidine, interact with numerous other medications. ANTACIDS prevent the stomach from absorbing H2 blockers, significantly reducing the effectiveness of the H2 blocker. Side effects of H2 blockers may include dizziness, HEADACHE, and DIARRHEA. Changing to a different H2 blocker medication often resolves any side effects.

I–K

icterus See JAUNDICE.

ileoanal reservoir An operation to connect the ILEUM, the final segment of the SMALL INTESTINE, directly with the anal canal (a short tract immediately before the ANUS) as an alternative to ILEOSTOMY when it is necessary to remove the entire COLON. The surgery may take place in one OPERATION or, more commonly, in two operations. First the surgeon removes the colon, leaving the anal canal, anus, and surrounding muscles intact. Then the surgeon uses the last 18 to 20 inches of the ileum to structure a pouch that replaces the RECTUM, and attaches it to the anal canal. The front end of the ileum remains as part of the small intestine. To allow these changes to heal the surgeon creates a temporary ileostomy, cutting the ileum and bringing the open end through an opening (stoma) in the abdominal wall. The ileostomy allows digestive waste, which, coming from the small intestine is fairly watery, to empty outside the body. When the ileoanal reservoir has healed, the surgeon performs a second operation to reconnect the ends of the ileum within the abdominal cavity and close the ileostomy.

With ileoanal reservoir the person retains control of the anal sphincter and has bowel movements, though stools are soft and bowel movements more frequent (7 to 10 per day). Bulking agents such as methylcellulose (Citrucel) or psyllium (Metamucil) help to solidify the stool. Foods that add bulk to the stool include bananas and rice. Risks of ileoanal reservoir include chronic INFECTION of the pouch, FECAL INCONTINENCE and stool leakage, and the need to make dietary changes (such as cutting out CAFFEINE and milk, which often cause diarrhea). Most people who undergo ileoanal reservoir surgery return to a satisfactory QUALITY OF LIFE.

See also COLOSTOMY; FAMILIAL ADENOMATOUS POLYPOSIS; INFLAMMATORY BOWEL DISEASE (IBD).

ileostomy An OPERATION in which the surgeon brings the end of the ILEUM, the final segment of the SMALL INTESTINE, through the abdominal wall to exit outside the body. A pouch fastens with adhesive to the SKIN around the ileostomal opening, or stoma, to collect digestive waste. The waste is significantly more watery than stool.

An ileostomy is necessary after total bowel resection (removal of the COLON and RECTUM) such as to treat COLON CANCER, and may be temporary or permanent. An ileostomy is temporary when the surgeon can construct an ileoanal reservoir and permanent when this is not a viable option. A variation on an ileostomy that eliminates the need for ostomy bags is the continent ileostomy, in which the surgeon creates a collection pouch from a section of the ileum that remains inside the abdominal cavity. The surgeon sutures a valve in place that exits through the stoma. Periodically the person opens the valve to allow digestive waste to exit.

Many people find the adjustment to an ileostomy challenging. It represents a significant change to the body's appearance and function. The ileostomy, however, need not interfere with the regular activities of life including athletic pursuits, job and career, and sexual activity. An ostomy-care specialist, usually a registered nurse, will provide education about caring for the ileostomy.

See also COLOSTOMY.

ileum The third, final, and longest segment of the SMALL INTESTINE. About 10 feet in length, the

ileum extends from the JEJUNUM to the CECUM. The ileum absorbs fats and fat-soluble vitamins as well as other remaining NUTRIENTS from the digestive content, which it then passes through the ileocecal valve into the cecum (the first segment of the COLON). Like the other segments of the small intestine, the ileum's walls contain extensive villi (fingerlike projections) that expand its surface area to increase its ability to absorb nutrients.

CONDITIONS THAT CAN AFFECT THE ILEUM

Crohn's disease	ILEUS
INTESTINAL ADHESIONS	LYMPHOMA
MALABSORPTION	SHORT BOWEL SYNDROME

For further discussion of the ileum and the small intestine within the context of gastrointestinal structure and function, please see the overview section "The Gastrointestinal System."

See also DUODENUM; ILEOANAL RESERVOIR; ILEOSTOMY; MINERALS AND HEALTH; VITAMINS AND HEALTH; NUTRITIONAL NEEDS.

ileus An obstruction or blockage of the intestinal tract. Ileus is potentially life-threatening and may require emergency surgery. Common causes include

- INTESTINAL ADHESIONS
- tumors (benign or malignant)
- swallowed objects
- severe FECAL IMPACTION
- a BEZOAR that moves into the intestinal tract from the STOMACH

Symptoms include ABDOMINAL PAIN, VOMITING, DIARRHEA, and failure to have bowel movements. Typically BOWEL SOUNDS are absent in the intestinal tract beyond the obstruction, and the abdomen is rigid. The diagnostic path may include abdominal X-RAY, ULTRASOUND, or laparoscopic surgery. Treatment is nearly always surgery to remove the obstruction, often laparoscopic though sometimes OPEN SURGERY is necessary. Delays in surgery can result in tissue necrosis (death), requiring the surgeon to reconstruct a portion of the bowel and increasing the risk of INFECTION.

See also APPENDICITIS; BOWEL MOVEMENT; INTUSSUSCEPTION; MINIMALLY INVASIVE SURGERY; PERITONITIS.

indigestion See DYSPEPSIA.

inflammatory bowel disease (IBD) A chronic disorder in which INFLAMMATION develops along segments of the gastrointestinal tract. There are two forms of IBD, Crohn's disease and ulcerative colitis. Crohn's disease can affect any portion of the intestinal tract though most commonly involves the lower SMALL INTESTINE and upper COLON. Ulcerative colitis affects the colon including the RECTUM. Doctors and researchers believe IBD is an autoimmune disorder in which the IMMUNE SYSTEM may create antibodies that attack the intestinal mucosa (mucus lining of the intestinal walls). Researchers have detected several GENE mutations that correlate to Crohn's disease, and both Crohn's disease and ulcerative colitis have strong familial tendencies. Doctors consider the two conditions collectively because the disease processes, symptoms, and treatments overlap, though each condition has unique clinical features.

Symptoms and Diagnostic Path

Both forms of IBD generate ulcerative sores in the intestinal mucosa that cause irritation and inflammation. The resulting symptoms may include

- DIARRHEA, often bloody when IBD involves the colon
- rectal bleeding
- ABDOMINAL PAIN, sometimes intense
- unintended weight loss
- fatigue
- FEVER

The inflammation and bleeding typically result in ANEMIA, which is one reason for the fatigue. Other systemic changes related to the autoimmune disease process further contribute to fatigue. Alternating periods of symptoms and REMISSION characterize IBD. When IBD is in remission, gastrointestinal function is normal. When the disease is active, often referred to as an "attack," the severity of symptoms may range from manageable to debilitating.

The symptoms typical with IBD also are common with many gastrointestinal disorders. Determining the diagnosis requires a careful history of the pattern of symptoms, thorough physical examination, laboratory tests to look for markers of inflammation and autoimmune activity in the blood and in the stool, and imaging procedures to detect ulcerations and changes in the intestinal mucosa.

BARIUM SWALLOW with small bowel follow-through, in which the radiologist takes additional X-rays to follow the flow of barium as it leaves the STOMACH and passes through the small intestine, can visualize the ulcers and strictures (narrowed areas) that characterize Crohn's disease when it involves the small intestine. Sigmoidoscopy allows visual exploration of the lower colon, the site of ulcerative colitis. Esophagogastroduodenoscopy (EGD) may reveal involvement of the upper gastrointestinal tract in Crohn's disease.

These procedures help rule out other conditions as much as to confirm IBD. Doctors typically withhold these procedures during active flares of disease, however, to avoid further irritating the intestinal mucosa and because the inflamed mucosa presents an increased risk for inadvertent complications such as bowel perforation.

CLINICAL FEATURES OF IBD

Crohn's Disease	Ulcerative Colitis
"skip" pattern of intestinal involvement	continuous intestinal involvement
can affect any part of gastrointestinal tract	affects only the COLON, starts with the RECTUM
infiltrates multiple layers of mucosa	involves only the surface layer of mucosa
right lower abdominal mass	

Treatment Options and Outlook

Most people achieve relief from IBD symptoms through medications that suppress the immune response or target gastrointestinal function. Treatment protocols draw from various classifications of medications to address acute (active disease) and maintenance (remission) levels of care. Among them are ANTIDIARRHEAL MEDICATIONS, anticholinergic medications, 5-AMINOSALICYLATE (5-ASA) MEDICATIONS, CORTICOSTEROID MEDICATIONS, IMMUNOSUPPRESSIVE MEDICATIONS, ANTIBIOTIC MEDICATIONS, and MONOCLONAL ANTIBODIES (MABS). While antibiotics treat enteric infections and abscesses that develop in the inflamed intestinal mucosa, they also seem to reduce complications and result in overall improvement of symptoms.

All of these medications have significant side effects. Because IBD is dynamic and unpredictable in its cycles of symptoms and remission, finding the most effective therapeutic balance remains a challenge. Medication regimens are highly individualized. As research progresses, new medications and treatment options enter the mix.

Surgery to remove the affected portion of the bowel becomes a treatment option to consider when damage to the intestine becomes extensive or symptoms no longer respond to medical treatments. For ulcerative colitis, surgery typically ends the disease process though the amount and location of bowel removed may have functional consequences, including colectomy (surgery to remove part or all of the colon). For Crohn's disease, surgery provides long-term relief though the disease may resurface or progress to involve remaining portions of the gastrointestinal tract.

Lifestyle is an important dimension of IBD not so much for its influence on the course of the disease but rather a result of IBD's influence on lifestyle. IBD is a long-term disorder for which, at present, there is no cure. The unpredictable nature of IBD's cycles and potential severity of attacks make it difficult for those who have it to stray far from its presence. Treatments attempt to manage symptoms for optimal QUALITY OF LIFE across the spectrum of the disease. During periods of remission most people who have IBD are able to participate fully in the activities they enjoy. During periods of active disease, many people find it difficult to maintain regular activities.

Complications associated with IBD are numerous, arising both from the disease and from its treatments. Autoimmune arthritis, notably ANKYLOSING SPONDYLITIS, often develops. Common with long-standing ulcerative colitis are the EYE infections EPISCLERITIS and UVEITIS, the biliary disorder sclerosing cholangitis, and significantly increased risk for COLORECTAL CANCER. Doctors recommend annual screening colonoscopy for people who have IBD with involvement of the colon or rectum beginning 8 to 10 years after diagnosis or earlier

COMMON IBD MEDICATIONS

Drug	Actions
5-aminosalicylates (5-ASAs)	local anti-inflammatory
balsalazide (Colazal)	oral products coated to dissolve in the SMALL INTESTINE or COLON
Canasa suppository	
mesalamine (Asacol, Pentasa)	
olsalazine (Dipentum)	
Rowasa ENEMA	
sulfasalazine (Azulfidine)	
anticholinergics	slow intestinal motility to reduce DIARRHEA
atropine	systemic action
dicyclomine (Bentyl)	
antidiarrheals	slow intestinal motility to reduce diarrhea
loperamide (Imodium)	gastrointestinal action
diphenoxylate (Lomotil)	
antibiotics	treat gastrointestinal INFECTION and abscesses
metronidazole (Flagyl)	
ciprofloxacin (Cipro)	
corticosteroids	systemic anti-inflammatory
budesonide (Encort-EC)	available for intravenous, oral, or rectal administration
hydrocortisone (Hydrocort)	
hydrocortisone enema (Cortenema)	
prednisone	
prednisolone	
immunosuppressives	decrease immune activity
azathioprine (Imuran)	
methotrexate (Amethopterin)	
6-mercaptopurine (Purinethol)	
MONOCLONAL ANTIBODIES (MABS)	blocks action of TUMOR NECROSIS FACTOR (TNFS), which reduces INFLAMMATION
infliximab (Remicade)	

when other risk factors exist. People who have Crohn's disease are particularly susceptible to kidney stones (NEPHROLITHIASIS) and gallstones (cholelithiasis). Abdominal fistulas (abnormal openings between structures), anal fissures, and RECTAL PROLAPSE are also common complications with Crohn's disease. During disease flareups, some people who have IBD develop SKIN conditions.

Risk Factors and Preventive Measures

The most significant risk factor for IBD is family history, and researchers have identified several genes that correspond to the Crohn's disease component of IBD. One in four who has IBD has a first-degree relative (parent, sibling, or child) who also has IBD. There are few other indications for why and how IBD develops, though most doctors believe a combination of factors convene to establish the disease process.

Neither the development nor outbreaks of IBD are preventable. Dietary precautions such as eating small meals and avoiding foods that irritate the gastrointestinal system (such as CAFFEINE, ALCOHOL, and

highly acidic foods) may help maintain overall gastrointestinal health. High-fiber foods often worsen the symptoms of ulcerative colitis and Crohn's disease that involves the colon. People who have IBD generally need NUTRITIONAL SUPPLEMENTS, particularly folic acid (folate) and iron, to offset nutritional deficiencies that result from MALABSORPTION. Smoking exacerbates Crohn's disease. In addition to irritating the gastrointestinal tract, alcohol interacts with many of the medications to treat IBD.

intestinal adhesions Areas of tissue that fuse together when SCAR tissue extends into normal tissue. Intestinal adhesions are most common in people who have had abdominal surgery (particularly multiple operations) though also may form with ENDOMETRIOSIS, INFLAMMATORY BOWEL DISEASE (IBD), CELIAC DISEASE, and other circumstances in which there is damage to the abdominal tissues that generates scar tissue. Intestinal adhesions may cause abdominal discomfort during certain movements or activities or can become extensive enough to create partial or complete intestinal obstruction (ILEUS). Intestinal adhesions that interfere with digestive functions usually require surgery to clear away the scar tissue. Inherent in this treatment approach, however, is the risk for additional intestinal adhesions to form as a result of the scar tissue that develops during HEALING. Most intestinal adhesions do not cause functional problems. Surgeons typically remove any intestinal adhesions that are present whenever they perform other surgeries.

See also SURGERY BENEFIT AND RISK ASSESSMENT.

intestinal obstruction See ILEUS.

intestinal polyp A fleshy growth, also called an intestinal polypoid ADENOMA, that grows from the mucous membrane lining of the COLON or RECTUM. There are two common types of intestinal polyps, neoplastic adenomas and hyperplastic adenomas, both of which grow almost exclusively in the colon. Neoplastic adenomas are neoplastic (abnormal growths that have no purpose or function in the body) and have the potential to turn malignant. Hyperplastic adenomas are not neoplastic and have no malignant potential.

Adenomas of either type arise from the epithelial cells, which make up the surfaces of membranes as well as the SKIN. Epithelial cells continuously renew themselves to replace worn and damaged epithelial tissues. Protein messengers tell healthy cells when to stop growing, containing the structures they form. When this regulatory mechanism goes awry cells continue to grow, forming abnormal structures such as adenomas. Adenomas, in the intestinal tract as well as elsewhere in the body, become more common with increasing age. Various circumstances converge that permit ADENOMA-TO-ADENOCARCINOMA transition. Though only a small percentage of intestinal polyps become cancerous, more than 95 percent of COLORECTAL CANCER evolves from intestinal polyps. Typically this transition takes 5 to 10 years or longer, during which biopsy can detect the changes in the cells (DYSPLASIA). Cancer experts recommend removal of all intestinal polyps to prevent this evolution. COLONOSCOPY is the most common method for detecting and removing intestinal polyps.

See also ACTINIC KERATOSIS; AGING, GASTROINTESTINAL CHANGES THAT OCCUR WITH; CANCER PREVENTION; CANCER RISK FACTORS; FAMILIAL ADENOMATOUS POLYPOSIS (FAP).

intussusception A circumstance in which one portion of the intestine slides over another in telescopic fashion, creating an intestinal obstruction (ILEUS). Intussusception typically occurs in infants between the ages of 3 and 10 months, though can develop in children up to age six years. It is three times more common in boys than girls.

Intussusception is a life-threatening emergency that requires immediate treatment.

Symptoms include waves (paroxysms) of PAIN that at first appear to be colicky. Within 12 hours, however, the course shifts sharply from that of colic. DIARRHEA and VOMITING develop, and pain

becomes continuous. Stools often are watery and bloody, and may contain large quantities of mucus. Though intussusception is more common in children who have CYSTIC FIBROSIS or Meckel's diverticulum, or who experience blunt trauma to the abdomen, there are no certain predisposing factors.

BARIUM ENEMA provides the diagnosis, and, about 75 percent of the time, the treatment as well because the barium causes the bowel to expand back out. When the intussusception persists, the situation requires immediate surgery. Without treatment intussusception rapidly progresses to PERITONITIS and SEPTICEMIA, and usually is fatal. With appropriate treatment, nearly all infants experience full and uneventful recovery with no long-term consequences. Intussusception typically does not recur.

See also DIVERTICULAR DISEASE.

irritable bowel syndrome (IBS) A constellation of symptoms that reflect functional disturbance of the gastrointestinal system. IBS is one of the most common gastrointestinal disorders that cause people to seek medical care, accounting for 10 percent of doctor visits each year. IBS symptoms are episodic and may range from mild to debilitating and typically manifest before age 35 years. IBS affects three times as many men as women.

Symptoms and Diagnostic Path

The hallmark symptoms of IBS are

- ABDOMINAL PAIN that goes away with bowel movements
- a change in the frequency and nature of bowel movements (DIARRHEA or CONSTIPATION that marks a change from usual bowel movements)
- mucus in the stool (mucorrhea)
- ABDOMINAL DISTENTION or sensation of bloating

Periods of exacerbation alternate with periods of REMISSION. In women, exacerbation may accompany other symptoms of PREMENSTRUAL SYNDROME (PMS). Stress, emotional or physical, is a significant catalyst of symptoms for many people who have IBS. The diagnostic path generally includes the gamut of gastrointestinal tests, though diagnosis of IBS relates to the length of time the person has had symptoms and the frequency with which symptoms occur. Current diagnostic guidelines support a diagnosis of IBS when all of these four symptoms persist for longer than three months and doctors cannot detect any underlying pathologic reasons for the gastrointestinal disturbances.

Treatment Options and Outlook

Treatment targets symptoms and may include ANTIDIARRHEAL MEDICATIONS, ANTICHOLINERGIC MEDICATIONS to slow intestinal motility, and certain ANTIDEPRESSANT MEDICATIONS that are successful in relieving symptoms in CHRONIC PAIN syndromes. Several medications specifically to treat IBS are available. There are significant risks and restrictions for some of these medications, and current regulatory and practice standards limit their use to people whose symptoms fail to respond to other treatments and interfere with daily living.

Alosetron (Lotronex) Alosetron specifically targets the neuroreceptors in the COLON to block the passage of NERVE signals that cause the colon to contract. This slows peristalsis only in the colon, increasing the amount of time digestive matter remains in the colon so the colon can absorb more water from it. Alosetron is available only for use in women who have debilitating diarrhea as the primary component of their IBS and under strict guidelines in which the prescribing doctor and the woman must agree to follow. Alosetron is not available for men because there is insufficient evidence of its effectiveness in men; clinical research studies enrolled primarily women. The most significant risks of alosetron are severe constipation that causes bowel obstruction (ILEUS) and ischemic COLITIS (blocked BLOOD flow to the colon that results in INFECTION).

Tegaserod (Zelnorm) Tegaserod mimics the action of serotonin, increasing the response of serotonin neuroreceptors in the intestinal tract. Serotonin is a NEUROTRANSMITTER most commonly recognized for its role in carrying nerve impulses related to emotion in the BRAIN. However, 95 percent of the serotonin in the body is concentrated in the gastrointestinal tract where it facilitates intestinal motility (peristalsis), gastric acid and other gastrointestinal fluid secretions, and the sensitivity of cells in the gastrointestinal tract to register pain. Like alosetron, tegaserod is available only for use in women who have debilitating diarrhea

and presents the risk of ischemic colitis. Tegaserod also can cause severe diarrhea.

Antidepressants Antidepressant medications affect the actions of several neurotransmitters, such as dopamine and serotonin, that play roles both in brain activity related to emotion and in gastrointestinal functions. The tricyclic antidepressants, such as amitriptyline (Elavil) and imipramine (Tofranil), have been instrumental in treating chronic pain syndromes and provide relief from IBS symptoms for some people. Selective serotonin reuptake inhibitor (SSRI) antidepressants, such as paroxetine (Paxil) and fluoxetine (Prozac), seem to have similar effects. These medications also treat the mild to moderate DEPRESSION that commonly accompanies IBS.

Lifestyle There is a strong correlation between episodes of IBS symptoms and stress. Stress management techniques, MEDITATION, guided imagery, BIOFEEDBACK, YOGA, ACUPUNCTURE, and therapeutic counseling are among the methods that can help keep symptoms in remission. Many people can control IBS largely through diet and lifestyle, after they understand the nature of the disorder and learn to recognize the triggers that bring on attacks of symptoms. Helpful dietary and lifestyle changes include

- reduce or eliminate CAFFEINE, which can contribute to diarrhea
- add fiber by eating more fruits, vegetables, and whole grain products, or by taking a fiber supplement such as psyllium (Metamucil) or methylcellulose (Citrucel)
- eliminate foods and beverages that cause intestinal upset (especially foods high in fat)
- maintain healthy weight
- develop a daily process for stress relief that may incorporate exercise, meditation, warm baths, designated quiet time or alone time, or other methods for de-stressing
- note circumstances and situations that appear to precipitate exacerbations of symptoms and work out approaches to mitigate them
- get 30 to 45 minutes of physical exercise, such as walking, daily to improve circulation, MUSCLE tone, and gastrointestinal function as well as to aid in relieving stress

Risk Factors and Prevention Efforts

Unlike many other chronic disorders affecting the gastrointestinal tract, IBS does not cause any damage to gastrointestinal tissue or increase the risk for CANCER. Even during attacks of symptoms, the bowel shows no evidence of INFLAMMATION or disease process. Tests that measure muscle contraction activity, usually performed only in clinical research studies because they have little diagnostic or therapeutic value, show accelerated peristalsis (intestinal motility).

A significant contingent of researchers and doctors believes IBS has a strong psychological component. This derives in part from the difficulty in identifying any organic, or physical, changes in the gastrointestinal tract that account for the symptoms and in part from a high correlation of diagnosed psychological conditions, such as GENERALIZED ANXIETY DISORDER (GAD) and depression, among people who have IBS. As well, a high percentage of people who have IBS have experienced physical or sexual abuse. Though few argue that these correlations exist, disagreement remains as to what the correlations mean in the context of either the psychological disorder or the IBS, especially in regard to treatment options.

One intriguing direction of research is the exploration of neurohormonal processes that handle both psychological and autonomic (involuntary) functions, raising the possibility of crossover between the two. Some clinical research studies have noted similarities in altered brain activity patterns, as detected via imaging procedures such as POSITRON EMISSION TOMOGRAPHY (PET) SCAN in people who have, independently, clinical depression and IBS. Other directions in research focus on gaining improved understanding of intestinal motility mechanisms. Though for some people IBS is a lifelong condition that requires vigilant management, for many others symptoms abate with an appropriate integration of medical and lifestyle interventions.

See also ACUTE STRESS DISORDER; BOWEL MOVEMENT; CELIAC DISEASE; DIET AND HEALTH; DIVERTICULAR DISEASE; FIBROMYALGIA; INFLAMMATORY BOWEL DISEASE (IBD).

jaundice Yellowish discoloration of the SKIN and whites of the eyes, also called icterus, resulting

from high levels of BILIRUBIN in the BLOOD. As well, the URINE may be dark brown or tea-colored and the stools pale, indicating a high concentration of BILE pigments dissolved in the urine and a lack of bile entering the intestinal tract. Intense itching (PRURITIS) often accompanies jaundice, the skin's reaction to the irritation of the bilirubin deposits. Bilirubin is a byproduct of the destruction of erythrocytes (red blood cells). The SPLEEN performs this destruction to rid the body of old erythrocytes that no longer function properly. The liver incorporates bilirubin into bile, which it then secretes into the gastrointestinal tract to aid in digestion as well as to excrete the excess as waste.

Jaundice indicates liver disease or GALLBLADDER DISEASE that interferes with this bilirubin handling, either in the breakdown stage (liver) or the elimination stage (GALLBLADDER). In most people the jaundice goes away with treatment of the underlying condition. Newborns commonly develop a form of jaundice not related to liver dysfunction called NEONATAL JAUNDICE or physiologic jaundice.

See also CHOLESTASIS; CIRRHOSIS; HEPATITIS.

jejunum The middle segment of the SMALL INTESTINE, between the ILEUM and the DUODENUM. The jejunum is six to eight feet long and handles absorption of carbohydrates and proteins, as well as vitamins such as VITAMIN K and minerals such as iron. The jejunum's tissue composition and excellent blood supply allow it to be the source of tissue grafts for reconstruction of the pharynx and upper ESOPHAGUS after radical surgery to treat laryngeal CANCER (cancer of the THROAT). Health conditions that can involve the jejunum include INFLAMMATORY BOWEL DISEASE (IBD), CELIAC DISEASE, and MALABSORPTION disorders.

For further discussion of the jejunum and the small intestine within the context of gastrointestinal structure and function, please see the overview section "The Gastrointestinal System."

See also BOWEL ATRESIA; SHORT BOWEL SYNDROME.

kernicterus See NEONATAL JAUNDICE.

L

laxatives Products to stimulate bowel movements. Laxatives work through various actions. Some help the stool to retain fluid, keeping the stool softer. Some lubricate the walls of the COLON, making it easier for digestive waste to move through the gastrointestinal tract. Others introduce fiber, which adds bulk to the stool as well as retains more fluid in the stool. Stimulant laxatives irritate the walls of the colon to accelerate PERISTALSIS (contractions of the bowel), which moves stool through the bowel. Laxatives intended to completely clear the colon, such as preparation for BARIUM ENEMA or COLONOSCOPY, are sometimes called cathartics or drastics because their actions are fast and intense. Laxatives come in oral (tablets, powders, and liquids) and rectal (suppositories and enemas) preparations. They are available over the counter.

Doctors recommend attempting natural methods to encourage regular bowel movements before using laxatives. The gastrointestinal tract's rhythm correlates to the kinds and amounts of foods ingested, as well as to the frequency of meals. Though many people believe a daily bowel movement is "normal," normal is an individual measure that can range from two or three times daily to once every three days, depending on dietary habits. Using laxatives to structure daily bowel movements interferes with the bowel's natural rhythms. Over time, the bowel becomes "lazy"

COMMON LAXATIVES

Kind of Laxative	Actions	Representative Products
stool softeners	add moisture to the stool	docusate sodium (Colace) docusate calcium (Surfak)
lubricants	lubricate the intestinal walls	glycerin suppositories mineral oil
bulking agents	add fiber to the stool, which increases bulk and draws moisture	bran calcium polycarbophil (FiberCon) methylcellulose (Citrucel) psyllium (Metamucil)
osmotic agents (hyperosmotics)	draw large amounts of fluid into the stool for rapid and thorough evacuation of intestinal contents	lactulose (Cephulac, Duphalac) magnesium citrate sodium citrate
STIMULANTS	irritate the walls of the colon to cause them to contract (PERISTALSIS)	bisacodyl (Dulcolax) casanthranol (Doxidan) senna (Senokot)

and does not contract unless a laxative stimulates it. Laxatives, and particularly suppositories and enemas, also can irritate the intestinal mucosa enough to cause chronic INFLAMMATION.

See also BOWEL MOVEMENT; DIARRHEA; FIBER AND GASTROINTESTINAL HEALTH; NUTRIENTS; NUTRITIONAL NEEDS; ROUTES OF ADMINISTRATION.

liver The largest internal organ in the body. Its soft, spongy tissue spreads like a flattened football between the DIAPHRAGM and the STOMACH, tucked protectively beneath the lower ribs on the right side of the abdomen. Weighing about three and a half pounds, the liver contains 15 percent of the body's blood (about a pint). About 60 percent of this blood is venous and comes from the gastrointestinal tract and SPLEEN, entering the liver via the portal VEIN. The venous blood delivers nutrients that the liver further metabolizes, the products of which it then sends back into the bloodstream. The hepatic ARTERY, which branches directly from the abdominal AORTA, delivers oxygenated blood to the liver to fuel the functions of its cells. On the underside of the liver is the GALLBLADDER, which concentrates and stores the BILE the liver produces.

The liver's two main lobes, the small left lobe and the large right lobe, support an intricate network of lobules, thousands of tiny communities of hepatocytes (the cells that carry out the liver's functions) that filter NUTRIENTS, wastes, BACTERIA, and toxins from the blood. The microscopic spaces between the lobules are the sinusoids, into which the blood from the portal vein drains. Each lobule is a hexagonal structure two layers of cells deep and several cells horizontally and vertically in a platelike configuration. At the vertical junctions of the lobules are the portal triads, each containing three microscopic structures: a venule, an arteriole, and a bile duct. The portal triads collect the substances the lobules produce and convey them to the larger vessels that will carry them out to the structures of the body. The membranous connective tissue that envelopes the liver also extends like a web through the liver, providing a supportive structure for the lobules, sinusoids, and portal triads.

The lobules are the work stations of the liver. They metabolize nutrients and toxins, and synthesize (manufacture) numerous substances including amino acids, proteins essential for PLASMA production, lipoproteins, cholesterol, immune factors, CLOTTING FACTORS, LYMPH, and bile. The lobules convert GLUCOSE to glycogen, a storage form of glucose the body can draw from when blood levels of glucose fall, and glycogen back to glucose, processes that integrate closely with the balance of glucose and INSULIN in the blood. The lobules also deconstruct old erythrocytes (red blood cells) to recycle the iron and BILIRUBIN they contain. Specialized phagocytic ("cell eating") cells, called Kupffer cells, reside in the sinusoids to consume bacteria and cellular waste. The liver stores iron, glycogen, vitamin A and vitamin B_{12}, and other chemicals the body needs for cellular activities. The liver is unique among the body's organs in its ability to regenerate itself. This extraordinary capacity speaks to the significant extent of damage that must take place to permanently destroy liver tissue. Even so, the liver can meet the needs of the body as long as 25 percent of its cells remain functional.

COMMON CONDITIONS THAT CAN AFFECT THE LIVER

BILIARY ATRESIA	CHOLESTASIS
CIRRHOSIS	DIABETES
HEPATIC ABSCESS	HEPATIC CYST
HEPATITIS	LIVER CANCER
LIVER DISEASE OF ALCOHOLISM	PANCREATITIS
PORTAL HYPERTENSION	PRIMARY BILIARY CIRRHOSIS
PRIMARY SCLEROSING CHOLANGITIS	STEATOHEPATITIS

For further discussion of the liver within the context of gastrointestinal structure and function, please see the overview section "The Gastrointestinal System."

See also BILE DUCTS; ESOPHAGEAL VARICES; HEPATOMEGALY; HEPATOTOXINS; JAUNDICE; LIVER FAILURE; LIVER FUNCTION TESTS; LIVER TRANSPLANTATION; NUTRITIONAL NEEDS; VITAMINS AND HEALTH.

liver cancer Malignant growths in the LIVER. Liver CANCER may be primary (originates in the liver) or secondary (metastasizes, or spreads, from other locations in the body). Primary liver cancer is less common than metastatic liver cancer. Most primary liver cancer develops as a complication of chronic HEPATITIS B or hepatitis C INFECTION, conditions that repeatedly damage liver tissue, and

arises from the liver's workhorse cells, the hepatocytes. Hepatocytes continually regenerate; researchers believe the continued replication of the hepatitis VIRUS eventually creates changes in the processes of regeneration (cellular DNA alterations) that cause hepatocyte growth to become uncontrolled. Primary liver cancer is rare in people who have otherwise healthy livers. Because of its rich BLOOD supply and numerous functions related to blood filtration, the liver is a common site for metastatic cancers.

Symptoms and Diagnostic Path

Liver cancer typically does not present symptoms until the cancer is quite advanced, and even then symptoms often are vague. Such symptoms might include upper ABDOMINAL PAIN, ASCITES (fluid accumulation in the abdominal cavity), NAUSEA, lack of APPETITE, and JAUNDICE. The diagnostic path typically includes blood tests to assess liver function and hepatitis status, abdominal ULTRASOUND or COMPUTED TOMOGRAPHY (CT) SCAN, and PERCUTANEOUS LIVER BIOPSY.

Some doctors advocate regular testing to measure blood levels of ALPHA FETOPROTEIN (AFP), a protein that many liver tumors produce, in people who are at high risk for developing liver cancer (such as those who have chronic hepatitis or severe CIRRHOSIS). However, there is no consensus within the medical community as to the effectiveness of AFP screening for those not at high risk because numerous factors cause erroneous test results.

Treatment Options and Outlook

Treatment for liver cancer depends on whether the cancer is primary or secondary. Treatment for secondary liver cancer is generally palliative, aiming to relieve symptoms such as PAIN. For primary liver cancer, surgical removal of the tumor is the preferred option. However, people who have longstanding cirrhosis may have too much damage for the liver to remain functional after surgery. Large or multiple tumors also are difficult to remove without causing substantial damage to the remaining liver tissue. The surgeon may use RADIOFREQUENCY ABLATION or chemical ablation to kill tumor cells without removing the tumor; this is primarily a palliative treatment. LIVER TRANSPLANTATION is occasionally an option when the liver cancer is primary, small, and well contained.

Conventional external-beam RADIATION THERAPY often is not very successful in altering the course of liver cancer to increase survival, though it can shrink liver tumors to relieve pain and other symptoms. A precise technique for targeting liver tumors with radiation, three-dimensional conformal radiation therapy (3DCRT), shows promise for improving the therapeutic value of radiation therapy in liver cancer. Similarly, conventional CHEMOTHERAPY is not very effective against liver cancer, though in some people directly infusing chemotherapy agents into the hepatic ARTERY, called hepatic artery infusion (HAI) chemotherapy, has therapeutic benefit.

Because liver cancer tends to be either well advanced or metastatic at the time of its diagnosis, the overall outlook remains among the least positive despite the numerous advances in cancer treatments overall. The five-year survival rate, the standard measure for cancer treatment success, is about 30 percent when surgery can remove the tumor and about 5 percent when surgery is not a viable treatment option. Prevention efforts offer the greatest opportunity for defeating liver cancer.

RISK FACTORS FOR LIVER CANCER

anabolic steroid use	chronic arsenic exposure
chronic hepatitis B infection	chronic HEPATITIS C INFECTION
CIRRHOSIS	HEMOCHROMATOSIS
LIVER DISEASE OF ALCOHOLISM	smoking and ALCOHOL abuse in combination
vinyl chloride exposure	
WILSON'S DISEASE	

Risk Factors and Preventive Measures

The most significant risk factor for liver cancer is infection with chronic hepatitis B or hepatitis C. Other circumstances that increase risk include cirrhosis, LIVER DISEASE OF ALCOHOLISM, exposure to hepatotoxic chemicals (especially arsenic, which remains a contaminant in water supplies throughout the United States as a result of past industrial waste practices, and the industrial chemical vinyl chloride), and smoking in combination with ALCOHOL abuse.

The single most important preventive measure for liver cancer is hepatitis vaccination to prevent

hepatitis B infection and appropriate measures to limit exposure to hepatitis C. People who already have chronic hepatitis, cirrhosis, or other conditions that increase the risk for liver cancer, the herb MILK THISTLE (silymarin) may help protect the liver from further damage. Other preventive measures include avoiding circumstances associated with liver cancer, notably excessive alcohol consumption. Though the number of people who develop primary liver cancer is rising, it remains less common than metastatic (secondary) liver cancer.

liver disease of alcoholism Permanent damage to the LIVER that results from long-term, excessive ALCOHOL consumption. Alcohol is one of the most toxic substances ingested into the body. It enters the bloodstream unchanged, about 20 percent absorbed from the STOMACH and 80 percent from the SMALL INTESTINE. The liver must filter alcohol from the blood, a process that certain enzymes in the liver regulate. The enzymes limit the amount of alcohol the liver can extract, allowing alcohol to accumulate in the bloodstream.

The first of these enzymes, alcohol dehydrogenase (ADH), converts the alcohol into acetaldehyde. Acetaldehyde gives the breath of a person who has been drinking alcohol its characteristic odor. It is also a toxin, available as an industrial chemical for numerous manufacturing uses such as a solvent, hardener, and preservative. The second of these enzymes, aldehyde dehydrogenase, facilitates acetaldehyde's break down into acetic acid (the same acid found in vinegar) and acetylcoenzyme A. These substances are less toxic than acetaldehyde. Though aldehyde dehydrogenase works rapidly, it cannot convert all of the aldehyde before this toxic chemical causes the deaths of hepatocytes. Other enzymes in the liver further metabolize the acetic acid and acetate into GLUCOSE (energy) and carbon dioxide (waste).

With repeated exposure to acetaldehyde, structural changes take place in the liver. The first of these is the accumulation of fat in the liver. The liver must direct nearly its full efforts to metabolize alcohol, in the effort to protect itself from the alcohol's toxic effects. As a consequence other metabolic functions in the liver slow, altering carbohydrate and lipid (fat) METABOLISM. The liver can metabolize alcohol at the rate of about 15 grams per hour, a pace that results in minimal hepatocytic damage. Alcohol consumption that exceeds this rate (equivalent to 1 ounce of 100-proof distilled spirits, one 12-ounce beer, or 4 ounces of wine) maintains alcohol circulation in the bloodstream until the liver can accommodate its metabolism. Repeated excessive alcohol consumption characteristically results in three liver disorders, which may exist singly or collectively.

Alcoholic hepatitis The HEPATITIS of ALCOHOLISM, also called Laennec's hepatitis, occurs when the repeated irritation of alcohol results in INFLAMMATION of the liver. When the flow of alcohol through the liver stops, symptoms abate and hepatocytes (the primary working cells of the liver) regenerate. Within a few months of alcohol cessation, the liver can restore itself to a normal level of function.

Alcoholic steatohepatitis Acetylcoenzyme A, one of the products of alcohol metabolism, interferes with the liver's synthesis and storage of fatty acids such that fatty tissue accumulates in the liver. Alcoholic STEATOHEPATITIS improves when the liver's metabolism of alcohol stops, and liver structure can return to normal with alcohol cessation.

Alcoholic cirrhosis Alcoholic CIRRHOSIS is a condition in which repeated INFLAMMATION (hepatitis) causes SCAR tissue to form and replace hepatocytes. As is the case with cirrhosis resulting from any cause, damage that has already occurred to the liver is not reversible. However, alcohol cessation halts the progression of cirrhosis to limit further damage.

Symptoms and Diagnostic Path

The symptoms of alcoholic liver disease are much the same as those of nonalcoholic liver disease and include JAUNDICE (yellowish discoloration of the SKIN), right upper ABDOMINAL PAIN, ASCITES (fluid accumulation in the abdominal cavity), NAUSEA, loss of APPETITE, and FATIGUE. The diagnostic path begins with LIVER FUNCTION TESTS and a thorough assessment of drinking habits. Additional diagnos-

tic procedures might include abdominal ULTRASOUND, COMPUTED TOMOGRAPHY (CT) SCAN, or PERCUTANEOUS LIVER BIOPSY.

Treatment Options and Outlook

Treatment is alcohol cessation and support for symptoms. The doctor may recommend an alcohol and SUBSTANCE ABUSE TREATMENT PROGRAM, counseling, 12-step program such as Alcoholics Anonymous, and other efforts to help maintain SOBRIETY. When liver disease of alcoholism reaches end-stage LIVER FAILURE, LIVER TRANSPLANTATION may be an option for a person who has maintained sobriety for at least six months and has a reasonable expectation of doing so following the liver transplantation. Though liver disease of alcoholism continues if alcohol consumption resumes, with alcohol abstinence the manifestations of liver disease are generally reversible (except cirrhosis).

Risk Factors and Preventive Measures

Chronic alcohol use is the only cause of liver disease of alcoholism. Though most often the use is excessive, alcohol-related damage can occur to the liver with moderate alcohol consumption that extends over a long period of time. Alcoholic steatohepatitis can develop in a person who consumes as few as four alcoholic drinks a week. The only, and absolute, preventive measure is abstinence from alcohol.

See also ENCEPHALOPATHY; HEPATOTOXINS.

liver failure The inability of the LIVER to function. Liver failure may be acute (comes on suddenly) or chronic (develops over time). Because the liver has the unique ability to regenerate, the damage it takes to cause liver failure is substantial. Liver failure generally occurs when more than 75 percent of the liver's hepatocytes, the cells that carry out most of the liver's functions, die, a circumstance called hepatocellular necrosis. LIVER TRANSPLANTATION is the only curative treatment for permanent liver failure.

The most common causes of hepatocellular necrosis leading to liver failure are

- ALCOHOL
- acetaminophen and especially acetaminophen OVERDOSE
- *Amanita* mushroom ingestion
- the illicit DRUG ecstasy (MDMA)
- isoniazid and rifampin in combination to treat TUBERCULOSIS
- industrial chemicals such as arsenic, phosphorus, carbon tetrachloride, and vinyl chloride
- disease processes

Hepatocellular necrosis is a SIDE EFFECT possible with numerous prescription medications, notably certain ANTIBIOTIC MEDICATIONS, "statin" lipid-lowering medications, and tricyclic ANTIDEPRESSANT MEDICATIONS. In some circumstances prompt medical intervention, such as with known overdose of drugs, can slow or halt hepatocellular necrosis and prevent liver failure, though liver damage may still occur. Such interventions might include aggressive medical efforts to remove or neutralize the responsible drug, administration of acetylcysteine for acetaminophen overdose, and liver hemodialysis (though this is of limited availability). In many circumstances, however, the destructive action of the toxin or the inflammatory process overwhelms the liver and attempted medical interventions have little effect.

CONDITIONS THAT CAN CAUSE LIVER FAILURE

BILIARY ATRESIA	chronic HEPATITIS
CIRRHOSIS	HEAT STROKE
HEMATOCHROMATOSIS	HEMORRHAGIC FEVER
LIVER CANCER	LIVER DISEASE OF ALCOHOLISM
PORTAL HYPERTENSION	PRIMARY BILIARY CIRRHOSIS
PRIMARY SCLEROSING CHOLANGITIS	REYE'S SYNDROME
secondary AMYLOIDOSIS	WILSON'S DISEASE

Acute liver failure Acute liver failure, also called fulminant HEPATITIS, develops in days to weeks. It nearly always follows a significant assault to the liver, such as drug overdose or severe trauma (such as gunshot wound) that destroys liver tissue. Hepatitis A INFECTION also can cause acute liver failure. Recovery without liver transplantation is uncommon and is most likely to occur with hepatitis A infection (about 50 percent recovery rate) and promptly treated acetaminophen toxicity.

Chronic liver failure Chronic liver failure, also called nonfulminant hepatitis, develops over

months. Repeated attacks of INFLAMMATION progressively kill hepatocytes until the level of hepatocytic function falls below 25 percent. In many situations a culminating event, such as a flare of hepatitis or an episode of acute alcohol INTOXICATION, pushes the liver across the boundary. CIRRHOSIS is the leading cause of chronic liver failure. Chronic liver failure without liver transplantation is fatal.

Symptoms and Diagnostic Path

People who are in liver failure are very ill. The most prominent symptoms are severe JAUNDICE (yellowish discoloration of the SKIN) and disturbances of cognitive and BRAIN functions, ranging from CONFUSION and HALLUCINATION to COMA, known collectively as hepatic ENCEPHALOPATHY. Neurologic signs that accompany these symptoms include disturbances of reflexes, tremors, and myotonus (MUSCLE spasms and rigidity). Evidence of clotting dysfunction, such as bruising and frank bleeding (internal or external), is also often present as the liver synthesizes many of the proteins and CLOTTING FACTORS necessary for COAGULATION. The diagnostic path includes LIVER FUNCTION TESTS that measure the levels of liver enzymes in the blood, toxicology screens to detect the presence of chemicals in the blood, and imaging procedures of the liver and the brain such as ULTRASOUND, COMPUTED TOMOGRAPHY (CT) SCAN, and MAGNETIC RESONANCE IMAGING (MRI).

ALCOHOL AND ACETAMINOPHEN: A DANGEROUS COMBINATION

Regular ALCOHOL consumption, even as little as one drink a day, depletes the LIVER's supply of glutathione, an amino acid compound essential for metabolizing toxins. Insufficient glutathione exposes the liver to rapid hepatocellular necrosis, with resulting acute liver failure. People who drink regularly can experience acetaminophen OVERDOSE with as little as 4 grams of acetaminophen a day for three or four consecutive days, an amount that is well within the therapeutic dosage range.

Treatment Options and Outlook

Treatment options for liver failure are primarily supportive. Some people benefit from novel approaches such as liver hemodialysis, which filters the blood similarly to renal dialysis (renal dialysis cannot remove the same substances from the blood), though such methods remain limited to major medical centers. Liver transplantation remains the only viable treatment for permanent liver failure, and the need for donor livers far outpaces the availability of donor organs. In some situations living donor liver segment transplantation, in which a living person donates a segment of his or her liver, is an alternative to cadaver donor liver transplantation.

Risk Factors and Preventive Measures

Chronic hepatitis infection and cirrhosis due to alcoholism are the leading risks for liver failure. Vaccination can prevent much, though not all, hepatitis. Drinking cessation can end the progression of cirrhosis, though damage already done is permanent.

See also ANALGESIC MEDICATIONS; COGNITIVE FUNCTION AND DYSFUNCTION; HEPATOTOXINS; ORGAN TRANSPLANTATION; REFLEX.

liver function tests A panel of BLOOD tests that measures the levels of ALBUMIN, BILIRUBIN, and certain LIVER enzymes in the blood. More specifically targeted tests further identify the reasons for abnormal results, as the findings may also indicate dysfunctions of other organs.

Reasons for Doing This Test

Liver function tests provide a general assessment of how effectively the liver is performing its metabolic tasks. They also allow the doctor to monitor the progression of liver disease and the effectiveness of treatment.

Albumin The liver synthesizes (produces) the key amino acids that make up albumin, the primary protein in blood PLASMA. Albumin transports numerous substances—including other proteins, NUTRIENTS, and hormones—through the blood. When albumin levels are low the blood cannot carry these substances, which has a variety of consequences throughout the body. Many liver conditions cause ASCITES (abdominal edema), in which a deficiency of albumin in the plasma allows plasma to seep across cell membranes to accumulate in the abdominal cavity. Decreased blood albumin

levels suggest liver dysfunction. The normal range of serum albumin is 3.4 to 5.4 grams per deciliter (g/dL).

Bilirubin One key function of the liver is to complete the break down of old erythrocytes (red blood cells) to recycle their ingredients for other uses in the body. The SPLEEN initiates this process, splitting the HEMOGLOBIN erythrocytes contain into its core proteins, heme and globin, and extracting the pigment bilirubin from the heme. Bilirubin is a waste product that the liver chemically alters to use in synthesizing BILE. The chemically processed bilirubin is conjugated or direct bilirubin; bilirubin that circulates in the blood is unconjugated or indirect bilirubin.

A healthy liver excretes most of the conjugated bilirubin it produces in the bile. A damaged liver cannot keep up the pace of bile production, allowing conjugated bilirubin to escape into the blood. Elevated circulation of conjugated, or direct, bilirubin suggests liver or GALLBLADDER dysfunction. The normal range of serum direct bilirubin is 0.0 to 0.4 milligrams per deciliter (mg/dL).

Enzymes Enzymes are catalytic substances that expedite chemical processes within the liver. In a healthy liver enzymes remain within the lobules, the working communities of hepatocytes. Hepatocytic damage results in enzymes leaking from the cells and spilling out into the blood. The commonly measured liver enzymes are

- the aminotransferases (also called transaminases), which catalyze amino acid METABOLISM—for example, aspartate aminotransferase (AST), also called serum glutamic oxaloacetic transaminase (SGOT), and alanine aminotransferase (ALT), also called serum glutamic pyruvic transaminase (SGPT)

LIVER FUNCTION BLOOD TESTS

Blood Test	Normal Values	Liver Implications of Abnormal Findings
ALBUMIN	3.4 to 5.4 grams per deciliter (g/dL)	decreased level may suggest hepatocellular necrosis, HEPATITIS, CIRRHOSIS
alkaline phosphatase (ALP)	44 to 147 International Units per liter (IU/L)	elevated level may suggest hepatitis, cirrhosis, biliary obstruction, LIVER DISEASE OF ALCOHOLISM
alanine aminotransferase (ALT)/serum glutamic pyruvic transaminase (SGPT)	20 to 125 IU/L	elevated level may suggest hepatocellular necrosis, hepatitis, cirrhosis, HEPATOTOXINS
aspartate aminotransferase (AST)/serum glutamic oxaloacetic transaminase (SGOT)	10 to 34 IU/L	elevated level may suggest hepatocellular necrosis, hepatitis, cirrhosis, LIVER CANCER, liver disease of alcoholism
direct BILIRUBIN	0.0 to 0.4 g/dL	elevated level may suggest hepatitis, cirrhosis, biliary obstruction, gallstones, GALLBLADDER DISEASE, CHOLESTASIS
gamma-glutamyltranspeptidase (GGT)	0 to 51 IU/L	elevated level may suggest hepatitis, cirrhosis, liver cancer, cholestasis, hepatocellular necrosis, hepatotoxins
prothrombin time (PT)	11 to 13.5 seconds	delayed time may suggest hepatitis, cirrhosis, gallstones, biliary occlusion

- alkaline phosphatase (ALP), which also goes up in biliary obstruction (blockage of the flow of BILE)
- gamma-glutamyltranspeptidase (GGT)

Collectively elevated levels of these enzymes in the blood indicate damage to the liver that has caused the death of hepatocytes (hepatocellular necrosis). Individual elevations may indicate damage to other tissues in the body such as might occur in the HEART with HEART ATTACK. The AST to ALT ratio is also significant; a ratio greater than 2:1 is common with LIVER DISEASE OF ALCOHOLISM.

Prothrombin time The prothrombin time (PT) measures the amount of time it takes for the clotting process to take place in the plasma. The normal range (for a person who is not taking ANTICOAGULATION THERAPY) is 11 to 13.5 seconds. Clotting time longer than normal suggests a general dysfunction of the body's clotting mechanisms. Liver function becomes suspect with an elevated clotting time because the liver synthesizes many of the proteins (CLOTTING FACTORS) necessary for COAGULATION.

Preparation, Procedure, and Recovery

Liver function tests require a blood sample, typically drawn from a VEIN in the arm. No preparation is necessary and there is no recovery period.

Risks and Complications

Some people experience minor bruising at the site of the venipuncture, which usually heals in a few days (though liver disease that affects clotting mechanisms may extend HEALING).

liver hemodialysis A treatment for acute LIVER FAILURE that employs extracorporeal (out-of-the-body) filtration of the BLOOD to remove the toxins the liver otherwise would metabolize. LIVER hemodialysis is currently of limited availability and remains largely an investigational treatment. Two procedures are in use, the extracorporeal liver assist device (ELAD) and the bioartificial liver. Each uses a biological approach (cultured human cells or porcine cells) to emulate the functions of the liver's hepatocytes (the cells in the liver that filter the blood). These methods provide a "bridge" of limited filtration until liver transplantation becomes possible.

See also CARDIAC ENZYMES; VENTRICULAR ASSIST DEVICES (VADS).

liver transplantation An OPERATION to replace a diseased LIVER with a donor liver as a treatment for end-stage LIVER FAILURE. Following liver transplantation, most people are able to return to full and active lives though must continue taking medications to suppress rejection of the donor liver (IMMUNOSUPPRESSIVE THERAPY).

Surgeons performed the first successful liver transplantation in the United States in 1967. The risk of organ rejection curtailed transplantation as a permanent treatment for liver failure, however, until the advent of the immunosuppressive medication cyclosporine in 1979. Cyclosporine and its contemporary counterparts (such as tacrolimus, which debuted 10 years later) have made transplantation a viable, long-term solution. In 2004 doctors added the monoclonal antibody basiliximab to the immunosuppressive arsenal, reducing rejection to about 10 percent. Surgeons now perform more than 5,500 such operations each year, with liver transplantation as a therapeutic solution limited only by the availability of donor organs.

Donor livers are either cadaveric (harvested from donors after death) or living-donor segment (a living person donates part of his or her healthy liver). Living-donor segment transplantations are possible because the liver has the unique ability to regenerate. After a living donor segment transplantation, the donor's liver eventually restores itself to full size and function. Ideally, the segment implanted in the recipient does the same. This regenerative capability means, too, that livers transplanted into children will grow as the child grows.

There are two basic types of liver transplantation:

- orthotopic liver transplantation (OLT), in which the surgeon removes the diseased liver and replaces it with the donor liver
- heterotopic liver transplantation (HLT), in which the surgeon leaves the person's own diseased liver (the native liver) in place and attaches the donor liver (or liver segment) in a "piggyback" fashion

Donor organs must match BLOOD TYPE and, for OLT, body size. With HLT body size is less important because the surgeon can select a liver segment of the appropriate size. The surgery to transplant a liver takes between 4 and 12 hours in most circumstances. Recovery includes up to three weeks of hospitalization and several months for full recuperation. Most people are able to return to regular activities including exercise, work, sexual activity, and eating habits.

The risks of liver transplantation include bleeding, INFECTION, and rejection of the donor liver. Rejection may occur within days of the transplant or at any time after recovery, though IMMUNOSUPPRESSIVE MEDICATIONS reduce the likelihood. Symptoms of rejection include JAUNDICE, NAUSEA, FEVER, and PAIN. These symptoms require immediate medical attention to salvage the transplant.

CONDITIONS FOR WHICH LIVER TRANSPLANTATION IS AN OPTION

acute (fulminant) LIVER FAILURE	AMYLOIDOSIS
autoimmune HEPATITIS	BILIARY ATRESIA
chronic liver failure	CIRRHOSIS
glycogen storage disease	HEMOCHROMATOSIS
hepatitis B/hepatitis C	hepatotoxic liver failure
LIVER DISEASE OF ALCOHOLISM	noncancerous LIVER tumors
PRIMARY BILIARY SCLEROSIS	PRIMARY SCLEROSING CHOLANGITIS
WILSON'S DISEASE	

See also ORGAN TRANSPLANTATION; SURGERY BENEFIT AND RISK ASSESSMENT.

M–N

malabsorption Inadequate absorption of NUTRIENTS into the BLOOD circulation from the SMALL INTESTINE during digestion, also called malabsorption syndrome. Malabsorption may result from damage to the small intestine that restricts the surface area of the intestinal mucosa (lining) or may develop as a consequence of digestive enzyme deficiencies. CELIAC DISEASE, LACTOSE INTOLERANCE, CYSTIC FIBROSIS, GASTROENTERITIS, and INFLAMMATORY BOWEL DISEASE (IBD) are among the more common causes of malabsorption. Conditions affecting the PANCREAS, LIVER, and GALLBLADDER can result in secondary malabsorption. Untreated malabsorption characteristically causes NUTRITIONAL DEFICIENCIES and MALNUTRITION.

The diagnostic path may include stool analysis, blood tests, and URINALYSIS. The gastroenterologist may perform an ENDOSCOPY with biopsy when preliminary test findings are inconclusive. Treatment, which often includes a combination of dietary and medical management methods, targets any underlying condition. Secondary malabsorption generally goes away when the underlying condition improves. Severe malabsorption with malnutrition requires PARENTERAL NUTRITION (intravenous solutions) to replenish the body's nutrients. Malabsorption related to enzyme deficiencies often resolves with dietary changes alone.

See also BORBORYGMUS; DIET AND HEALTH; DIGESTIVE ENZYMES; NUTRITIONAL NEEDS; PANCREATITIS; SHORT BOWEL SYNDROME; SMALL BOWEL TRANSPLANTATION; STEATORRHEA; WHIPPLE'S DISEASE.

meconium The first stool a newborn passes, made up of AMNIOTIC FLUID, BILE, and mucus. Meconium resembles tar in consistency and color. Its passing is a key indictor of the infant's health and gastrointestinal patency (clear passage). Infants with healthy gastrointestinal systems pass their first meconium stools within 24 hours of birth and may continue to pass meconium for two or three days. An infant that fails to pass meconium within 24 hours may have a congenital malformation of the gastrointestinal tract such as BOWEL ATRESIA. A complication common in infants who have CYSTIC FIBROSIS, a genetic disorder that affects multiple body systems, is meconium ILEUS in which impacted meconium obstructs the bowel. Enemas often relieve the impaction; when they do not, surgery is necessary.

See also CHILDBIRTH; CONGENITAL ANOMALY; ENEMA.

nasogastric aspiration and lavage The clinical term for the procedure commonly called "pumping the STOMACH." In nasogastric aspiration and lavage, the health-care provider inserts a narrow tube (catheter) through the NOSE, down the back of the THROAT and the ESOPHAGUS, and into the stomach. The stomach's contents are then sucked through the tube. The health-care provider may also use the tube to instill a rinsing solution, often a mixture of liquid and activated charcoal, into the stomach to absorb and neutralize remaining gastric content. Nasogastric aspiration and lavage is most commonly an emergency treatment for ingested toxins, including DRUG OVERDOSE, though also can help diagnose gastric bleeding.

See also GASTROINTESTINAL BLEEDING; INGESTED TOXINS.

nausea A sensation of queasiness and the feeling of being about to vomit. Though nausea feels as though it arises from the gastrointestinal tract, the signals that initiate its sensations originate in two areas of the BRAIN, the chemoreceptor trigger zone and the emetic (VOMITING) center. These areas are

bilateral, existing in pairs on each side of the brain. Both receive NERVE and chemical input from body systems. Nausea often precedes vomiting, the forceful expulsion of upper gastrointestinal contents. However, nausea also exists without resulting in vomiting. Many medications that suppress nausea and vomiting, called ANTIEMETIC MEDICATIONS, block the chemical and nerve signals entering or leaving the chemoreceptor trigger zone.

Nausea is typically a symptom, a reaction such as a medication SIDE EFFECT, or a response such as to an irritation of the gastrointestinal tract. Severe PAIN such as from migraine HEADACHE, HEART ATTACK, MENINGITIS, or injury (including postoperative pain) also activates the chemoreceptor trigger zone and the emetic center. The causes of nausea send different kinds of signals. Some antiemetic medications, such as prochlorperazine (Compazine) and meclizine (Antivert), generally target a broad range of these signals. Other medications, such as those prescribed to treat CHEMOTHERAPY-induced nausea and vomiting (CINV) or radiation-induced nausea and vomiting (RINV), narrowly and specifically target certain chemoreceptors.

ACUPUNCTURE, an ancient Eastern method in which the practitioner inserts hairlike needles in designated locations, is highly effective for some kinds of nausea including CINV, RINV, motion sickness, and MORNING SICKNESS. Acupressure, which uses pressure applied over key acupuncture points, is also effective for many people. Other remedies for nausea include GINGER and "flat" cola drinks or cola syrup.

See also CYCLIC VOMITING SYNDROME; FOOD-BORNE ILLNESSES; GASTROENTERITIS.

P

pancreas An elongated gland with both endocrine and exocrine functions that lies beneath the STOMACH on the upper left side of the abdomen, beneath the lower ribs. Both realms of function play roles in digestion, though the endocrine functions of the pancreas are also significant for maintaining the body's GLUCOSE-INSULIN balance and for regulating cellular use of glucose.

The main body of the pancreas is a loose collection of secretory cells, looking somewhat like a mass of fish eggs, that produce DIGESTIVE ENZYMES and juices. These cells organize in lobular formations, called acini, around ducts that channel their secretions to the main pancreatic duct coursing through the center of the pancreas (hence their designation as exocrine). The pancreatic duct joins the common BILE duct from the GALLBLADDER just before the DUODENUM (the first segment of the SMALL INTESTINE), adding its juices to the bile that then flows into the duodenum.

Interspersed among the secretory cells are about a million clusters of specialized cells that produce the hormones INSULIN, GLUCAGON, and SOMATOSTATIN. Called the ISLETS OF LANGERHANS, these clusters are the endocrine glands of the pancreas. An extensive BLOOD supply infiltrates the islets, which secrete their hormones directly into the bloodstream (hence their designation as endocrine). These hormones regulate numerous functions of METABOLISM throughout the body, including many that take place in the gastrointestinal system.

Pancreatic Enzymes and Juices

The pancreas produces numerous enzymes essential for digestion. DIGESTIVE HORMONES trigger their release. Key among the digestive enzymes are

- proteases, notably trypsin and chymotrypsin, which break down proteins; to protect itself from these proteases hydrolyzing its own tissue, the pancreas secretes them in proenzyme forms, trypsinogen and chymotrypsinogen, that an enzyme in the duodenum, enterokinase, activates
- pancreatic lipase, which breaks down dietary triglyceride into fatty acid molecules the intestinal mucosa can absorb
- amylase, which breaks down dietary starches (plant-based stored carbohydrates) into disaccharides (multiple molecule sugars) in preparation for further digestion later in the small intestine
- ribonuclease and deoxyribonuclease, which break down nucleic acids (chemicals that facilitate the body's use of proteins)
- elastase, which facilitates the break down of proteins into amino acids
- bicarbonate, which neutralizes gastric acid in the chyme (mixture of food and gastric juices) that flows from the stomach into the duodenum

Pancreatic Hormones

The primary hormones the pancreas produces are insulin, glucagon, and somatostatin. Insulin is key to carbohydrate and lipid (fatty acid) metabolism, in the gastrointestinal tract as well as at the cellular level throughout the body. The pancreas releases insulin in response to digestive hormones the gastrointestinal tract secretes as food enters the various stages of digestion. Insulin regulates glucose levels in the blood by controlling how much, and when, glucose enters the cells. It also signals the LIVER to convert excess glucose to the storage form glycogen. Somatostatin slows the release of insulin. Glandular tissue in the intestinal mucosa also produces somatostatin, which

acts to slow the release of other digestive enzymes as well. The pancreas releases glucagon when blood glucose levels fall. Glucagon signals the liver to convert glycogen to glucose.

COMMON CONDITIONS THAT CAN AFFECT THE PANCREAS

DIABETES	gallstones in the common bile duct
PANCREATIC CANCER	pancreatic cyst
pancreatic pseudocyst	PANCREATITIS

For further discussion of the pancreas and the functions of the islets of Langerhans within the context of gastrointestinal structure and function, please see the overview section "The Gastrointestinal System."

See also DIABETES; DIET AND HEALTH.

pancreatic cancer Malignant growths of the PANCREAS. Pancreatic CANCER seldom shows symptoms until the cancer is well advanced or metastasized, making it among the most lethal cancers and the fourth leading cause of deaths from cancer in the United States. The one-year survival rate is about 24 percent.

When symptoms do appear as the cancer advances, they include

- JAUNDICE, a yellowish discoloration of the SKIN that results from the cancer compressing the common bile duct and blocking the flow of BILE into the DUODENUM
- ABDOMINAL PAIN that may radiate to the back
- digestive disturbances that result from the cancer's interference with pancreatic enzyme production or blockage of the ducts that carry the secretions out of the pancreas

The diagnostic path includes imaging procedures such as ULTRASOUND, COMPUTED TOMOGRAPHY (CT) SCAN, or POSITRON EMISSION TOMOGRAPHY (PET) SCAN to determine the location and extent of the cancer as well as LYMPH NODE involvement and regional METASTASIS. Percutaneous (needle) biopsy confirms the diagnosis.

Treatment depends on how extensively the cancer has spread. Surgery is most effective when the cancer is small, remains confined to the pancreas, and is located in the head of the pancreas. Pancreatectomy, partial or complete, is complex surgery with significant risks and consequences (including DIABETES). It is a viable option only when the surgeon is reasonably certain it will completely remove the cancer. About 90 percent of pancreatic cancers have metastasized by the time of diagnosis. CHEMOTHERAPY may be effective in achieving REMISSION. External beam RADIATION THERAPY can shrink the cancer to relieve symptoms.

There are few clear risk factors or screening procedures for pancreatic cancer. There is some evidence of a hereditary component to pancreatic cancer, as it appears to run in families, though researchers have yet to detect the responsible genes. In people at high risk for developing pancreatic cancer because of family history, some cancer experts suggest annual ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY (ERCP). This endoscopic procedure allows the gastroenterologist to examine the pancreatic duct for signs of precancerous changes in the cells (DYSPLASIA). Areas of focus in research include GENE THERAPY and IMMUNOTHERAPY (also called biological therapy), though therapeutic application of these remains investigational.

See also CANCER TREATMENT OPTIONS AND DECISIONS; ENDOSCOPY; LYMPH NODES; PANCREATITIS; RISK FACTORS FOR CANCER; STOMACH CANCER; SURGERY BENEFIT AND RISK ASSESSMENT.

pancreatitis INFLAMMATION of the PANCREAS that can be acute (comes on suddenly) or chronic (ongoing).

Acute pancreatitis can be life-threatening and requires emergency medical treatment.

Between them, excessive ALCOHOL consumption and gallstones account for more than 80 percent of pancreatitis. Other causes include CYSTIC FIBROSIS, viral INFECTION (notably with the MUMPS VIRUS), SIDE EFFECTS of certain medications, and trauma to the abdomen (particularly blunt trauma such as might occur in MOTOR VEHICLE ACCIDENTS). A good deal of the time doctors cannot identify the cause of pancreatitis.

Symptoms and Diagnostic Path

Acute pancreatitis makes a person very ill, with symptoms that include moderate to severe ABDOMINAL PAIN, ABDOMINAL DISTENTION; NAUSEA, VOMITING, and FEVER. Often the PULSE and respiration rate are rapid. When symptoms are severe, the person may be in SHOCK, which is a life-threatening emergency. The diagnostic path includes BLOOD tests to measure the levels of the DIGESTIVE ENZYMES amylase and lipase, which become significantly elevated with pancreatitis. ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY (ERCP) can often identify signs of inflammation and can help determine whether gallstones are obstructing the BILE DUCTS, a common cause of acute pancreatitis. ULTRASOUND or COMPUTED TOMOGRAPHY (CT) SCAN also can provide therapeutically useful information.

People who have chronic pancreatitis may have intermittent upper ABDOMINAL PAIN, though with advanced damage to the pancreas pain is less common. The primary symptom of chronic pancreatitis is persistent weight loss despite adequate eating. This occurs because the damaged pancreas is unable to produce the digestive enzymes the SMALL INTESTINE needs to absorb nutrients, so consumed food passes through the gastrointestinal tract largely useless in the context of meeting the body's NUTRITIONAL NEEDS. The same procedures doctors use to diagnose acute pancreatitis help diagnose as well as monitor chronic pancreatitis. Specialized tests also can measure production of pancreatic enzymes.

Treatment Options and Outlook

Treatment for acute pancreatitis is primarily supportive, with intravenous fluids to restore fluid and electrolyte balance within the body as well as to deliver GLUCOSE. Surgery becomes necessary when there is bleeding in the pancreas. Though illness can be severe, most people recover without residual consequences. Some people do subsequently develop chronic pancreatitis. Other complications may include RENAL FAILURE and the development of fluid-filled pockets called pseudocysts that often become infected.

Treatment for chronic pancreatitis is elimination of any contributing factors (such as alcohol consumption or removal of gallstones), plus a high-carbohydrate, low-fat diet to get basic nutrients into the body. Enzyme supplements can improve digestion. Complications include DIABETES (requiring INSULIN THERAPY) and progressive loss of pancreatic function.

Risk Factors and Preventive Measures

Excessive alcohol consumption and gallstones are the leading risk factors for pancreatitis; alcohol abstinence and appropriate treatment for gallstones eliminates them. Other causes of pancreatitis are less defined and thus more difficult to prevent. Prompt medical assessment of symptoms and appropriate treatment improve the likelihood for uneventful recovery.

See also ALCOHOLISM; ENDOSCOPY; PANCREATIC CANCER.

peptic ulcer disease A condition in which ulcers form in the lining (mucosa) of the lower STOMACH and upper DUODENUM (first segment of the SMALL INTESTINE). The two most common causes of peptic ulcer disease are INFECTION with *HELICOBACTER PYLORI* and chronic or long-term use of NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS). Peptic ulcer disease affects millions of Americans. In most situations, appropriate treatment cures the condition.

Symptoms and Diagnostic Path

The symptoms of peptic ulcer disease range from mild and intermittent to severe and unrelenting. Severe symptoms suggest a perforated ulcer, which carries the risks of bleeding and infection. A perforated ulcer requires immediate medical attention.

Typical symptoms of peptic ulcer disease include

- DYSPEPSIA (heartburn or stomach upset), commonly occurring one to three hours after eating or at night
- NAUSEA and VOMITING
- GASTROINTESTINAL BLEEDING
- loss of APPETITE or intolerance for spicy or fatty foods
- unintended weight loss

Symptoms typically improve with ANTACIDS or acid-reducing medications. Some people experience CHEST PAIN mistaken for HEART ATTACK.

ENDOSCOPY to examine the ESOPHAGUS, stomach, and duodenum often makes the diagnosis, allowing the gastroenterologist to visualize the ulcers and extent of damage. Biopsy of a tissue sample or an urea breath test can determine whether *H. pylori* infection is present.

Treatment Options and Outlook

H. pylori infection accounts for nearly 80 percent of peptic ulcer disease. Treatment with appropriate ANTIBIOTIC MEDICATIONS to eradicate the BACTERIA allows the ulcers to heal. Chronic NSAID use is the second-most common cause of peptic ulcer disease; ulcers typically heal when the person stops taking the NSAID. Regardless of cause, the treatment of choice for peptic ulcer disease is acid-reducing medication to decrease irritation to the damaged tissue.

Gastroenterologists typically prescribe H2 ANTAGONIST (BLOCKER) MEDICATIONS or PROTON PUMP INHIBITOR (PPI) MEDICATIONS for this purpose. After the ulcers heal, most people no longer need to take the medication. Severe ulcers may require surgery, particularly if they are bleeding. The primary complication of peptic ulcer disease is perforation (an ulcer that "eats through" or penetrates the wall of the duodenum or stomach), which can result in life-threatening bleeding and usually requires surgery. There also is some evidence linking long-term peptic ulcer disease, particularly that resulting from *H. pylori* infection, with an increased risk for STOMACH CANCER.

Risk Factors and Preventive Measures

Doctors once believed stress was the primary cause of peptic ulcer disease, though now know this is not the case. The causes of peptic ulcer disease, are largely treatable (*H. pylori* infection) or preventable (NSAID overuse).

See also GASTROESOPHAGEAL REFLUX DISORDER (GERD); MULTIPLE ENDOCRINE NEOPLASIA (MEN); RISK FACTORS FOR CANCER; ZOLLINGER-ELLISON SYNDROME.

percutaneous liver biopsy A diagnostic procedure for removing a tissue sample from the LIVER. The doctor typically performs percutaneous liver biopsy on an outpatient basis in a hospital setting. Most people prefer to receive a mild sedative before the procedure. After anesthetizing the abdominal SKIN and tissue above the liver, the doctor makes a tiny incision and inserts a special biopsy needle. The needle withdraws a core of liver tissue, which a laboratory then analyzes to determine the nature and structure of cells and other substances it contains. Percutaneous liver biopsy helps diagnose numerous conditions affecting the liver, including HEPATITIS, CIRRHOSIS, LIVER FAILURE, STEATOHEPATITIS, and LIVER CANCER. Though minimally invasive, percutaneous liver biopsy exposes the liver to several risks including INFECTION, INFLAMMATION, and bleeding. These complications are uncommon though can be serious.

See also LIVER FUNCTION TESTS.

peristalsis The rhythmic waves of contraction that move food through the gastrointestinal tract. Pressure against the inner walls of the intestines, such as occurs when food enters an intestinal segment, signals the muscles to contract and relax in a progressive pattern. The muscles ahead of the pressure relax, widening the intestinal passage, and the muscles behind the pressure contract, narrowing the passage. This action "massages" the intestinal contents forward. Peristalsis is totally involuntary, under the control of the autonomic NERVOUS SYSTEM.

See also BORBORYGMUS; BOWEL SOUNDS.

peritonitis INFLAMMATION and INFECTION of the peritoneal membrane that encases the contents of the abdominal cavity. Peritonitis usually indicates a perforation of the intestinal tract that allows intestinal content, including normally present BACTERIA, to spill into the abdominal cavity. Such a breach may occur as the result of APPENDICITIS or COLITIS, or with INFLAMMATORY BOWEL DISEASE (IBD) or DIVERTICULAR DISEASE that erodes through the wall of the intestine. Peritoneal ABSCESS also often causes peritonitis. Peritoneal dialysis for KIDNEY failure, which circulates fluid within the peritoneal cavity to draw toxins from the body, may introduce bacteria into the peritoneal cavity to cause peritonitis.

Peritonitis is potentially life-threatening and requires emergency treatment and usually surgery.

Symptoms often appear suddenly and are severe. Initially the perforation may provide relief because it releases pressure but the spreading infection quickly worsens symptoms. There is often abdominal rigidity and guarding (extreme resistance to having anyone touch the abdomen), ABDOMINAL DISTENTION, high FEVER, and signs of SEPTICEMIA (septic SHOCK) such as rapid PULSE and respiration. Blood tests and abdominal X-RAY or ULTRASOUND generally confirm the diagnosis. The infection paralyzes the intestine, halting PERISTALSIS and the absorption of fluids, nutrients, and electrolytes. Electrolytes are critically important for proper regulation of many body activities including those of the BRAIN and HEART. Treatment is immediate intravenous fluids to restore the body's electrolyte balance, ANTIBIOTIC MEDICATIONS to begin fighting the infection, and usually emergency surgery to drain the infection from the peritoneal cavity and remove any necrotic (dead) tissue or bowel. Recovery is not certain, and often complications remain following treatment, depending on the reason for the peritonitis.

See also PELVIC INFLAMMATORY DISEASE (PID); RENAL DIALYSIS.

portal hypertension High pressure in the portal VEIN, the large BLOOD vessel that carries blood from the abdominal organs to the LIVER. CIRRHOSIS, in which SCAR tissue replaces liver tissue as a consequence of repeated INFLAMMATION, is the primary cause of portal hypertension. Right HEART FAILURE also can cause portal hypertension.

About 40 percent of the blood that enters the liver does so through the portal vein. Blood drains into the portal vein from the digestive organs of the abdomen, carrying NUTRIENTS and metabolic wastes to the liver for processing. Though blood flows through the arteries under high pressure, the pressure within the veins is low and venous blood flow mostly relies on a combination of lower resistance, gravity, and valves within the veins to prevent backflow.

The spongy tissue of a healthy liver accepts blood flow from the portal vein in a smooth process, literally soaking in the blood and channeling it through the thousands of lobules that form the liver's interior architecture. The solid structure of scar tissue does not absorb blood like the spongy tissue of the healthy liver, and blood must force its way around. The resistance that results causes the pressure within the portal vein to rise.

When scarring becomes severe, as in cirrhosis, the liver cannot contain the amount of blood attempting to enter and the blood backs up into the portal vein as well as the veins that feed into the portal vein. The walls of the portal vein stiffen against the resistance, which further raises pressure. Eventually the consequence of portal hypertension is twofold: blood cannot circulate through the liver and the supporting veins that feed into the portal vein distend and weaken. These VARICOSE VEINS typically protrude into the ESOPHAGUS (ESOPHAGEAL VARICES) and often bleed.

Symptoms and Diagnostic Path

The key symptoms suggesting portal hypertension are those of liver disease and may include

- JAUNDICE, a yellowish discoloration of the SKIN
- PRURITUS (widespread itching)
- fatigue and weakness
- ASCITES, an accumulation fluid in the abdomen
- evidence of GASTROINTESTINAL BLEEDING, which may appear as VOMITING blood (hematemesis) or passing dark stools (melena)

The doctor's examination can usually detect numerous signs of portal hypertension, such as abnormal PULSE, low systemic BLOOD PRESSURE (HYPOTENSION), and evidence of altered venous blood flow in the abdomen and lower extremities. The diagnostic path includes imaging procedures that can show the flow of blood through the liver, such as Doppler ULTRASOUND, COMPUTED TOMOGRAPHY (CT) SCAN, or MAGNETIC RESONANCE IMAGING (MRI). Endoscopic examination of the esophagus reveals esophageal varices, a conclusive sign of portal hypertension.

Treatment Options and Outlook

Bleeding esophageal varices require immediate medical attention. The gastroenterologist often can cauterize these during ENDOSCOPY. Vasodilator medications that relax the blood vessels, such as nitrates and beta blockers, relieve mild to moderate portal hypertension. Moderate to severe portal

hypertension requires surgical intervention. Shunts can help redirect the flow of blood into the liver and lower portal vein pressure. Sometimes removing the SPLEEN (SPLENECTOMY) and blood vessels surrounding the esophagus is necessary to control esophageal varices. The only curative treatment is LIVER TRANSPLANTATION, which, because donor organs are so limited, is a treatment of final resort when other therapies fail and LIVER FAILURE becomes life-threatening.

Medications and intermediary surgical procedures such as shunts can successfully manage portal hypertension in many people, allowing good QUALITY OF LIFE.

Risk Factors and Preventive Measures

Chronic liver disease and heart disease are the primary risk factors for portal hypertension. Lifestyle measures to minimize these conditions, and appropriate treatments to manage them when they do occur, significantly reduce the likelihood that portal hypertension will develop.

See also CARDIOVASCULAR DISEASE PREVENTION; HEMOCHROMATOSIS; HEPATITIS PREVENTION; LIFESTYLE AND HEALTH; WILSON'S DISEASE.

primary biliary cirrhosis An autoimmune disorder in which chronic and progressive INFLAMMATION destroys the intrahepatic BILE DUCTS (bile ducts within the LIVER), blocking the flow of BILE. Primary biliary CIRRHOSIS appears to run in families, suggesting a hereditary component. Early symptoms include fatigue, tenderness or PAIN in the upper right abdomen, and itching (PRURITIS). Over time, signs of liver damage, such as JAUNDICE and HEPATOMEGALY (enlarged liver), emerge. Primary biliary cirrhosis is most common in women between the ages of 40 and 60.

The diagnostic path includes

- LIVER FUNCTION TESTS, which typically show elevations of the enzymes alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), and gamma-glutamyl transpeptidase (GGTP).
- BLOOD tests to measure the level of immunoglobin (elevated) and detect the presence of antimitochondrial antibodies (positive)
- imaging procedures such as abdominal ULTRASOUND, COMPUTED TOMOGRAPHY (CT) SCAN, or MAGNETIC RESONANCE IMAGING (MRI)
- PERCUTANEOUS LIVER BIOPSY

The progressive destruction of the bile ducts results in CHOLESTASIS and cirrhosis, leading ultimately to LIVER FAILURE. Complications include OSTEOPOROSIS (arising from the body's inability to metabolize vitamin D and calcium), PORTAL HYPERTENSION, ESOPHAGEAL VARICES, and primary LIVER CANCER.

There are currently few medical treatment options. The medication ursodiol (Actigall), sometimes taken to help dissolve gallstones, slows the progression of the inflammatory process in some people. ANTIHISTAMINE MEDICATIONS can help relieve the itching in the early stages; in later stages some people experience relief from itching with bile sequestrant medications such as cholestyramine and colestipol, which bind with bile in the gastrointestinal tract. The only curative treatment, however, is LIVER TRANSPLANTATION.

See also AUTOIMMUNE DISORDERS; BILIARY ATRESIA; CANCER RISK FACTORS; GALLBLADDER DISEASE; PRIMARY SCLEROSING CHOLANGITIS.

primary sclerosing cholangitis A progressive and chronic condition in which segments of the BILE DUCTS become inflamed, causing SCAR tissue (sclerosis) that narrows and stiffens them. The scarring reduces and eventually destroys the ability of the ducts to carry BILE. About 75 percent of people who have primary sclerosing cholangitis also have INFLAMMATORY BOWEL DISEASE (IBD), suggesting a related autoimmune process. Primary sclerosing cholangitis is most common in men between the ages of 20 and 40.

In the early stages of the disease symptoms are mild and tend to wax and wane. Early symptoms may include fatigue, tenderness or PAIN in the upper right abdomen, and mild JAUNDICE (yellowish discoloration of the skin). Often the discovery of primary sclerosing cholangitis comes with elevated enzyme levels on LIVER FUNCTION TESTS done for other reasons, with confirmation by imaging procedures, such as ULTRASOUND or COMPUTED TOMOGRAPHY (CT) SCAN, and PERCUTANEOUS LIVER

BIOPSY. As more damage to the bile ducts occurs, symptoms intensify.

Medical interventions for primary sclerosing cholangitis are primarily supportive and aim to relieve symptoms such as PRURITIS (intense itching), which become more prominent as the condition progresses. The damage ultimately results in CIRRHOSIS and LIVER FAILURE. A significant risk during this progression is cholangiocarcinoma, a cancerous tumor that develops in the inflamed bile ducts. The course of the disease varies though tends to run about 10 years from onset of symptoms to liver failure. The only curative treatment is LIVER TRANSPLANTATION.

See also AUTOIMMUNE DISORDERS; BILIARY ATRESIA; CANCER RISK FACTORS; GALLBLADDER DISEASE; PRIMARY BILIARY CIRRHOSIS.

proctitis INFLAMMATION of the RECTUM that may also involve the ANUS. A number of circumstances may cause proctitis, including

- INFECTION, notably SEXUALLY TRANSMITTED DISEASES (STDS) such as CHLAMYDIA, GONORRHEA, and GENITAL HERPES
- inflammatory conditions such as INFLAMMATORY BOWEL DISEASE (IBD) and DIVERTICULAR DISEASE
- trauma to the anus and rectum
- bacterial INFECTION secondary to chronic inflammation or trauma
- RADIATION THERAPY (radiation proctitis)

Symptoms include the continuous sensation of needing to have a BOWEL MOVEMENT, CONSTIPATION, and rectal discomfort or PAIN. The doctor can usually diagnose proctitis via proctoscopy (viewing the anus and rectum endoscopically). Treatment targets the cause, which may include ANTIBIOTIC MEDICATIONS for infections and CORTICOSTEROID MEDICATIONS or other anti-inflammatory products for inflammation arising from trauma, radiation therapy, and inflammatory conditions of the gastrointestinal tract.

See also ANAL FISSURE; ENDOSCOPY; HEMORRHOIDS.

proton pump inhibitor (PPI) medications Medications that suppress gastric acid production in the STOMACH. Commonly prescribed PPIs available in the United States include

- esomeprazole (Nexium)
- lansoprazole (Prevacid)
- omeprazole (Prilosec)
- pantoprazole (Protonix)
- rabeprazole (Aciphex)

How These Medications Work

PPIs work by blocking the enzyme system that causes the parietal cells in the stomach's lining (gastric mucosa), called proton pumps, to produce and release hydrochloric acid. PPIs can block up to 99 percent of gastric acid production. PPIs also appear to slow the ability of *HELICOBACTER PYLORI* bacteria to move, reducing their ability to cause INFECTION. *H. pylori* infection is responsible for up to 80 percent of ulcers.

Therapeutic Applications

Doctors prescribe PPIs to treat PEPTIC ULCER DISEASE, GASTROESOPHAGEAL REFLUX DISORDER (GERD), and other conditions in which gastric acid becomes an irritation that causes symptoms such as INFLAMMATION and PAIN. PPIs are intended for relatively short-term use, during the HEALING phase of damaged gastrointestinal mucosa. After healing is complete, doctors recommend dietary modifications and H2 ANTAGONIST (BLOCKER) MEDICATIONS or ANTACIDS for people who still need to suppress gastric acid.

Risks and Side Effects

PPIs have relatively few side effects or risks. Among the most common are HEADACHE, dizziness, fatigue, NAUSEA, ABDOMINAL PAIN, and DIARRHEA. No one PPI is more likely than another to cause side effects. Pregnant women should not take PPIs because researchers do not yet know whether these medications can harm the developing FETUS.

See also ESOPHAGITIS; GASTRITIS; GASTROENTERITIS.

R

rapid gastric emptying A disorder, also called dumping syndrome, in which food moves from the STOMACH into the SMALL INTESTINE incompletely digested, resulting in the small intestine attempting to digest solid food particles. Normally the digestive content that reaches the small intestine is fairly liquefied. The incomplete gastric digestion causes various gastrointestinal symptoms and leads to MALABSORPTION. Rapid gastric emptying typically occurs in people who have had stomach surgery, particularly BARIATRIC SURGERY for weight loss. Some research studies suggest that rapid gastric emptying in people who have not had stomach surgery may be an early sign of type 2 DIABETES. The diagnostic path may include gastroscopy and BARIUM SWALLOW to rule out other conditions. Treatment integrates dietary changes and medications to slow PERISTALSIS. Dietary changes include eating six small, low-carbohydrate meals throughout the day and drinking liquids between, rather than with, meals.

See also ENDOSCOPY.

rebound tenderness A clinical sign of PERITONITIS (generalized INFLAMMATION and INFECTION of the abdominal cavity). During abdominal palpation, the doctor presses slowly and firmly on the abdomen, then suddenly releases the pressure. The person feels a stabbing PAIN with release when the result is positive and notices no change when the result is negative. Rebound tenderness has a high level of accuracy for both positive and negative results. Rebound tenderness often appears as referred pain in appendicitis. The pressure and release action applied to the left side of the abdomen results in the person feeling pain on the right side of the abdomen, at the approximate location of the appendix.

See also DIGITAL RECTAL EXAMINATION (DRE).

rectal fistula An abnormal opening in the wall of the RECTUM, often connecting the rectum with another structure such as the URETHRA (rectourethral fistula), the VAGINA (rectovaginal fistula), or the ANUS (anorectal fistula). Rectal fistulas may be congenital or acquired. Congenital fistulas often occur in combination with other congenital anomalies, notably those affecting the HEART such as tetralogy of Fallot (a collective of malformations in the structure of the heart). Acquired rectal fistulas may be idiopathic (without detectable cause), though are more likely to occur in people who have inflammatory conditions that affect the gastrointestinal tract such as INFLAMMATORY BOWEL DISEASE (IBD). RADIATION THERAPY as treatment for PROSTATE CANCER, CERVICAL CANCER, OVARIAN CANCER, COLORECTAL CANCER, or other cancers in the abdomen can weaken the rectal wall, allowing fistulas to develop. As well, fistulas involving any portion of the gastrointestinal tract are frequent complications of HIV/AIDS.

Symptoms vary with the location of the fistula though often include FECAL INCONTINENCE or inappropriate presence of stool in the other involved structure. The diagnostic path may include DIGITAL RECTAL EXAMINATION (DRE), BARIUM ENEMA, and sigmoidoscopy (endoscopic examination of the lower COLON). Treatment is surgery to repair the fistula, which can sometimes be extensive when the fistula is long or deep. Potential complications vary according to the nature of the OPERATION necessary. In many people the surgical repairs end the symptoms and the person returns to his or her usual activities with no further problems. In some people, complications such as fecal incontinence arise or new fistulas occur.

See also ANAL FISSURE; CONGENITAL HEART DISEASE; CYSTOCELE; ENDOSCOPY; HEMORRHOIDS; ILEUS; MECONIUM; PROCTITIS; RECTOCELE.

rectal prolapse Protrusion of the rectal mucosa (lining of the RECTUM) through the ANUS. Rectal prolapse often affects women beyond MENOPAUSE who experienced trauma during vaginal CHILDBIRTH and have residual weakness of the pelvic structures. However, rectal prolapse occasionally affects men, usually those who are elderly. Long-term, chronic CONSTIPATION is a common factor when rectal prolapse occurs in women who have not given birth or in men. Prolapse of other pelvic organs, such as the BLADDER (CYSTOCELE), is also common. Rectal prolapse generally is apparent with physical examination, though the doctor often will perform sigmoidoscopy to rule out other conditions. Treatment is surgery to repair the rectal wall.

See also ENDOSCOPY; HEMORRHOIDS; ILEUS; RECTAL FISTULA; RECTOCELE.

rectocele A weakness that develops in the wall of tissue that separates the RECTUM from the VAGINA, called the rectovaginal wall, causing the rectum to protrude into the vagina. Rectocele, a type of HERNIA, most commonly appears after MENOPAUSE. Circumstances that chronically stress the muscles of the perirectal area, such as straining with bowel movements or frequent coughing due to pulmonary conditions, are frequent causes. Weakening of or damage to the perineal structures during vaginal CHILDBIRTH may also contribute to rectocele. Many women who have small rectoceles do not have symptoms. Larger rectoceles may produce symptoms that include the sensation of pressure in the vagina, pelvic PAIN, painful vaginal intercourse, and occasionally FECAL INCONTINENCE. Treatment options include KEGEL EXERCISES to strengthen the pelvic and vaginal muscles, weight loss to decrease stress on the pelvic muscles, and the insertion of a PESSARY, a fitted ring placed in the vagina to support the rectovaginal wall. Pessaries may cause irritation and INFLAMMATION, however; and women may find them uncomfortable. Surgery to repair the herniation becomes an option when other treatments fail to correct the problem and symptoms continue.

See also CYSTOCELE; PELVIC EXAMINATION; RECTAL PROLAPSE; SURGERY BENEFIT AND RISK ASSESSMENT.

rectum The segment of the COLON between the sigmoid colon and the ANUS. About six inches long, the rectum retains solid digestive waste until a BOWEL MOVEMENT expels it. The SPINAL CORD regulates the NERVE impulses that initiate the reflexive contractions of the rectum that result in bowel movements. The walls of the rectum are smooth and flexible, allowing it to expand to accommodate collected fecal material. The rectum is a frequent site of intestinal polyps and is vulnerable to CANCER. Other health conditions that can involve the rectum include ulcerative COLITIS, Crohn's disease, and DIVERTICULAR DISEASE.

COMMON CONDITIONS THAT CAN AFFECT THE RECTUM

COLITIS	COLORECTAL CANCER
CONSTIPATION	DIARRHEA
DIVERTICULAR DISEASE	FAMILIAL ADENOMATOUS POLYPOSIS (FAP)
FECAL IMPACTION	HIRSCHSPRUNG'S DISEASE
INTESTINAL POLYP	PROCTITIS
RECTAL FISTULA	RECTAL PROLAPSE
RECTOCELE	SPINAL CORD INJURY

For further discussion of the rectum and colon within the context of gastrointestinal structure and function, please see the overview section "The Gastrointestinal System."

See also BARIUM ENEMA; CECUM; COLONOSCOPY; COLOSTOMY; CYSTIC FIBROSIS; DIGITAL RECTAL EXAMINATION (DRE); ENDOSCOPY; ENEMA; FECAL INCONTINENCE; INTESTINAL POLYP; SMALL INTESTINE.

S

short bowel syndrome Reduction in the structural or functional length of the SMALL INTESTINE that results in MALABSORPTION, chronic DIARRHEA, and other disturbances of digestion. MALNUTRITION is a common consequence. Short bowel syndrome most often results from surgery that removes segments of the small intestine as treatment for Crohn's disease, DIVERTICULAR DISEASE, cancers of the small intestine, traumatic injury, and other conditions that irreparably damage the small intestine. Short bowel syndrome was a common complication of a weight loss operation, jejunoileal bypass, that surgeons no longer perform. Functional short bowel syndrome also may develop following severe COLITIS (such as may occur with *ESCHERICHIA COLI* O157:H7 INFECTION) or radiation GASTROENTERITIS.

Treatment options for short bowel syndrome attempt to manage symptoms such as diarrhea as well as to meet NUTRITIONAL NEEDS. Most people who develop short bowel syndrome require PARENTERAL NUTRITION, a form of long-term intravenous feeding. Surgical options include operations to extend the remaining small intestine through various procedures and SMALL BOWEL TRANSPLANTATION or multivisceral transplantation (typically small bowel and LIVER or small bowel, liver, STOMACH, and PANCREAS). The extensive presence of lymphatic tissue in the gastrointestinal tract creates IMMUNE RESPONSE challenges with transplantation.

Liver and biliary dysfunctions (notably CHOLESTASIS) are common complications of short bowel syndrome, as the JEJUNUM and ILEUM produce a number of DIGESTIVE HORMONES that help to regulate liver activity and BILE release. When these segments of the small intestine are missing or no longer functional, the body has no secondary systems to synthesize these hormones. Long-term total parenteral nutrition exacerbates liver and biliary dysfunctions. These factors tend to lead to LIVER FAILURE. Research directions for solutions to the challenges of short bowel syndrome therapies include explorations in IMMUNOTHERAPY (with a focus on suppressing the immune response in transplantation), pharmacotherapy (with a focus on supplemental hormones), and surgical methods that might improve small bowel function without transplantation.

See also CYSTIC FIBROSIS; GUT-ASSOCIATED LYMPHOID TISSUE (GALT); FOOD-BORNE ILLNESSES; INFLAMMATORY BOWEL DISEASE (IBD); MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT); RADIATION THERAPY.

sitz bath A small basin designed to accommodate the perineal and rectal areas, with the water level only to the hips. Numerous commercial products are available for ease of use at home. Placing a shallow amount of water in the regular bathtub accomplishes the same objective, which is to soothe irritated tissues caused by, for example, EPISIOTOMY incision, ANAL FISSURE, and HEMORRHOIDS. The water may contain medications or herbs for additional therapeutic effect.

See also MEDICINAL HERBS AND BOTANICALS.

small bowel transplantation Replacement of a diseased SMALL INTESTINE with a cadaver donor small intestine. Small bowel transplantation is a final treatment option for SHORT BOWEL SYNDROME or other circumstances in which there is total loss of small intestine structure or function. The gastroenterologist may consider small bowel transplantation when all other treatments, including total PARENTERAL NUTRITION, have failed. Small bowel transplantation is an extraordinarily complex procedure. The complication rate is high, and

at present the three-year success rate is about 50 percent.

The small intestine produces numerous DIGESTIVE ENZYMES and DIGESTIVE HORMONES necessary for proper function of the entire gastrointestinal tract. One challenge with small bowel transplantation is the restoration of this production. Another challenge is the abundance of lymphatic tissue in the intestinal mucosa (mucous membrane that lines the inside of the small intestine). Researchers do not yet fully understand the role of this tissue, called GUT-ASSOCIATED LYMPHOID TISSUE (GALT). However, GALT appears to intensify the IMMUNE RESPONSE typical with transplanted organs, requiring large doses of IMMUNOSUPPRESSIVE MEDICATIONS such as cyclosporine. These medications suppress immune activity throughout the body, not only in the intestinal tract, resulting in significant risk for INFECTION. Up to a third of people who receive small bowel transplantation experience complications including organ rejection and infection during the first year.

See also CYSTIC FIBROSIS; GASTROENTERITIS; ORGAN TRANSPLANTATION.

small intestine The segment of the gastrointestinal tract immediately following the STOMACH. The small intestine's three sections—DUODENUM, JEJUNUM, and ILEUM—perform about 85 percent of the digestive functions of the gastrointestinal tract. Food passes from the STOMACH to the duodenum, from the duodenum to the jejunum, and from the jejunum to the ileum. The small intestine loops and folds through the inner abdomen, with the COLON (large intestine) encircling it like a frame. Microscopic extensions, villi, arise from the mucosa, forming peaks and valleys that dramatically increase the surface area of the mucosa.

CONDITIONS THAT CAN AFFECT THE SMALL INTESTINE

BOWEL ATRESIA	CELIAC DISEASE
Crohn's disease	GASTROENTERITIS
ILEUS	LACTOSE INTOLERANCE
MALABSORPTION	PEPTIC ULCER DISEASE
WHIPPLE'S DISEASE	

A meal's transit time through the 18 or so feet of the small intestine is about 10 hours, during which intestinal mucosa (mucous membrane that lines the intestinal tract) extracts all of the nutrients, many of the electrolytes, and much of the water.

For further discussion of the small intestine within the context of gastrointestinal structure and function, please see the overview section "The Gastrointestinal System."

See also ANUS; FOOD-BORNE ILLNESSES; INFLAMMATORY BOWEL DISEASE (IBD); IRRITABLE BOWEL SYNDROME (IBS); RECTUM.

steatohepatitis Fatty deposits throughout the LIVER, also called fatty liver, that create irritation and INFLAMMATION. Doctors believe steatohepatitis represents a malfunction of the body's lipid processing and transfer mechanisms, many of which take place in the liver. Steatohepatitis is common with long-term ALCOHOL use and ALCOHOLISM (alcoholic steatohepatitis). It also occurs without alcohol involvement (nonalcoholic steatohepatitis), notably with DIABETES (which alters lipid METABOLISM) and OBESITY.

The most common form of steatohepatitis, called macrovesicular because the fatty deposits are large, may not show symptoms. Rather, the doctor may detect it during physical examination as HEPATOMEGALY (enlarged LIVER). When symptoms are present they reflect noninfectious HEPATITIS: JAUNDICE (yellow discoloration of the SKIN), tenderness or PAIN in the upper right abdomen, fatigue, NAUSEA, and loss of APPETITE. LIVER FUNCTION TESTS may be inconclusive; ULTRASOUND or COMPUTED TOMOGRAPHY (CT) SCAN often reveals the fatty accumulations. PERCUTANEOUS LIVER BIOPSY confirms the diagnosis. The form of steatohepatitis associated with alcoholism, obesity, and diabetes is macrovesicular.

Steatohepatitis occasionally manifests as an acute illness with significant symptoms and rapid progression to clotting dysfunction (coagulopathy) and neurologic involvement (hepatic NEUROPATHY). This form of steatohepatitis, called microvesicular because the fatty deposits are small, can be fatal without appropriate supportive treatment until the liver recovers.

Macrovesicular steatohepatitis generally does not require treatment though treating any underlying condition helps restore normal lipid metabolism with the result that fatty acids move out of the liver. When alcohol consumption is a factor, steatohep-

atitis nearly always goes away with abstinence from alcohol though any CIRRHOSIS (replacement of liver tissue with SCAR tissue) that has already developed is permanent. Nonalcoholic steatohepatitis associated with diabetes generally improves with tighter management of the diabetes, and with obesity when weight loss occurs. Microvesicular steatohepatitis may require extensive support, including intravenous fluids and nutrients, during its acute phase. For many people recovery is complete and without residual damage to the liver.

See also DIET AND HEALTH; LIVER DISEASE OF ALCOHOLISM.

steatorrhea Excessive excretion of fat in the stool. Steatorrheic stools are often foamy and foul-smelling, and tend to break apart and float in the toilet bowl. Steatorrhea is a symptom of numerous gastrointestinal disorders including MALABSORPTION, CELIAC DISEASE, GALLBLADDER DISEASE, PANCREATITIS, and LIVER disease. Treating the causative condition ends the steatorrhea.

See also CONSTIPATION; CYSTIC FIBROSIS; DIARRHEA.

stomach The pouchlike organ that receives and digests food. The stomach can stretch up to six times its resting size to accommodate influxes of food and drink up to about the combined quantity of a gallon. Three layers of MUSCLE wrap around the deeply pitted gastric mucosa (mucous membrane lining of the stomach). The fibers of each muscle layer run in different directions: the layer innermost to the mucosa is oblique (diagonal), the middle layer of muscle is horizontal (encircles the stomach), and the outermost layer runs lengthwise. This arrangement allows the stomach to flex and contract in every direction to mix and break apart food particles.

CONDITIONS THAT CAN AFFECT THE STOMACH

BEZOAR	Crohn's disease
CYCLIC VOMITING SYNDROME	DYSPEPSIA
GASTRITIS	GASTROESOPHAGEAL REFLUX DISORDER (GERD)
GASTROPARESIS	PEPTIC ULCER DISEASE
HIATAL HERNIA	ZOLLINGER-ELLISON SYNDROME
STOMACH CANCER	

The stomach produces gastric acid, which is primarily hydrochloric acid, and several DIGESTIVE ENZYMES. Though the stomach digests carbohydrates and some proteins, its primary role is to prepare food for the SMALL INTESTINE where the bulk of digestion takes place.

For further discussion of the stomach within the context of gastrointestinal structure and function, please see the overview section "The Gastrointestinal System."

See also COLON; DIET AND HEALTH; DIGESTIVE HORMONES; ESOPHAGUS; GASTRECTOMY; *HELICOBACTER PYLORI*; H2 ANTAGONIST (BLOCKER) MEDICATIONS; INFLAMMATORY BOWEL DISEASE (IBD); NAUSEA; NUTRITIONAL DEFICIENCY; PROTON PUMP INHIBITOR (PPI) MEDICATION; VOMITING.

stomach cancer Malignant growths that occur in the STOMACH. Stomach CANCER is seventh among deaths from cancer in the United States. About 90 percent of stomach cancers are adenocarcinomas, malignant growths that originate in the glandular cells that carpet the gastric mucosa. These are the cells that produce the stomach's acid and mucus, as well as DIGESTIVE ENZYMES. Though stomach cancer readily metastasizes (spreads) to other tissues and organs, the stomach is seldom the site of secondary cancers that originate elsewhere in the body.

Though the causes of stomach cancer remain a mystery, researchers do know certain factors alter the DNA of cells in the stomach in ways that result in the uncontrolled growth that characterizes cancer. These factors cause chronic irritation to the stomach tissues. They include

- INFECTION with *HELICOBACTER PYLORI*, believed to cause about 85 percent of PEPTIC ULCER DISEASE
- a diet high in red meats, well-done barbecued meats, and smoked meats and fish that contain nitrates or nitrites (which convert to carcinogenic substances during the digestive action of gastric juices) as preservatives
- the combination of cigarette smoking and excessive ALCOHOL consumption
- untreated or poorly controlled GASTROESOPHAGEAL REFLUX DISORDER (GERD) or Crohn's disease

Symptoms and Diagnostic Path

Symptoms of early stomach cancer are often vague and nonspecific, such as DYSPEPSIA, NAUSEA

after eating, and a sense of fullness after eating only a small amount of food. Early stomach cancers often cause microscopic bleeding that a FECAL OCCULT BLOOD TEST (FOBT) can detect. As the cancer becomes more advanced, symptoms may include

- PAIN in the upper left abdomen
- VOMITING after meals
- dyspepsia that does not go away with antacids, eating, or medications to reduce acid in the stomach
- unintended weight loss
- blood in the vomit or in the stools, which may manifest as "coffee grounds" or tarry stools
- fatigue and weakness

The diagnostic path may include BARIUM SWALLOW, upper gastrointestinal ENDOSCOPY with biopsy, and COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI). The biopsy confirms the diagnosis and identifies the kind of cancer. The pathologic examination of the tissue sample also establishes the extent to which the cancer likely has spread, called cancer staging. The cancer's stage helps determine treatment options and protocols (standards of practice), and expectations about outlook (prognosis).

Treatment Options and Outlook

The main treatment for nearly all stages of stomach cancer is surgery to remove the cancerous tumor, involved tissues, and adjacent structures such as LYMPH NODES and fatty tissue. Surgery is curative for stomach cancer detected very early (stage 0). For stage 1, 2, and 3 stomach cancers oncologists recommend CHEMOTHERAPY and RADIATION THERAPY after surgery. The chemotherapy drugs commonly used to treat stomach cancer are 5FU, cisplatin, epirubicin, and etoposide, which the oncologist may administer individually (particularly 5FU for stage 1 cancers) or in combination with one another.

The surgical options for stomach cancer include

- endoscopic resection, in which the surgeon removes the tumor and a safe margin of stomach tissue endoscopically

BASIC STAGING OF STOMACH CANCER

Stage	Meaning	Treatment Protocol
stage 0	CANCER is in its earliest stages, completely confined to the gastric epithelium (lining of the STOMACH); also called CARCINOMA in situ	endoscopic resection, partial GASTRECTOMY, or total gastrectomy to remove the cancerous tumor
stage 1	cancer involves the gastric mucosa but remains confined to the stomach	partial or total gastrectomy with removal of adjacent fatty tissue and lymph nodes
stage 2	cancer extends into and beyond the MUSCLE layers of the stomach and may involve up to 15 adjacent LYMPH NODES	partial or total gastrectomy with extensive removal of adjacent fatty tissue and lymph nodes RADIATION THERAPY or CHEMOTHERAPY; occasionally a combination of both
stage 3	cancer extends beyond the stomach into adjacent lymph nodes and nearby organs such as the SPLEEN, LIVER, PANCREAS, or intestine	total gastrectomy with extensive removal of adjacent fatty tissue and lymph nodes surgery to remove tumors in other organs radiation therapy and chemotherapy
stage 4	cancer has spread from the stomach to other organs throughout the body	palliative surgery, chemotherapy, or radiation therapy to relieve symptoms, obstruction, and bleeding that may occur

- partial GASTRECTOMY, in which the surgeon removes the section of stomach containing the tumor
- total gastrectomy, in which the surgeon removes the entire stomach and an area of surrounding adipose (fatty) tissue called the omentum
- lymphadenectomy, in which the surgeon removes the adjacent lymph nodes

Few lifestyle modifications beyond those to decrease the risk for recurrent or other cancers, are necessary for people who have endoscopic resections. Partial gastrectomy requires moderate changes in diet and EATING HABITS to accommodate the reduced size of the stomach, primarily a shift to eating smaller meals more frequently and reducing the amount of carbohydrates in the diet. Total gastrectomy requires significant modifications in eating habits as the surgery connects the lower end of the ESOPHAGUS to the start of the DUODENUM, leaving no reservoir for ingested food. Most people can eat only a few bites of food at a time after total gastrectomy, making eating enough to meet the body's nutritional needs a fairly continuous process. As well, because the stomach produces the substances that make it possible for the body to absorb vitamins such as vitamin B_{12}, people who undergo total gastrectomy need NUTRITIONAL SUPPLEMENTS.

The outlook for stage 0 stomach cancer is excellent, with a 90 percent of people who undergo surgery reaching the five-year survival mark. The outlook remains very good for stage 1 stomach cancer, with about a 70 percent five-year survival rate. More advanced stages of stomach cancer, in which the cancer spreads to involve other tissues and organs, remain difficult to treat successfully. Clinical research studies may offer the opportunity to participate in investigational treatments that extend life as well as improve QUALITY OF LIFE.

Risk Factors and Preventive Measures

As is the case with many kinds of cancer, age is the most significant risk factor. Most stomach cancers occur in people over age 60. Family history of stomach cancer or COLORECTAL CANCER (which is also an ADENOCARCINOMA of the gastrointestinal tract), long-term cigarette smoking (particularly in combination with excessive alcohol consumption) and OBESITY also raise the risk for stomach cancer. The most valuable preventive measure is FOBT to screen for the presence of blood in the gastrointestinal tract. Bleeding raises suspicion for several kinds of cancer that are highly treatable with early detection and intervention. People who have peptic ulcer disease should be tested and treated for *H. pylori* infection. A diet high in vegetables and low in smoked or preserved foods seems to lower the risk for stomach cancer.

T–Z

toxic megacolon A serious condition in which a loss of MUSCLE tone in the lower COLON (typically the sigmoid colon) causes the preceding segment of colon to greatly enlarge (dilate). Air accumulates in the dilated bowel, increasing the pressure. Without prompt treatment intestinal perforation (rupture) is highly likely, with consequential PERITONITIS.

Toxic megacolon is a potentially life-threatening condition that requires emergency medical treatment and often surgery.

Toxic megacolon is usually a complication of inflammatory conditions affecting the gastrointestinal tract, such as INFLAMMATORY BOWEL DISEASE (IBD) or INFECTION (COLITIS). The congenital disorder HIRSCHSPRUNG'S DISEASE, in which the lower colon lacks nerves, can cause toxic megacolon in a newborn infant.

Symptoms and Diagnostic Path

A person who has toxic megacolon is very sick. Usually there is FEVER along with ABDOMINAL DISTENTION, rigidity, and PAIN. REBOUND TENDERNESS and absence of BOWEL SOUNDS are common findings. The person may be in SEPTICEMIA (septic SHOCK), indicating PERITONITIS. The doctor often can make the diagnosis with an abdominal X-RAY that shows the dilated colon.

Treatment Options and Outlook

ANTIBIOTIC MEDICATIONS, CORTICOSTEROID MEDICATIONS, depending on the cause of the condition, and intravenous fluids to counter DEHYDRATION may help stabilize the colon, in combination with positional changes to attempt to move air (intestinal gas) out of the bowel to help relieve the distention. Surgery to remove the dilated segment of bowel (colectomy) is often the only treatment to prevent or treat bowel perforation. The surgeon then connects the two healthy ends of bowel together to restore normal bowel function. With prompt and appropriate treatment, many people make a full recovery from toxic megacolon. However, it does present a serious challenge to the body's HEALING abilities. As well, any underlying conditions that precipitated the bowel dilation may continue to cause symptoms.

Risk Factors and Preventive Measures

The primary risk factor for toxic megacolon is any condition that causes INFLAMMATION of the colon. Taking medications to slow gastric motility (such as to treat DIARRHEA) may contribute to the circumstances resulting in toxic megacolon. Anyone who has colitis, GASTROENTERITIS, DIVERTICULAR DISEASE, CELIAC DISEASE, IBD, or other inflammatory condition affecting the gastrointestinal tract who experiences symptoms that could suggest toxic megacolon should see a doctor without delay.

ulcerative colitis See INFLAMMATORY BOWEL DISEASE (IBD).

virtual colonoscopy See COLONOSCOPY.

vomiting The forceful expulsion of contents from the STOMACH, also called emesis. The force of vomiting may also draw digestive material from

the DUODENUM (first section of the SMALL INTESTINE). Like sneezing and coughing, vomiting is a protective and reflexive mechanism to rid the body of substances that threaten its well-being.

Vomiting occurs in response to NERVE impulses from the BRAIN's emesis center (also called vomiting center). The emesis center receives input from numerous body systems, including the gastrointestinal tract, vestibular system (which regulates balance), and circulatory system, as well as from the chemoreceptor trigger zone, another region of the brain that receives signals from the body. PAIN signals, particularly those the vagus nerve conveys, also travel to the emesis center, which is why severe pain may result in NAUSEA (queasiness and the feeling of being about to vomit) and vomiting.

Other variables that influence the emesis center include sensory perceptions such as foul smells or disturbing sights (which activate the chemoreceptor zone), hormonal shifts (such as occur in pregnancy to cause MORNING SICKNESS), and signals from the gastrointestinal tract indicating chemical changes such as from the presence of INFECTION or INFLAMMATION. Nausea, the sensation of queasiness and the urge to vomit, typically though not always precedes vomiting.

A complex series of physiologic events takes place to permit vomiting. Simultaneously the epiglottis closes (blocking the airway), the larynx lifts, and the upper esophageal sphincter opens. Then the DIAPHRAGM violently contracts, pulling it down and causing the open the lower esophageal sphincter to open, while the abdominal muscles contract with comparable force to push gastric (stomach) contents upward through the now open esophagus. Vomitus is highly acidic; chronic vomiting such as occurs with anorexia nervosa causes erosion of the tooth enamel. This material has a bitter taste and often leaves a burning sensation in the upper THROAT. Though the mechanism of vomiting is involuntary, there is some voluntary control over its initiation.

Episodic vomiting generally has no lasting consequences, though the very young and the very old can quickly become dehydrated. Vomiting that continues longer than three or four weeks without apparent cause requires medical evaluation. Treatment may include ANTIEMETIC MEDICATIONS, dietary changes, or therapies to resolve underlying conditions. Complications of chronic or repeated vomiting may include ESOPHAGITIS, electrolyte imbalance, and ASPIRATION PNEUMONIA.

Whipple's disease A bacterial INFECTION of the SMALL INTESTINE, also called intestinal lipodystrophy, that impairs absorption of fats (lipids). The PATHOGEN (infective BACTERIA) is *Tropheryma whippelii*. Though *T. whippelii* can infect various body systems including the HEART and the EYE, the gastrointestinal tract is its most common site. In the small intestine the bacteria create lesions (disruptions in the continuity of the intestinal mucosa) that destroy the villi, the microscopic, fingerlike extensions of tissue where much of the intestine's absorption functions take place. Researchers do not know how people acquire *T. whippelii*, though do know the infection can take years to decades to manifest symptoms.

Symptoms include DIARRHEA, GASTROINTESTINAL BLEEDING, OSTEOARTHRITIS, MALNUTRITION, unintended weight loss, HEADACHE, and FEVER. The diagnostic path may include general blood tests, BARIUM SWALLOW with small intestine flow-through, and ENDOSCOPY with biopsy to culture a tissue sample from the inner intestine. Treatment is a course of intravenous ANTIBIOTIC MEDICATIONS, typically penicillin and streptomycin or chloramphenicol in combination, with 12 to 18 months of oral antibiotic therapy to completely eradicate the bacteria.

See also GASTROENTERITIS; MALABSORPTION.

Zollinger-Ellison syndrome A rare disorder in which the STOMACH dramatically increases hydrochloric acid production, resulting in rampant PEPTIC ULCER DISEASE. Zollinger-Ellison syndrome develops as a consequence of benign tumors, called gastrinomas, that secrete the digestive HORMONE gastrin. Gastrin signals the stomach to produce acid, which the stomach continues doing as long as gastrin remains present. The excess acid that results causes extreme irritation of the gastric mucosa (stomach's lining), leading to numerous ulcers. The gastrinomas may form in the PANCREAS or the DUODENUM (first segment of SMALL INTESTINE).

Though gastrinomas are noncancerous, they often spread to other locations (notably the LIVER) and may develop into CANCER over time. Doctors do not know what causes Zollinger-Ellison syndrome though it appears to have a correlation with MULTIPLE ENDOCRINE NEOPLASIA (MEN) type 1, a disorder in which tumors (including gastrinomas) develop in numerous endocrine glands.

The symptoms of Zollinger-Ellison syndrome are the same as those for peptic ulcer disease (DYSPEPSIA, NAUSEA, sensation of fullness, possible GASTROINTESTINAL BLEEDING). ENDOSCOPY of the upper gastrointestinal tract may reveal gastrinomas in the duodenum. Abdominal ULTRASOUND, COMPUTED TOMOGRAPHY (CT) SCAN, or MAGNETIC RESONANCE IMAGING (MRI) can detect gastrinomas in the pancreas or the duodenum. Treatment combines medication to reduce gastric acid production, such as H2 ANTAGONIST (BLOCKER) MEDICATIONS or PROTON PUMP INHIBITOR (PPI) MEDICATIONS, and surgery to remove or reduce the gastrinomas when possible.

THE ENDOCRINE SYSTEM

The endocrine glands produce hormones, chemical messengers that regulate many functions within the body. Physician specialists who treat endocrine conditions are endocrinologists and neuroendocrinologists. This section, "The Endocrine System," presents a discussion of the endocrine glands and other structures, the hormones they produce and their functions, an overview of endocrine health and disorders, and entries about the health conditions that involve the endocrine system.

Structures of the Endocrine System

HYPOTHALAMUS
PITUITARY GLAND
- anterior pituitary lobe
- posterior pituitary lobe

PINEAL GLAND
THYROID GLAND
PARATHYROID GLANDS
THYMUS
ISLETS OF LANGERHANS
ADRENAL GLANDS
- adrenal cortex
- adrenal medulla

OVARIES (female)
TESTICLES (male)

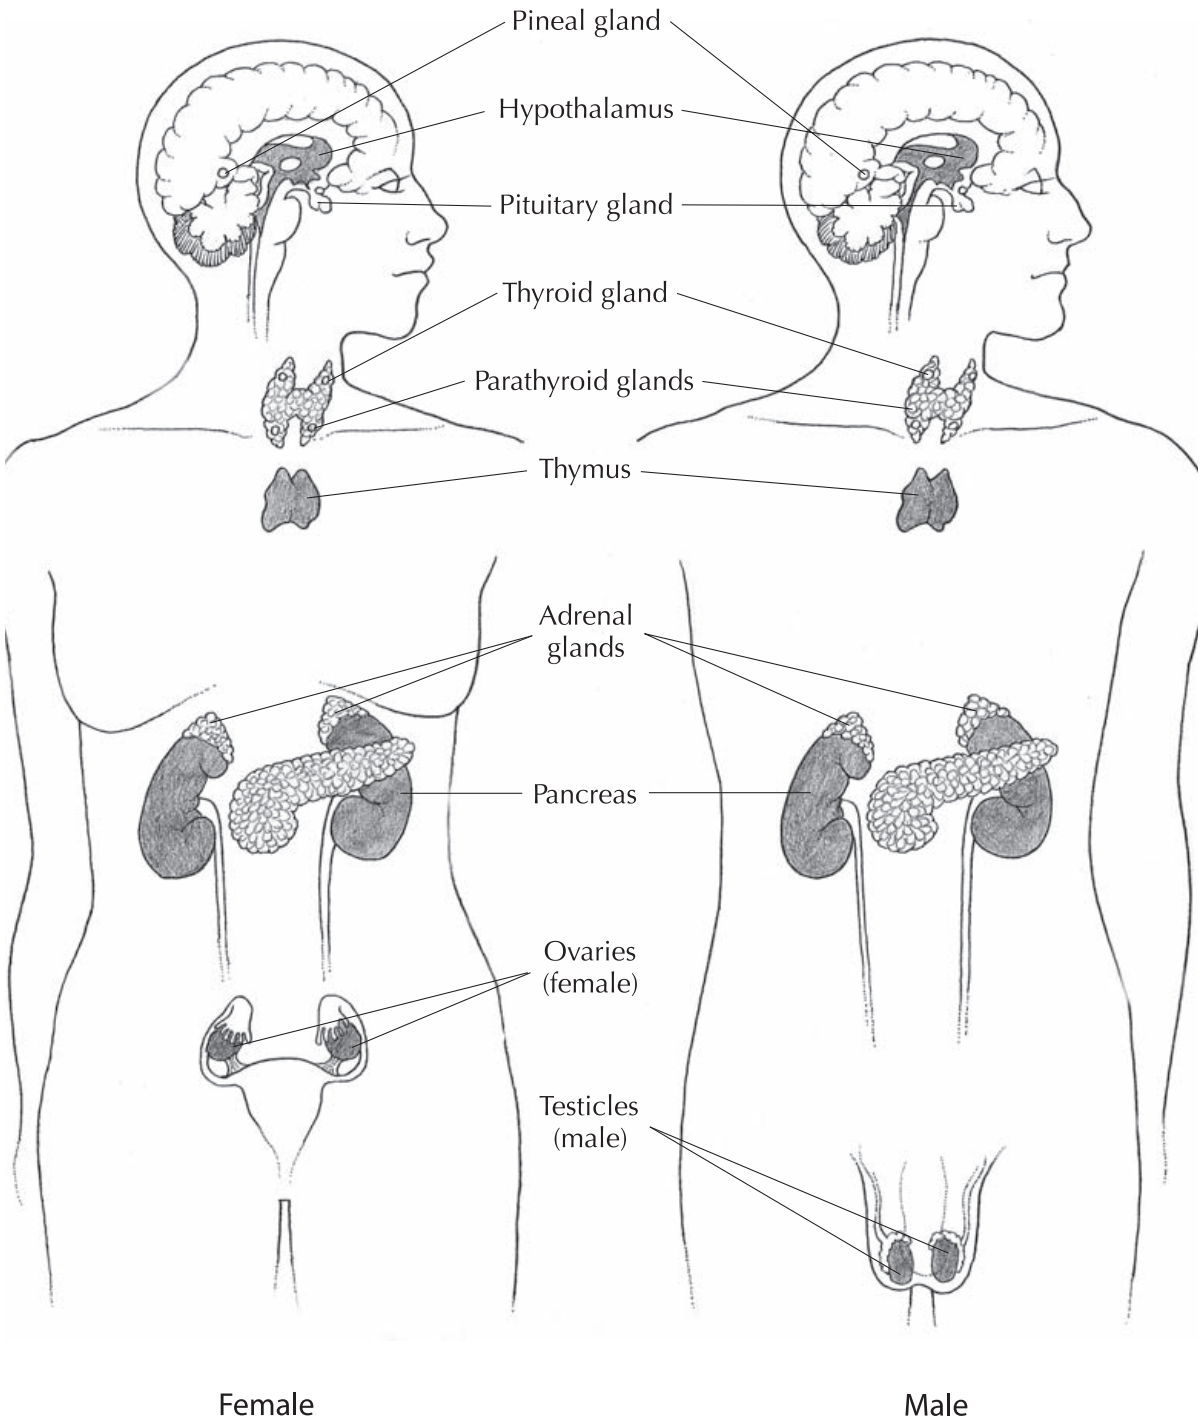
Functions of the Endocrine System

The endocrine system and the NERVOUS SYSTEM work in tandem to direct and regulate the myriad functions of the body, the nervous system through electrical impulses that travel along the nerves and the endocrine system via chemical messengers called hormones. Endocrine glands, sometimes called ductless glands, produce hormones. The endocrine glands release their hormones directly into the bloodstream, and the bloodstream transports them to the cells. Cells throughout the body contain receptors for specific hormones, so even though hormones circulate freely through the blood they affect the functions of only the cells that have receptors for them.

The endocrine glands may be clearly defined or loosely configured structures and are in numerous locations throughout the body. Some collections of endocrine cells inhabit other tissues and organs, such as those in the STOMACH and SMALL INTESTINE, and in the ISLETS OF LANGERHANS in the PANCREAS. Other endocrine cells form organized and independent structures, such as the ADRENAL GLANDS that cap the KIDNEYS and the THYROID GLAND which lies across the front of the THROAT. Each endocrine structure produces specific hormones. Collectively the endocrine structures function in intimate synchronization and interaction with each other, continuously adjusting their secretions to accommodate the ever-changing conditions and needs of the body. An intricate matrix of cascades and feedback mechanisms allows this dynamic coordination to initiate and inhibit cellular activity.

THE MAJOR ENDOCRINE STRUCTURES AND THEIR HORMONES

Endocrine Structure	Primary Hormones
ADRENAL GLANDS	
adrenal cortex	ALDOSTERONE
	CORTISOL
	DEHYDROEPIANDROSTERONE (DHEA)
adrenal medulla	DOPAMINE
	EPINEPHRINE
	NOREPINEPHRINE
gastrointestinal tract	cholecystokinin (CCK)
	enterogastrone
	gastric inhibitive polypeptide (GPI)
	gastrin
	motilin
	secretin
	SOMATOSTATIN
	vasoactive intestinal peptide (VIP)
HYPOTHALAMUS	ANTIDIURETIC HORMONE (ADH)
	CORTICOTROPIN-RELEASING HORMONE (CRH)



Pineal gland
Hypothalamus
Pituitary gland
Thyroid gland
Parathyroid glands
Thymus
Adrenal glands
Pancreas
Ovaries (female)
Testicles (male)
Female
Male

Endocrine Structure	Primary Hormones
HYPOTHALAMUS (continued)	dopamine
	GONADOTROPIN-RELEASING HORMONE (GNRH)
	GROWTH HORMONE-RELEASING HORMONE (GHRH)
	OXYTOCIN
	somatostatin
	THYROTROPIN-RELEASING HORMONE (TRH)
ISLETS OF LANGERHANS	GLUCAGON
	INSULIN
	somatostatin
KIDNEYS	ERYTHROPOIETIN (EPO)
	RENIN
ovaries	ESTROGENS
	INHIBIN
	PROGESTERONE
PARATHYROID GLANDS	PARATHYROID HORMONE
PINEAL GLAND	MELATONIN
PITUITARY GLAND	
anterior pituitary lobe	ADRENOCORTICOTROPIN HORMONE (ACTH)
	FOLLICLE-STIMULATING HORMONE (FSH)
	GROWTH HORMONE (GH)
	LUTEINIZING HORMONE (LH)
	PROLACTIN
	THYROID-STIMULATING HORMONE (TSH)
posterior pituitary lobe	stores and releases as needed: ADH
	oxytocin
PLACENTA	CHORIONIC GONADOTROPIN
	estrogen
	prolactin
	human placental lactogen (hPL)
	progesterone
	RELAXIN
testes	inhibin
	TESTOSTERONE
THYMUS	THYMOSIN
THYROID GLAND	CALCITONIN
	THYROXINE (T_4)
	TRIIODOTHYRONINE (T_3)

Bridge between control systems: the hypothalamus The HYPOTHALAMUS is the structural and functional bridge between the BRAIN and the endocrine system. Composed primarily of brain tissue, it receives a constant barrage of NERVE signals from the thalamus, a structure of the brain that serves as a neurologic switchboard for sensory information related to sight, sound, touch, and taste. The physical transition from thalamus to hypothalamus is difficult to distinguish, highlighting the blurred line between neurologic and endocrine activity that gives rise to the subspecialty of medicine known as neuroendocrinology.

The functions of the hypothalamus primarily relate to survival. Through a combination of nerve impulses and hormonal signals, the hypothalamus regulates BLOOD PRESSURE, HEART RATE, gastrointestinal activity and digestion, body temperature, hunger, and thirst. Hypothalamic hormones target the PITUITARY GLAND, acting either to stimulate or inhibit (stop) the pituitary's secretions. The hypothalamus receives hormonal messages directly from the pituitary gland and indirectly through HORMONE levels in the BLOOD, one of a number of feedback mechanisms that helps regulate the hypothalamus's hormonal activity and maintain hormonal balance within the body.

Hormonal choreography: the pituitary gland Extending downward from the base of the hypothalamus, the pituitary gland bulbs out from the end of a short stalk. A dedicated capillary network, the hypophyseoportal circulation, circulates blood between the hypothalamus and the pituitary gland to fast track hormone delivery from the hypothalamus to the pituitary gland. A separate network of blood vessels supplies each structure with blood from the body's circulation to meet the metabolic needs of its cells and to carry pituitary hormones into the body. Communication between the pituitary gland and the hypothalamus is by necessity intimate and continuous, as the relationship between these two structures regulates basic bodily functions of survival.

The pituitary gland has two structural and functional divisions: the anterior lobe and the posterior lobe. The anterior pituitary lobe directs the activities of the thyroid, parathyroid, adrenal, and sex glands (gonads). The posterior pituitary lobe stores and secretes two hormones it receives from the hypothalamus: ANTIDIURETIC HORMONE (ADH), sometimes called vasopressin, and OXYTOCIN. The release of ADH directs the KIDNEYS to withhold more water, increasing blood volume and thus blood pressure. Oxytocin stimulates contractions of the UTERUS during CHILDBIRTH, and the mother's letdown REFLEX when BREASTFEEDING. Oxytocin also appears to play a role in sexual arousal in both women and men.

Recent research suggests oxytocin interacts with the limbic system, the intersection of neurologic and biochemical response to emotional stress. Levels of oxytocin in the bloodstream rise when stress hormone levels rise, leading researchers to speculate that oxytocin presents a counterbalance to the fight-or-flight response the stress hormones evoke by helping calm the body and restore homeostasis.

Stress management: the adrenal glands The adrenal glands drape across the tops of the kidneys. They produce an array of hormones that increase body functions in response to physiologic stress, such as heart rate and blood pressure. The two portions of the adrenal gland—the cortex (outer portion) and the medulla (inner portion)—have unique functions. The adrenal cortex, rindlike in appearance, secretes steroid hormones that it synthesizes from cholesterol. The primary adrenal cortex hormones are ALDOSTERONE and CORTISOL. Aldosterone regulates the fluid balance in the blood by directing the absorption of water and sodium in the kidneys. This is a fundamental component of a blood pressure–regulation mechanism called the RENIN-angiotensin-aldosterone (RAA) system. Cortisol has numerous effects related to metabolic functions throughout the body. The adrenal cortex also produces small amounts of estrogen, PROGESTERONE, and TESTOSTERONE in men and women alike.

The adrenal medulla, the core of the adrenal gland, secretes EPINEPHRINE, NOREPINEPHRINE (also called adrenaline and noradrenaline), and DOPAMINE. These hormones initiate rapid increases in heart rate, respiration, and blood pressure, along with changes blood distribution, to allow the body to enter the classic fight-or-flight mode—the stress response. These hormones also provide the "adrenaline rush" that appeals to people who enjoy high-risk activities. Chemically these three substances are catecholamines. In the bloodstream the catecholamines are hormones regulating cell activity. In the interstitial (between-cell) fluid, they function as neurotransmitters, facilitating electrical impulses between nerves. The midbrain, including the hypothalamus, controls the adrenal medulla's secretory activity.

DOPAMINE "TRANSPLANT" FOR PARKINSON'S DISEASE

In the 1980s neurologists experimented with transplanting adrenal medullary tissue into the brains of people who had PARKINSON'S DISEASE, a progressively degenerative condition that results from depleted DOPAMINE in the BRAIN. Doctors hoped the adrenal medullary tissue would take root in the brain and continue to produce NOREPINEPHRINE, a precursor HORMONE to dopamine, which other brain chemicals would convert to much-needed dopamine. The risks of the procedure far outweighed the possible benefits, however, and failed to produce consistent results. Doctors today have largely abandoned the method.

Metabolic homeostasis: the thyroid gland Spread across the throat like an elongated butterfly, the thyroid gland secretes the hormones THYROXINE (T_4) and TRIIODOTHYRONINE (T_3), which direct the rate at which cells consume energy. These hormones regulate numerous body functions, notably heart rate, digestive rate, and thermoregulation (body temperature, particularly response to cold). The thyroid's two lobes perform the same functions. The thyroid gland also secretes CALCITONIN, which acts to decrease calcium levels in the blood.

Thyroid hormones are essential for life. People who have HYPOTHYROIDISM (underactive thyroid gland) or who have had their thyroid glands destroyed or surgically removed must take lifelong thyroid hormone supplement or replacement therapy. Congenital thyroid deficiency, once called cretinism, in which the thyroid gland is missing or

dysfunctional in the unborn child, results in permanent damage to growth, development, and intellect. HYPERTHYROIDISM, in which the thyroid gland secretes excessive thyroid hormones, can cause serious and permanent damage to the HEART and to the eyes (GRAVES'S OPHTHALMOPATHY).

Calcium balance: the parathyroid glands Arising from the surface of the thyroid gland where it wraps around the TRACHEA are the four tiny PARATHYROID GLANDS, arranged in pairs on each of the thyroid gland's two lobes. Though each parathyroid gland alone is barely the size of a grain of rice, the parathyroid glands collectively keep the heart beating, the muscles moving, and the bones solid. The parathyroid glands produce PARATHYROID HORMONE, also called parathormone, which regulates the balance between calcium and phosphate. This equilibrium is essential for the conduction of nerve impulses in the heart and the skeletal muscles, proper growth of the bones and TEETH in childhood, and BONE DENSITY and STRENGTH in adulthood. The relationship between the thyroid gland and the parathyroid glands is functionally as well as physically intimate. The release of parathyroid hormone causes calcium levels in the blood to rise, counterbalancing the actions of calcitonin.

Glucose balance: the islets of Langerhans Distributed throughout the exocrine cells that make up the pancreas are about a million clusters of endocrine cells ranging in size from a few dozen to a few hundred cells. These clusters are the islets of Langerhans, and their three distinct cell types secrete the hormones GLUCAGON, INSULIN, and SOMATOSTATIN. These hormones regulate the body's balance and use of GLUCOSE, the primary source of fuel for many functions of METABOLISM. The islet cells also secrete a number of other hormones whose functions remain less clearly understood.

Reproduction: the gonads (sex glands) The gonads (sex glands)—the OVARIES in women and the testes in men—produce the hormones responsible for sexual maturity and reproductive capability. The gonads become active at PUBERTY, when the hypothalamus signals the pituitary gland to begin producing FOLLICLE-STIMULATING HORMONE (FSH) and LUTEINIZING HORMONE (LH). These hormones in turn stimulate the gonads to produce the sex hormones. Men and women alike have all of these hormones in their bodies; men have a predominance of testosterone and women have a predominance of estrogen and progesterone.

In women the ovaries produce estrogen, progesterone, and a small amount of testosterone. In men the testes produce testosterone, INHIBIN (which regulates SPERM production), and a small amount of estrogen along with a number of other minor hormones that have narrowly specialized functions. In men and women alike, the adrenal cortex produces small amounts of estrogen, progesterone, and testosterone. Estrogen is important for lipid metabolism and storage, testosterone is important for building and maintaining MUSCLE mass, and progesterone is an important precursor hormone for the synthesis of other steroid (lipid-based) hormones.

Building the immune system: the thymus In the 1940s doctors believed there was a connection between an enlarged THYMUS and sudden, unexplainable death in infants. They termed this condition status thymicolymphaticus and treated it with RADIATION THERAPY to destroy the thymus. There was little evidence to support this connection, however, and doctors began to notice that children treated with irradiation were unusually susceptible to infection. By the 1960s, as understanding began to grow about the functions of the immune system and researchers began to recognize the thymus had a role in immune function, and doctors abandoned both the concept of status thymicolymphaticus and its treatment.

The thymus secretes the hormone THYMOSIN, which helps the immune system's T-cell lymphocytes reach maturity and stimulates blood stem cell production in the BONE MARROW. Researchers speculate the thymus also produces several as yet unidentified hormones that influence immune function. Doctors now know, too, that the normal release of GROWTH HORMONE (GH) during the middle years of childhood stimulates an increase in the size of the thymus, explaining the reason for its enlargement in young children. During this period of development the thymus becomes particularly active in maturing and releasing into the body the T-cells that will form the foundation of immune function for the remainder of life.

Circadian cycles: the pineal gland The PINEAL GLAND, a small pinecone-shaped structure buried

deep in the brain, releases MELATONIN, a hormone associated with sleep cycles. Eastern traditions have long viewed the pineal gland as the metaphysical "third eye," an energy pathway by which the brain communicates directly with the external environment. Western researchers are now discovering this perception may have tangible scientific substance. The pineal gland is located near the optic nerve, which appears to convey input about external light and dark to the pineal gland. Though researchers do not yet fully understand the mechanisms through which this occurs, they do know that melatonin secretion increases with darkness and decreases with lightness, apparently to facilitate the circadian cycle of sleep and wakefulness. Though as yet melatonin is the only identified hormone the pineal gland produces, researchers believe the pineal gland has additional functions and continue to study its role in the body.

Hormonal rhythms, cascades, and feedback loops The structures of the endocrine system function in tight synchronization with one another. Some hormonal processes are cyclic, under the control of the body's circadian rhythm. Others are "on demand," with physiologic events triggering the release of hormones.

For example, the hypothalamus releases CORTICOTROPIN-RELEASING HORMONE (CRH) on a regular cycle that begins a sharp spike a few hours before daybreak and peaks a few hours later, dropping off over the daylight hours to trough in the early evening. The release of CRH initiates a cascade of hormonal responses that accelerate metabolism in preparation for the body's heightened level of activity during waking hours: CRH stimulates the pituitary gland to release ADRENOCORTICOTROPIC HORMONE (ACTH), which subsequently stimulates the adrenal cortex to release cortisol. Cortisol then initiates numerous metabolic actions throughout the body.

Correspondingly, hormonal activity from the thyroid gland, islets of Langerhans, and gastrointestinal tract accelerates, instigating further cascades of hypothalamic-pituitary-adrenal activity. As the flow of CRH diminishes, the hormonal cascade slows. Feedback mechanisms also come into play. Cortisol reaches a certain level in the blood circulation, signaling the hypothalamus to stop releasing CRH. The body's metabolic activity begins to drop off. By nightfall the CRH level reaches its lowest point, and the body is metabolically ready for rest. The pineal gland's release of melatonin similarly follows, and may in fact establish, the body's circadian rhythm.

Other hormonal cycles follow different patterns. The hormonal cascades of puberty, for example, continue during the period of growth during which the secondary sex characteristics emerge—typically a range between the ages of 11 to 12 and 18 to 20. A woman's MENSTRUAL CYCLE repeats approximately every 28 days. The hormones of PREGNANCY follow a precise schedule. Additional hormonal activity occurs in response to physiologic needs in integration with routine hormonal cycles. Feedback loops regulate such activity, with the endocrine system responding to stimuli from other body systems.

During intense physical exercise, for example, the hypothalamus releases ADH in response to hormonal signals from the kidneys (renin release) and barosensory signals from the cardiovascular system, stimulating the adrenal glands to release aldosterone, epinephrine, and norepinephrine to readjust fluid volume, electrolyte balance, heart rate, BREATHING rate, and blood pressure. The various physiologic changes that occur then signal the hypothalamus to stop releasing ADH. Such changes may take the form of rising levels of hormones in the blood or events that indicate the body's needs are being met, such as increased blood volume and elevated blood pressure. Some hormones, such as ADH, are stimulatory; they initiate activity. Other hormones, such as somatostatin, are inhibitory; they stop activity.

Health and Disorders of the Endocrine System

Some endocrine structures are more active early in life, then recede to maintenance roles later in life. The thymus, for example, establishes the foundation of the immune system in early to middle childhood and subsequently shrinks in size and function at puberty to take a background, supportive role in immune function. Other endocrine structures become active at puberty such as the ovaries (female) or testes (male), known collectively as the gonads or sex glands. The sex glands establish the body's SECONDARY SEX-

UAL CHARACTERISTICS and reproductive maturity. The functions of the sex glands taper with aging, most prominently in women to define the conclusion of FERTILITY (MENOPAUSE). Though men can remain fertile throughout their lives, testosterone levels begin to gradually diminish in the mid-30s. Still other endocrine tissues function only under special circumstances, such as the PLACENTA which secretes dozens of hormones that regulate pregnancy.

The most common endocrine disorder in the United States is DIABETES (known clinically as diabetes mellitus). Approximately 13 million Americans know they have diabetes, and health experts believe another 5 to 6 million more have diabetes though do not yet know, more than half of whom are over age 60. Diabetes is a significant health influence among adults as the leading cause of heart disease, kidney disease, blindness, and nerve damage (NEUROPATHY). Diabetes accounts directly for more than 70,000 lives lost each year, making it the sixth leading cause of death in the United States. Some people are able to manage their diabetes through lifestyle factors such as diet, exercise, and WEIGHT LOSS AND WEIGHT MANAGEMENT. Others must take medication such as oral antidiabetic medications or insulin injections. Type 1 diabetes is an autoimmune disorder in which the immune system attacks the islets of Langerhans, killing the cells that produce insulin. Type 2 diabetes typically develops in midlife or later, nearly always as a consequence of INSULIN RESISTANCE arising from lifestyle factors. Health experts believe most type 2 diabetes is preventable.

Also common is hypothyroidism (underactive thyroid). About 5 million Americans know they have hypothyroidism. Hypothyroidism affects numerous body functions, including heat regulation, heart rate, blood pressure, body weight, fertility, energy levels, and sleep quality. As with diabetes, health experts believe many more—perhaps another 10 million—have the condition and do not yet know. Hypothyroidism is more common among women and becomes more frequent with advancing age, with some health experts estimating as many as 20 percent of women over age 60 have the condition.

OBESITY, in which body weight due to excessive body fat is 20 percent or more greater than healthy weight, is a complex confluence of endocrine, genetic, and lifestyle factors. Much research focuses on the role of hormones in body functions related to APPETITE (the desire to eat) and metabolism. Research in the 1990s identified two hormones, leptin and ghrelin, that strongly influence appetite. The stomach secretes ghrelin, and adipose (fat) cells throughout the body secrete leptin. The hypothalamus perceives the changing levels of these hormones in the bloodstream as signals of either hunger or satiety (sense of fullness), and correspondingly accelerates or decelerates digestion and metabolism (use of energy). This research holds intriguing implications, especially for type 2 diabetes. Doctors know that 90 percent of people who have type 2 diabetes also have obesity and estimate that a comparable percentage of people who have obesity also have either insulin resistance or diabetes. Health experts estimate obesity affects 15 percent of American children and 30 percent of American adults.

Traditions in Medical History

For centuries mystery shrouded the very existence of the endocrine glands and their functions. Until human autopsy (cutting open the body after death) became ethically and legally acceptable, doctors learned of endocrine glands or their functions only unintentionally. Physicians knew the signs consistent with the diseases of endocrine dysfunction but lacked the understanding of their causes and thus could not treat them. Historical records dating from ancient Mesopotamia, India, Greece, Rome, and China, for example, document the universal manifestation of diabetes, the first recognized, and even today the most common, endocrine disorder. In diabetes, the islets of Langerhans, collections of endocrine cells in the pancreas, stop secreting insulin, the hormone that "unlocks" cells to allow glucose (sugar), their primary fuel, to enter. As a result, glucose accumulates in the blood while cells literally starve to death.

Antiquarian healers diagnosed diabetes using the same concept modern doctors use (though with vastly different methods), testing the URINE for sugar. Because blood glucose levels rise with inadequate insulin presence, the kidneys attempt to restore the balance by extracting glucose from

the blood and passing it into the urine for excretion from the body. Though the modern method employs laboratory equipment that measures the amount of glucose present in the urine, the ancient physician relied on a far less sophisticated approach: An unfortunate assistant tasted the patient's urine, with sweetness confirming the diagnosis. More innovative or perhaps simply less influential healers had their patients urinate on the ground, then watched to see whether ants swarmed to the site. When ants were attracted to the urine, the diagnosis was "honey urine disease," known today as diabetes.

The diagnosis unfortunately offered little hope for treatment. Ancient healers knew honey urine was a harbinger of death but they did not understand the accountable disease mechanisms. Not until the early 20th century did the scientists Frederick Banting (1891–1941), Charles Best (1899–1978), and John James Rickard Macleod (1876–1935) discover insulin and correlate it to pancreatic function and diabetes. Their research ultimately demonstrated that regular injections of a purified solution prepared with ground pancreatic tissue from pigs or cows, which provided insulin, restored glucose metabolism in people who had diabetes.

The work earned the trio the 1923 Nobel Prize in Physiology or Medicine. More significant, it gave the prospect of normal life to countless people otherwise consigned to near-certain death. And it threw open the door to expanded knowledge of the role of the body's chemical messengers in health and in illness. Modern researchers hope to build on this knowledge to find a cure for diabetes, a disorder that despite treatment remains the leading cause of RENAL FAILURE and blindness and a significant cause of CARDIOVASCULAR DISEASE (CVD).

Breakthrough Research and Treatment Advances

The 20th century saw the field of endocrinology grow from the introduction of the term *hormone* in 1902 to amazing breakthroughs in understanding of, and treatments for disorders of, endocrine function and neuroendocrine interactions. Researchers now know of nearly 100 hormones the body produces and have developed synthetic hormones to replace or supplement the body's natural hormones as treatments for conditions such as diabetes, hypothyroidism, and osteoporosis. People who have insulin-dependent diabetes now take injections of insulin products genetically engineered in the laboratory to emulate human insulin's precise molecular structure, no longer dependent on purified extracts from animal tissues. Research exploring ISLET CELL TRANSPLANTATION shows promise for being among the therapies that might someday allow doctors to cure diabetes.

Researchers entered other frontiers of endocrine understanding as well. In 1935 scientists finally isolated and named testosterone, the male sex hormone. Shortly after came the discovery of estrogen, the female sex hormone. A quarter century later researchers had turned this knowledge into significant advances on both ends of the fertility spectrum, with the debut of the oral contraceptive (birth control pill) in 1960 and the birth of the first "test tube baby" in 1978. Both discoveries manipulate the hormones responsible for OVULATION, CONCEPTION, and pregnancy. Researchers also have come to recognize that hormones drive most primary cancers of the BREAST, uterus, PROSTATE GLAND, and testicles. New therapies use pharmaceutical interventions (synthetic hormones and chemicals that mimic the structure and action of hormones) to treat or prevent these cancers.

A

acromegaly A condition in which the PITUITARY GLAND secretes excessive GROWTH HORMONE (GH), causing the bones to thicken and become overgrown. This excessive growth is most apparent in the facial features and the extremities, especially the jaw, brow, hands, and feet. Most commonly acromegaly develops in midlife. When acromegaly occurs before the growth plates in the long bones of the arms and legs have fused, excessive height results. Doctors call this gigantism rather than acromegaly, though it is the same disease process. When excessive secretion of GH takes place after the growth plates have fused (generally after PUBERTY), the bones enlarge by thickening and spreading. This pattern of overgrowth results in the distortions characteristic of the disorder.

A BOND ACROSS TIME

Some medical historians believe the biblical giant Goliath and the sixteenth president of the United States, Abraham Lincoln (1809–1865), had in common the disorder of acromegaly. Both were exceedingly tall for the time in which they lived. Descriptions of Goliath and photographs of Lincoln suggest the characteristic features of acromegaly: overgrown facial features, excessive height, and unusually large hands and feet. Lincoln's headaches and fatigue, widely known, also were indications of acromegaly.

Though the small number of people doctors diagnose with acromegaly gives the perception this condition is rare, endocrinologists believe acromegaly is much more common than those numbers suggest. Acromegaly typically develops over years to decades, with symptoms emerging slowly and often nonspecifically. Many people learn they have acromegaly during evaluation for other conditions that could account for their symptoms, such as HYPERTENSION (high BLOOD PRESSURE) or DIABETES.

The most common cause of acromegaly is an ADENOMA (noncancerous tumor) in the anterior lobe of the pituitary gland, increasing the quantity of cells that secrete GH. Occasionally an adenoma or, rarely, an ADENOCARCINOMA (an adenoma that has turned cancerous) that secretes GH and is located elsewhere in the body, such as the gastrointestinal tract (notably the PANCREAS) or the LUNGS, is responsible. Growth hormone does not itself cause growth but instead stimulates the LIVER and other structures to produce other hormones, known collectively as insulinlike growth factors, or IGFs (sometimes called somatotropin mediators or somatomedins), that increase the rate at which cells divide. The most prominent of these is INSULIN growth factor 1 (IGF-1). High GH secretion results in excessive IGF-1 circulating in the BLOOD, which becomes one of the clinical markers for making the diagnosis.

Symptoms and Diagnostic Path

Often the earliest symptoms of acromegaly are gradual changes in the hands and feet, especially swelling of the palms and soles. A person may need larger sizes of shoes or gloves than usual and find that rings or watches no longer fit. Other symptoms include

- frequent headaches and vision disturbances
- excessive sweating and body odor
- thickened, often darkened, SKIN and NAILS
- increasing space between the TEETH
- PAIN in the joints

- DYSMENORRHEA (abnormal MENSTRUATION) in women and ERECTILE DYSFUNCTION in men
- weakness and fatigue

Headaches and visual disturbances occur when the pituitary adenoma grows large enough to create pressure against structures of the BRAIN. Often this pressure affects the OPTIC NERVE, which passes near the pituitary gland, causing an array of vision disturbances. The excessive GH causes the SWEAT GLANDS to enlarge and increase production, causing the unpleasant body odor and excessive sweating. The overgrowth of BONE in the jaws displaces the teeth, often first apparent as a shift in bite (the way the teeth meet when chewing).

There are no definitive tests to diagnose acromegaly, requiring the endocrinologist to compile a picture of clinical and observational findings. About a third of people who have acromegaly have elevated GH levels in the blood an hour after they drink an oral GLUCOSE solution. Because of the constant interactivity between GH, insulin, and glucose, GH stays in the blood circulation for only a short time, and its levels vary widely in a healthy person. The level of IGF-1 is more indicative of excessive GH secretion because IGF-1 stays in the circulation for an extended time. However, IGF-1 levels naturally diminish with age and in conditions such as OBESITY and diabetes.

Because endocrine functions are so tightly integrated, often the endocrinologist will measure the blood levels of other hormones, such as those the THYROID GLAND, ADRENAL GLANDS, and sex glands produce. Other diagnostic procedures may include imaging studies such as X-rays to identify changes in bone structure and MAGNETIC RESONANCE IMAGING (MRI) to determine whether a pituitary adenoma is present. The endocrinologist also may ask to see photographs of the person taken over the preceding 5 to 10 years to evaluate changes in physical structure and appearance.

Treatment Options and Outlook

The optimal treatment is an OPERATION to remove the pituitary adenoma. The surgeon reaches the tumor from an incision made inside the NOSE, entering the brain from the nasal cavity (called transsphenoidal resection). Therapies such as medications or radiation therapy may be necessary to shrink tumors larger than 10 centimeters (4 inches) or to treat tumors when surgery is not a viable option or cannot remove all of the tumor. In most people the surgery results in immediate relief of pressure-related symptoms such as HEADACHE and VISION IMPAIRMENT as well as a prompt return to normal levels of GH in the bloodstream. Many of the other symptoms then improve, though some of the changes the excessive GH has caused, such as bone overgrowth, remain.

MEDICATIONS TO TREAT ACROMEGALY

bromocriptine (Parlodel)
octreotide (Sandostatin)
pegvisomant (Somavert)

About a third of people who develop acromegaly also develop hypertension, resulting from the altered hormonal environment in the body, and HEART FAILURE, a consequence of the enlargement of the HEART in response to the excessive GH. Many also develop chronic OSTEOARTHRITIS, resulting from the overgrowth of CARTILAGE at the bone ends and the joints, and peripheral NEUROPATHY, resulting from overgrown tissues compressing the nerves. Often, these problems are what cause people to seek medical attention.

In health the interactions among GH, insulin, and SOMATOSTATIN regulate the hormonal balance that allows appropriate growth. In acromegaly, the excessive GH throws the equilibrium of this matrix out of kilter. As a result, people who have acromegaly are also likely to develop type 2 diabetes as a consequence of hormonal disturbances within the insulin–glucagon–somatostatin matrix. Diabetes and other consequential conditions may require ongoing therapy even after treatment for the acromegaly restores normal GH secretion. People who have acromegaly have an increased risk for developing COLORECTAL CANCER, which arises from adenomas of the intestinal wall (intestinal polyps).

Risk Factors and Preventive Measures

There are no known risk factors or preventive measures for acromegaly. Early diagnosis provides

the ideal opportunity to remove or suppress the responsible tumor.

Addison's disease Damage to or progressive failure of the adrenal cortex of the ADRENAL GLANDS, resulting in insufficient production of the hormones CORTISOL and ALDOSTERONE. The most common cause of Addison's disease, also called primary ADRENAL INSUFFICIENCY, is autoimmune, in which the IMMUNE SYSTEM attacks the cells of the adrenal cortex. Doctors do not know what precipitates such an attack. Other causes include events that can damage or destroy adrenal tissue such as INFECTION that infiltrates the adrenal gland tissue (notably TUBERCULOSIS), blunt trauma or other injury to the abdomen, and tumors. Because the body cannot make up for the lost function of the adrenal glands, treatment requires lifelong HORMONE THERAPY to provide adequate levels of cortisol and usually aldosterone as well. With treatment most people who have Addison's disease are able to enjoy normal lifestyles and activities, though must remain vigilant for indications of Addisonian crisis.

Addisonian Crisis (Adrenal Crisis)

Addisonian crisis, also called adrenal crisis, occurs when physical stress such as injury, infection, or illness increases the body's demand for cortisol beyond the capacity of the adrenal glands to produce. The body exhibits signs of SHOCK and cardiovascular shock, including extreme HYPOTENSION (low BLOOD PRESSURE), DYSPNEA (shortness of breath or difficulty BREATHING), and erratic HEART RATE.

Addisonian crisis is a life-threatening event that requires immediate injection of hydrocortisone and emergency medical care.

Prompt and appropriate medical intervention (injected hydrocortisone and supportive measures to sustain cardiovascular function) can restore normal functions. However, Addisonian crisis can quickly turn fatal. People who have Addison's disease often carry emergency doses of injectable hydrocortisone, with instructions for dosage, and should wear identification of some sort (bracelet or necklace) that identifies them as having Addison's disease so medical aid response can act promptly with the correct measures.

Symptoms and Diagnostic Path

One of the earliest, though nonspecific, symptoms of Addison's disease is craving salt and salty foods, which occurs because the aldosterone deficit allows the KIDNEYS to release excessive amounts of sodium into the URINE. Other symptoms also tend to be nonspecific and include

- fatigue and tiredness
- postural hypotension (drop in blood pressure when rising from a sitting position)
- loss of APPETITE and weight loss
- MUSCLE weakness
- hyperpigmentation (darkening of the SKIN)
- irritability
- irregular MENSTRUATION (women)

The diagnostic path includes blood tests to measure the amounts of potassium, sodium, GLUCOSE, cortisol, and ADRENOCORTICOTROPIC HORMONE (ACTH). Other tests typically include a cortisol challenge—ACTH stimulation and CORTICOTROPIN-RELEASING HORMONE (CRH) stimulation tests—to assess the body's ability to produce cortisol and diagnostic imaging procedures such as MAGNETIC RESONANCE IMAGING (MRI) to visualize the hypothalamus, pituitary gland, or adrenal glands.

DISTINGUISHING FEATURES OF ADDISON'S DISEASE AND ADRENAL INSUFFICIENCY

Addison's Disease	Adrenal Insufficiency
normal ADRENOCORTICOTROPIC HORMONE (ACTH)	low ACTH
areas of HYPERPIGMENTATION	normal SKIN color
elevated BLOOD potassium level (HYPERKALEMIA)	normal blood potassium level
low blood sodium level (HYPONATREMIA)	normal blood sodium level
low blood GLUCOSE level (HYPOGLYCEMIA)	normal blood glucose level
deficient ALDOSTERONE production	normal aldosterone production

It is essential for the endocrinologist to distinguish between Addison's disease, which is primary adrenal insufficiency (the dysfunction originates with the adrenal cortex) and secondary adrenal insufficiency (the dysfunction arises from inadequate ACTH, or less commonly from inadequate CRH). Diagnostic test results make this distinction clear.

Treatment Options and Outlook

Treatment consists of medications (HORMONE therapy) to supplement or replace the adrenal hormones. Endocrinologists commonly prescribe oral hydrocortisone to supplement cortisol and fludrocortisone to supplement aldosterone. Medication dosages may change over time, and lifelong treatment is necessary. Circumstances that stress the body require additional medication, preferably in advance of the stress, when possible, to avert an Addisonian crisis. These circumstances include PREGNANCY, labor and delivery, surgery, and serious illness or injury.

Risk Factors and Preventive Measures

People who have other AUTOIMMUNE DISORDERS such as HYPOTHYROIDISM or type 1 DIABETES have an increased likelihood of developing the autoimmune form of Addison's disease. About 70 percent of people who have Addison's disease have the autoimmune form. There are no known preventive measures for Addison's disease.

adenoma A noncancerous tumor arising from epithelial cells that typically forms within glandular tissues or structures. An adenoma contains the same cells as the gland from which it arises, causing it to secrete the same hormones. The result is an excess of the HORMONE within the BLOOD circulation, which disrupts the endocrine balance to cause an array of symptoms specific to the hormone and its influences. Adenoma is a common cause of many acquired endocrine disorders and is usually treatable with surgery, medication, or RADIATION THERAPY. Adenomas that do not cause symptoms (asymptomatic) are exceedingly common, and researchers estimate as many as 35 percent of people have them.

The diagnostic path includes blood tests to measure blood levels of the hormone and imaging procedures to identify the adenoma's location. Because of the risk for an adenoma to become cancerous, endocrinologists prefer to surgically remove adenomas that cause symptoms. The surgery can be straightforward or complex, depending on the adenoma's location. In some circumstances the surgeon may need to remove the entire affected gland to remove the tumor, or may be unable to remove all of the adenoma. Either circumstance may make it necessary for the person to take long-term HORMONE THERAPY (with removal of the entire gland) or to take medication to suppress the tumor's activity. Endocrinologists often prefer to take a course of watchful waiting with asymptomatic adenomas rather than initiating any treatment.

adrenal glands A pair of endocrine glands, sometimes called suprarenal glands, located one above each kidney. The right adrenal gland is clearly triangular in shape, and the left adrenal gland has more of a crescent shape. Pumpkin colored, each adrenal gland is about three inches long and two inches deep, and rises above the kidney one-half inch (left adrenal gland) to three-quarters inch (right adrenal gland). These differences are due to the asymmetrical placement of the KIDNEYS, with the left kidney placed higher than the right in the abdomen.

The adrenal gland consists of two structurally distinct divisions: the outer cortex and the inner medulla. The adrenal cortex, a thick rindlike structure that makes up about 90 percent of the adrenal gland structure, encloses the adrenal medulla. The adrenal cortex produces the steroid hormones ALDOSTERONE and CORTISOL, as well as ESTROGENS, PROGESTERONE, and TESTOSTERONE. The fibrous, soft inner structure of the adrenal gland, the adrenal medulla, secretes the peptide hormones DOPAMINE, EPINEPHRINE, and NOREPINEPHRINE.

The most familiar function of the adrenal glands is their management of the body's physiologic responses to stress, commonly identified as the fight-or-flight reaction. In response to NERVE and hormonal signals from the HYPOTHALAMUS, the

adrenal glands can flood cortisol, epinephrine, and norepinephrine into the BLOOD circulation. On a mundane basis the adrenal glands also broadly regulate myriad functions of survival, such as BLOOD PRESSURE and HEART RATE, continuously adjusting the levels of these hormones in the bloodstream to meet the body's daily needs.

EPINEPHRINE
NOREPINEPHRINE

The Adrenal Cortex

The primary hormones of the adrenal cortex—aldosterone and cortisol—regulate many functions necessary for survival. Cortisol directs numerous chemical interactions that facilitate GLUCOSE balance and are integral for carbohydrate and fat METABOLISM. Aldosterone regulates the sodium–potassium balance, maintaining appropriate blood volume and blood pressure. The adrenal cortex arises from the same tissue in the EMBRYO as the sex glands (OVARIES and TESTES) and retains a functional connection to them in that it also synthesizes and secretes estrogen, progesterone, and testosterone in males and females alike. These hormones have numerous roles in functions other than those of reproduction. Testosterone helps maintain MUSCLE mass and BONE DENSITY; estrogen is essential for cholesterol metabolism; and the adrenal cortex needs progesterone to synthesize aldosterone.

The adrenal gland has three distinct layers, or zones, each of which exclusively produces specific hormones. These zones are

- The zona glomerulosa, the outermost zone, synthesizes and secretes aldosterone under the regulation of ADRENOCORTICOTROPIC HORMONE (ACTH) and the enzyme angiotensin II (synthesized when the kidneys release RENIN).
- The zona fasciculata, the middle zone, synthesizes and secretes cortisol under the regulation of ACTH.
- The zona reticularis, the innermost zone, synthesizes and secretes sex hormones (estrogen, progesterone, and testosterone) under the primary regulation of ACTH with secondary influence from FOLLICLE-STIMULATING HORMONE (FSH) and LEUTEINIZING HORMONE (LH).

The Adrenal Medulla

The adrenal medulla develops from the same tissue as the NERVOUS SYSTEM and remains under neurologic control. The adrenal medulla produces the hormones dopamine, epinephrine (also called adrenaline), and norepinephrine (also called noradrenaline). These function in the body as hormones, facilitating chemical interactions among cells, and as neurotransmitters, facilitating the passage of nerve signals. The interactions occur within the adrenal gland as well; the adrenal medulla needs cortisol to synthesize epinephrine.

BODY AND BRAIN: SAME CHEMICALS, DIFFERENT CONCENTRATIONS

The adrenal medullary hormones DOPAMINE, EPINEPHRINE, and NOREPINEPHRINE are the same chemical composition as their NEUROTRANSMITTER counterparts in the BRAIN. However, the brain requires much higher concentrations of these substances than the body can tolerate. A protective mechanism called the BLOOD–BRAIN BARRIER, a membranous layer of cells in the BLOOD vessels of the brain, regulates the size of molecules that can enter and leave the brain's circulation. The molecules of these hormones are too large to pass through, keeping the body (central) and brain supplies of them separate.

Kidney Disease and Adrenal Function

RENAL FAILURE, RENAL CANCER, and KIDNEY TRANSPLANTATION may affect various aspects of adrenal function. When the kidneys fail, they stop producing the hormone renin, which is essential for blood pressure regulation within the renin–angiotensin–aldosterone (RAA) system. The kidneys release renin when blood volume drops as a hormonal signal to the adrenal cortex to release

aldosterone. Some people experience disruptions of the RAA hormonal matrix after kidney transplantation because the transplanted kidney may be slow to become fully functional. When this occurs the person may need medications to help regulate blood pressure and sodium–potassium balance.

Though a separate structure, the adrenal gland is in direct contact with the surface of the kidney. One of the three arteries that delivers oxygenated blood to the adrenal gland branches from the renal ARTERY before the renal artery reaches the kidney. NEPHRECTOMY (surgical OPERATION to remove the kidney) can disturb this blood supply and damage the adrenal gland. The risk of this is highest with total nephrectomy, such as when removing a kidney that has completely failed or when radical nephrectomy (removal of the kidney, URETER, adrenal gland, and substantial surrounding tissue) is necessary to treat kidney cancer. Though most people can adapt to having only one adrenal gland just as they can adapt to having only a single kidney, the loss of both adrenal glands requires lifelong HORMONE THERAPY to replace adrenal hormones (primarily cortisol and aldosterone, the hormones of the adrenal cortex, as other structures in the body also synthesize the hormones the adrenal medulla produces).

Adrenal Gland Disorders

The most common disorder affecting the adrenal glands is ADENOMA, a noncancerous tumor that secretes excessive hormones of the division of the adrenal gland (cortex or medulla) from which it arises. Most commonly adrenal adenomas typically develop in the zona fasciculata of the adrenal cortex, causing excessive secretion of cortisol (CUSHING'S SYNDROME). Adenomas that develop in the zona glomerulosa cause excessive secretion of aldosterone (HYPERALDOSTERONISM). PHEOCHROMOCYTOMA, a tumor (usually noncancerous) that secretes epinephrine and norepinephrine, may form in the adrenal medulla.

CONDITIONS AFFECTING THE ADRENAL GLANDS

ADDISON'S DISEASE	adrenal ADENOMA
ADRENAL INSUFFICIENCY	CUSHING'S SYNDROME
HYPOALDOSTERONISM	PHEOCHROMOCYTOMA
POLYGLANDULAR DEFICIENCY SYNDROME	

For further discussion of the adrenal glands within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also ADENOMA-TO-CARCINOMA TRANSITION; AGING, ENDOCRINE CHANGES THAT OCCUR WITH.

adrenal insufficiency A condition, also called secondary adrenal insufficiency, in which the ADRENAL GLANDS fail to produce enough CORTISOL because there is not enough ADRENOCORTICOTROPIC HORMONE (ACTH) in the bloodstream. The cause may be damage to the PITUITARY GLAND that prevents it from synthesizing ACTH (such as a tumor), or extended therapy with CORTICOSTEROID MEDICATIONS (such as to treat some AUTOIMMUNE DISORDERS).

A tumor or its treatment may destroy the anterior lobe of the pituitary gland, preventing it from synthesizing ACTH. When this occurs permanent HORMONE THERAPY becomes necessary to maintain appropriate hormonal balance in the body, as the pituitary gland is the body's only source for ACTH.

During corticosteroid therapy, the high level of circulating corticosteroid in the bloodstream signals the HYPOTHALAMUS that no further release of cortisol is necessary. This inhibits the release of CORTICOTROPIN-RELEASING HORMONE (CRH), so there is no signal to the pituitary gland to release ACTH. In such circumstances adrenal insufficiency is more likely to happen when the person abruptly stops taking a corticosteroid medication rather than tapering it, though it can occur whenever a person takes corticosteroids for longer than four weeks. Though the body nearly always returns to normal HORMONE production in time, it is often necessary for the person to take supplemental hormone therapy in the interim.

Symptoms and Diagnostic Path

The symptoms of adrenal insufficiency are similar to those of ADDISON'S DISEASE and include

- tiredness and fatigue
- HYPOTENSION (low BLOOD PRESSURE)
- loss of APPETITE and weight loss
- MUSCLE weakness
- irritability

A history of recent (within several months) corticosteroid therapy is a strong indicator for adrenal insufficiency. The diagnostic path includes tests to measure the levels of potassium, sodium, GLUCOSE, cortisol, and ACTH in the blood. Other procedures typically include ACTH- and CRH-stimulation tests to assess the body's ability to produce cortisol. The endocrinologist may conduct diagnostic imaging procedures such as MAGNETIC RESONANCE IMAGING (MRI) or COMPUTED TOMOGRAPHY (CT) SCAN to visualize and evaluate the pituitary gland and adrenal glands.

DISTINGUISHING FEATURES OF ADRENAL INSUFFICIENCY AND ADDISON'S DISEASE

Adrenal Insufficiency	Addison's Disease
low ACTH	normal ACTH
normal SKIN color	areas of hyperpigmentation
normal BLOOD potassium level	elevated blood potassium level (HYPERKALEMIA)
normal blood sodium level	low blood sodium level (HYPONATREMIA)
normal blood GLUCOSE level	low blood glucose level (HYPOGLYCEMIA)
normal ALDOSTERONE production	deficient aldosterone production

Treatment Options and Outlook

Treatment consists of medication (hormone therapy), typically oral hydrocortisone, to supplement adrenal production of cortisol until the pituitary gland returns to normal ACTH production. Most adrenal insufficiency resolves within a year of onset. When the cause of the adrenal insufficiency is permanent, such as damage to or destruction of the anterior lobe of the pituitary gland, permanent hormone therapy becomes necessary as well. During treatment it is important for the person to remain vigilant for signs of adrenal crisis, which requires emergency medical treatment. Circumstances that increase the risk for adrenal crisis include physiologic stress such as trauma, INFECTION, surgery, and PREGNANCY and CHILDBIRTH.

Risk Factors and Preventive Measures

The leading risk factor for adrenal insufficiency is corticosteroid therapy. The typical approach is to taper the corticosteroid DOSE gradually, to allow the body's normal hormonal mechanisms to resume. Abruptly stopping a corticosteroid medication after taking it for four weeks or longer greatly increases the risk for adrenal insufficiency.

See also CHRONIC FATIGUE SYNDROME; POLYGLANDULAR DEFICIENCY SYNDROME; STRESS AND STRESS MANAGEMENT.

adrenocorticotropic hormone (ACTH) A peptide HORMONE, also called corticotropin, the anterior lobe of the PITUITARY GLAND produces to stimulate the adrenal cortex of the ADRENAL GLANDS to synthesize and release CORTISOL. ACTH is one of the hormones in the STRESS RESPONSE HORMONAL CASCADE. The HYPOTHALAMUS releases the hormone CORTICOTROPIN-RELEASING HORMONE (CRH) to stimulate the pituitary's synthesis of ACTH. When cortisol levels reach the appropriate level in the bloodstream the hypothalamus shuts down its release of CRH and the pituitary gland subsequently ceases ACTH production until cortisol levels again drop. This cycle is ongoing as cortisol has numerous actions within the body, notably to facilitate carbohydrate and fat METABOLISM and suppress INFLAMMATION and other aspects of the IMMUNE RESPONSE.

For further discussion of ACTH within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

aging, endocrine changes that occur with The endocrine system initiates many of the significant changes that mark the phases of life, from CONCEPTION to old age. Because critical endocrine processes slow with advancing age, many people believe the endocrine system holds the secrets to aging and thus the answers to slowing or preventing the changes that occur in the body that cause aging.

The most obvious endocrine changes that occur with age are those that regulate sexual maturation and reproduction. The onset of PUBERTY heralds the transition from childhood to adulthood and nearly every ENDOCRINE GLAND plays a role. The HYPOTHALAMUS steps up production and secretion of GONADOTROPIN-RELEASING HORMONE (GNRH), GROWTH

HORMONE–RELEASING HORMONE (GHRH), and THYROID-RELEASING HORMONE (TRH), initiating the hormonal cascades that generate tremendous growth spurts as well as the development of the secondary sex characteristics. The PITUITARY GLAND responds with accelerated secretion of FOLLICLE-STIMULATING HORMONE (FSH), GROWTH HORMONE (GH), LUTEINIZING HORMONE, AND THYROID-STIMULATING HORMONE (TSH) which in turn stimulate the gonads (OVARIES in females and TESTES in males) and affect METABOLISM in cells throughout the body. Surges in the sex hormones—ESTROGENS, PROGESTERONE, and TESTOSTERONE—complete the metamorphosis.

The hormonal changes that take place during PREGNANCY are among the most profound the human body experiences. The PLACENTA, the developing fetus's lifeline, produces dozens of hormones otherwise not found in the body. These hormones, coupled with hormonal changes in the woman's body, sustain the woman's body as a supportive environment for the unborn child and prepare it for further support (lactation) after birth. The hormones of pregnancy allow the muscles and ligaments of the abdomen to soften stretch to accommodate the enlarging UTERUS, increase the woman's BLOOD supply and metabolism (including thyroid hormones and INSULIN production), and increase vital functions such as BLOOD PRESSURE and HEART RATE.

Over the subsequent four or so decades the reproductive hormonal cascades slow. By midlife women end FERTILITY and enter MENOPAUSE, the cessation of MENSTRUATION and OVULATION. Rapid drops in estrogen and progesterone elicit major changes in a woman's body. The changes in men are less dramatic though nonetheless apparent. Testosterone levels peak around age 22 and steadily decline, tapering by age 60 to about 50 percent of peak levels. Men notice redistribution of body fat, decreased MUSCLE mass, and thinning scalp HAIR.

Also with advancing age levels of the hormones of the adrenal cortex, particularly cortisol, begin to decline. This affects body functions ranging from blood pressure and heart rate to immune response and GLUCOSE metabolism. These changes are among the changes some researchers believe hold the key to slowing, halting, or even reversing some of the events and consequences of aging. Accompanying these and other endocrine changes that occur with advancing age are increased risks for numerous health conditions such as CARDIOVASCULAR DISEASE (CVD), DIABETES, LIVER disease, and kidney disease. Nearly all hormonal production and endocrine processes diminish by age 80, and the body itself slows.

See also ANTI-AGING APPROACHES; LIFE EXPECTANCY; LIFESTYLE AND HEALTH.

aldosterone A steroid HORMONE the adrenal cortex of the ADRENAL GLANDS produces that plays a key role in regulating BLOOD PRESSURE. Aldosterone is vital for life; the body can sustain its functions for only a few days without it. Chemically aldosterone is a mineralocorticosteroid, a type of steroid (cholesterol-based structure) that influences the body's balance of minerals such as sodium and potassium. Aldosterone targets cells in the KIDNEYS that regulate the amounts of these minerals which remain in the bloodstream. The adrenal cortex releases aldosterone when the amount of potassium in the BLOOD increases or when the kidneys release the hormone RENIN in response to decreased blood volume flowing through the kidneys. Renin initiates a series of enzyme conversions that result in the production of angiotensin II, which then stimulates aldosterone production in the adrenal cortex.

LICORICE AND ALDOSTERONE

Long-term, excessive consumption of natural licorice (*Glycyrrhiza glabra* extract or glycyrrhizic acid) interferes with aldosterone binding and allows aldosterone levels in the BLOOD to rise, establishing symptoms similar to those HYPERALDOSTERONISM. Doctors call the resulting condition pseudo-hyperaldosteronism. Most licorice-flavored candies and other products in the United States do not contain natural licorice. However, natural licorice is an ingredient in many products in other countries, notably in Europe.

The release of aldosterone increases sodium retention in the blood and potassium excretion into the URINE, raising levels of sodium and dropping the levels of potassium in the blood. The higher sodium level correspondingly draws more water into the blood, increasing the blood volume.

Aldosterone also acts on the peripheral arterioles, the tiny arteries within the tissues, causing them to constrict. The combined effect of increased blood volume and peripheral vasoconstriction causes blood pressure to rise. This is a fundamental cascade of one of the body's primary blood pressure–regulatory mechanisms, the renin–angiotensin–aldosterone (RAA) system. Some medications to treat congestive HEART FAILURE and HYPERTENSION (high blood pressure) work by blocking the action of aldosterone.

Aldosterone deficiency, such as may result with ADRENAL INSUFFICIENCY and ADDISON'S DISEASE, causes HYPOTENSION (low blood pressure) and electrolyte imbalances that can cause ARRHYTHMIA (disturbance of the HEART's rhythm and rate). Untreated aldosterone deficiency is fatal. Treatment with hormone-replacement therapy restores homeostasis. Excessive aldosterone in the bloodstream (HYPERALDOSTERONISM) typically results from an adrenal ADENOMA (noncancerous tumor) arising from the middle section of the adrenal cortex, the zona fasciculata, which produces aldosterone.

For further discussion of aldosterone within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

amyloidosis An uncommon and potentially fatal disorder of METABOLISM in which the BONE MARROW produces defective antibodies that result in an abnormal protein, amyloid. The amyloid leaves the bone marrow in the BLOOD and forms fibrous deposits in organs and tissues throughout the body. The deposits interfere with normal functions, which can result in severe damage to and failure of organs such as the HEART, LIVER, and KIDNEYS. Amyloid deposits can also accumulate in the nerves and NERVOUS SYSTEM, LYMPH NODES, and blood vessels. There are three forms of amyloidosis: primary, secondary, and hereditary.

Primary amyloidosis Primary amyloidosis, also called idiopathic amyloidosis, occurs independently of other disease processes and without known cause (idiopathic). Most people who have amyloidosis have this form, which tends to affect the heart, LUNGS, THYROID GLAND, liver, intestines, SKIN, and tongue.

Secondary amyloidosis Secondary amyloidosis accompanies or occurs as a consequence of other disease processes. The most common association is with MULTIPLE MYELOMA, a CANCER of the lymph system. About 15 percent of people who have multiple myeloma develop secondary amyloidosis. Secondary amyloidosis also may occur in conjunction with chronic inflammatory disorders such as RHEUMATOID ARTHRITIS or with chronic INFECTION such as TUBERCULOSIS and OSTEOMYELITIS. Secondary amyloidosis tends to affect the liver, SPLEEN, kidneys, ADRENAL GLANDS, and lymph nodes.

Hereditary amyloidosis Rarely, a person inherits amyloidosis as a result of genetic MUTATION. The amyloid deposits in hereditary amyloidosis are most likely to accumulate in the heart, kidneys, intestines, vitreous humor (the gelatinous substance inside the EYE), and PERIPHERAL NERVES.

Symptoms and Diagnostic Path

Symptoms of amyloidosis vary, depending on the organ systems affected. Many people experience generalized symptoms such as weakness, tiredness and fatigue, and unexplained weight loss. Other symptoms that may occur with amyloid deposits in specific organs or systems include

- DIARRHEA (gastrointestinal)
- tingling and numbness in the hands and feet (nerves)
- ARRHYTHMIA (irregularities in the heartbeat; heart)
- swollen tongue and difficulty swallowing (tongue; gastrointestinal; nerves)
- DYSPNEA (shortness of breath; lungs, heart)
- HEPATOMEGALY (enlarged liver; liver)

Amyloidosis also may manifest through symptoms of disease process such as HYPOTHYROIDISM (amyloid deposits in the thyroid gland) and kidney failure (amyloid deposits in the kidneys). The diagnostic path includes clinical assessment of symptoms, blood and URINE tests that may detect

the presence of abnormal proteins, and biopsy of representative amyloid deposits.

Treatment Options and Outlook

There is no curative treatment for amyloidosis. When amyloidosis is secondary, treatment for the underlying condition often mitigates the symptoms and progression of the amyloidosis. Treatment for primary amyloidosis targets symptom relief. In some people, a regimen of CHEMOTHERAPY halts the amyloidosis progression for up to several years. Kidney, heart, or liver transplantations are sometimes viable options when amyloid deposits accumulate in these organs. STEM CELL transplantation shows promise for long-term relief, though existing amyloid deposits remain in the tissues. Many people are able to control their symptoms for long periods of time through carefully selected therapeutic measures.

Risk Factors and Preventive Measures

There are no known risk factors or preventive measures for primary amyloidosis. Multiple myeloma and chronic inflammatory disorders and infections are significant risk factors for secondary amyloidosis. Amyloidosis is more likely to develop when these conditions are long-term and poorly controlled. Though it is not possible to prevent secondary amyloidosis, prompt and appropriate treatment for the underlying condition may mitigate its manifestation.

androgens A collective term for the "male" sex hormones, prohormones (chemical precursors the body converts to hormones), and metabolites (byproducts of HORMONE METABOLISM). Androgens are steroid hormones the body synthesizes from cholesterol; they are variably anabolic (they build MUSCLE mass, some more actively than others). Androgens are also the precursors (starting point) for the ESTROGENS ("female" sex hormones). The most abundant and familiar androgen is TESTOSTERONE. In addition to establishing male secondary sex characteristics and FERTILITY, androgens have multiple functions in men and women both with regard to muscle mass and STRENGTH, BONE DENSITY, LIBIDO (sex drive), and metabolism.

Men and women alike have androgens (just as both sexes also have estrogens). The gonads, or sex glands (OVARIES in women and TESTES in men), synthesize (produce) most of the androgens in the BLOOD circulation. The adrenal cortex of the ADRENAL GLANDS and adipose (fat) cells also synthesize androgens. The HYPOTHALAMUS's secretion of GONADOTROPIN-RELEASING HORMONE (GNRH) regulates the hormonal cascade for endogenous (within the body) androgen production and release. Some androgens are available as exogenous supplements used to treat disorders of androgen deficiency as well as taken illicitly to enhance athletic performance.

ENDOGENOUS ANDROGENS

androstane	androstanediol
androstenedione	androstenolone
androsterone	DEHYDROEPIANDROSTERONE (DHEA)
dihydrotestosterone	TESTOSTERONE

antidiuretic hormone (ADH) A peptide HORMONE, also called vasopressin, the HYPOTHALAMUS synthesizes (produces) and the posterior lobe of the PITUITARY GLAND stores and releases. ADH regulates the amount of water the KIDNEYS withhold in the bloodstream. The hypothalamus signals the pituitary gland to release ADH when the body needs additional fluid, such as during excessive sweating with heat or intense exercise. Increased ADH in the BLOOD causes the kidneys to withhold more water from the circulating blood, raising blood volume and decreasing URINE production. In high concentrations, ADH acts to constrict peripheral arterioles (the smallest arteries deep in the tissues). In combination, these effects are among the body's mechanisms for regulating BLOOD PRESSURE. Dysfunction of the pituitary gland, and less commonly the hypothalamus, can result in inadequate levels of ADH in the bloodstream, causing the rare

condition DIABETES INSIPIDUS (which is not the same disease process as DIABETES mellitus, a disorder of INSULIN production or METABOLISM). Kidney disease may also interfere with the ability of the kidneys to respond to ADH.

For further discussion of ADH within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also ADRENOCORTICOTROPIN HORMONE (ACTH); ALDOSTERONE; FOLLICLE-STIMULATING HORMONE (FSH); GROWTH HORMONE (GH); LUTEINIZING HORMONE (LH); OXYTOCIN; PROLACTIN; RENIN; THYROID-STIMULATING HORMONE (TSH).

C

calcitonin A peptide HORMONE the THYROID GLAND produces that increases the amount of calcium the bones can accept. Calcitonin functions in synchronization with PARATHYROID HORMONE, which the PARATHYROID GLANDS secrete, to maintain calcium balance in the BLOOD and in the body. Calcium is essential for BONE DENSITY and STRENGTH, as well as for the conduction of NERVE impulses in MUSCLE tissue, including that of the HEART. The balance between calcitonin and parathyroid hormone maintains a constant level of calcium in the blood to allow proper nerve conduction for heart function as well as skeletal muscle function. This balance may come at the expense of the amount of calcium in the bones, however, which the body uses as a "bank" for the storage and withdrawal of calcium. Calcitonin facilitates calcium "deposit" to the bones by channeling calcium from the blood into the bones. It binds with receptor sites on the surfaces of osteoblasts, the cells within the bones that produce new BONE tissue.

A form of THYROID CANCER, medullary thyroid cancer, forms in the parafollicular cells that produce calcitonin. Excessive levels of calcitonin in the blood may indicate such a cancer. Disorders of the parathyroid glands that affect the secretion of parathyroid hormone may also disrupt the levels of calcitonin in the blood.

For further discussion of calcitonin within the context of the endocrine system's structure and function, please see the overview section "The Endocrine System."

See also OSTEOPOROSIS; THYROXINE (T_4); TRIIODOTHYRONINE (T_3).

cholecystokinin See DIGESTIVE HORMONES.

chorionic gonadotropin A peptide HORMONE of PREGNANCY that the fertilized ovum (egg) secretes to stimulate the corpus luteum to continue producing PROGESTERONE, which maintains an environment within the UTERUS to support the implantation of the EMBRYO. The corpus luteum, a temporary endocrine structure, develops in an ovarian follicle after the follicle releases an ovum, marking the start of OVULATION. The corpus luteum then begins secreting progesterone, which causes the lining of the uterus to thicken and its BLOOD supply to enrich in preparation for pregnancy. Without chorionic gonadotropin the corpus luteum deteriorates and the uterine lining sloughs away (MENSTRUATION). About eight weeks into pregnancy the PLACENTA forms and takes over chorionic gonadotropin production, which continues until birth. Pregnancy tests measure the amount of chorionic gonadotropin in the URINE or the blood. Fertility specialists use injections of chorionic gonadotropin (called human chorionic gonadotropin, or hCG, in its pharmaceutical form) to stimulate ovulation in women and TESTOSTERONE production, to encourage SPERM production, in men.

For further discussion of chorionic gonadotropin within the context of the endocrine system's structure and function, please see the overview section "The Endocrine System."

See also ANABOLIC STEROIDS AND STEROID PRECURSORS; CONCEPTION; ESTROGENS; FERTILITY; OXYTOCIN; PROLACTIN; RELAXIN.

corticotropin-releasing hormone (CRH) A peptide HORMONE the HYPOTHALAMUS synthesizes and releases in response to endocrine and neurologic signals that report the status of the body's vital functions. CRH is one of the hormones in the

STRESS RESPONSE HORMONAL CASCADE and stimulates the anterior lobe of the PITUITARY GLAND to produce ADRENOCORTICOTROPIC HORMONE (ACTH). ACTH in turn stimulates the ADRENAL GLANDS to release CORTISOL, a steroid hormone that has numerous actions in the body. The level of cortisol in the bloodstream is one of the endocrine signals that determines the release of CRH. The hypothalamus also releases CRH in a rhythmic pattern that coincides with the body's circadian cycle of sleep and wake. CRH levels peak just before dawn and trough just before dusk, establishing higher ACTH and cortisol levels during the waking hours.

For further discussion of CRH within the context of the endocrine system's structure and function, please see the overview section "The Endocrine System."

See also GONADOTROPIN-RELEASING HORMONE (GNRH); GROWTH HORMONE–RELEASING HORMONE (GHRH); THYROTROPIN-RELEASING HORMONE (TRH).

cortisol A HORMONE the adrenal cortex of the ADRENAL GLANDS produces. Chemically cortisol is a glucocorticosteroid, a type of steroid (cholesterol-based structure) that influences carbohydrate and fat METABOLISM (GLUCOSE balance) in the body. Cortisol is the main player in the STRESS RESPONSE HORMONAL CASCADE, essential for activating other hormones and chemical processes required for many vital functions within the body. All cells in the body have receptors for cortisol. The body requires a minimum level of cortisol in the bloodstream, as well as increased amounts of cortisol to respond to stress by raising BLOOD PRESSURE, HEART RATE, BREATHING, and metabolic rate. Cortisol also counters the body's IMMUNE RESPONSE, helping to subdue areas of INFLAMMATION after they develop.

Cortisol levels fluctuate in a rhythmic pattern over the course of 24 hours, being highest during waking hours when the body is most active and lowest a few hours after falling asleep. To maintain this pattern the HYPOTHALAMUS initiates a cascade of hormonal activity by releasing CORTICOTROPIN-RELEASING HORMONE (CRH) in synchronization with the body's circadian rhythm (cycle of wake and sleep). CRH stimulates the anterior lobe of the PITUITARY GLAND to release ADRENOCORTICOTROPIN HORMONE (ACTH). ACTH in turn causes the adrenal cortex to produce and release cortisol. When the BLOOD level of cortisol is adequate, the hypothalamus ceases release of CRH, the pituitary gland ends release of ACTH, and the adrenal cortex stops cortisol production. When the cortisol level in the blood drops or physiologic sensors (such as barosensors that detect changes in blood pressure) indicate a need to respond to stress the hypothalamus again boosts CRH output.

Cortisol production increases in response to physiologic stress such as intense physical exercise, as well as to emotional stress such as fear or anger. Research suggests that persistently elevated cortisol levels result in long-term damage to the cardiovascular system, notably contributing to HYPERTENSION (high blood pressure) and ARTERIOSCLEROSIS (stiffening of the arteries). Chronically insufficient levels of cortisol in the blood result in ADDISON'S DISEASE; chronically excessive levels of cortisol in the blood result in Cushing's syndrome. People who take long-term CORTICOSTEROID MEDICATIONS to treat chronic inflammatory conditions may develop acquired Cushing's syndrome, also called hyperadrenocorticism. Pharmaceutical preparations of cortisol commonly used as anti-inflammatory medications are cortisone and hydrocortisone.

For further discussion of cortisol within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also ALDOSTERONE; DOPAMINE; EPINEPHRINE; NOREPINEPHRINE; STRESS AND STRESS MANAGEMENT; WORKPLACE STRESS.

Cushing's syndrome A constellation of symptoms that occur as a consequence of high levels of CORTISOL in the bloodstream. Cushing's syndrome may result from long-term CORTICOSTEROID MEDICATIONS (exogenous Cushing's syndrome) or from excessive cortisol production within the body (endogenous Cushing's syndrome). Untreated Cushing's syndrome affects many vital functions including BLOOD PRESSURE and HEART RATE, and can be fatal.

Exogenous Cushing's Syndrome

Exogenous Cushing's syndrome is the more common form of this condition and typically occurs in

people taking long-term corticosteroid therapy to suppress the IMMUNE RESPONSE such as following ORGAN TRANSPLANTATION (to prevent GRAFT VS. HOST DISEASE and organ rejection) or to treat chronic inflammatory conditions such as ASTHMA, SYSTEMIC LUPUS ERYTHEMATOSUS (SLE), RHEUMATOID ARTHRITIS, SARCOIDOSIS, and INFLAMMATORY BOWEL DISEASE (IBD). Occasionally multiple corticosteroid injections into inflamed joints can also produce exogenous Cushing's syndrome.

Endogenous Cushing's Syndrome

Cushing's disease is an older term for endogenous Cushing's syndrome, which most commonly occurs as a result of adrenal or pituitary ADENOMA (noncancerous tumor) that increases cortisol secretion. A pituitary adenoma causes the anterior lobe of the PITUITARY GLAND to produce excessive ADRENOCORTICOTROPIC HORMONE (ACTH). The ACTH stimulates the adrenal cortex of the ADRENAL GLANDS to secrete cortisol. An adrenal adenoma develops in the adrenal cortex and itself secretes cortisol independent of ACTH stimulation.

Other causes of endogenous Cushing's syndrome include adrenal hypertrophy (enlargement of the adrenal glands), which increases cortisol secretion, and ACTH-secreting tumors located elsewhere in the body such as some cancers of the lung, PANCREAS, and BREAST. As with pituitary adenoma, the ACTH secretion stimulates the adrenal cortex to increase cortisol production. Cushing's syndrome is sometimes one of the earliest indications of small-cell LUNG CANCER (SCLC), the tumors of which are characteristically ACTH secreting.

Symptoms and Diagnostic Path

The symptoms and signs of Cushing's syndrome are the same regardless of the condition's cause and typically include

- a rounded, flushed face ("moon face")
- transition to an "apple" body shape: thickened trunk due to accumulated abdominal fat and thinned arms and legs due to MUSCLE atrophy (wasting)
- accumulation of fat in a "hump" between the shoulder blades
- HIRSUTISM (increased body HAIR) and ACNE
- HYPERTENSION (high blood pressure)
- delayed wound HEALING and decreased resistance to INFECTION
- irritability, DEPRESSION, mood swings, and difficulty concentrating

The diagnostic path begins with BLOOD and URINE tests to measure the body's levels and excretion of cortisol. When the endocrinologist suspects exogenous Cushing's syndrome due to corticosteroid therapy, these tests are often conclusive for the diagnosis. The endocrinologist may conduct additional tests to assess the body's response to dexamethasone (a corticosteroid) and ACTH (dexamethasone test and ACTH-stimulation test, respectively) when endogenous Cushing's syndrome is likely. Imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) can reveal structural abnormalities, including tumors, of the pituitary gland and the adrenal glands.

Treatment Options and Outlook

Treatment targets reducing the amount of cortisol in the blood circulation. With exogenous Cushing's syndrome, treatment usually means transitioning to noncorticosteroid medications to manage the underlying condition and its symptoms. Treatment in endogenous Cushing's syndrome may be surgery to remove or RADIATION THERAPY to shrink a pituitary or adrenal adenoma, appropriate treatment for an ACTH-secreting tumor located elsewhere in the body, or medications such as ketoconazole or mitotane to suppress ACTH or cortisol synthesis. Some people require HORMONE THERAPY (sometimes long-term) to supplement or replace adrenal or pituitary hormones after treatments that target the gland directly.

Risk Factors and Preventive Measures

The primary risk factor for exogenous Cushing's syndrome is corticosteroid therapy. Transitioning to noncorticosteroid medications generally relieves Cushing's syndrome symptoms and often prevents the condition from developing. However, noncorticosteroid medications may have undesired side effects or be less effective in controlling the underlying condition for which the doctor prescribes

them. Endogenous Cushing's syndrome is not preventable though early diagnosis minimizes its consequences and affords a wider range of treatment.

D

dehydroepiandrosterone (DHEA) A precursor steroid HORMONE the adrenal cortex of the ADRENAL GLANDS synthesizes from cholesterol. The OVARIES or TESTES, and to a lesser extent the adrenal cortex, further formulate DHEA into TESTOSTERONE and ESTROGENS. LUTEINIZING HORMONE (LH) provides the hormonal stimulus for this synthesis. Levels of DHEA in the BLOOD circulation begin to rise around age 10, preceding the onset of PUBERTY, and peak in the mid-20s. DHEA levels in the bloodstream decline by about 15 percent a decade until about age 75, at which point the level stabilizes at about 15 percent of what it was at its peak 50 years earlier. Though there is speculation that diminishing DHEA levels may in some way precipitate the changes that take place with aging, researchers have yet to identify the mechanisms responsible.

See also ANABOLIC STEROIDS AND STEROID PRECURSORS; DHEA SUPPLEMENT.

diabetes A condition, clinically known as diabetes mellitus, in which the ISLETS OF LANGERHANS do not produce enough INSULIN or the body's cells do not appropriately respond to insulin, resulting in an inability of the cells to accept GLUCOSE. There are three major forms of diabetes: type 1, type 2, and gestational. Lifestyle factors significantly influence the development and course of diabetes, particularly type 2. Diabetes is the most common endocrine disorder.

Diabetes is a significant health concern in the United States, with more than 13 million people knowing they have the condition. Another 5 or 6 million have diabetes though are unaware. Diabetes is the sixth leading cause of death in the United States, directly claiming 70,000 lives each year. As a leading cause of CARDIOVASCULAR DISEASE (CVD), kidney disease, and RENAL FAILURE, diabetes contributes to thousands more deaths as well. Diabetes is also the primary cause of VISION IMPAIRMENT and blindness, and a significant cause of peripheral NEUROPATHY (NERVE damage), among American adults.

Medical texts that are several thousand years old make reference to diabetes. Ancient physicians identified diabetes as the "honey URINE" disease, a moniker that became refined through the centuries to the somewhat less graphic "sugar diabetes." Until the discovery of insulin in the early 1920s, the diagnosis of diabetes was a death sentence. Efforts to manage the disease by restricting sugar were futile because the true problem was not too much sugar but rather not enough insulin.

As researchers and doctors gained greater understanding of diabetes, they realized it was insulin that made possible glucose's entry into the cells. Doctors now know diabetes results from the body's inability to produce or use insulin, which allows glucose (sugar) to accumulate in the BLOOD and spill over into the urine. Insulin therapy became the breakthrough in treatment that restored the potential for relatively normal lives for those who developed diabetes.

Type 1 Diabetes

Type 1 diabetes is an autoimmune disorder in which the IMMUNE SYSTEM produces antibodies that attack and destroy the cells of the islets of Langerhans. As a result, the body cannot produce insulin. An interplay between genetic and environmental factors is likely, with some researchers suspecting the autoimmune reaction follows INFECTION with a VIRUS. People who have type 1 diabetes must take regular insulin injections to meet their insulin needs and check their blood glucose levels

frequently to maintain as tight of a balance as possible between insulin and glucose. Type 1 diabetes most often develops before the age of 20, giving rise to its former designation as juvenile diabetes. Onset is usually rapid and pronounced. Type 1 diabetes requires lifelong insulin therapy.

Before current treatments many people who developed type 1 diabetes died from the condition or its complications before living much longer than early adulthood, making this a disease of the young. However, treatment approaches are significantly improved and many people who have type 1 diabetes now live well into old age with careful medical and lifestyle management. Some people refer to type 1 diabetes as insulin-dependent diabetes, which is no more accurate than the term juvenile diabetes because about 40 percent of people who have type 2 diabetes also require insulin therapy.

People who have type 1 diabetes have a higher likelihood of developing other AUTOIMMUNE DISORDERS of the endocrine system, notably thyroid conditions such as autoimmune THYROIDITIS and HYPOTHYROIDISM as well as autoimmune ADRENAL INSUFFICIENCY. Type 1 diabetes is also a component of complex endocrine disorders such as POLYGLANDULAR DEFICIENCY SYNDROME and MULTIPLE ENDOCRINE NEOPLASIA (MEN). Women who have well-controlled type 1 diabetes generally can conceive, carry, and deliver a PREGNANCY with few complications, though require close medical monitoring and diligent prenatal care. However, type 1 diabetes can affect FERTILITY in both women and men.

Type 2 Diabetes

Type 2 diabetes develops slowly, evolving over years and sometimes decades as a consequence of progressive INSULIN RESISTANCE. This form of diabetes most commonly develops in people who are age 50 or older, though can occur at any age (including childhood). A strong correlation exists between OBESITY and type 2 diabetes. Many health experts believe type 2 diabetes is fully preventable through lifestyle measures that incorporate nutritious EATING HABITS, daily physical exercise, and maintaining a healthy body weight. About 30 percent of people diagnosed with type 2 diabetes can control the condition through weight loss and lifestyle measures. The rest require oral antidiabetes medications or insulin therapy. Type 2 diabetes may occur as a component of complex endocrine disorders, notably insulin resistance, as well as secondary to endocrine disorders affecting the adrenal cortex such as CUSHING'S SYNDROME (the adrenal steroid CORTISOL influences glucose METABOLISM).

Gestational Diabetes

Gestational diabetes develops during pregnancy as a consequence of the demands pregnancy places on the mother's body. A pregnant woman requires up to three times as much insulin to meet the needs of her body and the growing FETUS. However, the hormones that support pregnancy increase insulin resistance, reducing the woman's ability to use the insulin her body produces. The consequence may be temporary type 2 diabetes. Gestational diabetes affects about 4 percent of pregnant women in the United States. Some women can maintain appropriate insulin and glucose levels through careful nutritional habits, daily exercise, and WEIGHT LOSS AND WEIGHT MANAGEMENT. Others may require insulin therapy (many oral antidiabetes medications are not approved for use during pregnancy) for the duration of pregnancy.

Untreated gestational diabetes can have serious consequences for the baby, as the high levels of insulin in the mother's blood circulation increase the amount of glucose the baby's body can accept. One consequence is an unusually large baby. Rapid fetal growth is one indication that a woman might have gestational diabetes. About 70 percent of women who develop gestational diabetes recover completely. The rest develop permanent type 2 diabetes, either continuing after the end of the pregnancy or years to decades later.

Symptoms and Diagnostic Path

The symptoms of diabetes are similar across the types, though in type 1 may be rapid and severe. These symptoms include

- excessive thirst and frequent urination
- unexplained weight loss
- increased APPETITE
- changes in vision
- tingling in the hands and feet

- tiredness and weakness
- wounds or sores that heal slowly, or frequent infections (notably CANDIDIASIS)

The diagnostic path begins with a fasting blood glucose test, which measures the amount of glucose in the blood circulation after 12 hours without food or beverages other than water. Two separate results with blood glucose levels of 126 milligrams per deciliter of blood (126 mg/dL) confirm the diagnosis. Another blood test is glycosylated hemoglobin (HbA_{1c}), which measures a protein that indicates the stability of blood glucose levels over time. Normal HbA_{1c} is 4 to 6 percent; HbA_{1c} greater than 8 percent supports the diagnosis of diabetes. The doctor may choose to conduct a glucose-tolerance test, which measures the body's ability to respond to a rapid influx of glucose.

Treatment Options and Outlook

Treatment depends on the form of diabetes. Type 1 diabetes requires lifelong insulin therapy. About a third of people who have type 2 diabetes can manage the condition through weight loss and lifestyle measures (nutritious eating habits, daily exercise, and weight management), while the remainder require oral antidiabetes medications or insulin therapy. Ultimately about 40 percent of people who have type 2 diabetes will require insulin therapy, however, the underlying insulin resistance tends to be progressive within the disease process as well as with advancing age. Women who have gestational diabetes may be able to control the condition through lifestyle measures or may require treatment with oral antidiabetes medications approved for use in pregnancy or insulin therapy for the duration of the pregnancy.

Insulin therapy Therapeutic insulin is an injectable solution self-administered through subcutaneous injection (shots) one to several times a day. Until the 1990s most insulin products were the purified extracts culled from porcine (pig) and bovine (cow) pancreases. The biochemical structures of these extracts were close enough to human insulin to work in the human body, though in some people the differences were significant enough to activate an IMMUNE RESPONSE. In the 1990s laboratories began using RECOMBINANT DNA technologies to create synthetic insulin products biochemically and immunologically identical to endogenous human insulin. These insulins now allow precise dosaging and predictable actions within the body. Insulin doses are uniquely individual and may also vary with the person's activity level and other health conditions such as infections that cause FEVER. People taking insulin therapy check their blood glucose levels on a regular basis (one to several times daily) using a glucometer, which requires a fingerprick sample of blood.

Oral antidiabetes medications In 1958 the first oral medication to treat type 2 diabetes, the new

INSULIN PRODUCTS

Type of Action	Insulin Products	Onset	Peak Activity	Duration
rapid	lispro (Humalog)	5 to 15 minutes	45 to 90 minutes	3 to 4 hours
	aspart (NovoLog)	10 to 20 minutes	1 to 3 hours	3 to 5 hours
short	regular (R)	30 minutes	2 to 5 hours	5 to 8 hours
intermediate	neutral protamine	1 to 3 hours	6 to 12 hours	16 to 24 hours
	hagedorn (NPH) + lente (L)	30 minutes	7 to 12 hours	16 to 24 hours
	premixed (R + NPH)			
long	ultralente	4 to 6 hours	8 to 20 hours	24 to 28 hours
very long	glargine (Lantus)	1 hour	evenly over 24 hours	24 hours

sulfonylurea DRUG chlorpropamide (Diabinese), received approval for use in the United States. Sulfonylurea stimulates the beta islet cells to increase insulin production, raising the level of circulating insulin the blood. Subsequent generations of sulfonylureas have become more potent, more predictable, and less likely to cause side effects and are the foundation for oral therapy for type 2 diabetes. New sulfonylureas as well as new kinds of drugs to improve insulin sensitivity and influence glucose metabolism became available in the 1980s and 1990s. Many people who require treatment beyond lifestyle measures for type 2 diabetes take combinations of antidiabetes medications for optimal individualized control.

ORAL ANTIDIABETES MEDICATIONS

Sulfonylureas	
acetohexamide (Dymelor)	chlorpropamide (Diabinese)
glimepiride (Amaryl)	glipizide (Glucotrol, Glucotrol Xl)
glyburide (DiaBeta)	glyburide (Glynase PresTab, Micronase)
tolazamide (Tolinase)	
tolbutamide (Orinase)	
Biguanides	
metformin (Glucophage, Glucophage XR)	
Alpha-glucosidase inhibitors	
miglitol (Glyset)acarbose (Precose)	
Thiazolidinediones	
pioglitazone (Actos)rosiglitazone (Avandia)	
Meglitinides	
repaglinide (Prandin)	
d-Phenylalanine derivatives	
nateglinide (Starlix)	
Combination products	
glyburide + metformin (Glucovance)	

Lifestyle measures Nutritious eating habits, daily physical exercise, and healthy weight are critical factors especially in type 2 diabetes. Physical exercise improves the sensitivity of cells to insulin, allowing the body to become more efficient with insulin production. Most people who have diabetes do not require special diets though must monitor their consumption of food types to remain in balance with their medications (oral or insulin). Health-care providers recommend that all people diagnosed with diabetes and their family members attend diabetes education workshops and classes available through hospitals and health-care clinics.

Risk Factors and Preventive Measures

Type 1 diabetes is not preventable, and likely results from an interaction of genetic and environmental factors that remain for researchers to identify. Type 2 diabetes, however, may be fully preventable through lifestyle choices that support healthy weight, nutritious eating habits, and daily physical activity. Long-term elevation of glucose in the blood causes extensive damage to the blood vessels and nerves. Complications of diabetes can be significant, though careful management of the diabetes can mitigate most of them. People who have any form of diabetes have increased risk for:

- CORONARY ARTERY DISEASE (CAD)
- HYPERTENSION (high BLOOD PRESSURE)
- RETINOPATHY of diabetes (damage to the RETINA)
- peripheral neuropathy (damage to the nerves)
- delayed wound HEALING and frequent infections, particularly a risk with the feet
- kidney disease and renal failure
- ERECTILE DYSFUNCTION in men and INFERTILITY in men and women

Most people who have diabetes are able to enjoy regular activities with appropriate treatment and lifestyle management.

See also ANTIBODY; DIABETES AND CARDIOVASCULAR DISEASE; DIABETES PREVENTION; HEALTH RISK FACTORS.

diabetes insipidus A condition of inadequate ANTIDIURETIC HORMONE (ADH) production or response. In health the HYPOTHALAMUS produces and the posterior lobe of the PITUITARY GLAND stores ADH. ADH acts on the KIDNEYS to regulate the amount of water they excrete into the URINE. The pituitary gland releases ADH when fluid levels in the body drop, causing the kidneys to withhold more water in the BLOOD. Diabetes insipidus can result from dysfunction of either the hypothalamus or the pituitary gland or disruption of communication between the two endocrine structures (central diabetes insipidus, or CDI), or as a conse-

quence of kidney disease (nephrogenic diabetes insipidus, or NDI).

A DIFFERENT DIABETES

Diabetes insipidus has no relationship to the familiar and common form of DIABETES, known clinically as diabetes mellitus, which is a dysfunction of INSULIN. Diabetes insipidus is a dysfunction of ANTIDIURETIC HORMONE (ADH). To avoid confusion, doctors commonly refer to diabetes insipidus as CDI (central diabetes insipidus) or NDI (nephrogenic diabetes insipidus).

Central Diabetes Insipidus (CDI)

CDI may result from lesions (growths) that affect the function of the hypothalamus, though more commonly as a result of trauma to the region of the BRAIN where the hypothalamus and pituitary gland are located. Such trauma may as a consequence of accidental injury (TRAUMATIC BRAIN INJURY), STROKE, or surgery. The hypothalamus may release inadequate amounts of ADH or the pituitary gland may fail to respond. CDI may also occur when an ADENOMA (noncancerous tumor) grows in the posterior lobe of the pituitary gland and inhibits ADH secretion.

Nephrogenic Diabetes Insipidus (NDI)

In severe kidney disease or RENAL FAILURE the kidneys themselves do not respond to ADH. This leaves the kidneys unable to concentrate the urine. They consequently pass into the urine as much water as passes through them in the blood. Medications that interfere with kidney function may cause NDI. Lithium, taken to treat BIPOLAR DISORDER, and the ANTIBIOTIC MEDICATIONS demeclocycline and amphotericin B, are the most common culprits when NDI is DRUG induced.

Symptoms and Diagnostic Path

Whether central or nephrogenic, diabetes insipidus symptoms are the same. They are

- extreme thirst (called polydipsia) and often a craving for ice water
- frequent urination (called polyuria), including through the night (NOCTURIA)

It is not uncommon for a person who has diabetes insipidus to drink and urinate up to 20 liters or more every 24 hours. When symptoms develop gradually and water intake keeps pace with urination, the person may not experience the symptoms as unusual events. Diabetes insipidus results in health complications (such as electrolyte imbalance) only when the person is unable to match fluid input and output. The diagnostic path is primarily clinical (based on symptoms) with a water deprivation test to confirm the diagnosis. For this test, the person remains under continuous medical observation while consuming no water. Hourly urine tests measure the concentration of the urine. In a healthy person the urine becomes increasingly concentrated with restricted fluid consumption. In diabetes insipidus the urine remains dilute.

Because excessive thirst and urination are also symptoms of diabetes mellitus, the endocrinologist is likely to conduct blood tests to measure blood GLUCOSE and INSULIN levels. The endocrinologist may also choose to conduct diagnostic imaging procedures such as MAGNETIC RESONANCE IMAGING (MRI) or COMPUTED TOMOGRAPHY (CT) SCAN to identify traumatic injury or tumors in CDI.

Treatment Options and Outlook

Treatment targets any identified underlying cause. Thiazide diuretic medications, which ordinarily increase urination, have the opposite effect in both CDI and NDI because of their actions on the kidneys. HORMONE THERAPY with medications such as desmopressin or lypressin nasal spray is usually effective for CDI. Even when the person is able to maintain fluid balance, it is important to treat diabetes insipidus because the untreated condition results in kidney damage over time. Treatment minimizes or eliminates symptoms for most people.

Risk Factors and Preventive Measures

The primary risk factor for CDI is head trauma, in which case early intervention and treatment are most effective. Chronic kidney disorders such as POLYCYSTIC KIDNEY DISEASE are commonly the cause of NDI. Appropriately treating these disorders mitigates the NDI. It is important for people who have CDI or NDI to drink enough water to remain hydrated, to prevent complications arising from electrolyte imbalance.

See also HYPERCALCEMIA; HYPOKALEMIA; HYPONATREMIA; LESION; SARCOIDOSIS; SICKLE CELL DISEASE.

dopamine A peptide the adrenal medulla of the ADRENAL GLANDS, the HYPOTHALAMUS, and other structures in the BRAIN produce. Dopamine functions in the body as a HORMONE, when synthesized by the adrenal medulla, and as a NEUROTRANSMITTER when synthesized by brain structures or NERVE cells. NOREPINEPHRINE is a dopamine precursor (substance the body uses as the basis for dopamine synthesis).

Hormonal dopamine, also called PROLACTIN release–inhibiting factor (PRIF), is an inhibitory hormone that acts to prevent the release of the pituitary hormone prolactin. Dopamine also has less pronounced inhibitory action for FOLLICLE-STIMULATING HORMONE (FSH), LUTEINIZING HORMONE (LH), and THYROID-STIMULATING HORMONE (TSH). The hypothalamus directs the adrenal medulla to release dopamine through the neurotransmitter acetylcholine. As a neurotransmitter, dopamine is critical to voluntary MUSCLE control and movement, cognitive function, mood, emotion, and perceptions of pleasure. Dopamine appears to play a key role in ADDICTION such as to NARCOTICS and NICOTINE (cigarette smoking).

Dopamine is also a pharmaceutical DRUG used to treat CARDIAC ARREST and cardiovascular SHOCK. When injected intravenously to establish dopamine levels higher than normal in the bloodstream, dopamine constricts (narrows) peripheral BLOOD vessels to direct more blood to critical organs, intensifies the force of the HEART's contractions to increase the amount of blood the heart pumps, and increases the HEART RATE. The dopamine precursor levodopa is a treatment for PARKINSON'S DISEASE (a degenerative neurologic disorder that results from inadequate dopamine production in the sections of the brain that control movement).

For further discussion of dopamine within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also EPINEPHRINE.

endocrine gland A structure, sometimes called a ductless gland, within the body that produces chemicals, called hormones, it secretes directly into the bloodstream. Hormones influence the function of cells that contain receptors for them. The PITUITARY GLAND, ADRENAL GLANDS, and THYROID GLAND are examples of endocrine glands. An exocrine gland, by contrast, secretes the chemicals it produces into ducts (specialized channels) for release into body structures. The SALIVARY GLANDS and SWEAT GLANDS are examples of exocrine glands. The KIDNEYS, gastrointestinal tract, and PLACENTA in a pregnant woman also contain endocrine structures.

Three mechanisms can trigger endocrine activity. They are

- humoral, in which the endocrine system responds to chemicals in the bloodstream such as calcium (triggering CALCITONIN release from the thyroid gland or PARATHYROID HORMONE from the PARATHYROID GLANDS)
- hormonal, in which the hormones from one endocrine gland direct activity from other endocrine glands such as the STRESS RESPONSE HORMONAL CASCADE
- neurologic, in which NERVE impulses stimulate endocrine action such as from the HYPOTHALAMUS to the posterior lobe of the pituitary gland

Sometimes the neurologic system and the endocrine system secrete the same chemicals, such as EPINEPHRINE and NOREPINEPHRINE. When endocrine structures synthesize these chemicals, they are hormones and they travel to their target cells through the blood circulation. When the neurologic system synthesizes these structures, they are neurotransmitters, and they travel to their target cells through interstitial fluid (fluid between cells). Neurotransmitters travel to their destinations, elicit reactions, and dissipate more rapidly than hormones.

THE ENDOCRINE GLANDS

ADRENAL GLANDS	HYPOTHALAMUS	ISLETS OF LANGERHANS
OVARIES	PARATHYROID GLANDS	PINEAL GLAND
PITUITARY GLAND	PLACENTA	TESTES
THYMUS	THYROID GLAND	

For further discussion of the endocrine glands within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also DIGESTIVE HORMONES; NEUROTRANSMITTER.

epinephrine A chemical the adrenal medulla of the ADRENAL GLANDS and the synaptic vesicles of the NERVE endings produce. Epinephrine, also called adrenaline, functions in the body as a peptide HORMONE when synthesized by the adrenal medulla and as a NEUROTRANSMITTER when synthesized in the BRAIN or nerve endings. Among the hormones activated in the STRESS RESPONSE HORMONAL CASCADE, epinephrine

- constricts peripheral BLOOD vessels to centralize blood flow and raise BLOOD PRESSURE
- dilates bronchial structures in the LUNGS to increase air flow
- initiates rapid conversion of glycogen to GLUCOSE in the LIVER to raise the blood glucose level and increase energy to the cells
- intensifies the HEART's contractions to increase CARDIAC OUTPUT (the amount of blood the heart pumps out with each CARDIAC CYCLE)
- accelerates the HEART RATE

In the brain, epinephrine is an active and abundant neurotransmitter in numerous neurologic functions, including heightened alertness and cognitive function during stressful situations. Epinephrine is also a pharmaceutical DRUG used to treat CARDIAC ARREST and cardiovascular SHOCK. When injected intravenously to produce blood levels significantly higher than normal in the bloodstream, epinephrine causes accelerated actions such as those it initiates as an endogenous hormone in the stress response. It also stabilizes the electrical activity of the heart to normalize the heart's rhythm (antiarrhythmic). In other pharmaceutical applications epinephrine blocks the body's inflammatory response in severe allergic reactions and anaphylactic shock, and can reduce bleeding and extend the effectiveness of injected local anesthetics.

EPINEPHRINE, ADRENALINE, OR ADRENALIN?

Epinephrine, adrenaline, and Adrenalin are the same chemical. Adrenalin (no *e*) is a proprietary DRUG trademarked in the United States. Epinephrine and adrenaline designate either the endogenous chemical (HORMONE or NEUROTRANSMITTER) or the GENERIC DRUG. Only the United States uses the term *epinephrine*. Other countries follow the international standard terminology, which uses the term *adrenaline*. This is because in the United States trademark protections prevent alternate names for trademarked products that could be confused with the trademark.

For further discussion of epinephrine within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also DOPAMINE; NOREPINEPHRINE.

estrogens A collective term for the "female" sex hormones, including prohormones (chemical precursors the body converts to hormones) and metabolites (byproducts of HORMONE METABOLISM). Estrogens are among the steroid hormones the body synthesizes from cholesterol. Estrogens derive from ANDROGENS (the "male" sex hormones).

Common use applies the singular term estrogen to refer to any or all of the three endogenous (naturally occurring within the body) estrogen hormones: estradiol, estriol, and estrone. Estradiol is the most potent and most biochemically active of the estrogens. Estrone is very similar in chemical structure to estradiol though exerts a weaker response. Estriol is a metabolite of both estradiol and estrone.

In a woman's body the levels of these closely related hormones change at MENARCHE and at MENOPAUSE, and fluctuate within the menstrual cycle and with PREGNANCY. Estradiol is the predominant estrogen during the years of FERTILITY, with the less-potent estrone moving into dominance after menopause. In a man's body estrogen levels remain fairly constant. The HYPOTHALAMUS's secretion of GONADOTROPIN-RELEASING HORMONE (GNRH) regulates the hormonal cascade for production and release of the estrogens. In women this cascade is cyclic, establishing the monthly menstrual cycle during the four decades or so a woman is fertile.

Men and women alike have estrogens (just as both sexes also have androgens). The OVARIES in women, the TESTES in men, and the adrenal cortex of the ADRENAL GLANDS in men and women synthesize (produce) most of the estrogens in the BLOOD circulation. During pregnancy the PLACENTA produces estrogens as well. Adipose (fat) cells and the LIVER in both sexes, and the breasts in women, also synthesize small amounts of estrogens.

In women the estrogens establish secondary sex characteristics and fertility, and maintain pregnancy. The estrogens are essential in both sexes for cholesterol metabolism, BONE calcium content and density, thyroid function, SKIN health, and collagen maintenance. The estrogens also have roles in mood and emotion, probably in both men and women though more pronounced in women because estrogen levels fluctuate with the menstrual cycle.

Various endocrine disorders may result in estrogen levels that are too high or too low, with consequences for fertility in women and for cholesterol metabolism in men and women. Doctors use pharmaceutical preparations of estrogens and estrogen analogs (drugs that bind with estrogen receptors though do not have estrogen activity) for a diverse array of therapeutic applications including CONTRACEPTION (birth control pills), treatment for HORMONE-DRIVEN CANCERS (notably PROSTATE

CANCER) in men, OSTEOPOROSIS and BREAST CANCER prevention in women (estrogen analogs), and fertility treatments in women.

Estrogen products were a mainstay of therapy (alone or in combination with PROGESTERONE) to relieve the discomforts of menopause for much of the latter half of the 20th century. Research in the early 2000s demonstrated significant risks with routine hormone replacement therapy (HRT), however, resulting in a change in medical practice to use such products within narrow therapeutic guidelines and for the shortest amount of time possible to achieve a therapeutic result.

For further discussion of estrogen within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

euthyroid sick syndrome A circumstance in which BLOOD tests show irregular thyroid HORMONE levels in the blood but hypothalamic, pituitary, and thyroid functions are all normal. Euthyroid sick syndrome typically accompanies a severe acute illness or chronic condition. Many medications interfere with thyroid function, altering thyroid hormone levels in the blood. Because the body experiences significant physiologic stress with severe illness, many of the body's natural hormonal responses have the consequence of altering thyroid hormone levels.

Typically there are no symptoms of hypothyroidism with euthyroid sick syndrome, though the symptoms of the health condition may make this difficult to assess. Declining thyroid hormone levels, measured through blood tests, provide important insight into the overall crisis state the body is experiencing. There appears to be no benefit in treating euthyroid sick syndrome with replacement thyroid hormones, so most doctors choose a course of watchful waiting in regard to thyroid function and focus therapeutic efforts on the causative condition. Thyroid hormone levels gradually return to normal as the person recovers from the underlying acute illness or when the chronic condition improves.

CONDITIONS THAT MAY RESULT IN EUTHYROID SICK SYNDROME

BONE MARROW TRANSPLANTATION	BURNS
CANCER	CARDIOMYOPATHY
chronic CIRRHOSIS	CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD)
DIABETES	GLOMERULONEPHRITIS
GLOMERULOSCLEROSIS	HEART FAILURE
INFLAMMATORY BOWEL DISEASE (IBD)	major surgery
ISCHEMIC HEART DISEASE (IHD)	ORGAN TRANSPLANTATION
MYOCARDIAL INFARCTION	POLYGLANDULAR DEFICIENCY SYNDROME
PANCREATITIS	severe GASTROENTERITIS
RENAL FAILURE	major trauma
SARCOIDOSIS	
SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)	

See also GOITER; HYPERTHYROIDISM; THYROID GLAND.

follicle-stimulating hormone (FSH) A peptide HORMONE the anterior lobe of the PITUITARY GLAND secretes in response to stimulation from the HYPOTHALAMUS's release of GONADOTROPIN-STIMULATING HORMONE (GNHR). In women, FSH stimulates the follicles in the OVARIES to bring eggs (OVA) to maturity. In men, FSH stimulates growth of cells in the TESTES and synthesis of proteins necessary to support spermatogenesis (production of SPERM). The actions of FSH closely intertwine with those of another pituitary hormone, LUTEINIZING HORMONE (LH). Pituitary tumors can interfere with FSH synthesis, causing the pituitary gland to produce inadequate or excessive amounts. Extended use of ANABOLIC STEROIDS AND STEROID PRECURSORS suppresses both GnRH and FSH (as well as LH), resulting in symptoms of HYPOGONADISM that are most pronounced in men though can occur in women as well. HORMONE THERAPY as treatment for PROSTATE CANCER has the same effect.

For further discussion of FSH within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

G

gastric inhibitive polypeptide (GPI) See DIGESTIVE HORMONES.

gastrin See DIGESTIVE HORMONES.

glucagon A peptide HORMONE the alpha cells of the ISLETS OF LANGERHANS produce in response to low blood GLUCOSE levels (humoral regulation). Intense physical exercise also causes the release of glucagon into the bloodstream. Glucagon stimulates the LIVER to convert glycogen (a storage form of glucose) into glucose to raise the level of glucose in the BLOOD. Glucagon opposes the action of INSULIN (which stimulates glucose use or conversion to glycogen to decrease blood glucose levels). High blood glucose levels inhibit glucagon production as does release of SOMATOSTATIN, another peptide hormone synthesized by the HYPOTHALAMUS, gastrointestinal tract, and delta cells of the islets of Langerhans. Glucagon is also available as a pharmaceutical DRUG used to treat HYPOGLYCEMIA (low blood glucose) and insulin shock.

For further discussion of glucagon within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also DIABETES; DIGESTIVE HORMONES; LIVER; METABOLISM.

glucose A simple sugar molecule (monosaccharide) that is the primary energy source for most cells in the body. The body metabolizes (breaks down) carbohydrates, which enter the body from the gastrointestinal tract, into glucose. The body requires a fairly narrow but constant level of available glucose circulating in the BLOOD at all times (70 to 110 milligrams of glucose per deciliter of blood). Glucose and two hormones the ISLETS OF LANGERHANS in the PANCREAS produce, INSULIN and GLUCAGON, function in synchronization and opposition to maintain this level.

Rising glucose levels in the blood signal the islets of Langerhans to secrete insulin. The insulin binds with receptors on cell membranes, enabling glucose to enter the cells. Within the cell the glucose causes a series of biochemical actions that result in the formation of adenosine triphosphate (ATP), which fuels cellular METABOLISM. Insulin (in coordination with CORTISOL) also stimulates the LIVER to extract excess glucose from the blood and convert it to glycogen, a storage form of glucose the liver then deposits within its tissues as well as within MUSCLE tissue throughout the body. When the blood glucose level drops, the islets of Langerhans release glucagon, a hormone that causes the liver to convert glycogen back to glucose and release it into the blood circulation. Glucagon also stimulates DIGESTIVE HORMONES and enzymes that result in the sensation of hunger, encouraging food intake that can more rapidly replenish the body's glucose supply.

FASTING BLOOD GLUCOSE LEVELS

Health Condition	Milligrams of Glucose per Deciliter of Blood
hypoglycemia	< 50
normal	70–110
hyperglycemia (prediabetes)	111–125
DIABETES	> 126

See also CELL STRUCTURE AND FUNCTION.

goiter Swelling and enlargement of the THYROID GLAND. Most often goiter occurs as a symptom of thyroid dysfunction though can develop when thyroid function is normal, such as sometimes

occurs as a consequence of PREGNANCY (when the body's need for thyroid hormones increases) or in EUTHYROID SICK SYNDROME (when a health crisis disrupts the entire endocrine matrix). A goiter may cause uniform enlargement of the thyroid gland (diffuse goiter) or isolated enlargement (nodular goiter). Though typically a goiter is visible on the front of the neck, occasionally a nodular goiter forms on the back of a thyroid lobe, near the end, pressuring the airway. Among the numerous causes of goiter are

- iodine deficiency
- HYPOTHYROIDISM (underactive thyroid)
- HYPERTHYROIDISM (overactive thyroid), including GRAVES'S DISEASE
- THYROIDITIS (INFLAMMATION of the thyroid gland)
- radiation exposure (such as from RADIATION THERAPY to treat CANCER of the larynx, MOUTH, or upper chest)
- thyroid nodules (noncancerous growths)
- THYROID CANCER

Hypothyroidism, hyperthyroidism, and thyroiditis are the most common causes of diffuse goiter. Thyroid nodules, which are fairly common, and thyroid cancer, which is relatively uncommon, are more likely to cause nodular goiter. Iodine deficiency is rare in the United States because most table salt is iodized. Symptoms of goiter may include

- visible swelling on one side or both sides of the neck
- palpable lump in the neck, especially when swallowing
- difficulty swallowing or the sensation of something being stuck in the THROAT
- difficulty breathing, usually with exhalation

Many people also have symptoms of hypothyroidism or hyperthyroidism, when either condition is the cause of the goiter. The diagnostic path includes blood tests to measure the level of thyroid hormones, ULTRASOUND of the neck, and often a radionuclide scan or COMPUTED TOMOGRAPHY (CT) SCAN. Treatment depends on the findings and the extent to which symptoms interfere with functions such as swallowing or BREATHING. If surgery to remove the thyroid gland is necessary (thyroidectomy), the person will need to take lifelong thyroid supplementation (thyroid HORMONE THERAPY). Endocrinologists typically take an approach of watchful waiting with a goiter that causes no symptoms and does not affect thyroid function (thyroid hormone levels are normal).

See also AUTOIMMUNE DISORDERS; LYMPHOMA; THYROID NODULE.

gonadotropin-releasing hormone (GnRH) A peptide HORMONE, also called luteinizing hormone-releasing hormone (LHRH), the HYPOTHALAMUS produces to stimulate the anterior lobe of the PITUITARY GLAND to synthesize and release LUTEINIZING HORMONE (LH) and FOLLICLE-STIMULATING HORMONE (FSH). LH and FSH in turn stimulate the gonads, or sex glands, to produce their respective hormones. In women the effect stimulates the OVARIES to produce ESTROGENS and PROGESTERONE, and in men stimulates the TESTES in men to produce TESTOSTERONE. When these sex hormones reach certain levels in the bloodstream the hypothalamus stops secreting GnRH, and the gonadotropic cascade stops—a negative-feedback loop. In women these levels fluctuate according to the menstrual cycle. Other hormones may also influence the release of GnRH.

Doctors sometimes use a pharmaceutical preparation of GnRH, called a GnRH analog, to treat ENDOMETRIOSIS. Because its chemical composition is nearly identical to that of endogenous GnRH, a GnRH analog binds with GnRH receptors to block endogenous GnRH binding. This prevents the release of LH and FSH, and consequently suppresses the menstrual cycle and OVULATION.

For further discussion of GnRH within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also ANTIDIURETIC HORMONE (ADH); GROWTH HORMONE (GH); INHIBIN; MENSTRUATION; OXYTOCIN; PROLACTIN; THYROID-STIMULATING HORMONE (THS).

Graves's disease An autoimmune disorder in which the body produces antibodies that attack the THYROID GLAND, producing symptoms of HYPERTHYROIDISM (overactive thyroid gland). The most

common cause of hyperthyroidism, Graves's disease affects seven times as many women as men and is most frequent among women between the ages of 30 and 60. Graves's disease is more likely to occur among people who have other AUTOIMMUNE DISORDERS, notably type 1 DIABETES, SYSTEMIC LUPUS ERYTHEMATOSUS (SLE), and POLYGLANDULAR DEFICIENCY SYNDROME.

In health the HYPOTHALAMUS, PITUITARY GLAND, and thyroid gland work in synchronization to maintain an appropriate balance of thyroid hormones, which regulate METABOLISM, in the BLOOD circulation. Low blood levels of the major thyroid hormones TRIIODOTHYRONINE (T_3) and THYROXINE (T_4) signal the hypothalamus to produce THYROTROPIN-RELEASING HORMONE (TRH). TRH in turn stimulates the pituitary gland to secrete THYROID-STIMULATING HORMONE (TSH). TSH binds with TSH receptors on the cells of the thyroid gland, activating synthesis of T_3 and T_4. When T_3 and T_4 reach appropriate levels in the bloodstream, the hypothalamus stops producing TRH and the thyroid hormone cascade ends.

The antibodies the IMMUNE SYSTEM produces in Graves's disease, called thyroid-stimulating immunoglobulins (TSIs), continuously stimulate the TSH receptors in the thyroid gland, falsely signaling that blood T_3 and T_4 levels are too low. The thyroid gland responds by increasing synthesis of these hormones. It is an overproduction, however. TSH and TRH levels fall as they should but thyroid hormone production continues in the thyroid gland, resulting in hyperthyroidism. Graves's disease accounts for about 70 percent of hyperthyroidism in the United States.

A serious corollary condition is GRAVES'S OPHTHALMOPATHY, in which the excessive thyroid hormones cause swelling in and around the structures of the eyes. Graves's ophthalmopathy is often the earliest indication of Graves's disease and can result in permanent damage to the eyes, including loss of vision. The characteristic symptom of Graves's ophthalmopathy is EXOPHTHALMOS (bulging eyes, also called poptosis). Some endocrinologists believe Graves's ophthalmopathy is a distinct autoimmune disease process separate from Graves's disease, as it may exist without apparent hyperthyroidism or develop years to decades before or after hyperthyroidism manifests.

Symptoms and Diagnostic Path

The symptoms of Graves's disease are those of hyperthyroidism and may include symptoms of Graves's ophthalmopathy as well. These symptoms are

- PALPITATIONS
- weight loss
- heat intolerance
- difficulty concentrating
- irritability, anxiety, and insomnia (difficulty sleeping)
- bulging eyes (poptosis), "lid lag" (delay in the eyelid's movement when the EYE moves downward), and vision disturbances (Graves's ophthalmopathy)

The diagnostic path includes blood tests to measure thyroid hormones (typically T_3, T_4, and TSH) and the presence of TSIs. The former establish hyperthyroidism; the latter confirms the diagnosis of Graves's disease.

Treatment Options and Outlook

Treatment targets disabling the thyroid gland's ability to synthesize thyroid hormones. Because Graves's disease is a progressive autoimmune disorder, endocrinologists tend to opt for permanent therapies such as radioactive iodine (^{131}I) to destroy thyroid tissue so it cannot produce thyroid hormones. One consequence of this approach is that the destruction of the thyroid gland results in permanent hypothyroidism and makes necessary lifelong HORMONE THERAPY with thyroid hormone supplements. Thyrotoxic medications such as methimazole and propylthiouracil (PTU), though effective in other forms of hyperthyroidism, are less successful because the autoimmune response continues.

Risk Factors and Preventive Measures

Women who have other autoimmune disorders have increased risk for Graves's disease. For them, regular blood tests to measure thyroid hormones can help detect the condition early. Routine ophthalmologic examinations can detect Graves's ophthalmopathy, which may develop even with treatment for Graves's disease, before it causes

permanent damage to the eyes and vision. No known preventive measures exist for Graves's disease.

See also IMMUNE RESPONSE; LYMPHOCYTE; THYROIDITIS; THYROID STORM; VISION HEALTH.

growth hormone (GH) A peptide HORMONE the PITUITARY GLAND produces in response to secretion of GROWTH HORMONE–RELEASING HORMONE (GHRH) by the HYPOTHALAMUS. GH affects growth directly by initiating an increase in cell division and indirectly by stimulating the production of insulinlike growth factors (IGFs), proteins that affect cell METABOLISM and other functions. GH levels are highest in childhood, then taper off in early adulthood to maintain a stable level. GH remains essential in adulthood to maintain appropriate cell metabolism, notably in BRAIN, MUSCLE, and fat cells. GROWTH HORMONE DEFICIENCY in childhood results in stunted growth, and in adulthood can result in diminished cognitive function, decreased muscle mass, and increased body fat. Some researchers believe the decline in GH in adulthood contributes to the aging process, though the mechanisms through which this occurs remain unknown. Excessive GH secretion, such as may occur with a pituitary ADENOMA, results in ACROMEGALY.

For further discussion of growth hormone within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also ADRENOCORTICOTROPIN HORMONE (SCTH); ANABOLIC STEROIDS AND STEROID PRECURSORS; ANTIDIURETIC HORMONE (ADH); FOLLICLE-STIMULATING HORMONE (FSH); HUMAN GROWTH HORMONE (HGH) SUPPLEMENT; LUTEINIZING HORMONE (LH); OXYTOCIN; PROLACTIN; THYROID-STIMULATING HORMONE (TSH).

growth hormone deficiency An endocrine disorder in which the anterior lobe of the PITUITARY GLAND produces an inadequate amount of GROWTH HORMONE (GH). GH is fundamental for proper growth and development in childhood and remains essential for appropriate metabolic function in adulthood. In childhood GH binds to receptors in BONE cells that increases the rate at which they divide, causing bone growth that results in increased height. In adulthood GH deficiency can affect cognitive functions and memory, body mass and fat distribution, and numerous aspects of cell METABOLISM.

It is important to distinguish between abnormal growth and a child who is simply short in stature. The average rate of growth for children is about two inches a year. Many factors influence a child's ultimate height. Indications in addition to short stature that a child may have GH deficiency include accumulations of body fat in the abdomen and the face (giving a rounded, chubby appearance), delayed eruption of TEETH, and in an older child, delayed PUBERTY. The diagnostic path includes

- BLOOD tests to measure thyroid hormones (HYPOTHYROIDISM can cause slowed growth) and insulinlike growth factors (IGFs)
- measuring height and weight over a period of time to detect growth patterns
- X-rays and sometimes COMPUTED TOMOGRAPHY (CT) SCAN to evaluate bone structure
- a GROWTH HORMONE–RELEASING HORMONE (GHRH) challenge test to measure the ability of the pituitary gland to respond to stimulation by GHRH

Treatment for confirmed GH deficiency in children is injections of recombinant human growth hormone (hGH), a genetically engineered substance that has the precise configuration of endogenous GH, continued until the child reaches appropriate growth. Some people develop antibodies to the recombinant hGH, decreasing its effectiveness. When the pituitary gland is congenitally absent (a birth defect) or permanently damaged, long-term hGH therapy may be necessary. Whether treatment continues into adulthood depends on symptoms and the cause of the deficiency. Doctors do not agree on the definition or the need for treatment of adult growth hormone deficiency that does not begin in childhood.

See also ACROMEGALY; ADRENAL INSUFFICIENCY; HUMAN GROWTH HORMONE (HGH) SUPPLEMENT; POLYGLANDULAR DEFICIENCY SYNDROME; TURNER'S SYNDROME.

growth hormone–releasing hormone (GHRH) A peptide HORMONE the HYPOTHALAMUS produces to stimulate the PITUITARY GLAND to synthesize and

release GROWTH HORMONE (GH). The secretion of GHRH initiates a cascade of chemical activity that results in intensified cell METABOLISM and processes that promote cell division and the growth of body tissues and structures. The hormone SOMATOSTATIN, which the hypothalamus and the delta cells of the ISLETS OF LANGERHANS produce, provides the stimulus for the hypothalamus to stop releasing GHRH. Multiple factors regulate the balance between GHRH and somatostatin.

For further discussion of GHRH within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also ACROMEGALY; ADRENOCORTICOTROPIN HORMONE (ACTH); ANABOLIC STEROIDS AND STEROID PRECURSORS; ANTIDIURETIC HORMONE (ADH); FOLLICLE-STIMULATING HORMONE (FSH); GROWTH HORMONE DEFICIENCY; LUTEINIZING HORMONE (LH); OXYTOCIN; PROLACTIN; THYROID-STIMULATING HORMONE (TSH).

H

Hashimoto's disease See THYROIDITIS.

hemochromatosis A genetic disorder in which the gastrointestinal tract absorbs too much iron into the bloodstream. The BLOOD deposits the excess iron in various tissues and organs, where it accumulates and eventually causes damage. Common sites for deposits include the HEART, causing HEART FAILURE, PANCREAS, causing DIABETES, and LIVER, causing CIRRHOSIS and LIVER FAILURE. Though hemochromatosis is congenital (present from birth), most people do not experience consequences or symptoms until midlife when enough iron has accumulated in the organs to affect their functions.

Health experts believe hemochromatosis is far more common than the number of people diagnosed with the condition suggests. Women may not show symptoms until 10 or more years after MENOPAUSE because the bleeding associated with MENSTRUATION reduces blood iron concentrations, serving as a natural therapy for the hemochromatosis. Researchers have identified several GENE mutations that can cause hemochromatosis. The most common mutations are those involving the HFE gene that regulates gastrointestinal iron absorption. Researchers have designated them C282Y and H63D, and they account for about 85 percent of diagnosed hemochromatosis in the United States.

Symptoms and Diagnostic Path

Doctors often detect hemochromatosis during evaluation for other health concerns, when blood tests show higher than normal HEMOGLOBIN or iron levels. The symptoms of hemochromatosis result from damage to organs and structures where iron deposits accumulate and often take the form of fairly advanced disease states by the time of detection. General symptoms may include

- JOINT PAIN (the most common symptom)
- fatigue and lethargy
- abdominal discomfort or PAIN

The excessive iron in the body may also interfere with FERTILITY (causing early menopause in women) and LIBIDO (sex drive). The diagnostic path includes general blood tests to measure hemoglobin, hematocrit, red blood cells, and specialized blood tests that measure iron. The most commonly used are

- transferrin saturation, which measures how much iron the hemoglobin carries (protein saturation)
- total iron binding capacity (TIBC), which measures the capacity of the hemoglobin to transport iron
- serum ferritin, which measures the iron the liver contains

Elevated results in any of these tests suggests hemochromatosis. Further blood analysis to detect the HFE gene mutation and liver biopsy are the final steps in the diagnostic path and provide a definitive diagnosis.

Treatment Options and Outlook

Treatment for hemochromatosis is phlebotomy, the withdrawal of blood a pint at a time. Initial treatment may take place several times a week until blood levels of iron return to normal. Most people then require phlebotomy sessions only once every two to four months, though lifelong treatment is necessary. Treatment also targets any

health conditions that have developed as a consequence of iron deposits, such as heart disease or diabetes. The damage iron deposits cause is irreversible, though once treatment begins most secondary conditions improve.

DONATING BLOOD

Some BLOOD banks and blood collection centers accept blood withdrawn as treatment hemochromatosis for donation and use it to produce blood products. As blood products are limited and sometimes scarce, it is worthy for people who are receiving therapeutic phlebotomy for hemochromatosis to look for centers who will accept their blood for such use. Otherwise the center discards the blood.

Risk Factors and Preventive Measures

Because hemochromatosis is hereditary, the key risk for developing it is family history. Doctors have only recently recognized the potentially widespread existence of hemochromatosis, however; and many family medical histories make no reference to the condition. People who have family histories for early-onset liver disease, heart disease, or diabetes should have basic blood tests for iron levels included with their routine medical examinations as a screening precaution. Early diagnosis and treatment prevent most of the complications that can develop and minimize the severity of the condition and its affect on health.

See also BLOOD DONATION; PHENYLKETONURIA (PKU); WILSON'S DISEASE.

hirsutism Excessive growth of body HAIR in a male pattern, typically involving the face, chest, back, arms, and legs. The hair follicles on these SKIN surfaces are sensitive to TESTOSTERONE and other ANDROGENS ("male" hormones), the hormones that stimulate hair growth in both men and women. Though hirsutism affects men and women, it is especially a concern for women for clinical as well as cosmetic reasons. Hirsutism may result from the hair follicles being overly sensitive to the effects of androgens (with normal levels of androgens in the BLOOD) or an excess of androgens in the blood circulation.

In the latter circumstance, researchers believe the culprit is overactivity of an enzyme, 5-alpha reductase, that converts testosterone to dihydrotestosterone, the androgen form that stimulates hair growth. Excessive blood levels of testosterone may result from androgen-secreting tumors that form in the OVARIES or the adrenal cortex of the ADRENAL GLANDS, the two primary sources of endogenous testosterone. Women athletes who use ANABOLIC STEROIDS AND STEROID PRECURSORS may also develop hirsutism. INSULIN RESISTANCE and POLYCYSTIC OVARY SYNDROME (PCOS), existing independently or as constituents of INSULIN resistance, are strongly associated with hirsutism in women. In some situations the endocrinologist cannot determine a definitive cause for hirsutism (idiopathic hirsutism).

The diagnostic path includes blood tests to measure hormone levels, hormonal responses, and insulin sensitivity. The precise tests depend on the findings of preliminary tests. ULTRASOUND or MAGNETIC RESONANCE IMAGING (MRI) of the ovaries or imaging procedures to visualize the adrenal glands may identify any tumors. Treatment depends on any identified cause and may combine HORMONE THERAPY to suppress androgen production or binding with cosmetic therapies to remove or minimize excessive hair. The most commonly used hormone therapy is the oral contraceptive (birth control pill), which regulates the hormonal cycle of the ovaries. The endocrinologist may prescribe other hormone products, such as CORTICOSTEROID MEDICATIONS, to suppress the HORMONE production of the adrenal cortex. These methods are effective for many though not all people who have hirsutism. Cosmetic approaches include electrolysis or laser therapy to permanently destroy hair follicles. Shaving and chemical depilatories (hair removers) are sometimes effective though require frequent use. Hirsutism can be emotionally difficult for those who have it, especially women, though men as well may find the condition distressing.

See also CONTRACEPTION; GENETIC DISORDERS; PORPHYRIA.

hormone A chemical that travels through the blood circulation and influences the functions of cells within the body. The body produces dozens of hormones of two primary chemical forms, peptides and steroids. A hormone affects only the cells that have receptors for it, and only when it binds

to those receptors. A receptor is somewhat like an outlet that has a unique configuration. The hormone for which the receptor is sensitive matches that configuration, forming a chemical "lock" between the hormone molecule and the cell. Through such binding hormones cause chemical changes within the cell that may activate enzymes or alter the cell's genetic encoding by creating new proteins (called genetic transcription). Each hormone has unique receptors. Many cells have receptors only for certain hormones, eliciting specific and narrowly focused changes. Only cells in the TESTES and OVARIES, for example, have receptors for FOLLICLE-STIMULATING HORMONE (FSH) and LUTEINIZING HORMONE (LH). Some hormones, such as GROWTH HORMONE (GH), have receptors in all cells, in which case the hormone has widespread actions.

Some hormones stimulate and others inhibit activity. Most hormonal responses occur in cascades, with multiple activities resulting from the hormone's release. For example, the HYPOTHALAMUS releases GROWTH HORMONE–RELEASING HORMONE (GHRH), which stimulates the PITUITARY GLAND to release GH. Growth hormone initiates metabolic changes within some cells, such as the BONE and MUSCLE, and also activates the production of insulinlike growth factors (IGFs) that induce metabolic activity in other cells.

Peptide Hormones

Peptide hormones consist of amino acid chains and are the most abundant form of endogenous hormone. Scientists further define peptide hormones as small peptide (fewer than 10 amino acids), polypeptide (more than 10 and fewer than 100 amino acids), or protein (100 or more amino acids), depending on the length and configuration of the amino acid chain. These distinctions influence the hormone's mechanisms of action, stability, and receptor binding. Most of the body's hormones are peptide hormones.

Peptide hormones are water soluble and travel through the bloodstream attached to protein molecules called protein carriers. These larger structures keep the hormone intact during transit. Most peptide hormones cannot penetrate the wall of the cell. Instead, they bind with protein receptors on the cell's surface (also called the plasma membrane). The binding causes a chemical reaction that activates proteins within the cell that then carry the hormone's message within the cell, indirectly influencing cell activity. Among the exceptions are the thyroid hormones, which do cross the cell membrane to bind with receptors in the cell nucleus and directly influence the cell's activity.

PEPTIDE HORMONES

ANTIDIURETIC HORMONE (ADH)	CALCITONIN
cholecystokinin (CCK)	CHORIONIC GONADOTROPIN
CORTICOTROPIN-RELEASING HORMONE (CRH)	enterogastrone
gastric inhibitive polypeptide (GPI)	FOLLICLE-STIMULATING HORMONE (FSH)
GLUCAGON	gastrin
GROWTH HORMONE (GH)	GONADOTROPIN-RELEASING HORMONE (GNRH)
GROWTH HORMONE–RELEASING HORMONE (GHRH)	INHIBIN
LUTEINIZING HORMONE (LH)	INSULIN
motilin	MELATONIN
PARATHYROID HORMONE	OXYTOCIN
RELAXIN	PROLACTIN
secretin	RENIN
THYROID-STIMULATING HORMONE (TSH)	SOMATOSTATIN
THYROXINE (T_4)	THYROTROPIN-RELEASING HORMONE (TRH)
vasoactive intestinal peptide (VIP)	TRIIODOTHYRONINE (T_3)

Steroid Hormones

Steroid hormones are lipid structures that derive from cholesterol. Scientists further define steroid hormones as corticosteroids (glucocorticoids and mineralocorticoids), sex steroids (ANDROGENS, ESTROGENS, PROGESTERONE), and vitamin D derivatives. Like peptide hormones, steroid hormones bind to protein carriers to transport them through the bloodstream to their target cells. Steroid hormones penetrate the wall of the cell to bind with receptors (specialized proteins) within the cytoplasm or cell nucleus to directly alter the cell's activity. Steroid hormones elicit genetic transcription responses in the cells that contain their receptors.

ENDOGENOUS STEROID HORMONES

ALDOSTERONE	CORTISOL	ESTROGENS
PROGESTERONE	TESTOSTERONE	vitamin D

Pharmaceutical Hormones

Most of the major endocrine hormones are available as purified extracts or synthesized products for therapeutic supplementation or replacement therapy. Endocrinologists and other doctors prescribe pharmaceutical conditions to treat a wide range of endocrine disorders such as ADDISON'S DISEASE, HYPOTHYROIDISM, and DIABETES. Doctors may also prescribe pharmaceutical hormones for CONTRACEPTION (the birth control pill), to enhance FERTILITY, to slow or prevent OSTEOPOROSIS, and to treat HORMONE-DRIVEN CANCERS such as PROSTATE CANCER, ENDOMETRIAL CANCER, and some forms of BREAST CANCER.

Many hormone supplements are recombinant products genetically engineered in laboratories to precisely match the chemical configurations of endogenous (native to the human body) hormones. Some hormone products contain purified extracts drawn from animal sources, most commonly human (extracted from donor cadaver organs), porcine (pig) and bovine (cow). Most people can tolerate either type of supplement, though adverse reactions (including allergic responses) tend to be more common with extracts.

For further discussion of hormones within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also ANABOLIC STEROIDS AND STEROID PRECURSORS; DIGESTIVE ENZYMES; DIGESTIVE HORMONES; ENDOCRINE GLAND; HORMONE THERAPY.

hormone therapy Treatment in which a person takes HORMONE extracts or synthetic hormones to influence the body's natural production of hormones or to replace hormones the body is no longer producing. Nearly all of the body's major hormones are available as purified extracts, laboratory-synthesized pharmaceuticals, or recombinant products. Common hormone therapy regimens include replacement supplements to treat:

- ACROMEGALY
- ADDISON'S DISEASE
- ADRENAL INSUFFICIENCY
- DIABETES
- GROWTH HORMONE DEFICIENCY
- HYPOPARATHYROIDISM
- HYPOPITUITARISM (especially following treatment for adenoma)
- HYPOTHYROIDISM

Hormone therapy may also be a treatment approach for HORMONE-DRIVEN CANCERS such as PROSTATE CANCER, some BREAST CANCERS, and ENDOMETRIAL CANCER (cancer of the UTERUS). Doctors may also prescribe short-term hormone replacement therapy (HRT) for moderate to severe symptoms related to MENOPAUSE. FERTILITY treatments typically involve hormone therapy to stimulate OVULATION in women or SPERM production in men.

CHANGE IN HRT PRACTICES

For the latter half of the 20th century doctors routinely prescribed moderate doses of ESTROGENS and progestins for women going through and beyond MENOPAUSE, based on the presumption that such hormone replacement therapy (HRT) protected women from heart disease and OSTEOPOROSIS. Several large studies in the early 2000s disproved this premise, establishing concern that routine HRT increased the risk for heart disease as well as HORMONE-DRIVEN CANCERS. Doctors now prescribe small doses of these hormones for short periods of time and only for women who are experiencing moderate to severe symptoms such as hot flashes and sleep disturbances.

See also CANCER TREATMENT OTIONS AND DECISIONS; OSTEOPOROSIS.

hydrocortisone See CORTISOL.

hyperaldosteronism A condition, also called aldosteronism, in which the adrenal cortex of the ADRENAL GLANDS produces excessive ALDOSTERONE. This causes the KIDNEYS to withhold higher amounts of sodium in the BLOOD and pass into the URINE greater amounts of potassium, which consequently draws greater amounts of water into the blood. The aldosterone also causes the peripheral arterioles (tiny arteries in the CAPILLARY BEDS) to constrict. The combined effect is elevated BLOOD PRESSURE along with an imbalance between sodium and potassium. This imbalance causes disturbances

of the HEART's rhythm (ARRHYTHMIA) that can have serious consequences.

The most common cause of hyperaldosteronism is an ADENOMA (a noncancerous tumor) that grows in the zona glomerulosa, the region of the adrenal cortex that produces aldosterone. Symptoms may appear gradually or rapidly depending on the location and rate of growth of the adenoma. In addition to HYPERTENSION (high blood pressure) and arrhythmias, symptoms may include HEADACHE and fatigue. Some people also experience weakness or dizziness, a potential consequence of arrhythmias.

The diagnostic path includes blood tests to measure the levels of aldosterone and potassium, imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) to determine the presence of an adrenal tumor, and ELECTROCARDIOGRAM (ECG) to detect and evaluate any arrhythmias. Treatment is surgery to remove the tumor, when possible. The endocrinologist may also prescribe medications such as the potassium-sparing diuretic spironolactone, which works by suppressing aldosterone secretion, in conjunction with a low-sodium diet to help control symptoms either in lieu of surgery or after surgery if the hypertension persists.

Hyperaldosteronism may also develop as a secondary condition resulting from severe CARDIOVASCULAR DISEASE (CVD) such as uncontrolled hypertension or HEART FAILURE. Treatment when this is the case targets the underlying condition and often also incorporates similar dietary restrictions and medications to those prescribed for primary hyperaldosteronism.

See also ADDISON'S DISEASE; ADRENAL INSUFFICIENCY; CUSHING'S SYNDROME.

hypercalcemia A circumstance of excessive calcium in the BLOOD circulation. The most common cause of hypercalcemia is HYPERPARATHYROIDISM (excessive secretion of PARATHYROID HORMONE). Other causes include HYPERTHYROIDISM (overactive THYROID GLAND), long-term therapy with lithium (treatment for BIPOLAR DISORDER) or thiazide diuretics ("water pills"), excessive vitamin D or vitamin A consumption, excessive consumption of calcium carbonate (a form of antacid often taken as a calcium supplement), and some cancers, notably metastatic BONE CANCER.

Hypercalcemia occurs when the bones release excessive calcium into the BLOOD circulation. The loss of calcium weakens the structure of the bones, causing symptoms similar to OSTEOPOROSIS such as BONE PAIN and, when calcium loss is severe, spontaneous fractures. However, hypercalcemia is likely to cause other, more apparent symptoms before the calcium loss reaches such a point.

Calcium is essential for MUSCLE contractions and for the conduction of NERVE impulses, an especially critical combination in the HEART. Hypercalcemia may cause ARRHYTHMIAS (irregularities in the HEART RATE), which are apparent with ELECTROCARDIOGRAM (ECG), and HYPERTENSION (high BLOOD PRESSURE). Hypercalcemia also often has neurologic symptoms as well, such as confusion and cognitive dysfunction, because the excessive calcium in the blood disrupts nerve communication in the BRAIN.

The diagnostic path begins with blood tests to measure calcium and parathyroid hormone levels in the blood. The doctor may conduct an ECG to evaluate any cardiovascular symptoms, and X-rays Or bone scan to assess BONE DENSITY loss or the presence of tumors, particularly in people who have or have been treated for LYMPHOMA, LEUKEMIA, MULTIPLE MYELOMA, or CARCINOMA. People who have received RADIATION THERAPY to the neck, such as to treat THYROID CANCER or HYPERTHYROIDISM, are vulnerable to parathyroid ADENOMA (noncancerous tumor of a parathyroid gland) or hyperparathyroidism.

Treatment depends on the severity of the hypercalcemia and any underlying causes. Mild to moderate hypercalcemia may improve with increased HYDRATION in combination with medications that suppress the release of calcium from the bones or the diuretic medication furosemide (Lasix), which blocks the KIDNEYS from reabsorbing calcium from the blood. When the cause is hyperparathyroidism, the most viable treatment option may be surgery to remove the parathyroid glands. When hypercalcemia results from benign causes, treatment usually resolves the situation and blood calcium levels return to normal.

See also CALCITONIN; MULTIPLE ENDOCRINE NEOPLASIA (MEN); NEPHROLITHIASIS; PHEOCHROMOCYTOMA.

hyperkalemia A circumstance of elevated potassium in the BLOOD circulation. The most common

cause of hyperkalemia is kidney dysfunction in which the KIDNEYS retain excessive potassium in the blood. Such dysfunction may develop as a consequence of RENAL FAILURE or due to endocrine disorders such as ADRENAL INSUFFICIENCY. Hyperkalemia may develop in people who have poorly controlled DIABETES as a consequence of chronically elevated blood GLUCOSE levels, which damages kidney function. Sometimes potassium-sparing diuretic medications, which doctors may prescribe to treat HEART FAILURE or HYPERTENSION (high BLOOD PRESSURE), can result in hyperkalemia. Moderate to severe hyperkalemia causes ARRHYTHMIA (disturbance of the heartbeat).

Weakness and tiredness are the most common symptoms. The diagnostic path includes blood tests to measure the level of potassium and other electrolytes in the blood and ELECTROCARDIOGRAM (ECG) to evaluate the HEART's electrical activity. Treatment consists of appropriate methods to reduce potassium levels according to the underlying cause. Such methods may include changing medications or doses for diuretics, HORMONE THERAPY to supplement adrenal function, reducing consumption of foods high in potassium (such as bananas, green leafy vegetables, and raisins), or therapies to improve kidney function. Most people who have uncomplicated hyperkalemia fully recover with appropriate treatment.

See also ADRENAL GLANDS; ALDOSTERONE; HYPERALDOSTERONISM.

hypernatremia A circumstance of elevated sodium in the BLOOD circulation. The most common cause of hypernatremia is DEHYDRATION that results from prolonged NAUSEA and VOMITING. Rarely, hypernatremia results from DIABETES INSIPIDUS or other dysfunctions of ANTIDIURETIC HORMONE (ADH) release from the HYPOTHALAMUS or PITUITARY GLAND that causes the KIDNEYS to increase the amount of water they pass from the body. The concentration of sodium in the blood correspondingly rises.

The primary symptom of hypernatremia is extreme thirst. As the concentration of sodium increases symptoms become neurologic and include confusion and seizures. The diagnostic path starts with blood tests to measure sodium and other electrolyte levels in the blood and may include a water-deprivation test, which measures the body's endocrine responses (such as increased ADH release) to the shift in electrolyte concentrations. Treatment is increased fluid to restore the appropriate water–sodium balance in the blood. When the cause is diabetes insipidus or other ADH-related insufficiency (such as pituitary dysfunction), treatment typically incorporates HORMONE THERAPY with ADH supplement.

See also ADENOMA; HYPERCALCEMIA; HYPOKALEMIA.

hyperparathyroidism A condition in which the PARATHYROID GLANDS secrete an excessive amount of PARATHYROID HORMONE. The four tiny parathyroid glands are on the back of the THYROID GLAND. Parathyroid hormone regulates the balance of calcium and phosphorus in the BLOOD. Excessive parathyroid hormone results in too much calcium pulled from the bones and absorbed from the gastrointestinal tract into the BLOOD circulation (HYPERCALCEMIA). At the same time blood levels of phosphorus drop (hypophosphatemia). Phosphorus helps retain calcium in the bones and is important for BONE STRENGTH. Calcium is also essential for the conduction of NERVE impulses and for MUSCLE contraction. Excessive calcium in the blood disrupts neuromuscular functions.

The most common cause of hyperparathyroidism is an ADENOMA (noncancerous tumor) of a parathyroid gland. Sometimes the parathyroid glands enlarge (parathyroid HYPERPLASIA) without apparent cause. Either circumstance results in increased secretion of parathyroid hormone. Symptoms of hyperparathyroidism tend to be nonspecific and include

- weakness and rapid tiring with physical exertion
- loss of APPETITE
- lethargy and fatigue
- generalized aches and discomforts

OSTEOPOROSIS may be the first indication of hyperparathyroidism in many people. Sometimes conditions such as HYPERTENSION (high BLOOD PRESSURE), a consequence of calcium's actions, or kidney stones (NEPHROLITHIASIS) reveal the underlying cause to be hyperparathyroidism. The diagnostic path includes blood tests to measure the levels of

calcium, phosphorus, and parathyroid hormone in the blood circulation. Further diagnostic procedures to determine the cause of the hyperparathyroidism may include ULTRASOUND of the neck to evaluate the parathyroid glands, as well as tests of kidney function and X-rays to evaluate bone structure and density. Treatment for parathyroid adenoma or parathyroid hyperplasia typically involves surgery to remove the affected parathyroid gland, which permanently ends the oversecretion. Most people recover fully and without residual consequences unless osteoporosis has become significant and requires subsequent treatment.

See also CALCITONIN; HYPOPARATHYROIDISM; PAGET'S DISEASE OF THE BONE; SURGERY BENEFIT AND RISK ASSESSMENT.

hyperprolactinemia A circumstance of elevated PROLACTIN in the BLOOD circulation that occurs when the anterior lobe of the PITUITARY GLAND secretes excessive prolactin. One of the most common causes of hyperprolactinemia is HYPOTHYROIDISM (underactive THYROID GLAND). Hypothyroidism causes the HYPOTHALAMUS to increase THYROTROPIN-RELEASING HORMONE (TRH) secretion in an attempt to increase the thyroid gland's production of thyroid hormones. TRH also stimulates the pituitary gland to release prolactin. Hyperprolactinemia may also result from a prolactin-secreting ADENOMA of the pituitary gland, a noncancerous tumor also called a prolactinoma. Numerous medications may interfere with the endocrine cascades by suppressing DOPAMINE, a HORMONE that "turns off" prolactin secretion.

Hyperprolactinemia has both direct action and cascading effects on the endocrine function. The direct action of prolactin activates the milk ducts in the breasts, causing milk production and lactation. The cascading effects begin with the hypothalamus and carry through the endocrine cascade to the gonads (sex glands) Elevated levels of prolactin in the blood circulation shut off the hypothalamus's production of GONADOTROPIN-RELEASING HORMONE (GNRH), which consequently slows the pituitary gland's production of LUTEINIZING HORMONE (LH) and FOLLICLE-STIMULATING HORMONE (FSH). These events further lead to reduced production of ESTROGENS, PROGESTERONE, and TESTOSTERONE by the OVARIES, TESTICLES, and ADRENAL GLANDS.

In women the primary symptoms of hyperprolactinemia include disturbances of MENSTRUATION (notably infrequent or absent menstrual periods), INFERTILITY, and milk production (galactorrhea) when not pregnant or BREASTFEEDING. In men the primary symptoms of hyperprolactinemia include ERECTILE DYSFUNCTION and HYPOGONADISM resulting from diminished testosterone levels. When the cause of the hyperprolactinemia is a prolactinoma, both men and women may experience headaches and disturbances of vision from pressure the tumor applies on adjacent structures, such as the OPTIC NERVE, in the BRAIN.

The diagnostic path begins with blood tests to measure the levels of key hormones such as the thyroid hormones, the sex hormones, and prolactin. The results of these tests determine the further course of diagnostic procedures, which may include MAGNETIC RESONANCE IMAGING (MRI) of the head to evaluate the possibility of prolactinoma or ULTRASOUND of the neck to assess the thyroid gland. Treatment targets the underlying cause of the excessive prolactin secretion, which may require surgery to remove an adenoma or medications (dopamine agonists, which suppress prolactin secretion) to treat prolactinoma, or hormone replacement therapy to treat hypothyroidism. Most people recover fully and without residual consequences after appropriate treatment, though may require ongoing treatment for the identified underlying conditions.

See also HYPOPITUITARISM; OSTEOPOROSIS; SURGERY BENEFIT AND RISK ASSESSMENT.

hyperthyroidism A condition, also called thyrotoxicosis, in which the THYROID GLAND overproduces thyroid hormones. The excessive thyroid hormones accelerate METABOLISM.

In health the endocrine system maintains a precise balance among the thyroid hormones to regulate many of the functions of metabolism. The thyroid hormonal cascade begins when the HYPOTHALAMUS produces THYROTROPIN-RELEASING HORMONE (TRH). TRH stimulates the anterior lobe of the PITUITARY GLAND to release THYROID-STIMULATING HORMONE (TSH). TSH stimulates the thyroid gland to synthesize TRIIODOTHYRONINE (T_3) and THYROXINE (T_4), the major active thyroid hormones, as well as several minor or precursor (inactive) thyroid hormones.

When T_3 and T_4 reach appropriate levels in the BLOOD circulation, the hypothalamus ceases TRH production and the thyroid hormone cascade tapers off.

Hyperthyroidism may result from a dysfunction of the thyroid hormone cascade (usually a failure of the pituitary gland to appropriately produce TSH) or overactivity of the thyroid gland. Pituitary ADENOMA is the most common cause of TSH-based hyperthyroidism. Pituitary adenomas secrete TSH that is more potent than normal TSH, eliciting a stronger response from the thyroid gland. Hyperthyroidism that arises from overactivity of the thyroid gland may have various causes. Among them are

- GRAVES'S DISEASE, an autoimmune disorder in which the IMMUNE SYSTEM produces antibodies that attack thyroid tissue
- damage to the thyroid gland resulting from radiation exposure (including RADIATION THERAPY involving structures of the neck, lower face, or upper chest)
- thyroid nodules (nearly always noncancerous)
- excessive consumption of iodine, often resulting from medications that contain iodine (such as the antiarrhythmia medication amiodarone)
- THYROIDITIS (INFLAMMATION of the thyroid gland)
- excessive consumption of therapeutic thyroid hormone supplements (also called thyrotoxicosis factitia)
- THYROID CANCER, which is rare

A dangerous weight loss practice is the intentional consumption of thyroid HORMONE supplement by people who have normal thyroid function. Though this accelerates METABOLISM to generate weight loss, the resulting state of hyperthyroidism can cause serious disturbances of the HEART'S rhythm (ARRHYTHMIA) and the life-threatening condition THYROID STORM, which requires emergency medical treatment. Only people with diagnosed HYPOTHYROIDISM (underactive thyroid) should take thyroid hormone supplement, and only at the DOSE the doctor prescribes.

Symptoms and Diagnostic Path

Hyperthyroidism tends to develop over weeks to months with few indications until thyroid HORMONE levels become significantly elevated, such that the condition may be quite advanced by the time the person becomes aware of symptoms. The most common symptoms of hyperthyroidism are

- racing PULSE and PALPITATIONS
- weight loss
- feeling hot and intolerance to environmental heat
- moist, warm SKIN
- irritability, anxiety, and insomnia (difficulty sleeping)

GOITER (enlarged thyroid gland) is common. People who have Graves's disease may also have EXOPHTHALMOS (bulging eyes, also called poptosis) and autoimmune symptoms involving the SKIN and other body systems. The diagnostic path begins with blood tests to measure the levels of the thyroid hormones in the blood circulation. In hyperthyroidism that originates with the thyroid gland, T_3 and T_4 are usually elevated and TSH is lower than normal. When there is a dysfunction of TSH or the thyroid hormone cascade, T_3 and T_4 are elevated and TSH is normal. Further diagnostic procedures to determine the cause of the hyperthyroidism may include ULTRASOUND or radioiodine scan (also called radioactive-reuptake scan) of the neck to detect nodules or inflammation of the thyroid gland.

Treatment Options and Outlook

Treatment targets reducing thyroid hormone production. Such an approach may include antithyroid medications, radioactive iodine, or surgery to remove part or all of the thyroid gland. The appropriate treatment depends on the circumstances of the hyperthyroidism and the person's overall health status. Antithyroid medications, commonly methimazole and propylthiouracil (PTU), work by interfering with thyroid hormone synthesis and with conversion of T_4 to T_3. Antithyroid medication therapy must be continuous; most people experience a return of hyperthyroidism when they stop taking the medications.

Radioactive iodine, ^{131}I, which destroys thyroid tissue, and surgery to remove part or all of the

thyroid gland provide permanent solutions to thyroid hormone overproduction. Most people subsequently require long-term thyroid hormone supplements (HORMONE THERAPY) to maintain adequate thyroid hormone levels in the blood, as these treatments often leave the thyroid gland incapable of synthesizing thyroid hormones. Total thyroidectomy always requires thyroid hormone replacement.

When the hyperthyroidism is likely transitory, as with thyroiditis, treatment may target only symptom relief because thyroid function will return to normal when the inflammation subsides. Beta blocker medications (notably propanolol) relieve the symptoms that are the most distressing—palpitations, irritability, and heat insensitivity. Endocrinologists also sometimes prescribe beta blockers in conjunction with antithyroid therapies when these symptoms cause pronounced discomfort, until thyroid function returns to normal.

A life-threatening complication of untreated hyperthyroidism is THYROID STORM, in which there are extensive cardiovascular and NERVOUS SYSTEM responses to the elevated thyroid hormone levels. Often, thyroid storm manifests in a person who is unaware of having hyperthyroidism who develops another health condition that stresses the body. Congestive HEART FAILURE, serious arrhythmias, and cardiovascular SHOCK can develop very rapidly and require emergency medical treatment.

Risk Factors and Preventive Measures

Exposure to radiation and excessive iodine consumption are the primary known risk factors for hyperthyroidism. People who have other AUTOIMMUNE DISORDERS are more likely to develop Graves's disease. The only preventable forms of hyperthyroidism are those which result from overconsumption of thyroid-hormone supplements and medication therapies that result in excessive iodine consumption. Otherwise, there are no known measures for preventing hyperthyroidism.

See also GRAVES'S OPHTHALMOPATHY; HYPOTHYROIDISM.

hypoadrenocorticism See ADDISON'S DISEASE.

hypocalcemia A circumstance of insufficient calcium in the BLOOD circulation. Common causes of hypocalcemia include chronic DIARRHEA, which prevents calcium absorption from dietary sources, and lack of sun exposure, which prevents activation of vitamin D (crucial for calcium absorption). HYPOPARATHYROIDISM is the most common endocrine cause for hypocalcemia, and may result from atrophy, dysfunction, or surgical removal of the PARATHYROID GLANDS. Some people develop resistance to PARATHYROID HORMONE, usually as a consequence of vitamin D deficiency.

Calcium is essential for many functions within the body, notably the conduction of NERVE impulses and MUSCLE contractions. Inadequate calcium in the blood disrupts these functions and may result in ARRHYTHMIA (irregular HEART RATE), HYPOTENSION (low BLOOD PRESSURE), mental confusion and irritability, and muscle spasms (tetany). Severely low levels of calcium in the blood can cause seizures, and prolonged hypocalcemia can result in PAPILLEDEMA (swelling where the OPTIC NERVE exits the RETINA) and permanent damage to the CORNEA.

The diagnostic path includes blood tests to measure the levels of calcium and parathyroid hormone in the blood, a comprehensive NEUROLOGIC EXAMINATION, and an ELECTROCARDIOGRAM (ECG) to assess any irregularities in the functioning of the HEART. Other diagnostic procedures may include X-rays of the bones, ULTRASOUND, COMPUTED TOMOGRAPHY (CT) scan, or MAGNETIC RESONANCE IMAGING (MRI) to visualize the parathyroid glands. Treatment targets any underlying conditions, then focuses on restoring appropriate calcium balance in the body, typically through dietary changes to increase the amount of calcium in the diet, and with calcium and vitamin D supplements. Most people recover fully and without residual consequences with appropriate treatment. Long-term treatment may be necessary, depending on the cause of the hypocalcemia.

See also CHEMOTHERAPY; FANCONI'S SYNDROME; PANCREATITIS; POLYGLANDULAR DEFICIENCY SYNDROME; SEIZURE DISORDERS.

hypoglycemia A circumstance in which the BLOOD GLUCOSE level is too low. A normal blood glucose level is 70 milligrams per deciliter (ml/dL) to 100 mg/dL. The clinical standard for hypoglycemia is a blood glucose level below 50 mg/dL,

though some people may experience symptoms of hypoglycemia with blood glucose levels between 50 mg/dL and 70 mg/dL.

Hypoglycemia most commonly occurs in people who have DIABETES, manifesting as a consequence of taking more INSULIN or antidiabetes medication than is necessary to balance carbohydrate consumption or due to a more intense level of physical activity than usual, which increases the body's need for glucose. Hypoglycemia also can occur in people who do not have diabetes, often as a result of inadequate carbohydrate consumption particularly during intense physical exercise or with extended fasting (going without food). Excessive ALCOHOL consumption, particularly in people who have CIRRHOSIS of ALCOHOLISM or other LIVER disease, may also cause hypoglycemia. An uncommon form of nondiabetes hypoglycemia is reactive hypoglycemia, in which the blood glucose level drops within three to four hours after eating. Researchers do not know what causes reactive hypoglycemia.

Imbalances or dysfunctions of the endocrine system's hormonal cascades may slow the body's efforts to restore adequate blood glucose levels. In health, a low blood glucose level triggers the ISLETS OF LANGERHANS to release GLUCAGON, which directs the liver to convert glycogen (a storage form of glucose) to glucose. Simultaneously, the HYPOTHALAMUS releases CORTICOTROPIN-RELEASING HORMONE (CRH) and GROWTH HORMONE–RELEASING HORMONE (GHRH), which set in motion hormonal cascades to alter METABOLISM in ways that slow the body's use of glucose.

The symptoms of hypoglycemia include

- feeling weak and shaky
- hunger
- excessive sweating
- drowsiness and confusion
- acting intoxicated
- dizziness and lightheadedness

People who have diabetes should check their blood glucose levels at the onset of any of these symptoms. Immediate treatment generally resolves the symptoms, and may include drinking a glass of juice or soda (regular, not diet or sugar-free products), eating a spoonful of sugar or honey, or eating a small amount of candy. The doctor may follow up with diagnostic tests to determine the cause of the hypoglycemic episode, such as blood tests to measure glucose levels during symptoms. The body's needs for insulin and glucose vary with physical activity, so people who have diabetes may need to adjust their medication doses if they increase their exercise levels and experience repeated episodes of hypoglycemia. Eating small meals frequently (every three hours) maintains a more consistent level of glucose in the blood circulation and is the therapeutic approach doctors recommend for people who have reactive hypoglycemia. Though untreated hypoglycemia can have significant consequences including coma and death, most people respond quickly to treatment and recover without residual effects.

See also INSULIN RESISTANCE.

hypokalemia A circumstance of low potassium in the BLOOD circulation. There are many causes of hypokalemia. Among the most common are persistent DIARRHEA (which depletes electrolytes from the body), long-term therapy with diuretic medications (many of which cause the KIDNEYS to excrete potassium), and kidney disease (which affects the ability of the kidneys to regulate potassium retention). Endocrine causes for hypokalemia include HYPERALDOSTERONISM (oversecretion of ALDOSTERONE) and excessive ADRENOCORTICOTROPIN HORMONE (ACTH) such as occurs with CUSHING'S SYNDROME.

The symptoms of hypokalemia are those of electrolyte imbalance. Mild to moderate symptoms may include MUSCLE weakness or cramping, fatigue, and excessive thirst. Significant hypokalemia can cause confusion, disorientation, and ARRHYTHMIA (irregular heartbeat). Without treatment hypokalemia has the potential to be fatal as it can result in HEART ATTACK or PARALYSIS of the muscles that impairs BREATHING.

The diagnostic path begins with blood tests that measure the levels of potassium, sodium, magnesium, and other electrolytes in the blood. An ELECTROCARDIOGRAM (ECG) identifies any arrhythmias. Treatment is potassium supplementation, which may need to be intravenous when symptoms are severe. Potassium tablets (as the doctor prescribes)

or foods high in potassium such as bananas, oranges, potatoes, and green leafy vegetables can provide adequate potassium supplementation for mild to moderate hypokalemia.

See also FANCONI'S SYNDROME; HYPERKALEMIA; MEDICATIONS TO TREAT CARDIOVASCULAR DISEASE; RENAL FAILURE.

hyponatremia A circumstance of insufficient sodium in the BLOOD circulation. Hyponatremia is a symptom of numerous underlying health conditions rather than itself a disorder. The most common cause of hyponatremia is DEHYDRATION, typically as a consequence of extended VOMITING and DIARRHEA or of diuretic therapy (medications taken to reduce the volume of fluid in the body, many of which work by causing the KIDNEYS to increase the amount of sodium they pass from the body in the URINE). Among the endocrine conditions that cause hyponatremia are HYPOTHYROIDISM, ADRENAL INSUFFICIENCY, ADDISON'S DISEASE, and hypoaldosteronism. Nonendocrine systemic disorders that can cause hyponatremia include NEPHROTIC SYNDROME, RENAL FAILURE, CIRRHOSIS, LIVER FAILURE, and congestive HEART FAILURE.

Mild hyponatremia may show no symptoms, with the doctor making the detection during blood tests done for various reasons to measure electrolyte levels. Moderate to severe hyponatremia has primarily neurologic symptoms, as the imbalance between sodium and water in the BRAIN affects communication among neurons (NERVE cells). Symptoms include confusion, cognitive dysfunction, and changes in mood or personality. The diagnostic path typically includes blood tests to measure the amounts of sodium and other electrolytes in the blood, urinalysis to measure the proportions of excreted electrolytes to water, and appropriate tests and procedures to evaluate any suspected endocrine or other health conditions that could be responsible for the hyponatremia.

Hyponatremia requires prompt medical treatment to restore the sodium balance in the blood circulation. Often, identifying and targeting the underlying cause (such as reducing the DOSE of a diuretic medication or hormone supplementation therapy to restore hormonal balance) brings about homeostasis. Untreated hyponatremia can lead to cerebral edema (swelling in the brain), loss of consciousness, and death. When the cause is endocrine dysfunction, such as hypothyroidism or Addison's disease, lifelong HORMONE THERAPY is typically necessary. Many people fully recover from hyponatremia though may need ongoing medical treatment for the underlying health condition.

See also ALCOHOLISM; COGNITIVE FUNCTION AND DYSFUNCTION; HYPERNATREMIA; MALNUTRITION; MEDICATIONS TO TREAT CARDIOVASCULAR DISEASE.

hypoparathyroidism A rare condition in which the amount of PARATHYROID HORMONE in the BLOOD circulation is insufficient, as a consequence of either dysfunction or absence of the PARATHYROID GLANDS. Thyroidectomy (surgical removal of the THYROID GLAND, such as to treat THYROID CANCER) is the most common reason for absence of the parathyroid glands, as the four parathyroid glands rest on the back surface of the thyroid gland. Occasionally the parathyroid glands are the target of an autoimmune attack that destroys their ability to function. Rarely, the parathyroid glands are absent from birth, a congenital anomaly that requires lifelong calcium and vitamin D supplement therapy to maintain adequate blood calcium levels as well as BONE STRENGTH and density.

Hypoparathyroidism results in inadequate calcium (HYPOCALCEMIA) and excessive phosphorus (hyperphosphatemia) in the blood. The symptoms of hypoparathyroidism are those of hypocalcemia and may include

- tingling of the toes, fingers, and lips
- MUSCLE cramps
- rarely, seizures

The diagnostic path includes blood tests to measure the levels of calcium, phosphate, and parathyroid hormone in the blood circulation. Treatment for confirmed hypoparathyroidism is supplementation with calcium and vitamin D. When the parathyroid glands are missing or destroyed, lifelong treatment is necessary.

See also HYPERCALCEMIA; HYPERPARATHYROIDISM; MINERALS AND HEALTH; OSTEOPOROSIS; VITAMINS AND HEALTH.

hypopituitarism A condition in which the PITUITARY GLAND secretes an insufficient amount of one

or more of the hormones it produces. There are numerous causes for hypopituitarism, some of which are transient and others that require lifelong HORMONE THERAPY to supplement hormone deficiencies. Tumors, INFECTION, trauma, and AUTOIMMUNE DISORDERS are the most common causes of pituitary damage resulting in hypopituitarism. AMYLOIDOSIS and SARCOIDOSIS may also cause hypopituitarism. Occasionally the deficiencies result from damage to the HYPOTHALAMUS, which regulates pituitary function, or to the communication between the hypothalamus and the pituitary gland. Deficiencies may involve any of the hormones the anterior lobe of the pituitary gland synthesizes.

The diagnostic path includes BLOOD tests to measure HORMONE levels. The endocrinologist may choose to conduct diagnostic imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) to evaluate the structural integrity of the involved endocrine glands. Treatment consists of appropriate hormone therapy, usually lifelong, to supplement deficient hormones.

See also HYPERPROLACTINEMIA; POLYGLANDULAR DEFICIENCY SYNDROME.

hypothalamus A structure of the midbrain that has both neurologic and endocrine functions, serving as a bridge between the neurologic system and the endocrine system. A construction of primarily NERVE cells, the hypothalamus receives and processes myriad signals from the BRAIN and central NERVOUS SYSTEM about vital functions such as BREATHING, HEART RATE, BLOOD PRESSURE, body temperature (thermoregulation), and fluid balance. In response to these neurologic signals specific centers in the hypothalamus synthesize (produce) numerous hormones that direct the PITUITARY GLAND to secrete or stop secreting the hormones it synthesizes or stores.

A dedicated network of BLOOD vessels connects the hypothalamus and the pituitary gland, which lies beneath the hypothalamus, allowing hypothalamic hormones to travel through the blood directly to the pituitary gland and fostering intimate and continuous communication between the two structures. In turn, the hormones the pituitary gland produces enter the general circulation to direct the functions of other endocrine glands. Through this cascading hormonal regulation the hypothalamus controls, in integration with neurologic processes, most core functions essential for survival.

Hypothalamic Hormones

The hormones the hypothalamus produces are peptides (amino acid structures) that target specific cell clusters within the pituitary gland's two lobes, acting either to stimulate or inhibit pituitary gland activity. The hypothalamic hormones are

PITUITARY HORMONE DEFICIENCIES

Deficient Hormone	Consequences
deficient ADRENOCORTICOTROPIN HORMONE (ACTH)	ADRENAL INSUFFICIENCY: HYPOTENSION, HYPOGLYCEMIA, fatigue
deficient GROWTH HORMONE (GH)	children: stunted growth adults: slowed METABOLISM
deficient LUTEINIZING HORMONE (LH) and FOLLICLE-STIMULATING HORMONE (FSH)	women: cessation of OVULATION and MENSTRUAL CYCLES, INFERTILITY, masculinization men: HYPOGONADISM, infertility, ERECTILE DYSFUNCTION, feminization
deficient THYROID-STIMULATING HORMONE (TSH)	HYPOTHYROIDISM: weight gain, confusion, intolerance to cold, chronic CONSTIPATION
deficient PROLACTIN	BREASTFEEDING women: inability to produce milk

- ANTIDIURETIC HORMONE (ADH), which the pituitary gland stores and releases to regulate the amount of water the KIDNEYS retain in the blood as one of the body's mechanisms for controlling blood pressure
- CORTICOTROPIN-RELEASING HORMONE (CRH), which stimulates the pituitary gland to release ADRENOCORTICOTROPIN HORMONE (ACTH) as the first level in the body's STRESS RESPONSE HORMONAL CASCADE
- DOPAMINE, which inhibits pituitary gland production of FOLLICLE-STIMULATING HORMONE (FSH), LEUTEINIZING HORMONE (LH), THYROID-STIMULATING HORMONE (TSH), and PROLACTIN
- GONADOTROPIN-RELEASING HORMONE (GNRH), which stimulates the pituitary gland to synthesize and release LH and FSH, hormones that are fundamental to reproduction
- GROWTH HORMONE–RELEASING HORMONE (GHRH), which stimulates the pituitary gland to synthesize and release GROWTH HORMONE (GH)
- OXYTOCIN, which the pituitary gland subsequently stores and releases when needed to stimulate contractions of the UTERUS during CHILDBIRTH and to influence sexual arousal in both men and women
- THYROTROPIN-RELEASING HORMONE (TRH), which stimulates the pituitary gland to synthesize and release TSH, initiating hormonal regulation of vital functions such as thermal regulation and cellular METABOLISM, and to produce prolactin, which stimulates milk production during BREASTFEEDING

Structure of the Hypothalamus

Despite the vital and extensive nature of its functions, the hypothalamus is physically a small structure not quite the size and shape of an almond. Within the hypothalamus are a number of functionally distinct substructures, called nuclei, each having unique and specific roles that require intimate integration with one another. The major nuclei that have endocrine functions are the

- supraoptic nucleus, which synthesizes and releases ADH
- paraventricular nucleus, which synthesizes and releases oxytocin, CRH, and TRH
- arcuate nucleus, which synthesizes and releases GHRH
- suprachiasmatic nucleus (SCN), which influences the circadian cycle and various body rhythms through the cyclic release of certain hormones
- ventromedial nucleus, which regulates APPETITE

Disorders and dysfunctions of the hypothalamus are extremely rare, and when they do occur tumors are the most likely cause. Disorders and dysfunctions of other endocrine glands can affect the ways those glands respond to hypothalamic hormones. Long-term, chronic ALCOHOL abuse destroys hypothalamic cells, affecting the endocrine and neurologic functions of the hypothalamus.

HYPOTHALAMIC HORMONES

ANTIDIURETIC HORMONE (ADH)	CORTICOTROPIN-RELEASING HORMONE (CRH)
DOPAMINE	GROWTH HORMONE–RELEASING HORMONE (GHRH)
GONADOTROPIN-RELEASING HORMONE (GNRH)	SOMATOSTATIN
OXYTOCIN	
THYROTROPIN-RELEASING HORMONE (TRH)	

For further discussion of the hypothalamus within the context of the endocrine system's structure and function please see the overview section "The Endocrine System." For further discussion of the hypothalamus within the context of neurologic structures and functions please see the overview section "The Neurologic System."

See also ADRENAL GLANDS; OBESITY; PINEAL GLAND; THYMUS; THYROID GLAND.

hypothyroidism A condition in which the THYROID GLAND secretes an insufficient amount of thyroid hormones. It is the most common disorder of thyroid function, affecting about 7 million Americans. Women are eight times more likely than men to have hypothyroidism. Risk for hypothyroidism increases among men and women with advancing age. Health experts estimate 80 percent of people over age 70 have hypothyroidism, though the rate of diagnosis is not this high.

The thyroid hormones, primarily THYROXINE (T_4) and TRIIODOTHYRONINE (T_3), regulate METABOLISM in every cell. Deficiencies of these hormones cause numerous symptoms that reflect slowed metabolism. The consequences can be particularly significant when hypothyroidism occurs in children, interfering with physical growth and intellectual development. Congenital hypothyroidism (formerly called cretinism) can cause permanent impairments. Fortunately congenital hypothyroidism is rare in the United States because newborn and well-child health-care screenings test for hypothyroidism.

The follicular cells of the thyroid gland synthesize (manufactures) thyroid hormones from the amino acid tyrosine and the mineral iodine, both of which it acquires from dietary sources. A shortage of either in the diet, though very uncommon in the United States, can impair thyroid HORMONE synthesis. The hypothalamus initiates the hormonal cascade that results in thyroid hormone production, secreting THYROID-RELEASING HORMONE (TRH) when T_3 and T_4 levels in the BLOOD circulation drop. TRH stimulates the anterior lobe of the PITUITARY GLAND to produce THYROID-STIMULATING HORMONE (TSH), which in turn stimulates the thyroid gland's follicular cells. Rising T_3 and T_4 levels in the blood then reverse the hormonal cascade.

Sometimes the cause of hypothyroidism is clear. Hypothyroidism is certain in anyone who has had a total thyroidectomy (removal of the thyroid gland, such as to treat THYROID CANCER or GRAVES'S DISEASE) and likely in a person who has had a partial thyroidectomy. Treatment for HYPERTHYROIDISM (overactive thyroid gland) often results in eventual hypothyroidism as follicular cells within the thyroid gland continue to die after treatment ends. The most common identifiable cause is THYROIDITIS, an INFLAMMATION of the thyroid gland that destroys follicular cells and that may be an autoimmune process. Most often, however, hypothyroidism is idiopathic—the cause remains unknown.

Symptoms and Diagnostic Path

The symptoms of hypothyroid appear gradually and are often nonspecific. They typically include

- chronic tiredness
- weight gain or inability to lose weight
- DEPRESSION and irritability
- coarsening HAIR and hair loss
- dry, flaky SKIN
- loss of eyebrow hair
- intolerance to cold or feeling cold regardless of the environmental temperature
- irregular MENSTRUATION and INFERTILITY

Some people also have a GOITER, a painless swelling of the thyroid gland that may be visible when looking in the mirror or that the doctor can feel. The diagnostic path begins with blood tests to measure the levels of thyroid hormones in the blood circulation. A low level of T_3 and T_4 coupled with elevated TSH indicates the thyroid gland is not responding to the pituitary gland's hormonal signals and provides a conclusive diagnosis of hypothyroidism. Some people have borderline blood test results though have hypothyroidism nonetheless. When blood thyroid levels are marginal, the doctor may recommend a trial of treatment to see if symptoms improve.

Treatment Options and Outlook

Treatment is HORMONE THERAPY with thyroid hormone supplement to deliver adequate levels of thyroid hormones. The most common form of thyroid hormone supplement is a synthetic pharmaceutical preparation of T_4 (levothyroxine). This provides adequate thyroid hormones for most people because the cells in the body convert T_4 to T_3 when it binds with them. There are several levothyroxine products available. Endocrinologists recommend staying with the same product consistently, as the formulations of each product are somewhat different. Some doctors also prescribe T_3 hormone supplement, which is faster-acting, in combination with a T_4 hormone supplement, as an approach that attempts to more precisely replicate the body's thyroid hormone synthesis. The doctor also may prescribe a short course of T_3 to rapidly bring thyroid hormone levels up when hypothyroidism is severe, then taper off and resume T_4 supplement.

Most people experience some improvement of symptoms within two weeks of starting hormone therapy. However, it may take six months to a

year to establish the most effective DOSE, during which time the doctor will routinely measure the thyroid hormones in the blood and compare them with changes in symptoms and the overall clinical picture. Most people experience a vast improvement within a month of beginning hormone therapy. Treatment is lifelong. Undertreated or untreated hypothyroidism results in progressively worsening symptoms that can culminate in permanent damage to the cardiovascular and neurologic systems. People over age 60 typically need lower doses of thyroid hormone supplement for therapeutic results.

Risk Factors and Preventive Measures

The key risk factors for hypothyroidism are being female and age over 60; being both female and over 60 in combination increases the risk because of estrogen's role in hormone balance. People who have received RADIATION THERAPY to the lower face, neck, or upper chest have increased risk for hypothyroidism. Lithium, a medication taken for BIPOLAR DISORDER, may disrupt thyroid function and cause hypothyroidism. There are no measures to prevent hypothyroidism.

See also AUTOIMMUNE DISORDERS; CALCITONIN; ESTROGENS; EUTHYROID SICK SYNDROME.

I

inhibin A peptide HORMONE the corpus luteum in ovulating women and the TESTES in men produce that stops the HYPOTHALAMUS from secreting GONADOTROPIN-RELEASING HORMONE (GNRH). This in turn stops the PITUITARY GLAND from secreting LUTEINIZING HORMONE (LH) and FOLLICLE-STIMULATING HORMONE (FSH), halting the subsequent cascade of sex hormones from the gonads (sex glands). Researchers do not yet fully understand the full range of inhibin's actions, though it influences spermatogenesis (SPERM production) in men and likely has additional roles in OVULATION. Some research suggests inhibin may serve as a marker to indicate an emerging OVARIAN CANCER or PROSTATE CANCER. With the cessation of ovulation a woman's OVARIES no longer produces inhibin, so inhibin is no longer present in the BLOOD circulation of postmenopausal women. Inhibin production returns, however, when there is an ovarian cancer. Conversely, inhibin levels appear to drop in men who have BENIGN PROSTATIC HYPERTROPHY (BPH) or prostate cancer.

For further discussion of inhibin within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also FERTILITY; PREGNANCY; TESTOSTERONE.

insulin A peptide HORMONE the ISLETS OF LANGERHANS in the PANCREAS produce that is essential for the body to use GLUCOSE. Insulin has numerous roles in the body, the best known of which is the regulation of glucose levels in the BLOOD (carbohydrate METABOLISM). Glucose, a basic sugar molecule, is a primary energy source for many cellular activities. When insulin binds with insulin receptors on a cell membrane, the cell allows glucose molecules to enter. Insulin facilitates lipid (fatty acid) metabolism, stimulates the LIVER to convert excess glucose into the intermediary storage form glycogen, and facilitates the conversion of amino acids to proteins for building new MUSCLE tissue. Insulin also participates in cell activities related to growth.

The beta cells of the islets of Langerhans synthesize insulin in response to declining glucose levels in the blood. The release of insulin allows cells to accept glucose and at the same time directs the liver to begin converting glucose to glycogen for storage. Insulin also slows the conversion of fatty acids to glycogen, a process intended to conserve the long-term energy resources of the body (fat). These functions become less efficient in INSULIN RESISTANCE, a condition in which the cells are slow to bind with insulin. Disturbances of insulin sensitivity can allow lipids to accumulate in the blood circulation, contributing to cardiovascular diseases such as ATHEROSCLEROSIS and CORONARY ARTERY DISEASE (CAD). Insufficient insulin production results in DIABETES, for which insulin is available as an injectable pharmaceutical as HORMONE THERAPY. Most forms of insulin available today are recombinant constructions engineered in the laboratory to precisely match the molecular structure and actions of endogenous human insulin.

For further discussion of insulin within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also CORTISOL; DIGESTIVE ENZYMES; DIGESTIVE HORMONES.

insulin resistance A condition, also called metabolic syndrome X or syndrome X, in which the cells

throughout the body do not respond to the normal amounts of INSULIN the ISLETS OF LANGERHANS produce. The short-term result is an excessive level of GLUCOSE in the BLOOD circulation and the need for the islet cells to produce increasing amounts of insulin. Over the long term a constellation of health conditions appears that may include OBESITY, HYPERLIPIDEMIA, type 2 DIABETES, CORONARY ARTERY DISEASE (CAD), HYPERTENSION (high BLOOD PRESSURE), and POLYCYSTIC OVARY SYNDROME (PCOS). Doctors diagnose insulin resistance when a person has two or more of these health conditions.

Treatment must first target the health condition, and may include medications to reduce blood pressure and blood cholesterol levels. CAD may have significant implications for cardiovascular function, and is a major risk for HEART ATTACK as well as HEART FAILURE, CARDIOMYOPATHY, and ISCHEMIC HEART DISEASE (IHD). Weight loss is crucial as OBESITY is a key factor in these conditions as well as in insulin resistance. Lifestyle measures such as nutritious EATING HABITS and daily physical exercise help improve metabolic efficiency and sensitivity to insulin and also aid weight-management efforts. These lifestyle measures practiced consistently over time are often able to reverse some of the health consequences as insulin resistance diminishes, in particular facilitating improvements in obesity, hypertension, and type 2 diabetes.

See also BODY MASS INDEX (BMI); DIABETES AND CARDIOVASCULAR DISEASE; DIET AND HEALTH; EXERCISE AND HEALTH; HEALTH RISK FACTORS; INFERTILITY; LIFESTYLE AND HEALTH; WEIGHT LOSS AND WEIGHT MANAGEMENT.

islets of Langerhans Clusters of endocrine cells distributed throughout the PANCREAS that produce INSULIN, GLUCAGON, and SOMATOSTATIN. There are about a million islet clusters, each containing several hundred islet cells. Each islet contains all three types of islet cells: alpha islet cells, beta islet cells, and delta islet cells.

In the center of each islet are the beta cells, which secrete insulin. Insulin's primary role in the body is the regulation of carbohydrate METABOLISM. Arranged in somewhat of a circle around the core of the islet beta cells are the alpha cells, which secrete glucagon, and the delta cells, which secrete somatostatin. Glucagon stimulates the LIVER to convert glycogen to GLUCOSE, making more energy available to cells. Somatostatin suppresses the release of GROWTH HORMONE (GH). It also slows the release of insulin and glucagon, as well as the gastrointestinal system's secretion of DIGESTIVE HORMONES.

The most significant disorder affecting the islets of Langerhans is DIABETES. Type 1 diabetes, an autoimmune disorder, destroys the islet cells. Though other cells in the body synthesize the hormones of alpha and delta islet cells—glucagon and somatostatin, respectively—no other cells in the body synthesize insulin. People who have type 1 diabetes must take insulin therapy (injections of pharmaceutical insulin) to meet the needs of their bodies for this crucial hormone. PANCREATITIS, an INFLAMMATION of the pancreas, also can interfere with islet cell functions. Though HORMONE production usually returns when the inflammation subsides, sometimes extensive scarring destroys islet cells, resulting in type 2 (insulin-deficient) diabetes.

For further discussion of the islets of Langerhans within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also AUTOIMMUNE DISORDERS; DIGESTIVE ENZYMES; POLYGLANDULAR DEFICIENCY SYNDROME.

islet cell transplantation An experimental treatment for DIABETES in which the surgeon injects clusters of healthy ISLET OF LANGERHANS cells from a donor (most often a cadaver donor) into the PANCREAS of a person who has type 1 diabetes. Islet cells produce the HORMONE INSULIN as well as two other hormones, GLUCAGON and SOMATOSTATIN. A healthy pancreas contains about a million clusters of islet cells distributed widely throughout the pancreatic tissue. Type 1 diabetes occurs when an autoimmune response destroys the islet cells, eliminating the body's ability to produce insulin. Islet cell transplantation replaces the destroyed cells with healthy islet cells. It may take weeks to months for the transplanted islet cells to establish networks of BLOOD vessels that connect them to the recipient and provide the outlet for the

hormones they produce. At present islet cell transplantation requires subsequent lifelong IMMUNOSUPPRESSIVE THERAPY to prevent rejection of the transplanted cells. Though still experimental, islet cell transplantation holds considerable promise as a long-term or permanent treatment for type 1 diabetes.

See also ORGAN TRANSPLANTATION.

L–O

luteinizing hormone (LH) A peptide HORMONE the anterior lobe of the PITUITARY GLAND produces that stimulates hormonal activity related to reproduction. In men, LH stimulates the development and function of interstitial cells in the TESTES that synthesize and release TESTOSTERONE, the primary male sex hormone. In menstruating women, a mid–menstrual cycle surge of LH stimulates OVULATION (the maturation and release of an ovum, or egg). In a woman who is pregnant, the PLACENTA also produces LH. The HYPOTHALAMUS's release of GONADOTROPIN-RELEASING HORMONE (GNRH) stimulates the pituitary gland to secrete LH. Rising levels of the sex hormones (ESTROGENS, PROGESTERONE, and TESTOSTERONE) and INHIBIN cause the hypothalamus to stop releasing GnHR, ending the pituitary gland's secretion of LH.

For further discussion of LH within the context of the endocrine system's structure and function, please see the overview section "The Endocrine System."

See also ADRENOCORTICOTROPIN HORMONE (ACTH); ANABOLIC STEROIDS AND STEROID PRECURSORS; ANTIDIURETIC HORMONE (AH); CHORIONIC GONADOTROPIN; FOLLICLE-STIMULATING HORMONE (FSH); GROWTH HORMONE (GH); MENSTRUATION; OXYTOCIN; PROLACTIN; RELAXIN; THYROID-STIMULATING HORMONE (TSH).

melatonin A peptide HORMONE that the PINEAL GLAND secretes, the primary function of which is to regulate the body's circadian cycle (pattern of sleep and wake). The pineal gland synthesizes melatonin from the amino acid tryptophan. The OPTIC NERVE appears to convey NERVE messages of outside light and dark from the RETINA to a section of the HYPOTHALAMUS called the suprachiasmatic nucleus (SCN). The SCN sends nerve signals to the pineal gland, which suspends melatonin synthesis. Darkness causes the nerve messages from the optic nerve to stop, which in turn ends the signals from the SCN. When receiving signals from the SCN, the pineal gland stops melatonin production. When the signals from the SCN end, the pineal gland resumes melatonin production. Researchers believe melatonin causes sleepiness by slowing cell METABOLISM. Other endocrine processes, such as the adrenocorticosteroid hormonal cascade that regulates CORTISOL levels, also slow in conjunction with the circadian cycle, though researchers are uncertain about how these processes may be interrelated.

For further discussion of melatonin within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also MELATONIN SUPPLEMENT; STRESS RESPONSE HORMONAL CASCADE.

multiple endocrine neoplasia (MEN) An inherited genetic disorder in which numerous tumors form in various endocrine glands. Several GENE mutations are responsible for the errant growth of glandular tissue, which may take the form of tumors or hypertrophy (overgrowth). Oversecretion of the affected gland's hormones then occurs. The three forms of MEN are

- MEN-1, in which adenomas develop in the PITUITARY GLAND, PARATHYROID GLANDS, and ISLETS OF LANGERHANS in the PANCREAS
- MEN-2a, characterized by HYPERPARATHYROIDISM, PHEOCHROMOCYTOMA, and medullary THYROID CANCER

- MEN-2b, characterized by pheochromocytoma, neuromas in the mucous membranes of the MOUTH and eyes, and medullary thyroid cancer

The gene MUTATION determines the type of MEN. Not all manifestations occur within each type. Because researchers only identified the gene mutations responsible for MEN in the late 1990s, people who have this autosomal dominant disorder may not realize it runs in their families. Symptoms depend on the endocrine glands affected and the extent of the tumors or hypertrophy. The endocrinologist may suspect MEN based on the patterns of symptoms though GENETIC TESTING is necessary to confirm the mutation. Treatment is surgery to remove the tumors whenever possible, with follow-up CHEMOTHERAPY or RADIATION THERAPY. Doctors typically recommend prophylactic thyroidectomy for people who carry the gene mutation for MEN-2a or MEN-2b, to head off thyroid cancer as medullary thyroid cancer can be aggressive and is nearly certain to develop. People who have MEN require ongoing medical observation and treatment for hormonal deficiencies that result from therapies for the MEN.

See also GENETIC DISORDERS; INHERITANCE PATTERNS; POLYGLANDULAR DEFICIENCY SYNDROME; ZOLLINGER-ELLISON SYNDROME.

norepinephrine A peptide substance the adrenal medulla of the ADRENAL GLANDS and the synaptic vesicles in the NERVE endings produce. Norepinephrine functions in the body as a HORMONE, when synthesized by the adrenal medulla, and as a NEUROTRANSMITTER when synthesized by BRAIN structures or nerve cells. Norepinephrine is also a DOPAMINE precursor (substance the body uses as the basis for dopamine synthesis). Among the hormones activated in the STRESS RESPONSE HORMONAL CASCADE, norepinephrine acts on the BLOOD vessels to cause them to constrict (vasoconstriction), helping to raise BLOOD PRESSURE and centralize blood flow. It also facilitates GLYCOGEN conversion to GLUCOSE and lipid METABOLISM, activities related to glucose balance. The HYPOTHALAMUS directs the adrenal medulla, via the neurotransmitter acetylcholine, to release norepinephrine. As a neurotransmitter in the brain, norepinephrine appears to play a role in mood and emotion. Norepinephrine is also available as a pharmaceutical DRUG, used primarily to raise blood pressure in severe HYPOTENSION (low blood pressure) resulting from neurologic causes.

For further discussion of norepinephrine within the context of the endocrine system's structure and function please see the overview section, "The Endocrine System."

See also EPINEPHRINE; SHOCK.

oxytocin A peptide HORMONE the HYPOTHALAMUS synthesizes (produces) and the posterior lobe of the PITUITARY GLAND stores and releases. Oxytocin influences sexual arousal in men and women. In women, oxytocin stimulates uterine contractions during CHILDBIRTH and the milk letdown REFLEX during BREASTFEEDING. Oxytocin may have additional functions in men, including a role in SPERM production. Obstetricians may administer oxytocin as a pharmaceutical DRUG to stimulate uterine contractions to induce labor or to strengthen contractions during childbirth.

For further discussion of oxytocin within the context of the endocrine system's structure and function, please see the overview section "The Endocrine System."

See also ADRENOCORTICOTROPIN HORMONE (ACTH); ANTIDIURETIC HORMONE (ADH); FOLLICLE-STIMULATING HORMONE (FSH); GROWTH HORMONE (GH); LUTEINIZING HORMONE (LH); PROLACTIN; THYROID-STIMULATING HORMONE (TSH).

P

parathyroid glands Four small endocrine glands, somewhat orange or yellowish in color, normally located in two pairs on the back of each lobe of the THYROID GLAND. Sometimes one or more of the parathyroid glands is embedded in the tissue of the thyroid gland, which does not appear to affect either gland's ability to function. Though the thyroid gland and the parathyroid glands are physically connected, they are separate structures with distinct functions. The thyroid gland remains undisturbed if it is necessary to remove any of the parathyroid glands. However, the parathyroid glands have no structure to support them independently and cannot remain if it is necessary to remove the thyroid gland. Absence of all four parathyroid glands requires lifelong HORMONE THERAPY with PARATHYROID HORMONE supplement.

Occasionally the top two parathyroid glands are located in the neck well above the thyroid gland or the bottom two well below in the chest, a consequence of incomplete migration when the structures separate during fetal development. In the EMBRYO the top two parathyroid glands arise from the same tissue as the thyroid gland and the bottom two from the same tissue as the THYMUS. Because each parathyroid gland has its own substantial blood supply, its location is not critical for proper function.

For the significance of their function the parathyroid glands are amazingly small, with each gland ranging in size from about that of a grain of rice to that of a small pea. The parathyroid glands produce parathyroid HORMONE (also called parathormone), which is essential for proper calcium balance in the body. Calcium is essential for BONE DENSITY and STRENGTH as well as the conduction of NERVE impulses and MUSCLE contractions. The parathyroid glands continuously monitor the level of calcium in the BLOOD circulation as blood flows through them. Parathyroid hormone increases the amount of calcium in the blood circulation and exists in dynamic balance with CALCITONIN, a hormone the thyroid gland produces that increases the amount of calcium the bones absorb from the blood circulation.

Disorders of the parathyroid glands include HYPERPARATHYROIDISM (oversecretion of parathyroid hormone) and HYPOPARATHYROIDISM (undersecretion of parathyroid hormone). Either condition may result from hypertrophy (enlargement) of a parathyroid gland or from the development of an ADENOMA, a noncancerous tumor. Cancer of the parathyroid glands is very rare. Also rarely a person is born without parathyroid glands, a CONGENITAL ANOMALY with significant health consequences.

For further discussion of the parathyroid glands within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also OSTEOPOROSIS; PAGET'S DISEASE OF THE BONE.

parathyroid hormone A peptide HORMONE, also called parathormone, the PARATHYROID GLANDS secrete that regulates the level of calcium in the BLOOD circulation. Parathyroid hormone causes the bones to release calcium into the blood to meet the body's needs. Calcium is essential for the conduction of impulses among nerves and for MUSCLE contraction. Calcium helps maintain normal HEART RATE and rhythm.

Parathyroid hormone functions in dynamic balance with CALCITONIN, a hormone the THYROID GLAND produces that lowers blood calcium levels by stimulating the bones to absorb more calcium. Parathyroid hormone also enhances the activation

of vitamin D, increases the amounts of calcium the KIDNEYS retain and the intestines absorb, and increases the amount of phosphorus the kidneys excrete in the URINE.

Long-term excessive parathyroid hormone secretion (HYPERPARATHYROIDISM) leads to OSTEOPOROSIS, a condition in which there is substantial loss of BONE DENSITY and STRENGTH. Inadequate parathyroid hormone secretion (HYPOPARATHYROIDISM) results in disruptions of NERVE impulses and can cause muscle rigidity or cramping.

See also BONE; HYPERCALCEMIA; HYPOCALCEMIA.

pheochromocytoma A neuroendocrine tumor that secretes DOPAMINE, EPINEPHRINE, and NOREPINEPHRINE (collectively called catecholamines). About 90 percent of pheochromocytomas are noncancerous. Most pheochromocytomas develop in the adrenal medulla, the inner structure of the ADRENAL GLANDS, though can occur in other tissues throughout the body. About 10 percent of pheochromocytomas occur in conjunction with MULTIPLE ENDOCRINE NEOPLASIA (MEN), an inherited genetic disorder in which tumors form in numerous endocrine structures. The primary consequence of pheochromocytoma is HYPERTENSION (high BLOOD PRESSURE), which results from the excessive secretion of catecholamines. RETINOPATHY (damage to the RETINA and OPTIC NERVE in the EYE) and CARDIOMYOPATHY (enlarged and weakened HEART) may result with long-term untreated pheochromocytoma.

Symptoms and Diagnostic Path

Symptoms, aside from hypertension, often resemble those of other endocrine disorders, notably HYPERTHYROIDISM. Symptoms of pheochromocytoma may include

- rapid, irregular PULSE (TACHYCARDIA)
- rapid breathing (tachypnea) or shortness of breath (DYSPNEA)
- PALPITATIONS and ARRHYTHMIA (irregularities in the heartbeat)
- orthostatic HYPOTENSION (a sudden drop in blood pressure when rising from a seated or prone position)
- HEADACHE, often severe and persistent
- bouts of NAUSEA and VOMITING
- anxiety and inability to concentrate

The diagnostic path includes blood tests to assess blood electrolyte levels and to rule out more common causes of the symptoms such as hyperthyroidism, ELECTROCARDIOGRAM (ECG) to assess the HEART's electrical activity, and URINE tests to measure the amounts of catecholamine metabolites excreted in the urine. The endocrinologist may also conduct diagnostic imaging procedures such as MAGNETIC RESONANCE IMAGING (MRI) to detect the presence and location of the pheochromocytoma.

Treatment Options and Outlook

Surgery to remove the pheochromocytoma is nearly always the treatment of choice, as nonsurgical therapies are not very successful in controlling the tumor's activities. Adrenergic blocker medications (alpha blockers and beta blockers) can relieve many of the symptoms. Hypotension (low blood pressure) following the tumor's removal is common, with blood pressure gradually returning to normal as the body's production of catecholamines returns to normal. CHEMOTHERAPY follows surgery when the tumor is cancerous. Most people recover fully and without complications after surgery for noncancerous pheochromocytoma, though tumors may recur in people who have MEN. Recovery from malignant pheochromocytoma depends on the extent of METASTASIS.

Risk Factors and Preventive Measures

People who have MEN have significant risk for pheochromocytoma and should be alert to its symptoms. There are no measures to prevent these tumors from developing.

pineal gland A small ENDOCRINE GLAND, about a quarter of an inch long, located within the BRAIN very near the HYPOTHALAMUS. The pineal gland is somewhat cone shaped and reddish in color. It produces MELATONIN, a peptide HORMONE that regulates the body's circadian (sleep–wake) cycle.

Researchers believe the pineal gland produces other hormones and has functions related to immune activity, though what they are remains unknown.

In the philosophies and traditions of Eastern medicine, the pineal gland is the metaphysical "third eye." Modern researchers have discovered that the pineal gland does in fact receive NERVE signals via the OPTIC NERVE and a structure of the hypothalamus called the suprachiasmatic nucleus (SCN). These signals influence the pineal gland's synthesis of melatonin, which slows when the external environment is light and accelerates with the external environment is dark.

Dysfunctions of the pineal gland are, as far as endocrinologists know, very rare. Some research has established a link between low melatonin levels and breast cancer, though further research continues to examine this connection. Researchers are also exploring possible connections between pineal function and insomnia (difficulty sleeping).

For further discussion of the pineal gland within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also SLEEP DISORDERS.

pituitary gland An ENDOCRINE GLAND located within the BRAIN that secretes the hormones that regulate the activity of the other endocrine structures, except the HYPOTHALAMUS, in the body. A distinctively glandular structure, gray in color and somewhat egg shaped, the pituitary gland nestles into a hollow of BONE at the base of the skull directly beneath the hypothalamus. This physical proximity makes possible a dedicated network of BLOOD vessels that carry hormones from the hypothalamus directly to the pituitary gland, allowing a continuous flow of chemical messages.

The pituitary gland has two lobes, the anterior lobe and the posterior lobe. The posterior lobe stores hormones it receives from the hypothalamus and releases them when hypothalamic signals it to do so. The anterior lobe produces hormones essential for growth and maturation. The hormones of the pituitary gland are peptide hormones. Disorders of the pituitary gland affect FERTILITY, growth, and METABOLISM.

Anterior Lobe Structure and Hormones

The anterior lobe of the pituitary gland, also called the adenohypophysis, is under the hormonal control of the hypothalamus. The hormones the anterior lobe of the pituitary gland synthesizes include

- ADRENOCORTICOTROPIN HORMONE (ACTH), which signals the ADRENAL GLANDS to release CORTISOL, EPINEPHRINE, and NOREPINEPHRINE
- GROWTH HORMONE (GH), which stimulates growth during childhood by increasing the rate at which cells divide and helps maintain MUSCLE mass in adulthood
- THYROID-STIMULATING HORMONE (TSH), which stimulates the THYROID GLAND to release the primary thyroid hormones THYROXINE (T_4) and TRIIODOTHYRONINE (T_3)
- FOLLICLE-STIMULATING HORMONE (FSH), which initiates egg maturation in the OVARIES and SPERM production in the TESTES
- LUTEINIZING HORMONE (LH), which stimulates egg release in the ovaries and TESTOSTERONE secretion from the testes
- PROLACTIN, which stimulates milk production during BREASTFEEDING

These hormones all initiate hormonal cascades among other endocrine structures. Negative-feedback loops regulate the amounts of hormones the pituitary gland secretes, with secretions slowing or stopping when terminal hormones reach appropriate levels in the blood circulation. The hormones of the anterior pituitary are integral to the body's STRESS RESPONSE HORMONAL CASCADE.

HORMONES OF THE ANTERIOR PITUITARY LOBE

ADRENOCORTICOTROPIN HORMONE (ACTH)	FOLLICLE-STIMULATING HORMONE (FSH)
LUTEINIZING HORMONE (LH)	GROWTH HORMONE (GH)
THYROID-STIMULATING HORMONE (TSH)	PROLACTIN

Posterior Lobe Structure and Hormones

The posterior lobe of the pituitary gland, also called the neurohypophysis, receives the hormones ANTIDIURETIC HORMONE (ADH) and OXYTOCIN from the hypothalamus and then stores them. The

posterior lobe does not itself synthesize any hormones. The hypothalamus regulates the posterior lobe primarily through neurologic signals (notably via the NEUROTRANSMITTER acetylcholine) that stimulate it to release its hormones into the blood circulation.

HORMONES OF THE POSTERIOR PITUITARY LOBE	
ANTIDIURETIC HORMONE (ADH)	OXYTOCIN

For further discussion of the pituitary gland within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

polyglandular deficiency syndrome An autoimmune disorder in which the IMMUNE SYSTEM produces antibodies that attack various endocrine glands and structures, resulting in deficiencies of the hormones the structures produce. The endocrine glands most commonly affected are the ADRENAL GLANDS, the THYROID GLAND, the PARATHYROID GLANDS, and the PITUITARY GLAND. When one autoimmune deficiency condition develops in an endocrine structure, others are likely to follow. The three types of polyglandular deficiency syndrome are

- type 1 polyglandular deficiency syndrome, which affects children under the age of 12 and typically affects the parathyroid glands, causing HYPOPARATHYROIDISM, and the adrenal glands, causing ADRENAL INSUFFICIENCY or ADDISON'S DISEASE
- type 2 polyglandular deficiency syndrome, which affects adults over the age of 30 and includes type 1 DIABETES, adrenal insufficiency or Addison's disease, and HYPOTHYROIDISM
- type 3 polyglandular deficiency syndrome, which affects women age 40 to 50 and includes THYROIDITIS, early MENOPAUSE, Addison's disease, and VITILIGO

Symptoms correlate to the endocrine glands affected and the endocrine disorders that result from damage to those glands. As well, symptoms may also affect functions such as FERTILITY, particularly when the thyroid gland is among the involved endocrine glands. Fertility requires a fairly precise endocrine balance throughout the body. The diagnostic path combines clinical evidence, history of symptoms, and laboratory tests that measure various HORMONE levels. All forms of polyglandular deficiency syndrome are chronic and require appropriate, lifelong HORMONE THERAPY to supplement or replace deficient hormones.

See also ANTIBODY; AUTOIMMUNE DISORDERS; ENDOCRINE GLAND; HYPERTHYROIDISM; INSULIN RESISTANCE; MULTIPLE ENDOCRINE NEOPLASIA (MEN).

progesterone A steroid HORMONE the adrenal cortex of the ADRENAL GLANDS, the OVARIES, and the TESTES synthesize from a base of cholesterol. Adipose cells (fat cells) also synthesize small amounts of progesterone. Progesterone is a precursor hormone from which men and women synthesize TESTOSTERONE. The HYPOTHALAMUS initiates the hormonal cascade that results in progesterone synthesis with the release of GONADOTROPIN-RELEASING HORMONE (GNRH), which stimulates the anterior lobe of the PITUITARY GLAND to produce LUTEINIZING HORMONE (LH) and FOLLICLE-STIMULATING HORMONE (FSH). LH and FSH act on the gonads (sex glands), stimulating their hormone productions.

Women have significantly higher levels of progesterone, which vary cyclically with MENSTRUATION, than men. In women the primary role of progesterone is to prepare the UTERUS for PREGNANCY. Progesterone levels spike with OVULATION and remain elevated for about 10 days. If pregnancy occurs, the corpus luteum continues to secrete progesterone to maintain the uterine environment. Progesterone also stimulates growth of the mammary glands in the breasts. If pregnancy does not occur the corpus luteum deteriorates, ceases progesterone production, and MENSTRUATION begins. The primary role of progesterone in men is to testosterone production.

For further discussion of progesterone within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also ANDROGENS; BREAST HEALTH; ESTROGENS.

prolactin A peptide HORMONE the anterior lobe of the PITUITARY GLAND synthesizes and secretes in response to the HYPOTHALAMUS's release of GONADOTROPIN-RELEASING HORMONE (GNRH). THYROID-RELEASING HORMONE (TRH) also stimulates prolactin production. Prolactin is biochemically similar to GROWTH HORMONE (GH). The primary function of prolactin is to stimulate BREAST development and milk production in women who are BREASTFEEDING. Prolactin also appears to play a role in certain immune responses. Other cells throughout the body also synthesize and secrete prolactin, which researchers believe is to enhance prolactin's immune functions. High levels of ESTROGENS in the BLOOD, such as occur near the end of PREGNANCY, increase prolactin secretion. DOPAMINE, a peptide hormone the hypothalamus secretes, signals the pituitary gland to stop secreting prolactin. Pituitary ADENOMA (a noncancerous tumor) can cause excessive prolactin secretion, resulting in galactorrhea (abnormal milk production) in men as well as women.

For further discussion of prolactin within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also ADRENOCORTICOTROPIN HORMONE (ACTH); ANTIDIURETIC HORMONE (ADH); FOLLICLE-STIMULATING HORMONE (FSH); HYPERPROLACTINEMIA; LUTEINIZING HORMONE (LH); OXYTOCIN.

R–S

relaxin A peptide HORMONE with poorly understood roles in reproduction and CHILDBIRTH. Relaxin receptors are widespread throughout the body in both men and women. In women the OVARIES, corpus luteum, and breasts—and the PLACENTA during PREGNANCY—produce relaxin. In men, the PROSTATE GLAND and the seminal vesicles produce relaxin. Relaxin is biochemically similar to INSULIN and has numerous effects on smooth MUSCLE tissue and collagen (connective tissue) in the UTERUS, reproductive tract, cardiovascular system, urinary system, and gastrointestinal system. During pregnancy relaxin facilitates collagen remodeling, the alterations that take place in the collagen structures of the ligaments and tendons that support the enlarging uterus. During CHILDBIRTH relaxin appears to, as the name implies, relax the smooth muscles of the CERVIX and uterus after contractions. In men relaxin may facilitate the transportation of SPERM through the seminal vesicles.

For further discussion of relaxin within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also CHORIONIC GONADOTROPIN; ESTROGENS; OXYTOCIN; PROLACTIN; PROGESTERONE.

renin A peptide HORMONE the KIDNEYS produce that sets in motion the sequence of events to convert angiotensinogen, an inert enzyme the LIVER stores, to angiotensin II, a potent vasoconstrictor (chemical that causes the blood vessels to narrow and stiffen, which raises BLOOD PRESSURE). Angiotensin II also stimulates the adrenal cortex of the ADRENAL GLANDS to release ALDOSTERONE. The kidneys secrete renin whenever they sense a reduction in the fluid volume in the BLOOD that passes through them. Aldosterone causes the kidneys to increase the amount of sodium they withhold from the blood, which in turn draws more water back into the blood circulation. In combination, these actions increase blood volume and blood pressure. Aldosterone's presence in the blood circulation and its actions on the kidneys also suppress renin secretion. The sequence of events is the renin–angiontensin–aldosterone (RAA) system, the body's key mechanism for regulating blood pressure and blood volume.

The RAA balance adjusts nearly continuously, as the blood's pressure and volume fluctuate with body activities down to even the most minute metabolic alterations. The release of renin may surge when a person stands up, for example, and slow when a person lies down, and even when a person transitions from sleep to wake. The RAA system relies on the proper functioning of all three component elements; dysfunction of any results in HYPERTENSION (high blood pressure). Kidney disease, particularly RENAL FAILURE, and HYPERALDOSTERONISM are the most important health conditions that influence the RAA system because both interfere with the release of renin. The excessive aldosterone in the blood circulation with hyperaldosteronism suppresses renin release, and kidney disease may interfere with the ability of the kidneys to sense fluid volume or may damage the cells that synthesize renin.

For further discussion of renin within the context of the endocrine system's structure and function, please see the overview section "The Endocrine System."

See also ANTIDIURETIC HORMONE (ADH).

somatostatin A peptide HORMONE the delta cells of the ISLETS OF LANGERHANS in the PANCREAS primarily synthesize (produce). The HYPOTHALAMUS and

the gastrointestinal tract also synthesize somatostatin. Somatostatin is an inhibitory hormone that has numerous functions related to METABOLISM and growth. It stops the release of GROWTH HORMONE (GH), INSULIN, GLUCAGON, and the DIGESTIVE HORMONES. Somatostatin also slows the activity of the gastrointestinal tract by reducing the release of acids and enzymes necessary for digestion. These actions slow the rate with which the gastrointestinal tract absorbs NUTRIENTS. Somatostatin further blocks the LIVER from converting glycogen to GLUCOSE.

Endocrinologists use an injectable pharmaceutical somatostatin preparation, octreotide, to treat ACROMEGALY, a condition that results from excessive GH production. Like endogenous somatostatin, octreotide blocks the anterior lobe of the PITUITARY GLAND from secreting GH. Type 1 DIABETES, an autoimmune disorder that destroys islet cells, often reduces the ability of the islets of Langerhans to produce somatostatin. However, the numerous other sources within the body appear capable of maintaining an adequate supply.

For further discussion of somatostatin within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also AUTOIMMUNE DISORDERS; DIGESTIVE ENZYMES.

stress response hormonal cascade The hormonal responses that occur across endocrine structures to prepare the body to manage physiologic stress such as a strong increase in physical activity (for example, running). The stress response hormonal cascade begins when the HYPOTHALAMUS receives input that the body is experiencing stress. It releases a surge of CORTICOTROPIN-RELEASING HORMONE (CRH), which stimulates the anterior lobe of the PITUITARY GLAND to produce ADRENOCORTICOTROPIN HORMONE (ACTH). Concurrently the hypothalamus releases THYROTROPIN-RELEASING HORMONE (TRH), which stimulates the anterior pituitary to produce THYROID-STIMULATING HORMONE (TSH). The hypothalamus further stimulates, through neurotransmitters, the adrenal medulla to increase the release of EPINEPHRINE and NOREPINEPHRINE. These hormones stimulate NERVE cell communication such as in the muscles.

ACTH instructs the adrenal cortex of the ADRENAL GLANDS to release CORTISOL, which has numerous effects on cardiovascular and pulmonary functions. Cortisol is the body's fight-or-flight HORMONE that increases BLOOD flow to critical organs, HEART RATE, BLOOD PRESSURE, and BREATHING rate. Cortisol also stimulates the LIVER to convert glycogen to GLUCOSE, ramping up the blood supply of this essential energy source. The increase in blood glucose causes the ISLETS OF LANGERHANS to release INSULIN, which prepares cells throughout the body to receive additional glucose. TSH directs the THYROID GLAND to increase secretion of the thyroid hormones to accelerate METABOLISM, increasing cellular use of the now-available glucose supplies.

This hormonal cascade remains in action for as long as the body needs the ability to respond to the physiologic stress it faces. For the example of running, this might be until the running stops and cardiovascular and pulmonary functions return to normal levels. When the stress passes the cascades gradually reverse until the body's hormone levels also return to normal. Fear, anger, and other intense emotions also can activate the stress response hormonal cascade. Persistent activation of the stress response hormonal cascade eventually becomes dysfunctional, with the potential to cause damage to blood vessels and organ systems.

T

testosterone A steroid HORMONE the adrenal cortex of the ADRENAL GLANDS, the TESTES in men, and the OVARIES in women synthesize from a base ingredient of cholesterol. Adipose (fat) cells throughout the body also produce small amounts of testosterone. Testosterone is one of the ANDROGENS and the predominant male sex hormone. It is responsible for male secondary sex characteristics, male FERTILITY, and spermatogenesis (SPERM production). In men and women both testosterone is important for MUSCLE mass, BONE DENSITY, and LIBIDO (sex drive).

In men testosterone levels peak around age 22, then decline at the rate of about 10 percent per decade until about age 75. Changes in a man's body shape begin to take place when the testosterone level reaches about 60 percent of its peak level, when a man is in his late 50s and early 60s. These changes include diminishing muscle mass, increased and redistributed body fat, loss of the HAIR on the head, and slower sexual response. Some men equate these midlife changes with "male MENOPAUSE" or ANDROPAUSE. In women testosterone levels cyclically fluctuate with the MENSTRUATION until menopause, after which the levels of testosterone and ESTROGENS drop significantly. Some women experience diminished sexual response as a result.

Endocrinologists may prescribe low-DOSE testosterone supplement to restore sexual response in men and women. Testosterone supplement also enhances spermatogenesis in men and may be a treatment for male INFERTILITY.

For further discussion of testosterone within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also ALOPECIA; ANABOLIC STEROIDS AND STEROID PRECURSORS; HIRSUTISM; HYPOGONADISM; INHIBIN; PROGESTERONE.

thymosin A peptide HORMONE the THYMUS produces that influences how and when T-cell lymphocytes (white BLOOD cells that fight INFECTION) mature. The epithelial cells of the outer structure of the thymus synthesize thymosin most actively during childhood. Researchers do not fully understand the functions of the thymus or thymosin, particularly in adulthood. Current research is exploring the potential for using thymosin supplement to treat diseases such as HEPATITIS C and HIV/AIDS.

For further discussion of thymosin within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also IMMUNODEFICIENCY; LYMPHOCYTE.

thyroid cancer Malignant growths that develop within the tissues of the THYROID GLAND. Thyroid CANCER may be primary (originating in the thyroid gland) or secondary (metastasizing from cancer that originates elsewhere in the body). Thyroid cancer is uncommon in the United States, with about 11,000 cases diagnosed each year, and occurs primarily in people who are over age 70. There are four kinds of thyroid cancer: papillary, follicular, medullary, and anaplastic.

Papillary thyroid cancer About 75 percent of people who have thyroid cancer have papillary CARCINOMA, which is highly curable when detected and removed while the tumor is still encapsulated and clearly defined. Papillary thyroid cancer generally begins as a painless, single lump (nodule)

arising from the follicular cells and tends to grow slowly. This form of thyroid cancer is more common in people who have had previous RADIATION THERAPY to the neck, lower face, or upper chest, and in people who have autoimmune (Hashimoto's) THYROIDITIS. When papillary thyroid cancer metastasizes, it does so through the lymphatic system and usually only to adjacent lymph nodes.

Follicular thyroid cancer About 15 percent of thyroid cancers are follicular carcinomas, which also develop in the follicular cells. Follicular carcinoma does not correlate to previous radiation therapy or benign thyroid conditions. This form of thyroid cancer tends to metastasize through the BLOOD circulation, causing secondary tumors remote from the original tumor. With early detection and treatment (before METASTASIS), follicular thyroid cancer is highly curable. After metastasis, however, the prognosis declines considerably.

Medullary thyroid cancer About 8 percent of thyroid cancers are medullary carcinomas, which develop in the parafollicular cells which synthesize CALCITONIN. Consequently, excessive blood levels of calcitonin in the absence of other health conditions strongly suggest this thyroid cancer. Because these cells are less organized structurally, cancer that arises from them is less clearly delineated and accordingly more difficult to see or feel. This form of thyroid cancer often occurs in the inherited genetic disorder MULTIPLE ENDOCRINE NEOPLASIA (MEN). Rarely, medullary thyroid cancer is inherited without MEN. Medullary thyroid cancer tends to metastasize early to adjacent lymph nodes. Distant metastasis to remote sites significantly worsens the prognosis.

Anaplastic thyroid cancer About 2 percent of people who develop thyroid cancer have anaplastic carcinoma, which is the most lethal of the cancers that involve the thyroid gland. It grows rapidly and spreads aggressively. Anaplastic thyroid cancer is more likely to develop in men over the age of 70 and is very rare in people under age 50.

Symptoms and Diagnostic Path

The typical symptom of any form of thyroid cancer is a painless lump or swelling in the neck. The person may see the swelling in the mirror or feel the lump. Many times a doctor discovers a thyroid cancer during a routine medical examination or when examining the neck for other reasons. Some people experience difficulty swallowing or talking, depending on the location and size of the tumor.

The diagnostic path typically includes blood tests to measure the levels of the thyroid hormones, including THYROID-STIMULATING HORMONE (TSH), though the results may be normal. ULTRASOUND and a radioisotope iodine reuptake test can identify the tumor and provide some clues as to whether it is cancerous, though fine-needle aspiration (FNA) biopsy provides the definitive diagnosis. In FNA the endocrinologist uses a small needle and syringe to withdraw a sample of cells from the growth. Laboratory examination then determines whether the cells are cancerous, and what type of cancer is present.

Treatment Options and Outlook

For nearly all thyroid cancers, treatment is surgery to remove the thyroid gland (thyroidectomy) followed by radioactive iodine to kill any remaining thyroid cells. The radioactive iodine acts as a form of CHEMOTHERAPY and invades thyroid cells no matter where they are in the body. The exception is for medullary thyroid cancer, which arises from the parafollicular cells that do not take in iodine. The doctor may choose conventional chemotherapy or radiation therapy to follow surgery for medullary thyroid cancer. When a papillary thyroid cancer is small and contained, the doctor may feel lobectomy (removal of the involved lobe of the thyroid gland) is adequate. The decision must consider numerous factors, however, and the person who has thyroid cancer should make an informed choice based on full consideration of those factors.

Thyroid cancers detected and removed early in their development have the highest treatment success rate, and can be up to 90 percent curable (papillary and follicular). Medullary and anaplastic thyroid cancers are more difficult to diagnose in their early stages, and thus tend to be more advanced and often have metastasized by the time treatment begins. After thyroidectomy, it is necessary to take lifelong thyroid hormone supplements.

Risk Factors and Preventive Measures

The primary risk factor for papillary and anaplastic thyroid cancers is previous radiation therapy to the neck, lower face, or upper chest. Radiation exposure causes about 80 percent of papillary thyroid cancers. Family history may establish a risk for medullary thyroid cancer, as does having MEN. Risk factors for anaplastic thyroid cancer are unknown. Early diagnosis is the most effective measure for successful treatment.

See also CANCER TREATMENT OPTIONS AND DECISIONS; GOITER; SURGERY BENEFIT AND RISK ASSESSMENT; THYROID NODULE; THYROID STORM.

thyroid gland An ENDOCRINE GLAND that spreads across the front of the THROAT somewhat in the shape of a butterfly. Reddish brown in color, the thyroid gland has two lobes that equally produce the hormones CALCITONIN, THYROXINE (T_4), and TRIIODOTHYRONINE (T_3), as well as a number of precursor (inactive) thyroid hormones. The cells responsible for thyroid hormone production are the thyroid epithelial cells, also called follicular cells, which appear in clusters called thyroid follicles. The follicular cells are the only cells in the body that take in iodine, a mineral essential for thyroid hormone formation. Interspersed among the thyroid follicles are the parafollicular cells, also called C cells, which synthesize calcitonin.

The Thyroid Hormones: Metabolic Regulation

About 90 percent of the thyroid gland's hormone production is T_4, so-called because its chemical structure contains four iodine molecules. The other 10 percent is primarily T_3 (a structure of three iodine molecules) along with a number of minor hormones with unknown functions in the body. Because the thyroid hormones are not water soluble, they leave the thyroid gland attached to protein carriers the LIVER produces called thyroid-binding globulin (TBG). The TBG transports the thyroid hormones through the BLOOD to cells throughout the body.

All cells have receptors for T_3 and T_4, as these thyroid hormones regulate cellular METABOLISM (the exchange of energy within the cell). The thyroid hormones are the only peptide hormones that can pass through the cell membrane to activate receptors within the cell cytoplasm. T_3 and T_4 appear to concentrate the enzymes that regulate the transfer of energy within cells. T_3 is about 10 times more potent than T_4, though about one tenth as abundant in the blood circulation. Researchers believe that after T_4 binds with cell receptors it drops an iodine molecule to transform into the more active T_3; however, they do not understand the precise mechanisms by which this takes place. T_3 that binds with cell receptors remains T_3.

On a larger scale the thyroid hormones regulate the body's metabolism as well, controlling how the body uses energy. The thyroid hormones regulate body temperature, lipid and carbohydrate metabolism, HEART RATE, the force of the HEART's contractions, and normal growth and development. Adequate thyroid hormone levels are also necessary for FERTILITY (HYPOTHYROIDISM is one of the most common causes of INFERTILITY) and for cognitive function.

Thyroid hormones are critical for normal BRAIN development in the unborn child as well as throughout childhood. Rarely a child is born without a thyroid gland or with a severely dysfunctional thyroid gland. This establishes congenital hypothyroidism, formerly called cretinism, a syndrome of pronounced growth and intellectual deficits. The damage is permanent without immediate HORMONE THERAPY to provide the body with the necessary thyroid hormones. Undetected fetal hypothyroidism results in permanent damage to the brain, NERVOUS SYSTEM, and other organ systems and structures. Congenital hypothyroidism is rare in the United States because routine newborn and child health-care standards include regular screening for thyroid hormone levels.

Calcitonin: Bone Density and Calcium Balance

The parafollicular cells of the thyroid gland produce the peptide hormone calcitonin, which regulates the balance of calcium and phosphorus in the bones and blood. The thyroid gland releases calcitonin in response to elevated levels of calcium in the blood. Calcitonin binds with receptors in the KIDNEYS, increasing the amount of phosphorus excreted into the URINE, and in osteoblasts (cells within the bones that create new BONE tissue), stimulating them to accept calcium. Calcitonin functions in dynamic balance with PARATHYROID

HORMONE, which draws calcium from the bones into the blood to meet the calcium needs elsewhere in the body.

Generally, disorders of the thyroid gland have little effect on calcitonin synthesis because such disorders affect the follicular cells. A notable exception is an uncommon form of THYROID CANCER called medullary carcinoma, which develops in the parafollicular cells that synthesize calcitonin. Elevated levels of calcitonin in the blood circulation without corresponding parathyroid dysfunction raise the suspicion that such a cancer is present.

COMMON DISORDERS OF THE THYROID GLAND

GOITER	GRAVES'S DISEASE
HYPERTHYROIDISM	HYPOTHYROIDISM
POLYGLANDULAR DEFICIENCY SYNDROME	THYROID CANCER
THYROIDITIS	THYROID NODULE
THYROID STORM	

For further discussion of the thyroid gland within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also AGING, ENDOCRINE CHANGES THAT OCCUR WITH; HYPERCALCEMIA; HYPERPARATHYROIDISM; HYPOCALCEMIA; HYPOPARATHYROIDISM.

thyroiditis INFLAMMATION of the follicular cells of the THYROID GLAND. The inflammation prevents these cells from synthesizing thyroid hormones, resulting in HYPOTHYROIDISM. In some forms of thyroiditis the inflammation resolves and the follicular tissue returns to normal thyroid HORMONE production. In other forms the inflammation heals but forms SCAR tissue (fibrosis), permanently destroying the ability of the affected follicular cells to synthesize thyroid hormones. Thyroiditis does not affect the parafollicular cells in the thyroid gland that produce CALCITONIN.

The three main types of thyroiditis are

- autoimmune thyroiditis, sometimes called Hashimoto's thyroiditis or chronic lymphocytic thyroiditis, which often develops in people who have other AUTOIMMUNE DISORDERS and is the most common type of thyroiditis
- silent thyroiditis, which often develops in women who have recently given birth and generally begins with HYPERTHYROIDISM
- subacute thyroiditis, also called granulomatous thyroiditis or subacute lymphocytic thyroiditis, which typically develops after a viral INFECTION

Other rare types of thyroiditis include Reidel's thyroiditis, in which the thyroid becomes fibrotic

THYROIDITIS SYMPTOMS AND TREATMENT

Autoimmune (Hashimoto's) Thyroiditis	Silent Thyroiditis	Subacute Thyroiditis
no PAIN	no pain	pain
gradual hypothyroid onset: progressive fatigue, weight gain, mild GOITER	hyperthyroid onset within four months of CHILDBIRTH: weight loss, anxiety, insomnia, agitation	rapid hyperthyroid onset: weight loss, anxiety, insomnia, agitation
permanent destruction of thyroid follicular cells	no treatment for HYPERTHYROIDISM because duration is short	transition to hypothyroid: weight gain, fatigue, lethargy
permanent HYPOTHYROIDISM with lifelong thyroid supplement HORMONE THERAPY	transition to hypothyroid eight months after childbirth: weight gain, fatigue, lethargy, DEPRESSION	swelling and tenderness of neck
	damage to thyroid follicular cells often permanent, with resulting permanent hypothyroidism	NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) may relieve pain and some INFLAMMATION
	lifelong thyroid supplement hormone therapy	THYROID GLAND often fully recovers and no treatment is necessary
		permanent hypothyroidism requires lifelong thyroid supplement hormone therapy

(scarred) and merges with surrounding structures, and acute thyroiditis, which is a serious and potentially life-threatening bacterial infection of the thyroid gland that requires emergency medical treatment.

Symptoms and Diagnostic Path

Sometimes the first indications of thyroiditis are the symptoms of hyperthyroidism, as the inflammation causes the follicular cells to release a surge of thyroid hormones into the BLOOD circulation. When the effect of this surge subsides thyroid hormone levels in the blood drop below normal, establishing a state of hypothyroidism. The diagnostic path begins with blood tests to measure thyroid hormone and ANTIBODY levels, and may include diagnostic imaging procedures such as ULTRASOUND or radioisotope iodine reuptake test to further evaluate thyroid function and the presence of any nodules or swelling.

Treatment Options and Outlook

When thyroid symptoms are transitory, as with silent thyroiditis and often with subacute thyroiditis, HORMONE THERAPY with thyroid supplement is not necessary. Nor is it necessary to treat the hyperthyroid phase, because this is typically of short duration. Lifelong thyroid supplement hormone therapy becomes necessary when scarring permanently destroys thyroid follicular cells.

Risk Factors and Preventive Measures

The primary risk for autoimmune thyroiditis is the existence of any other autoimmune disorders. Silent thyroiditis nearly always follows CHILDBIRTH, and subacute thyroiditis follows a viral infection. Knowing of these risks increases the chance of early diagnosis, which can minimize the course of the duration. However, there are no preventive measures for thyroiditis.

See also GRAVES'S DISEASE; THYROID CANCER; THYROID NODULE; THYROID STORM.

thyroid nodule A small growth that develops within the tissues of the THYROID GLAND. Most thyroid nodules (about 90 percent) are noncancerous. Thyroid nodules, like other thyroid disorders, are significantly more common in women than men and become increasingly common with advancing age. Endocrinologists call a thyroid nodule "hot" when its tissue secretes thyroid hormones and "cold" when it does not. Most malignant (cancerous) thyroid nodules are cold, while nearly all hot nodules are benign (noncancerous).

Most thyroid nodules do not cause symptoms. The person may notice a lump on the front of the neck when looking in the mirror. Often the doctor detects a thyroid nodule during a ROUTINE MEDICAL EXAMINATION. Thyroid nodules may oversecrete thyroid hormones, resulting in symptoms of HYPERTHYROIDISM. The diagnostic path may include ULTRASOUND examination of the neck and a radioisotope iodine reuptake test, which measures the ability of the nodule to take in iodine. Normal thyroid tissue uses iodine to synthesize thyroid hormones. A nodule composed of tissue other than thyroid tissue (a cold nodule) does not take up iodine. A fine-needle aspiration (FNA) biopsy, in which the endocrinologist withdraws a small tissue sample from the nodule using a thin needle and a syringe, provides cells for laboratory examination to determine whether the nodule is cancerous. A single node is more suspicious than are multiple nodes.

Some thyroid nodules resolve on their own without treatment. The endocrinologist may prefer to surgically remove a thyroid nodule that is causing symptoms, including those of hyperthyroidism, or that is growing though often chooses a course of watchful waiting for asymptomatic nodules that biopsy negative for CANCER and are not growing. Thyroid nodules may occur in THYROIDITIS (INFLAMMATION of the thyroid gland) or HYPOTHYROIDISM (underactive thyroid gland).

See also AGING, ENDOCRINE CHANGES THAT OCCUR WITH; GOITER; THYROID CANCER.

thyroid-stimulating hormone (TSH) A peptide HORMONE the anterior lobe of the PITUITARY GLAND synthesizes in response to the HYPOTHALAMUS's production of THYROTROPIN-RELEASING HORMONE (TRH). TSH subsequently binds with TSH receptors on the follicular cells in the THYROID GLAND, stimulating them to synthesize the primary thyroid hormones TRIIODOTHYRONINE (T_3) and THYROXINE (T_4), as well as a number of minor or precursor hormones. TSH also influences the pituitary gland's secretion of PROLACTIN and GROWTH HORMONE (GH). TSH levels in

the blood may remain artificially high in HYPOTHYROIDISM, as the levels of thyroid hormones are chronically inadequate in this condition of underactive thyroid gland. TSH levels may be normal or low in HYPERTHYROIDISM (overactive thyroid gland), depending on the cause of the oversecretion of thyroid hormones.

For further discussion of TSH within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also ADRENOCORTICOTROPIN HORMONE (ACTH); ANTIDIURETIC HORMONE (ADH); FOLLICLE-STIMULATING HORMONE (FSH); GROWTH HORMONE (GH); LUTEINIZING HORMONE (LH); OXYTOCIN; PARATHYROID GLANDS; PARATHYROID HORMONE.

thyroid storm A rare but life-threatening condition resulting from HYPERTHYROIDISM in which the body experiences an exaggerated response to the overproduction of thyroid hormones.

Thyroid storm is a medical emergency that requires rapid treatment.

Thyroid storm generates severe ARRHYTHMIA and tachycardia (disturbances of the HEART's electrical activity), high FEVER (disruption of the body's heat regulation mechanisms), congestive HEART FAILURE, significant electrolyte imbalances, and seizures or psychotic behaviors. Typically thyroid storm develops when a person who has undiagnosed hyperthyroidism, most commonly the result of GRAVES'S DISEASE, experiences physiologic stress such as INFECTION, trauma, or surgery. The circulating thyroid hormones overwhelm the cells, dramatically accelerating METABOLISM. The body's usual negative-feedback loop mechanisms fail, and the THYROID GLAND continues to pour thyroid hormones into the BLOOD circulation.

Symptoms and Diagnostic Path

The symptoms and signs of thyroid storm manifest rapidly and include

- severe NAUSEA, VOMITING, and DIARRHEA
- high fever (above 105°F)
- confusion and anxiety
- DYSPNEA (difficulty BREATHING) and TACHYPNEA (rapid breathing)
- racing or pounding PULSE (140 beats per minute or greater)

The diagnostic path begins with blood tests to measure the levels of thyroid hormones. Typically, THYROXINE (T_4) and TRIIODOTHYRONINE (T_3) are significantly elevated and THYROID-STIMULATING HORMONE (TSH) is low. However, the diagnosis is primarily clinical (based on signs and symptoms).

Treatment Options and Outlook

Treatment aims to bring thyroid hormone levels down as quickly as possible, usually with the medications methimazole or propylthiouracil (PTU). Follow-up administration of intravenous iodine blocks the thyroid gland from resuming thyroid hormone production. Plasmapheresis to filter thyroid hormones from the blood may be a treatment option for people who do not respond to these measures. Beta blocker medications such as propanolol help thwart the actions of thyroid hormones that reach cells throughout the body. Other therapies target symptoms, such as cooling to bring the body temperature down and medications to regulate the heart's rhythm. Once the person's status stabilizes, the endocrinologist typically begins treatment for the underlying hyperthyroidism, which may include surgery to remove the thyroid gland or radioactive iodine to destroy the thyroid gland's ability to produce thyroid hormones.

Without treatment, or when treatment begins too late, thyroid storm is fatal. With appropriate and timely treatment about 80 percent of people who experience thyroid storm survive. After treatment, lifelong HORMONE THERAPY with thyroid hormone supplement is necessary.

Risk Factors and Preventive Measures

The primary risk factor for thyroid storm is undiagnosed hyperthyroidism. Appropriate treatment for hyperthyroidism can eliminate the risk for thyroid storm.

See also HYPOTHYROIDISM; THYROIDITIS.

thyrotoxicosis See HYPERTHYROIDISM.

thyrotropin-releasing hormone (TRH) A peptide HORMONE the HYPOTHALAMUS produces in response to decreased levels of the thyroid hormones in the BLOOD circulation. TRH initiates the hormonal cascade that regulates the synthesis and release of thyroid hormones from the THYROID GLAND. TRH stimulate the anterior lobe of the PITUITARY GLAND to release THYROID-STIMULATING HORMONE (TSH). TSH in turn binds with TSH receptors on the surface of the follicular cells in the THYROID GLAND, stimulating them to produce TRIIODOTHYRONINE (T_3) and THYROXINE (T_4), the primary thyroid hormones. Increased levels of T_3 and T_4 in the blood circulation signal the hypothalamus to "turn off" TRH secretion.

For further discussion of TRH within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also ANTIDIURETIC HORMONE (ADH); CORTICOTROPIN-RELEASING HORMONE (CRH); GONADOTROPIN-RELEASING HORMONE (GNRH); GROWTH HORMONE–RELEASING HORMONE (GHRH).

thyroxine (T_4) A peptide HORMONE the THYROID GLAND synthesizes from iodine and the amino acid tyrosine, both of which enter the body from dietary sources. The follicular cells in the thyroid gland synthesize T_4. Thyroxine is designated T_4 because its chemical structure contains four iodine molecules (as well as two tyrosine molecules). About 80 percent of the thyroid gland's hormone production is T_4. T_4 travels through the blood circulation bound to the protein carrier thyroxine-binding globulin (TBG), which the LIVER synthesizes. All cells in the body have receptors for T_4, which passes across the cell membrane (cell wall) to bind with receptors in the cell cytoplasm. Upon binding T_4 appears to drop an iodine molecule to become the more potent TRIIODOTHYRONINE (T_3). In combination, T_3 and T_4 regulate cellular METABOLISM (the conversion of energy within cells).

The HYPOTHALAMUS regulates the thyroid hormone cascade, which it initiates by producing THYROTROPIN-RELEASING HORMONE (TRH). TRH stimulates the anterior lobe of the PITUITARY GLAND to secrete THYROID-STIMULATING HORMONE (TSH). TSH, in turn, stimulates the thyroid gland to synthesize and release T_4 (as well as T_3). An underactive thyroid gland produces inadequate amounts of T_3 and T_4, resulting in HYPOTHYROIDISM and slowed metabolism. An overactive thyroid gland produces too much T_3 and T_4, resulting in HYPERTHYROIDISM and an accelerated metabolic rate. T_4 is the most common ingredient in thyroid hormone supplements.

For further discussion of T_4 within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

See also THYROIDITIS; THYROID STORM.

triiodothyronine (T_3) A peptide HORMONE the THYROID GLAND synthesizes from iodine and the amino acid tyrosine, both of which the body acquires through dietary sources. The follicular cells in the thyroid gland synthesize T_3. Triiodothyronine is designated T_3 because its chemical structure contains three iodine molecules in addition to two tyrosine molecules. About 20 percent of the thyroid gland's hormone production is T_3. T_3 is about 10 times more potent than THYROXINE (T_4), the other major thyroid hormone. All cells in the body have receptors for T_3, which passes across the cell membrane (cell wall) to bind with those receptors within the cell cytoplasm. T_3 then directly influences the cell's DNA, guiding its production of proteins. In combination, T_3 and T_4 regulate cellular METABOLISM.

The HYPOTHALAMUS regulates the thyroid hormone cascade, which it initiates by producing THYROTROPIN-RELEASING HORMONE (TRH). TRH stimulates the anterior lobe of the PITUITARY GLAND to secrete THYROID-STIMULATING HORMONE (TSH). TSH, in turn, stimulates the thyroid gland to synthesize and release T_3 (as well as T_4). An underactive thyroid gland produces inadequate amounts of T_3 and T_4, resulting in HYPOTHYROIDISM and slowed metabolism. An overactive thyroid gland produces too much T_3 and T_4, resulting in HYPERTHYROIDISM and an accelerated metabolic rate. T_3 is sometimes an ingredient in thyroid hormone supplements.

For further discussion of T_3 within the context of the endocrine system's structure and function please see the overview section "The Endocrine System."

V–W

vasoactive intestinal peptide (VIP) See DIGESTIVE HORMONES.

Wilson's disease A hereditary disorder in which the body does not properly metabolize copper, which allows deposits of copper to accumulate in various organs. Without treatment Wilson's disease is fatal; with treatment it is easily manageable.

Copper is an important mineral for the body's production of various enzymes, including those that facilitate HEMOGLOBIN synthesis. However, the body needs only a very small quantity of copper. In health the LIVER discharges excess copper, which enters the body through dietary sources, into the BILE. The bile carries the copper into the gastrointestinal tract for removal from the body in the feces. The KIDNEYS also extract some copper from the BLOOD circulation, passing it from the body in the URINE. In Wilson's disease a genetic MUTATION prevents the liver from discharging excess copper. Instead, it stores copper within its own tissues as well as sends it back out into the blood circulation. The blood deposits the copper in tissues throughout the body. As the copper accumulates, it causes scarring and other damage that interferes with the normal functions of the tissues.

Symptoms and Diagnostic Path

The symptoms of Wilson's disease vary according to the body system most severely affected, which is most often the liver or the BRAIN and SPINAL CORD. Liver involvement produces symptoms such as

- JAUNDICE (yellowish color to the SKIN)
- HEPATOMEGALY (enlarged liver) and SPLENOMEGALY (enlarged SPLEEN)
- ASCITES (fluid accumulation in the abdomen)
- NAUSEA and VOMITING
- abdominal discomfort or PAIN

Involvement of the brain, spinal cord, and other structures of the NERVOUS SYSTEM produces symptoms that may include

- difficulty moving the arms and legs
- tremors
- confusion
- difficulty speaking and swallowing
- cognitive and memory dysfunction

A conclusive clinical sign for Wilson's disease is the appearance of a copper-colored ring around the iris of the EYE, called a Kayser-Fleischer ring. Other diagnostic indications include low levels of copper in the blood and high levels of copper in the urine. Biopsy of the liver or the kidneys shows the copper deposits in the tissues.

Treatment Options and Outlook

Treatment targets blocking the body's absorption of copper as well as removal of excessive copper already in the body (chelation). Commonly used chelation agents include penicillamine and trientine. These drugs bind with the copper, allowing the kidneys to excrete the bound molecules from the body in the urine. Zinc acetate can help reduce gastrointestinal absorption of copper from the diet. Doctors recommend eating foods that are low in copper. People who have Wilson's disease should drink bottled water because copper is common in household plumbing and should avoid cooking with copper pans or implements. The endocrinologist may also recommend a zinc supplement, as zinc interferes with copper absorption.

FOODS HIGH IN COPPER

avocado
chocolate
dried fruits: apricots, figs, nectarines, raisins
energy bars and drinks
legumes: black beans, garbanzo beans, kidney beans, lentils, navy beans, pinto beans, peanuts, soybeans, split peas
mushrooms
nuts: almonds, cashews, hazelnuts, macadamia, pecans, walnuts
organ meats: gizzard, heart, liver, kidney
shellfish: clams, mussels, oysters, scallops, shrimp
whole grains: barley, bran

Risk Factors and Preventive Measures

Wilson's disease occurs as a result of autosomal recessive GENE mutation. People with a family history of Wilson's disease can undergo GENETIC TESTING for this mutation. Minimizing copper intake prevents excessive accumulation and its resultant damage and symptoms. Damage that has already occurred at the time of diagnosis is often permanent.

THE URINARY SYSTEM

The urinary system cleanses metabolic wastes and toxins from the blood. Physician specialists who treat conditions of the urinary system are urologists (surgeons) and nephrologists (internists). This section, "The Urinary System," presents a discussion of the organs and structures of the urinary system, an overview of urinary and renal health and disorders, and entries about the health conditions that involve the urinary system.

Structures of the Urinary System

KIDNEYS
- cortex
- medulla
- renal pelvis

NEPHRON
- ureters

BLADDER

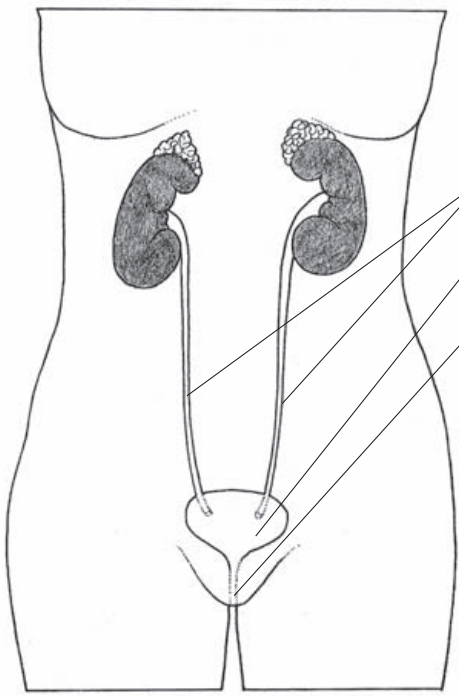
URETHRA

Functions of the Urinary System

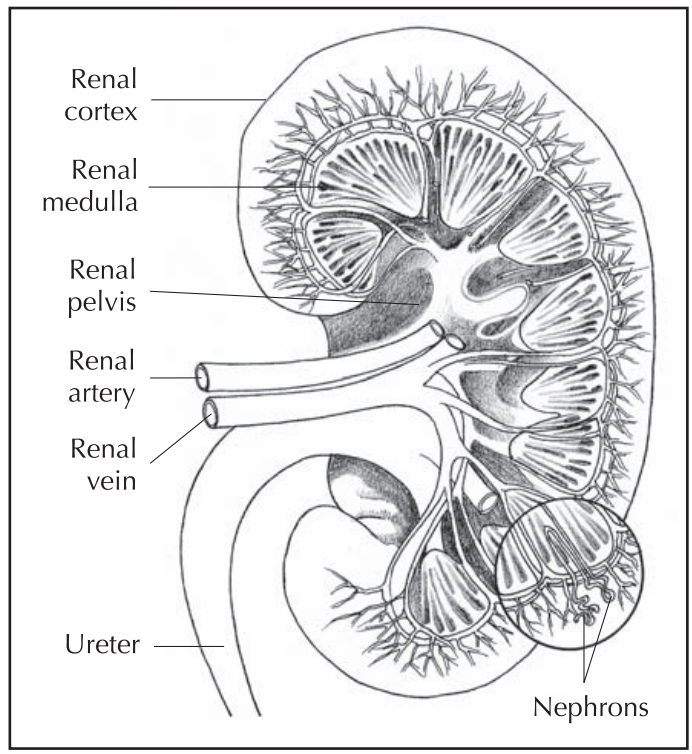
The primary functions of the urinary system's organs and structures are to filter and excrete wastes from the BLOOD and to maintain the body's fluid and electrolyte balances. The KIDNEYS make, and the bladder contains and then excretes, urine, a watery fluid that carries dissolved and suspended wastes from the body. As well, the KIDNEYS produce two essential hormones: RENIN, which helps regulate BLOOD PRESSURE, and ERYTHROPOIETIN (EPO), which stimulates the BONE MARROW to produce erythrocytes (red blood cells). The kidneys also convert vitamin D from its inactive dietary form to its active form as the HORMONE calcitriol, which is necessary for proper calcium absorption.

The kidneys: cleansing the blood The paired KIDNEYS reside in the upper posterior abdomen, behind the peritoneum along the spine and within the protection of the rib cage. The kidneys are slightly offset from one another in the symmetry of their positioning, with the right kidney being about an inch lower than the left to accommodate the LIVER. Each kidney is about the size of a man's fist, shaped like the bean that bears its name. The dark reddish brown kidneys curve toward each other, turning their backs to the body's sides. Though the kidneys have a combined weight of about 10 ounces, they hold 20 percent of the body's blood supply. The renal arteries branch directly from the abdominal AORTA, ensuring that the kidneys are among the first of the organs to receive blood with each contraction of the HEART. The renal veins channel blood returning to the circulation from the kidneys directly to the inferior VENA CAVA.

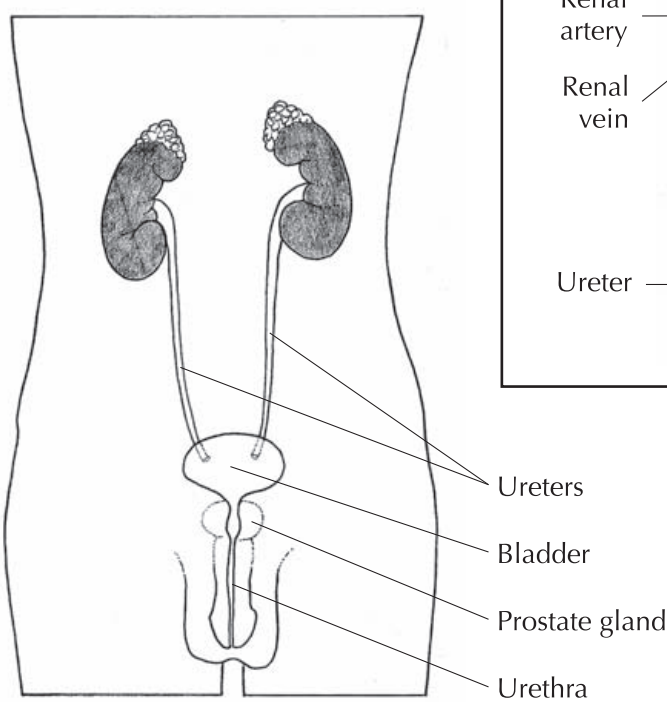
The kidney's structure features two general divisions. The outer layer is the renal cortex, intensely vascular tissue where the filtration of blood takes place. The inner layer is the renal medulla, where URINE collects. The workhorse structure of the kidney is the microscopic NEPHRON, which is made up of two elements: the renal corpuscle, contained in the renal cortex, and the tubule, contained in the renal medulla. The renal corpuscle consists of a containment capsule (called Bowman's capsule) that encloses the GLOMERULUS, a tightly coiled capillary network that receives blood from the body for filtration. The space between the inner wall of Bowman's capsule and the walls of the glomerulus collects the molecules of water, electrolytes, and metabolic wastes that pass from the blood, forming a mixture called the filtrate. The tubule is a loosely coiled structure that wraps around the renal corpuscle. It reabsorbs electrolytes and water the body needs from the filtrate and sends the remainder on with the wastes to become urine. Each tubule is about 1.25 inches in total length; were a kidney's tubules removed and stretched



Female



Kidney



Male

end to end in a straight line, they would cover more than 50 miles.

RENAL DIALYSIS: MACHINES TO CLEANSE THE BODY WHEN THE KIDNEYS CANNOT

Researchers began working in the 1920s to develop a safe, effective substitute to cleanse metabolic wastes from the BLOOD when the KIDNEYS failed. By the early 1950s such a substitute—the hemodialysis machine—entered clinical use. And by the 1970s hemodialysis was the standard treatment for END-STAGE RENAL DISEASE (ESRD). Today nearly 300,000 Americans rely on hemodialysis.

The kidneys and blood pressure The kidneys regulate blood pressure by controlling the volume of the blood and through the production of the hormone renin, which is the cornerstone of the body's RENIN–ALDOSTERONE–angiotensin (RAA) system for regulating blood pressure. Renin and aldosterone initiate chemical actions that result in constricting blood vessels and increasing blood volume to raise blood pressure.

The tubules in the nephrons continuously adjust the amounts of sodium, potassium, and chloride they reabsorb from the filtrate. Where goes the electrolytes, so goes the water. The more of electrolytes the tubules draw back into the blood, the higher the amount of water that follows. Increased reabsorption increases blood volume and raises blood pressure. Decreased reabsorption sends the electrolytes in the filtrate, along with the water that they draw, out of the body in the urine to drop both blood volume and blood pressure.

Within each nephron, where the distal tubule and the afferent arteriole (the blood vessel that brings blood into the glomerulus) nearly touch, are two clusters of specialized sensory cells. The macula densa resides within the walls of the distal tubule; its cells sense the concentration of electrolytes, primarily sodium, in the filtrate. In the interstitial space between the distal tubule and the afferent arteriole are the juxtaglomerular cells, which sense the pressure of the blood as it courses through the afferent arteriole.

The clusters are in constant communication with one another, using chemical signals to regulate how much electrolytes and water the tubules reabsorb from the filtrate. As well, these cell clusters send a continuous barrage of NERVE signals to the brainstem, which just as continuously determines the adjustments in renin release necessary to maintain the blood pressure at the level the body needs. Renin sets in motion the cascade of chemical events that converts the inactive protein angiotensinogen (also called angiotensin I) into the very potent vasoconstrictor (chemical that causes the blood vessels to narrow and stiffen, raising blood pressure) angiotensin II. Angiotensin I causes the peripheral arterioles to constrict.

Angiotensin II also signals the adrenal cortex of the ADRENAL GLANDS to release ALDOSTERONE, a hormone that stimulates the tubule to pull even more sodium (and, of course, water) back into the blood from the filtrate. The result is a rise in blood pressure. The brainstem also instructs the HYPOTHALAMUS to release ANTIDIURETIC HORMONE (ADH) when blood volume and pressure fall below a certain threshold and to withhold ADH when blood volume is above that threshold. The threshold varies with the body's activities, and the cascade of actions is a process of perpetual adjustment.

Doctors take advantage of these mechanisms to treat HYPERTENSION (high blood pressure). Diuretic medications—"water pills"—act on the tubules to block them from reabsorbing sodium and chloride. This increases the amount of water in the filtrate, preventing the tubules from increasing blood volume. Various antihypertensive medications, such as angiotensin-converting enzyme (ACE) inhibitors, target different stages of the angiotensin conversion process.

The kidneys and fluid balance The processes of the kidney that regulate blood pressure also maintain the body's fluid and electrolyte balances. The hypothalamus monitors the amount of water in the body, using ADH as the chemical messenger that tells the kidneys the body needs more water or less water.

The kidneys and erythropoiesis It seems a bit odd, at first, that the kidneys produce the hormone that stimulates the bone marrow to produce new erythrocytes (red blood cells). But no other organs have such intimate exposure to the blood that they can literally "examine" each cell. With every heartbeat 20 percent of the body's blood

volume surges through the kidneys. This blood disperses among the million or so glomeruli, the microscopic capillaries within the nephrons. Specialized sensors in the walls of the glomeruli detect the levels of oxygen in the erythrocytes as they pass by. Low levels of oxygen stimulate the kidneys to synthesize (produce and release) EPO. EPO travels through the blood circulation to the bone marrow, where it stimulates the production of new erythrocytes (erythropoiesis).

Erythropoiesis suffers in RENAL FAILURE because the blood cannot circulate through the glomeruli, resulting in ANEMIA. This is why people who have renal failure feel so fatigued. And erythropoiesis comes to a near-halt in ESRD, when the kidneys no longer function at all. Not only do toxins accumulate in the blood when the kidneys fail but also the blood cannot deliver enough oxygen because it does have enough red blood cells to carry the load. Many people who have renal failure take EPO supplement, a product of RECOMBINANT DNA technology, to maintain adequate erythropoiesis.

The kidneys and bone health Mention *strong bones* and the first association is likely to be "calcium." It might just as well be calcitriol, the hormone form of vitamin D, because without calcitriol, the body cannot use the calcium it receives. The kidneys convert dietary vitamin D, a fat-soluble vitamin inert within the body in its dietary form, to calcitriol. The kidneys further participate in the body's calcium balance because they determine how much calcium to reabsorb from the filtrate and return to the blood circulation.

Calcium is essential for numerous body activities ranging from HEALING and cell repair to nerve and MUSCLE cell communication. Calcium makes it possible to walk across the room, from the SKELETON that supports the body to the nerve impulses that instruct muscle fibers from heart to soles to contract. People who have chronic renal failure and other forms of chronic renal disease often take vitamin D supplement (calciferol). Adequate vitamin D is essential for appropriate growth in children; without it there is no growth. PARATHYROID HORMONE acts on the distal tubule to increase the amount of calcium the tubule reabsorbs.

The kidneys and urine production This most familiar and seemingly simple function of the kidneys is, of course, its most important. Without the urine to carry metabolic wastes from the blood, none of the kidney's other functions would be necessary for very long. Urine is a mixture of the water, electrolytes, and metabolic wastes (primarily urea) the kidneys extract from the blood. As blood passes through the glomerulus pressure squeezes much of the blood's water, along with electrolytes and wastes, through the glomerular walls into Bowman's capsule. This mixture, the filtrate, collects in the capsule and drains into the tubule. The tubule reabsorbs about two thirds of the water and electrolytes, passing on the remainder to become urine. Collecting tubules carry the urine into the renal pelvis, where it drains into the ureters that then channel it to the BLADDER.

Holding the urine: the bladder Suspended in the lower pelvis is the bladder, an expandable muscular sac that collects the urine that drains from the kidneys. When empty the bladder is about the size of a lemon; when filled to its capacity of about 500 milliliters the bladder is about the size of a cantaloupe. Its three-layer wall consists of a mucous inner layer, middle layer of smooth muscle, and fibrous membrane outer layer. The middle layer, called the detrusor muscle, relaxes to allow the bladder to distend when filling with urine and contracts to push urine from the bladder into the URETHRA for passage from the body.

The bladder holds the urine in a more colloquial sense as well, allowing conscious override of the micturition REFLEX, an involuntary function of the sympathetic NERVOUS SYSTEM, that initiates URINATION. At about two or three years of age the brain, muscles, and nerves have matured enough for conscious control to take over certain involuntary functions. Voluntary urination—toilet training—is the hallmark of this effort and marks the rite of passage from baby to child. Voluntary control of urination uses certain centers in the brain in coordination with voluntary muscles such as the pubococcygeal muscle to manage the timing of urination, though if the bladder becomes too full the micturition reflex becomes too intense for conscious control to overcome.

Tubes of urine transport: the ureters and urethra From each kidney a thin muscular tube drops about 12 inches to join with the bladder. Urine trickles from the kidney's collecting tubules into the renal pelvis, a deltalike structure that

channels the urine toward the URETER, which will carry the urine, like a drain, into the bladder. Though small in diameter the ureter has relatively thick, sturdy walls that contract in rhythmic waves to move urine in a steady flow. The ureter's peristaltic action also helps prevent urine from flowing back up into the kidney. Each ureter inserts into the back of the bladder wall, tunneling through the detrusor muscle for a short distance before emerging into the urothelium (inner epithelial layer of the bladder). The tunnel is another safeguard to keep urine from backflowing to the kidney, flattening unless pressure from flowing urine causes it to open.

The urethra carries urine from the base of the bladder to outside the body. A woman's urethra is less than two inches long and exits her body between the CLITORIS and the VAGINA. A man's urethra is about eight inches long and exits his body at the tip of the PENIS. A ring of muscle, the urethral sphincter, encircles the urethra at the neck of the bladder. When contracted the sphincter holds the urethra closed and urine remains in the bladder; when relaxed the sphincter allows the urethra to open and urine to leave the bladder.

Health and Disorders of the Urinary System

The kidneys have remarkable capacity. Each kidney contains more than a million nephrons. Though the normal design of the human body features two kidneys, one healthy kidney is perfectly able to meet the needs of the body. The kidneys can lose as much as 65 to 70 percent of their ability to function and still maintain the health of the body. When kidney function reaches 25 percent, however, the filtration workload overwhelms the nephrons and symptoms of kidney failure begin to manifest. And when kidney function drops to 15 percent or lower, the kidneys can no longer perform at a level that sustains life.

The most significant health challenges that confront the kidneys are DIABETES and hypertension, which are especially dangerous when they occur in combination as they do in about half of people who have diabetes as hypertension is a complication of diabetes. These two conditions place inordinate stress on the glomeruli, hypertension because it increases the pressure under which blood enters the glomeruli and diabetes because the elevated levels of GLUCOSE in the blood damage capillaries throughout the body. The glomeruli, being among the most intensely concentrated capillary networks in the body, bear the brunt of such damage. About 20 million Americans live with some degree of kidney failure and another 10 million are at risk of kidney failure because of health conditions such as diabetes and hypertension as well as conditions that directly affect the kidneys.

HEALTH CONDITIONS THAT AFFECT THE URINARY SYSTEM

ALPORT'S SYNDROME	BLADDER CANCER
BLADDER EXSTROPHY	CYSTINURIA
CYSTITIS	CYSTOCELE
END-STAGE RENAL DISEASE (ESRD)	EPISPADIAS
FANCONI'S SYNDROME	GLOMERULONEPHRITIS
GLOMERULOSCLEROSIS	GOODPASTURE'S SYNDROME
HEMOLYTIC UREMIC SYNDROME	HEPATORENAL FAILURE
HORSESHOE KIDNEY	HYDRONEPHROSIS
HYPOSPADIAS	NEPHRITIS
NEPHROLITHIASIS	NEPHROPATHY
NEPHROTIC SYNDROME	POLYCYSTIC KIDNEY DISEASE
RENAL CANCER	RENAL CYST
RENAL FAILURE	RENAL TUBULAR ACIDOSIS
UREMIA	URETHRAL STRICTURE
URETHRITIS	URINARY INCONTINENCE
URINARY TRACT INFECTION (UTI)	UROLITHIASIS
VESICOURETERAL REFLUX	WILMS'S TUMOR

Traditions in Medical History

Among the earliest known medical treatments are those for kidney stones and bladder stones. Ancient healers across cultures documented various remedies, including surgical removal, for the painful conditions known today as NEPHROLITHIASIS and UROLITHIASIS, respectively. Though early physicians could not examine the urinary structures themselves in any great detail, these structures abundantly produced a substance that many physicians turned into a diagnostic oracle: the urine. The gifted physician was one who could study the color, cloudiness, consistency, odor, and even taste of the urine to diagnose conditions ranging from HEART FAILURE to PREGNANCY to SYPHILIS and, of course, diabetes. This was the practice of uroscopy, the forerunner of modern urinalysis.

Greek philosopher and scientist Aristotle (384–322 B.C.E.), whose father was a physician,

described the urinary system's basic structure and function in his writings. However, nearly 2000 years would pass before one of science's most significant inventions, the light microscope, would give 17th-century scientists the opportunity to explore the amazing structure and function of the kidney beyond the human EYE's ability to detect. Advances in modern times such as the electron microscope, which debuted in the 1950s, and the mapping of the human GENOME, completed in 2003 after 13 years of research, extended to the molecular level understanding of the seemingly simple yet incredibly intricate mechanisms that filter the blood and cleanse the body of metabolic wastes.

Breakthrough Research and Treatment Advances

The first successful KIDNEY TRANSPLANTATION in 1954, in which surgeons removed one healthy kidney from a man and transplanted it into his identical twin brother whose kidneys had completely failed, marked the advent of a new era in modern medicine. The discovery of cyclosporine, a powerful immunosuppressive DRUG, in 1954, made kidney transplantation a viable treatment for ESRD and paved the way for the transplantation of other vital organs such as livers and hearts. Today, surgeons in the United States perform more than 15,000 kidney transplantations each year, making the kidney the most frequently transplanted organ (aside from SKIN and corneas). Yet 45,000 people wait for donor kidneys. The shortage of donor kidneys has spurred efforts to find new solutions. One direction of research focuses on living kidney donation, in which a person agrees to provide one of his or her kidneys to a person whose own kidneys have failed. Advances in MINIMALLY INVASIVE SURGERY have significantly reduced the risks and inconveniences for living donors. Other directions of research focus on molecular medicine and genetics, looking for ways to correct problems with the kidneys to prevent kidney failure.

aging, urinary system changes that occur with At birth the structures of the urinary system are fully developed and function under the automatic control of the NERVOUS SYSTEM. The newborn's KIDNEYS filter BLOOD and make URINE. The BLADDER collects the urine and, when it fills to a point that triggers the micturition REFLEX, it empties to drain urine via the URETHRA to outside the body. Voluntary control over URINATION develops between three and five years of age, the rite of passage from babyhood to childhood. The urinary system typically then functions at a steady level for decades, unless disease alters its structures (notably the KIDNEYS).

Changes in the Kidneys and Bladder

Beginning around age 40 the number, size, and efficiency of nephrons, the filtering units of the kidneys, begins to diminish. At birth each kidney contains a million or more nephrons. By age 70 the kidneys have lost about 30 percent of the nephrons they contained at birth. They are smaller overall in size and take longer to filter the blood that flows through them. They may allow more water to enter the urine and keep more electrolytes in the blood circulation. The imbalance, even when slight, often affects BLOOD PRESSURE and other vital functions and increases the risk for DEHYDRATION.

Other changes in the body often affect the kidneys as well as other structures of the urinary system. With aging fibrous tissue throughout the body begins to lose elasticity, becoming more rigid. This reduced FLEXIBILITY can harden and narrow the blood vessels that supply the kidneys, slowing blood flow into the kidneys and through the nephrons. It also diminishes the bladder's ability to distend (expand), decreasing bladder capacity. Age-related changes in NERVE and BRAIN function also slow the micturition REFLEX, allowing the bladder to become more full before triggering the urge to urinate. These changes can result in URINARY URGENCY and URINARY FREQUENCY.

The Effects of Other Changes and Health Conditions

Age-related changes in the reproductive system—MENOPAUSE in women and BENIGN PROSTATIC HYPERPLASIA (BPH) in men—affect the urinary system as well. The normal and usually harmless enlargement with aging of the PROSTATE GLAND in men can constrict the urethra, interfering with the flow of urine during urination. Relaxation of the pelvic structures that accompanies the decline of the levels of ESTROGENS in women who are past menopause affects the woman's ability to control the flow of urine, allowing problems such as stress incontinence (urine leakage with coughing, sneezing, or laughing). As well, stretching and tearing of the pelvic muscles and ligaments that may have occurred during PREGNANCY and CHILDBIRTH may weaken these structures, allowing the bladder to sag and pressure the VAGINA (CYSTOCELE).

HYPERTENSION (high blood pressure) and DIABETES, two conditions that become increasingly common with advancing age, are particularly hazardous to the kidneys and between them account for about 80 percent of RENAL FAILURE (acute and chronic) and END-STAGE RENAL DISEASE (ESRD). Early and appropriate treatment for these conditions can significantly slow their actions on the kidneys, highlighting the importance of routine health screening for them. The risks for BLADDER CANCER, RENAL CANCER, NEPHROPATHY, NEPHROLITHIASIS (kidney stones), and UROLITHIASIS (bladder stones) also increase with age.

Measures to Maintain Urinary Health

Though it is not possible to prevent many of the health conditions affecting the urinary system that become more common with age, there are preventive lifestyle measures that can help maintain urinary health. These include

- drink a minimum of 8 to 12 eight-ounce glasses of water daily, more when it is hot or with exercise (urine should be colorless or slightly yellow)
- get blood pressure checked by a health-care provider at least yearly
- get checked for diabetes regularly
- urinate when the urge occurs and empty the bladder completely when urinating
- minimize use of over-the-counter products containing acetaminophen or NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS)
- do not smoke (cigarette smoking accounts for 50 percent of bladder cancers)

Maintaining a healthy weight, nutritious EATING HABITS, and daily physical exercise are important for good health overall. People who have diagnosed hypertension or diabetes should strive to maintain the best possible control over these conditions through appropriate lifestyle measures and by taking medications as prescribed.

See also ATHEROSCLEROSIS; HEPATORENAL FAILURE; LIFESTYLE AND HEALTH; URINARY INCONTINENCE.

albuminuria Excessive excretion of ALBUMIN, a form of protein, into the URINE. Albuminuria, also called proteinuria, typically indicates kidney conditions that affect the glomeruli (the tubular structures within the KIDNEYS that filter wastes and excess water from the BLOOD to excrete in the urine). Such conditions include GLOMERULONEPHRITIS, GLOMERULOSCLEROSIS, NEPHROTIC SYNDROME, and NEPHROPATHY of DIABETES or of HYPERTENSION (high BLOOD PRESSURE). Albuminuria may accompany cardiovascular diseases such as ENDOCARDITIS and chronic inflammatory diseases such as SYSTEMIC LUPUS ERYTHEMATOSUS (SLE) and RHEUMATOID ARTHRITIS. Strenuous physical exercise also can cause transient albuminuria without kidney disease.

Albuminuria does not itself cause symptoms. Most often the doctor detects albuminuria through urinalysis done during a ROUTINE MEDICAL EXAMINATION. Treatment targets the underlying cause. In the circumstance of chronic kidney disease, monitoring the urine albumin level is one method for assessing the status of kidney function. The urologist may conduct further diagnostic procedures such as ULTRASOUND or kidney biopsy when the cause of the albuminuria is undetermined. Persistent albuminuria typically suggests progressive damage to the kidneys regardless of the underlying cause.

See also AMYLOIDOSIS; MINIMAL CHANGE DISEASE.

Alport's syndrome An inherited genetic disorder in which one, two, or three mutations occur in the GENE that encodes type IV collagen formations, also called basement membranes. The mutations affect up to three of the six protein chains (alpha-3, alpha-4, and alpha-5) that make up type IV collagen, which is a foundation for a number of structures in the body including the glomeruli in the KIDNEYS, COCHLEA in the inner EAR, LENS of the EYE, and alveoli in the LUNGS. Among the three variations of Alport's syndrome, two include damage to these other structures as well as to the kidneys. All variations of Alport's syndrome include kidney damage that manifests as chronic GLOMERULONEPHRITIS (INFLAMMATION of the glomeruli), resulting in progressive scarring and fibrosis of the glomeruli. The fibrotic tissue replaces healthy tissue, preventing normal glomerular function.

The most common inheritance pattern for Alport's syndrome is X-linked, which affects about 80 percent of those who have the disorder. The syndrome may also occur as an autosomal recessive pattern (15 percent) or an autosomal dominant pattern (5 percent). All types of Alport's syndrome eventually progress to END-STAGE RENAL DISEASE (ESRD) in nearly everyone who has the disorder, though the rate of progression is highly variable and differs among the three inheritance patterns for the syndrome.

Symptoms and Diagnostic Path

The most common symptom of Alport's syndrome is HEMATURIA (bloody URINE) that may appear in

early childhood, typically following an upper respiratory viral INFECTION such as a cold. As the damage to the kidneys progresses, symptoms expand to include ALBUMINURIA (excessive albumin or protein in the urine) and HYPERTENSION (high BLOOD PRESSURE). About 80 percent of those who have Alport's syndrome develop neurosensory HEARING LOSS by ADOLESCENCE, and 15 percent have irregularities in the shape of the lens of the eye (lenticonus).

Symptoms in combination with family history strongly suggest Alport's syndrome, though kidney biopsy is the definitive diagnostic tool. Kidney biopsy, in which the urologist extracts a core of kidney tissue using a large-gauge needle, allows the him or her to determine the absence of any of the three affected protein chains as well as to assess the degree of damage already present. SKIN biopsy can confirm X-linked Alport's syndrome because the skin in this type of the disorder lacks the alpha-5 protein chain.

Treatment Options and Outlook

Treatment is primarily supportive and targets symptoms such as hypertension, hearing loss, and VISION IMPAIRMENT. For people who reach ESRD, KIDNEY TRANSPLANTATION often offers a viable therapeutic course. With treatment, many people who have Alport's syndrome are able to enjoy the lifestyles of their choosing well into the fifth or sixth decade of life. The likelihood of RENAL FAILURE increases with age, however.

Risk Factors and Preventive Measures

Because Alport's syndrome is an inherited genetic disorder, the only risks for this condition are the causative gene mutations. There are no measures to prevent the condition. Early treatment for consequential health conditions and close medical monitoring of kidney function help maintain optimal health.

See also ALVEOLUS; GENETIC DISORDERS; GLOMERULUS; INHERITANCE PATTERNS; MUTATION; RENAL DIALYSIS.

anuria The failure to produce URINE. Numerous circumstances can result in anuria, from severe DEHYDRATION and severe HYPOTENSION (low BLOOD PRESSURE) to END-STAGE RENAL DISEASE (ESRD) and RENAL FAILURE. Anuria requires prompt medical evaluation to determine and remedy the underlying cause. Without such correction, waste byproducts accumulate to toxic levels and the body cannot continue to function.

azotemia See UREMIA.

B

bladder A muscular, saclike structure in the lower pelvis that serves as a reservoir for the URINE the KIDNEYS produce. In women the bladder is in front of and slightly below the UTERUS. During PREGNANCY the expanding uterus limits the bladder's ability to expand, accounting for the URINARY FREQUENCY common in pregnancy's last trimester. In men the bladder is in front of the RECTUM, with the PROSTATE GLAND encircling the first segment of the URETHRA as it exits the bladder. Swelling of the prostate gland, such as typically occurs with advancing age, as in BENIGN PROSTATIC HYPERPLASIA (BPH), can constrict the flow of urine through the urethra in a man, accounting for symptoms such as urinary frequency and dribbling.

Three layers of tissue form the bladder. The outermost and innermost layers are membranous, the outer being a continuation of the peritoneum that lines the abdominal cavity and the inner being mucous-secreting epithelium. The bladder's middle layer is smooth MUSCLE called the detrusor muscle that itself has three layers, the fibers of each running differently. The outer muscle fibers run longitudinally (lengthwise), the middle muscle fibers form patterns of circles that ultimately culminate in the sphincter muscle that encloses the bladder's neck, and the inner muscle fibers run laterally (crosswise). Together these muscle layers allow the bladder to expand to accommodate the urine draining from the kidneys and also to contract, in coordination with relaxation of the urethral sphincter, to expel urine from the bladder through the urethra.

The ureters drain urine from the kidneys into the bladder; the urethra drains urine from the bladder to the outside of the body. One URETER, a narrow tubelike structure, drops from each kidney and enters the back wall of the bladder near its midline. Urine drips continuously from the ureters into the bladder. The urethra, a somewhat muscular tube, carries urine from the bladder to outside the body. When empty the bladder is about the size of a large lemon; when filled to its capacity of about 500 milliliters (32 to 34 ounces) the bladder can reach the size of a small cantaloupe. As the bladder expands it extends upward into the abdominal cavity.

URINATION, the process of expelling urine from the bladder (also called micturition), is an involuntary function that becomes an action of learned control. NEURON sensors in the muscle fibers of the bladder wall send NERVE signals to the sacral portion of the SPINAL CORD. This activates the micturition REFLEX, which sends nerve signals via the spinal cord to micturition centers in the BRAIN. These centers activate nerve impulses that cause the urethral sphincter to relax and the detrusor muscle to begin a series of wavelike contractions. These involuntary actions create the urge to urinate, experienced as a sensation of pressure.

Learning to control the pubococcygeal muscle, which forms the floor of the pelvis, serves to override the micturition reflex for a period of time. Relaxing the pubococcygeal muscle and contracting the abdominal muscles synchronize with the involuntary responses of the micturition reflex, and urination occurs. Most children acquire the developmental ability, a blend of conscious effort and neuromuscular maturity, to learn to control urination (commonly called bladder control) between the ages of three and five. With advanced age this control may diminish, a consequence of a weakened urethral sphincter, neurologic conditions, and other factors.

For further discussion of the bladder within the context of the urinary system's structure and

function please see the overview section "The Urinary System."

HEALTH CONDITIONS THAT CAN AFFECT THE BLADDER	
BLADDER CANCER	BLADDER EXSTROPHY
CYSTINURIA	CYSTITIS
CYSTOCELE	NEUROGENIC BLADDER
pyelonephritis	SPINA BIFIDA
URINARY INCONTINENCE	URINARY RETENTION
URINARY TRACT INFECTION (UTI)	URINARY URGENCY
UROLITHIASIS	VESICOURETERAL REFLUX

See also AGING, URINARY SYSTEM CHANGES THAT OCCUR WITH; BLADDER CATHETERIZATION; CYSTOSCOPY; FECAL INCONTINENCE; KEGEL EXERCISES.

bladder cancer The growth of a malignant (cancerous) tumor in the BLADDER. Bladder CANCER may be primary or metastatic (travel to the bladder from a point of origin elsewhere in the body). Doctors diagnose bladder cancer in about 55,000 Americans each year. Bladder cancer is about three times more common in men, and in the United States is the fourth most common cancer among men. Bladder cancer claims about 12,000 lives in the United States each year. The likelihood of developing bladder cancer increases with age.

Cigarette smoking causes about 50 percent of bladder cancers, and exposure to industrial chemicals accounts for another 25 to 30 percent. Among the chemicals known to cause bladder cancer are the aromatic amines: aniline, benzidine, chlornaphazine, methylene dianiline, naphthylamine, and xenylamine. Numerous industries use these chemicals. Tobacco smoke, too, contains aromatic amines.

There are several types of bladder cancers though in the United States one type, transitional-cell CARCINOMA (TCC), accounts for more than 90 percent of bladder cancers. TCC arises from the epithelial (also called urothelial) cells that form the innermost layer of the bladder's structure and typically undergo a series of predictable cell structure changes before becoming malignant. Other types of bladder cancer are relatively rare and include squamous cell carcinoma, small-cell carcinoma, LYMPHOMA, ADENOCARCINOMA, leiomyosarcoma, and metastatic malignant melanoma. Treatment options and outlook differ among the types of cancer.

Symptoms and Diagnostic Path

Painless HEMATURIA (bloody URINE) is often the earliest indication of bladder cancer. The hematuria may be gross, meaning there is enough BLOOD present to discolor the URINE, or microscopic, detected through urinalysis. Symptoms and signs of bladder cancer may include

- pink, red, or dark brown urine (hematuria)
- DYSURIA (discomfort when urinating)
- URINARY FREQUENCY
- URINARY URGENCY
- sensation of incomplete emptying of the bladder with URINATION

The diagnostic path begins with a standard urinalysis as well as specific urine tests to measure antigens and proteins present in the urine with TCC. These tests include

- NMP22 BladderChek, which detects the presence of nuclear matrix protein (NMP) 22
- BTA-Stat, which detects the presence of bladder tumor antigen (BTA)
- fibrin degradation products (FDPs), which detects the breakdown of blood clots

Further diagnostic procedures include CYSTOSCOPY, INTRAVENOUS PYELOGRAM (IVP), or COMPUTED TOMOGRAPHY (CT) SCAN to visualize the bladder and urethra to detect tumors, and biopsy (which the urologist typically does during cystoscopy) of identified tumors or suspicious tissue. Biopsy provides the conclusive diagnosis, allowing the pathologist to identify the type of cancer and degree to which it has spread (staging and grading).

Treatment Options and Outlook

The cancer's type and stage determine treatment options and outlook. Doctors diagnose about 70 percent of TCC in its early stages, when the tumor is small and remains confined to a localized region of the epithelium. These tumors, designated as superficial or stage 0, are highly treatable with minimally invasive therapies that generally preserve the bladder and normal urinary functions. These therapies may include

STAGING OF BLADDER CANCER (TCC)

Stage	Extent of Cancer	Treatment Protocols/Options
0	cancer cells are in a single localized area in the the superficial cells of the urothelium (epithelial cells that form the lining of the BLADDER) also called carcinoma in situ (CIS)	one or a combination of • transurethral resection (TUR) with fulguration (cystoscopic removal of the tumor and electrocautery to the adjacent tissue) • intravesical BCG (bacillus Calmette-Guérin instilled into the bladder via urethral catheter) • intravesical chemotherapy (chemotherapy instilled into the bladder via urethral catheter) • photodynamic therapy
1	tumor remains confined to the urothelium	TUR with fulguration *or* segmental cystectomy (partial removal of the bladder) in combination with one or more adjunctive therapies: • intravesical BCG • intravesical CHEMOTHERAPY • radioactive seeding (implantation of radioactive pellets) • systemic chemotherapy
2	tumor extends into but not beyond the detrusor MUSCLE	radical cystectomy (removal of bladder and surrounding organs and tissues in combination with one or more adjunctive therapies: • RADIATION THERAPY • radioactive seeding • chemotherapy urinary diversion (urostomy, reservoir)
3	tumor extends beyond the bladder wall to surrounding tissue tumor may invade the PROSTATE GLAND (men) or CERVIX, UTERUS, VAGINA, or OVARIES (women)	preoperative chemotherapy radical cystectomy (including removal of lymph nodes and any other organs to which the cancer has spread) urinary diversion postoperative radiation therapy, chemotherapy, or both
4	tumor extends into the structures of the pelvis and abdomen tumor may extend into adjacent lymph nodes metastatic cancer may appear in sites distant from the bladder	preoperative chemotherapy radical cystectomy (including removal of lymph nodes and any other organs or structures to which the cancer has spread) urinary diversion postoperative chemotherapy, radiation therapy, or both alternatively, palliative radiation therapy to shrink the tumors and relieve symptoms
Recurrent	tumor comes back after treatment tumor may recur in the bladder or appear elsewhere in the urinary tract or distant from the bladder	surgery, chemotherapy, radiation therapy or a combination, depending on the cancer's location and previous treatments

- transurethral resection (TUR) with fulguration, a bladder-sparing treatment in which the urologist removes the tumor via cystoscopy and uses electrocautery to burn an area of surrounding tissue to kill any stray cancer cells
- intravesical BCC, in which the urologist instills a solution of bacillus Calmette-Guérin (BCC) to stimulate an IMMUNE RESPONSE that targets any residual cancer cells or isolated cancer cells elsewhere in the urothelium
- intravesical CHEMOTHERAPY, in which the urologist instills chemotherapy drugs into the bladder to target residual cancer cells topically
- photodynamic therapy, in which the person takes a chemical the cancer cells absorb that makes them extraordinarily sensitive to certain frequencies of light

Cancer that spreads into the urothelium or beyond requires more aggressive treatment, typically surgery to remove the tumor and surrounding tissue in combination with chemotherapy, RADIATION THERAPY, or both, and sometimes other therapies such as photodynamic therapy and intravesical BCC. In a segmental cystectomy the urologist removes part of the bladder; in a radical cystectomy the urologist removes all the bladder along with adjacent structures and organs, depending on the extent of the cancer. Segmental cystectomy usually preserves enough of the bladder to retain function and urinary continence.

Radical cystectomy requires further surgery to construct URINARY DIVERSION such as a urostomy, which drains urine continuously into a bag worn attached to the outside of the body, or an internal pouch structured from a loop of intestine that collects urine. With the pouch method, the urologist may be able to fashion a reservoir that collects the urine from the kidneys, and attach it to the urethra for normal continence and urination. When this is not possible or practical, the urologist may be able to construct an opening (stoma) into which the person inserts a catheter to regularly drain urine that collects in the reservoir.

Many of the treatment options for bladder cancer entail significant lifestyle changes. Radical cystectomy and radiation therapy often result in ERECTILE DYSFUNCTION in men, inability to have vaginal intercourse in women, and sterility in men and women. It is important to fully understand the potential side effects, complications, and QUALITY OF LIFE implications of the various treatment options when making treatment decisions and to obtain a second opinion consultation. Research is ongoing for new therapies, and some people may benefit from participating in clinical trials.

Risk Factors and Preventive Measures

Bladder cancer is very rare in people under age 40. Cigarette smoking and occupational exposure to aromatic amines are the leading causes of bladder cancer, and health experts believe both to be preventable. It appears the highest risk of bladder cancer associated with cigarette smoking is for people who have smoked for several decades. The risk for bladder cancer appears to remain elevated even after stopping smoking. Some health experts believe current and former smokers should have annual urinalysis and urine cytology tests such as NMP22 BladderChek beginning at age 60.

Though exposure-related bladder cancer takes years to decades to develop, researchers believe even brief, limited exposure to aromatic amines may be sufficient to cause damage to the cells of the bladder that later results in bladder cancer. Most people who develop exposure-related bladder cancer have had long-term exposure to aromatic amines, however. Exposure-related bladder cancer generally develops over 15 to 20 years from the time of exposure, though can emerge up to 40 or 50 years later. Strict federal regulations limiting occupational exposure to known carcinogens such as aromatic amines have reduced risk somewhat over the past several decades, though the use of these chemicals remains so pervasive across numerous industries that exposure remains second only to cigarette smoking as a risk factor for bladder cancer.

OCCUPATIONS WITH HIGH AROMATIC AMINES EXPOSURE

chemical manufacturing	hairdresser
leatherworker	machinist
metalworker	painter
printer	rubber manufacturing
textile worker	

Certain treatments for other cancer may raise the risk for bladder cancer. These include radiation therapy to the pelvic region, notably women who received such treatment for ENDOMETRIAL CANCER or CERVICAL CANCER or men for PROSTATE CANCER, and chemotherapy with cyclophosphamide or ifosfamide. People who have had such treatments should receive ROUTINE MEDICAL EXAMINATION with urinalysis and diagnostic procedures as doctor recommended for early detection of bladder cancer.

See also CANCER TREATMENT OPTIONS AND DECISIONS; LYMPH NODE; METASTASIS; SKIN CANCER; STAGING AND GRADING OF CANCER; SURGERY BENEFIT AND RISK ASSESSMENT.

bladder catheterization The insertion of a narrow, flexible tube into the BLADDER through the URETHRA to drain URINE from the body. Bladder catheterization may be necessary to collect an uncontaminated (sterile) urine sample or to drain urine from the bladder. The catheter placement may be short term, such as after surgery or during serious illness, or long term, such as when STROKE, PARALYSIS, or other condition results in loss of bladder control (complete URINARY INCONTINENCE).

Long-term catheterization may be intermittent, in which the caregiver periodically inserts the catheter to drain collected urine and then removes the catheter, or indwelling (often called a Foley catheter), in which the catheter remains tethered in the bladder (a small inflatable balloon at the tip of the catheter keeps the catheter from sliding out of the urethra). An indwelling catheter drains into a collection bag which the person or caregiver empties frequently and regularly. A caregiver must replace an indwelling catheter every four to six weeks for hygienic reasons. Many people who have indwelling catheters or who use long-term intermittent catheterization take ANTIBIOTIC PROPHYLAXIS to prevent URINARY TRACT INFECTION (UTI). Bladder catheterization greatly increases the risk for UTI. Proper hygiene is essential when inserting and removing a bladder catheter and when an indwelling catheter is in place.

See also CYSTITIS; SPINAL CORD INJURY; TRAUMATIC BRAIN INJURY (TBI).

bladder exstrophy An uncommon CONGENITAL ANOMALY in which the structures of the lower pelvis fail to form properly. As a consequence, the BLADDER protrudes outside the body and may be open or inverted. The URETHRA often fails to close as well. Bladder exstrophy is a random birth defect and is not a hereditary birth defect. About 100 infants are born with bladder exstrophy, which varies widely in severity, each year in the United States.

Treatment in most cases is surgery within several days of birth to reconstruct and reposition the bladder, urethra, symphysis pubis, and other pelvic structures. Most children born with bladder exstrophy require follow-up operations through early childhood and perhaps at PUBERTY when secondary sex characteristics alter the appearance and function of the GENITALIA. However, even with surgical repair or reconstruction the urethral sphincter muscle at the neck of the bladder may not function properly, resulting in incomplete control over the flow of URINE. This URINARY INCONTINENCE may remain throughout life, though there are medical therapies and lifestyle methods to manage the condition. VESICOURETERAL REFLUX, in which urine flows (refluxes) from the bladder back up the ureters, is also common.

Appropriate reconstructive surgery maintains FERTILITY. Men may experience RETROGRADE EJACULATION, in which SPERM travel inward through the urethra and into the bladder during ejaculation rather than outward through the urethra to exit the PENIS. In such a circumstance a fertility expert can retrieve the sperm and place them into the woman to achieve fertilization. Women born with bladder exstrophy generally are able to carry PREGNANCY to term and deliver vaginally as long as the circumstances of the pregnancy permit.

See also BIRTH DEFECTS; EPISPADIAS.

bladder stone See UROLITHIASIS.

C–D

cystinuria An inherited genetic disorder in which the KIDNEYS do not properly reabsorb amino acids collectively called cystine. The excessive excretion of cystine to the URINE causes crystalline calcifications, commonly called stones, to form in the kidneys, ureters, and BLADDER. Most people learn they have the GENE MUTATION, which is autosomal recessive, during analysis of the calcifications. Doctors have known of cystine calcifications in the bladder since the early 1800s. Researchers identified cystinuria as hereditary in the early 1900s and discovered the first effective medication to reduce the formation of cystine calcifications, penicillamine, in the early 1960s. In the late 1990s researchers identified the mutated genes as SLC3A1 on CHROMOSOME 2 and SLC7A9 on chromosome 19.

Pain in the side or back, often on only one side, is the typical symptom of an occlusive (blocking) calcification. The urine may also smell of sulfur (rotten eggs) The diagnostic path may include ULTRASOUND, COMPUTED TOMOGRAPHY (CT) SCAN, or MAGNETIC RESONANCE IMAGING (MRI) of the abdomen to visualize the calcifications. Laboratory analysis of fragments filtered from the urine identifies their composition as cystine, confirming the diagnosis. Most of the time the stones pass on their own, though the process often is painful. Doctors usually prescribe ANALGESIC MEDICATIONS for PAIN relief during the time a stone is passing. Occasionally treatments such as EXTRACORPOREAL SHOCK WAVE LITHOTRIPSY (ESWL), which uses high-frequency sound waves to break the calcification into fragments, or surgery (percutaneous nephrolithotomy) are necessary to remove an obstructive and impacted stone.

Because there are as yet no treatments to correct the gene mutation, the cystine calcifications recur throughout life. Penicillamine, which binds with cystine in the urine to form a compound that easily dissolves in water, remains the medication urologists most often prescribe to reduce the formation of stones. The urologist may also prescribe medications to increase the alkalinity of the urine, such as potassium citrate, which helps dissolve cystine. It is important for people who have cystinuria to drink enough water to maintain good urine output, which dilutes the concentration of cystine and pass it from the body before it forms calcifications. Other lifestyle modifications include decreasing dietary sodium and protein consumption (protein is the source of the cystine).

See also ENDOSCOPY; FANCONI'S SYNDROME; GENE THERAPY; HYPEROXALURIA; INHERITANCE PATTERNS; NEPHROLITHIASIS; SURGERY BENEFIT AND RISK ASSESSMENT; UROLITHIASIS.

cystitis INFLAMMATION of the BLADDER. The most common cause of cystitis is bacterial INFECTION, called URINARY TRACT INFECTION (UTI). Other pathogens, such as fungi (yeasts) and viruses, also can cause infectious cystitis. Nonpathogenic causes of cystitis include irritation of the lining of the bladder, which may occur with excessive consumption of irritating substances such as CAFFEINE, high-acid foods, or certain medications. Cigarette smoking is a significant bladder irritant. RADIATION THERAPY, CHEMOTHERAPY, and AUTOIMMUNE DISORDERS also may cause cystitis. Interstitial cystitis is a chronic condition the hallmark of which is inflammation of the bladder along with a constellation of symptoms for which there are no clearly identifiable causes.

Symptoms and Diagnostic Path

The symptoms of cystitis may include

- DYSURIA (burning or PAIN with URINATION)

- HEMATURIA (bloody URINE)
- URINARY URGENCY
- URINARY FREQUENCY, including NOCTURIA (the need to urinate at night)
- cloudy, foul-smelling, or discolored urine
- pain in the lower abdomen
- pain with SEXUAL INTERCOURSE

The diagnostic path begins with urinalysis, which often shows whether BACTERIA or other pathogens are present in the urine. *Escherichia coli* is the most commonly the culprit for infectious cystitis (UTI). *Chlamydia* and herpes simplex viruses (HSV-1 and HSV-2) are also common causes of UTIs. The urologist may choose further diagnostic procedures such as CYSTOSCOPY or abdominal ULTRASOUND to rule out causes such as tumors or stones (UROLITHIASIS). Cystoscopy allows the urologist to assess bladder capacity, an important factor in determining a diagnosis of interstitial cystitis as reduced bladder capacity is a characteristic of this condition. The current standard of diagnosis for interstitial cystitis further requires the presence of key symptoms over a period of time as well as the exclusion of other causes for the symptoms.

Treatment Options and Outlook

UTIs require therapy with the appropriate medications, such as ANTIBIOTIC MEDICATIONS for bacterial infections or ANTIFUNGAL MEDICATIONS for yeast-based infections. The symptoms of infectious cystitis generally subside within a few days of beginning treatment, and the infection clears with the full course of medication. The oral medication phenazopyridine (Pyridium) acts as a topical anesthetic to block pain signals from the lining of the bladder, easing dysuria until the medication affects the infection. It is essential to take prescribed medications as the doctor directs and to take medications to treat infections until the medication is gone (the full course of treatment) even after symptoms improve. Undertreated or untreated UTIs can migrate from the bladder to the KIDNEYS, where they can cause serious illness and sometimes permanent damage to the kidneys.

Treatment for autoimmune cystitis targets the IMMUNE SYSTEM with ANTIHISTAMINE MEDICATIONS, IMMUNOSUPPRESSIVE MEDICATIONS, and other approaches that aim to block the inflammatory response. Irritation cystitis often resolves with a combination of increased fluid consumption and ending the cause of the irritation, when possible. Common culprits include coffee, tea, carbonated beverages, citrus fruits and juices, tomatoes and tomato products, chocolate, ALCOHOL, and pickled or smoked foods.

Interstitial cystitis is difficult to treat. People respond differently to treatment regimens, and sometimes a successful treatment becomes ineffective. Urologists may prescribe various kinds of medications to relieve symptoms such as tricyclic ANTIDEPRESSANT MEDICATIONS (which appear to suppress certain pain response mechanisms), NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS), and antihistamines. The medication pentosan (Elmiron) is the only oral medication specifically for interstitial cystitis, though women who are pregnant cannot take it. Pentosan also takes up to six months to provide relief and may cause temporary HAIR loss. Other treatments include intravesical therapies in which the urologist instills medications directly into the bladder via urethral catheterization. Bladder distention under ANESTHESIA (via cystoscopy) provides long-term though temporary relief for some people.

FOODS AND DRINKS THAT CAN IRRITATE THE BLADDER

beer	cantaloupe
chocolate	chocolate-covered espresso beans
coffee	cranberries and cranberry juice
cola beverages	onions
lemons and lemonade	peanuts and peanut butter
mixed ALCOHOLIC drinks	pineapple
oranges and orange juice	tomatoes and tomato juice
peppers (sweet or hot)	wine (white or red)
tea (hot or iced)	
vinegar and dressings with vinegar	

Risk Factors and Preventive Measures

Women are more likely to develop infectious cystitis and interstitial cystitis, primarily because a woman's shorter URETHRA allows easier access for pathogens. Diligent personal hygiene, including urination soon after sexual intercourse and wiping toilet tissue from front to back, helps reduce exposure to bacteria. Doctors are unsure why intersti-

tial cystitis occurs more often in women. However, doctors do not know what causes interstitial cystitis, either. Finding the cause will likely shed light on all dimensions of this chronic and disruptive condition.

See also BLADDER CATHETERIZATION; NEPHRITIS.

cystocele A hernialike condition in which a woman's BLADDER bulges into her VAGINA. Cystocele is more common after MENOPAUSE and in women who have given birth vaginally. It occurs as a consequence of weakened vaginal and pelvic muscles and ligaments that allow the supportive structures for the bladder to relax and the bladder itself to drop. Doctors believe the prime culprit is the intense straining that occurs during vaginal birth, which weakens muscles, coupled with changes in the elasticity of MUSCLE tissue that take place when levels of ESTROGENS drop in a woman's body with menopause.

The symptoms of cystocele may include the sensation of vaginal pressure, difficulty urinating, or URINARY RETENTION. Chronic URINARY TRACT INFECTION (UTI) may also occur, especially when the extent of the cystocele is such that residual URINE remains in the bladder after URINATION. The doctor can usually diagnose cystocele via vaginal palpation during a PELVIC EXAMINATION, as the sagging bladder causes the vaginal wall to bulge inward. When the diagnosis or the extent of the cystocele is uncertain the doctor may conduct a voiding CYSTOURETHROGRAM to determine whether the bladder fully empties with urination.

Mild cystocele that causes no symptoms may require only watchful waiting. The urologist or gynecologist may also recommend a pessary, a device placed within the vagina that gives added support to the vaginal wall. Surgical repair is the treatment of choice for cystocele that interferes with urination, particularly when such interference causes chronic UTI. The surgery tightens the ligaments and muscles of the pelvic floor, restoring support for the bladder. Open surgery requires six to eight weeks for full recovery. Often the surgeon can do the repair laparoscopically, reducing recovery time to two to three weeks.

See also HYDROCELE; KEGEL EXERCISES; MINIMALLY INVASIVE SURGERY; RECTOCELE; SPERMATOCELE; SURGERY BENEFIT AND RISK ASSESSMENT; VARICOCELE.

cystoscopy An endoscopic procedure for visualizing the interior of the BLADDER. The cystoscope is a narrow tube with a tiny light and camera on the tip. Cystoscopy requires no preparation or recovery time and takes place in an outpatient surgery setting under sterile procedures. The urologist anesthetizes the URETHRA, then inserts the cystoscope through the urethra and into the bladder, visualizing the progress on a closed-circuit television monitor. Some people find the insertion mildly uncomfortable. The urologist then injects saline through the cystoscope to fill the bladder, which may create the urge to urinate. However, the bladder must be full to distend its walls for complete examination. Cystoscopy takes 10 to 20 minutes.

Cystoscopy allows the urologist to visualize the interior of the bladder to examine it for signs of INFLAMMATION or tumors (BLADDER CANCER). The urologist can use cystoscopy to biopsy suspicious findings, remove bladder stones, and administer medications such as antibiotics or anti-inflammatory drugs. Cystoscopy also allows the urologist to evaluate BENIGN PROSTATIC HYPERPLASIA (BPH) in men. Some people experience HEMATURIA (BLOOD in the urine) and discomfort or burning (DYSURIA) with URINATION for a day or two after cystoscopy, a consequence of the cystoscope irritating the urethral tissues. The urologist should evaluate dysuria or hematuria that continues beyond two days as this may indicate a URINARY TRACT INFECTION (UTI) requiring ANTIBIOTIC MEDICATIONS; the cystoscope may carry BACTERIA from the SKIN's surface into the urethra and bladder.

See also ENDOSCOPY; UROLITHIASIS.

cystourethrogram A diagnostic imaging procedure that shows the flow of URINE from the BLADDER through the URETHRA. The radiologist instills a radio-opaque solution (contrast medium) into the bladder through a catheter, then takes a series of X-rays as the solution fills the bladder and urethra. The radio-opaque solution makes these soft tissue structures visible on X-RAY. In a voiding cystourethrogram, the radiologist takes additional X-rays with the person urinating, to visualize the entire flow of urine.

Cystourethrogram shows structural abnormalities, such as narrowing or stricture, of the urethra

and functional problems, such as VESICOURETERAL REFLUX (a condition in which urine flows back into the ureters from the bladder). The procedure requires no preparation or recovery and takes about 20 minutes to complete. Some people experience discomfort during the instillation of the contrast medium because it creates the pressure of a full bladder. Minor discomfort or burning may occur with URINATION for a day or two after the procedure.

See also BENIGN PROSTATIC HYPERPLASIA (BPH); BLADDER CATHETERIZATION; CYSTOSCOPY; URETER; URETHRAL STRICTURE.

dialysis See RENAL DIALYSIS.

dysuria PAIN, discomfort, or burning with URINATION. Dysuria may be primarily external (occur with the passing of URINE through the URETHRA) or internal (felt as discomfort, pressure, or pain within the lower pelvis). Dysuria is most commonly a symptom of CYSTITIS (INFLAMMATION or INFECTION of the BLADDER and urethra), though it occurs as a symptom of numerous conditions involving the genitourinary tract. The diagnostic path begins with urinalysis and may include other diagnostic procedures, depending on the full spectrum of symptoms and the findings of the urinalysis. Treatment targets the identified causative condition.

CONDITIONS FOR WHICH DYSURIA IS A COMMON SYMPTOM

BENIGN PROSTATIC HYPERPLASIA (BPH)	CHLAMYDIA
CYSTITIS	EPIDIDYMITIS
GONORRHEA	NEUROGENIC BLADDER
PELVIC INFLAMMATORY DISEASE (PID)	PROSTATITIS
pyelonephritis	sexual trauma
TRICHOMONIASIS	URETHRITIS
URINARY TRACT INFECTION (UTI)	UROLITHIASIS
VAGINITIS	

See also ANURIA; ENURESIS; HEMATURIA; NOCTURIA; OLIGURIA; URINARY INCONTINENCE; UROLITHIASIS.

end-stage renal disease (ESRD) A condition of permanent RENAL FAILURE in which the KIDNEYS can no longer function to filter wastes from the BLOOD. People who have ESRD require ongoing RENAL DIALYSIS and may be appropriate candidates for KIDNEY TRANSPLANTATION. DIABETES, HYPERTENSION (high BLOOD PRESSURE), and GLOMERULONEPHRITIS are the most common causes of ESRD in the United States. About 300,000 Americans live with ESRD, about 15,000 of whom undergo kidney transplantation each year. ESRD typically follows a period of chronic renal failure that extends for years to several decades. More than 40 percent of Americans who have ESRD are between the ages of 45 to 64.

About a third of people who have ESRD survive five years on renal dialysis, whereas 80 to 90 percent who receive transplanted kidneys live five years after the transplant operation, the five-year marker being a key assessment point for the success of treatment. The waiting list for a cadaver donor kidney (a kidney donated after a person's death) varies widely because donors and recipients must match, and it can be two or three years before one receives a kidney because the supply of donor organs is so limited. An increasingly popular option is living donor transplantation, in which a person (often a family member) who provides a close match for BLOOD TYPE and blood antigens and has two healthy kidneys donates one kidney for transplantation into the person who has ESRD. Each year in the United States nearly 80,000 people die from ESRD.

The U.S. federal government's health-care program for older Americans, Medicare, extends coverage to those of any age who have ESRD. Medicare covers many though not all the costs of renal dialysis and kidney transplantation. Private health insurance and state-funded programs may provide further benefits for those who qualify.

See also MEDICARE COVERAGE FOR PERMANENT RENAL FAILURE; ORGAN TRANSPLANTATION; SURGERY BENEFIT AND RISK ASSESSMENT.

enuresis An inability to hold the URINE, particularly at night (nocturnal enuresis). A common term for enuresis is bedwetting. Enuresis is primarily a condition of childhood though may persist into adulthood, depending on the cause and treatment efforts. About 85 percent of children are developmentally mature enough to master voluntary control of the bladder sphincter between the ages of 3 and 6. Generally enuresis that persists beyond the age of 12 is either secondary to other physical conditions or psychological in origin. Enuresis is more common among boys.

Conditions commonly associated with enuresis include CYSTITIS, NEUROGENIC BLADDER, and urethral obstruction such as CONGENITAL ANOMALY or obstructive calcifications. Occasionally the cause is damage to the lower SPINAL CORD or to the SPINAL NERVES that control BLADDER function. In teens or adults who develop enuresis, the enuresis may be an early sign of DIABETES or indicate other health conditions such as OBSTRUCTIVE SLEEP APNEA (which disrupts the body's normal sleep rhythms), SEIZURE DISORDERS, or HYPERTHYROIDISM (overactive THYROID GLAND). Obstructive sleep apnea may also be a factor in children between the ages of two and five who have enlarged adenoids, which is a common circumstance among this age group, that block the back of the throat when lying down. Research in the late 1990s suggests some people who have enuresis experience dysfunction of the neurologic interactions that regulate the depth of sleep and initiate sleep arousal.

In some children the causes of enuresis are primarily behavioral, such as ignoring the urge to urinate until it becomes overwhelming, not emptying the bladder immediately before going to bed, or drinking large quantities of fluids throughout the day and especially in the three to four hours preceding bedtime. Generally these behaviors are easy for parents to modify through positive reinforcement and diligent monitoring of the child's drinking and URINATION patterns. Psychological enuresis typically occurs due to profound emotional distress and is not the result of conscious behavior.

Enuresis becomes a significant embarrassment to most who have it after they reach about the age of 8 to 10 and especially for teens and adults. Children may refuse to spend the night with friends or have friends spend the night with them and may avoid overnight activities such as camping or vacationing in motels. Their refusal may be overt or they may express unreasonable fears.

Symptoms and Diagnostic Path

The symptom of enuresis is inappropriate urination, often during naps or when sleeping at night, but it may occur any time. The diagnostic path consists of a careful history of eating, drinking, urination, and bowel habits as well as patterns of enuresis (such as all the time or only during sleep). The urologist may conduct diagnostic procedures such as urinalysis, ULTRASOUND of the bladder, voiding CYSTOURETHROGRAM, or CYSTOSCOPY, depending on the suspected underlying cause. In most situations in which the urinalysis is normal, however, the urologist delays extensive diagnostic procedures until after a trial of basic treatment and behavioral interventions.

Treatment Options and Outlook

Treatment may combine medical interventions with behavioral approaches such as limiting fluids in the evening and fully emptying the bladder right before going to bed. Enuresis alarms (moisture-sensitive devices) are especially effective for children. Medication therapy may include desmopressin (DDAVP), which decreases urine production, or oxybutynin (Ditropan) or tolterodine (Detrol), medications that slow smooth muscle stimulation.

Risk Factors and Preventive Measures

Nocturnal enuresis appears to run in some families, though researchers are not sure what accounts for this. The key risk factors for enuresis are organic causes such as congenital anomalies or physiologic dysfunctions and severe emotional stress. Health experts stress that neither punishment nor the so-called bladder training method (holding a full bladder for a determined amount of time, ostensibly to strengthen sphincter control) is effective in ending enuresis. These approaches fail to address the causes of enuresis, result in further embarrassment and discomfort, and may exacerbate the underlying cause of the enuresis. Time, patience, and positive reinforcement (such as praise and small rewards) as well as appropriately addressing any physiologic dysfunctions, result in ending enuresis about 98 percent of people.

See also ANURIA; CONGENITAL ANOMALY; DYSURIA; HEMATURIA; NEURAL TUBE DEFECTS; NOCTURIA; OLIGURIA; SLEEP DISORDERS; URINARY INCONTINENCE; URINARY URGENCY.

epispadias A random CONGENITAL ANOMALY in which the URETHRA forms incorrectly. Epispadias often occurs as an element within a constellation of congenital malformations involving the pelvic structures (including the pelvic bones) and the GENITALIA.

In boys the urethra may exit the PENIS other than at the tip or appear as an open channel that runs the length of the PENIS, and often occurs in conjunction with CHORDEE (a deformity in which the penis curves sharply). In girls the urethra may exit anywhere between the neck of the BLADDER and the upper labial fold, and typically occurs in conjunction with genital deformities such as bifid (two-fold or split) CLITORIS and abnormalities of the VULVA.

Epispadias is rare in either sex though much more so in girls, and typically apparent at birth. Early surgery is the preferred means to correct the defects, which preserves FERTILITY and sexual function, restores the genitalia to normal appearance, and helps establish urinary continence (the ability to control the flow of URINE). Prenatal ULTRASOUND sometimes can detect epispadias before birth. There are no measures to prevent epispadias.

See also BIRTH DEFECTS; BLADDER EXSTROPHY; HYPOSPADIAS; PRENATAL CARE.

extracorporeal shock wave lithotripsy (ESWL) A therapeutic procedure in which a machine called a lithotriptor generates shock waves that cause calcifications within the urinary tract, commonly called kidney stones (NEPHROLITHIASIS) or bladder stones (UROLITHIASIS), to break apart into smaller fragments the URINE can carry out of the body. Lithotripsy became available in 1980 and has evolved into the current treatment of choice for stones smaller than 2 centimeters (about 0.75 inch) in diameter that form in the KIDNEYS, URETER, and BLADDER. ESWL is sometimes effective for gallstones (cholelithiasis) as well. Today there are several types of lithotriptors, each of which uses a different energy source though all apply the same basic approach which is to focus a pulse of intense energy (the shock wave) at the stone.

Women who are or could be pregnant should not undergo ESWL.

Typically preparation requires having nothing to eat or drink for six hours before the scheduled time of the procedure. The urologist or nephrologist may recommend stopping routine use of NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS), aspirin, and anticoagulation medications for 7 to 10 days before the scheduled ESWL to reduce the risk of bleeding during or after the procedure, as these medications interfere with PLATELET AGGREGATION and prolong the length of time a BLOOD clot takes to form. ESWL takes about an hour to perform, with about two hours in the recovery room afterward. The person undergoing ESWL treatment will need someone to take him or her to and from the treatment center.

Procedure

The urologist or radiologist generally gives the person an anesthetic or sedative for comfort before the ESWL begins. The pressure of the shock waves coming in contact with the stones can be uncomfortable. The lithotriptor integrates FLUOROSCOPY or ULTRASOUND to pinpoint the location of the targeted stone and can target several stones in one ESWL session. The person wears a hospital gown and lies on a cushioned table. The ESWL technician positions the lithotriptor over the person to deliver the shock waves, with continual monitoring and adjustment to maintain accurate focus. The radiologist or urologist makes sure the person has adequate ANESTHESIA or SEDATION to remain comfortable for the duration of the procedure.

Risks and Complications

The most common risk associated with ESWL is bleeding from the tissues around the site of the stone, resulting in HEMATURIA (bloody urine) and some discomfort. Many people experience discomfort for up to several days after the ESWL, for which the urologist prescribes ANALGESIC MEDICATIONS (pain relief). Most people should plan on taking it easy for a few days after ESWL. It may take days to weeks for all of the fragments to pass, and larger fragments may cause pain when they pass. Sometimes fragments of the stone cluster in the ureter or URETHRA, temporarily blocking the flow of urine and causing considerable PAIN. Generally movement (such as walking) and drinking lots of fluids help flush these clusters from the body, with appropriate analgesic medication to mitigate the pain. Some people require several ESWL sessions to completely disperse all of the stones and fragments.

Outlook and Lifestyle Modifications

Once the stone breaks apart and the fragments pass from the body in the urine, no further treatment for the stone is necessary. The urologist or nephrologist may recommend dietary changes, increased physical activity, increased water consumption, and sometimes medications to help prevent new stones from forming. Such factors depend on the stone's content and the person's medical history, including other health conditions. Both kidney stones and bladder stones tend to recur.

See also CYSTINURIA; GALLBLADDER DISEASE; SURGERY BENEFIT AND RISK ASSESSMENT.

Fanconi's syndrome A dysfunction of the KIDNEYS in which the renal tubules do not function properly, resulting in a constellation of diverse symptoms. The renal tubule, a structure of the kidney's filtering mechanism within the NEPHRON, filters many substances from the BLOOD to retain those the body needs and excrete those the body

does not need. In Fanconi's syndrome, the renal tubule excretes into the URINE numerous vital substances it should retain in the blood. Among these substances are GLUCOSE, uric acid, calcium, magnesium, potassium, phosphate, and amino acids. The renal tubule also excretes excessive water into the urine.

Numerous GENETIC DISORDERS cause Fanconi's syndrome. Among the most common are metabolic conditions that affect the body's ability to use or store substances such as cystine, glycogen, fructose, and tyrosine. HEAVY-METAL POISONING, such as from lead or mercury, and DRUG toxicity account for most acquired Fanconi's syndrome. Conditions such as AMYLOIDOSIS, in which protein deposits accumulate in organs such as the kidneys, also can damage the renal tubules to cause Fanconi's syndrome. The syndrome occasionally develops in people who undergo KIDNEY TRANSPLANTATION.

Equally numerous symptoms can suggest Fanconi's syndrome and may appear initially to be unrelated. In children the most common symptoms are stunted growth, BONE deformities similar to those which occur in RICKETS, and MUSCLE weakness. In adults, the most common symptoms are spontaneous FRACTURE, electrolyte imbalance, and serum acidosis (increased acidity of the blood). General symptoms sometimes present in children or adults include excessive thirst and URINATION, CONSTIPATION, and DEHYDRATION. Blood and urine tests identify the depletions and excesses of the substances the renal tubules are failing to reabsorb.

Treatment targets the underlying cause when doctors can identify it and the resulting conditions when the underlying cause remains unknown (idiopathic Fanconi's syndrome). Doctors can treat many genetic disorders of METABOLISM from early childhood, forestalling or preventing complications such as Fanconi's syndrome. With appropriate treatment kidney function can return to normal. Untreated Fanconi's syndrome can progress to END-STAGE RENAL DISEASE (ESRD), requiring long-term RENAL DIALYSIS or kidney transplantation.

glomerulonephritis INFLAMMATION of the glomeruli within the nephrons of the KIDNEYS. The glomerulus is the coiled capillary network through which BLOOD circulates for filtration. Glomerulonephritis, also called glomerular disease, may be acute (come on suddenly) or chronic (develop slowly over time). Acute glomerulonephritis is often a temporary condition that improves with treatment and causes minimal or no residual damage to the glomeruli. Chronic glomerulonephritis tends to be progressive, eventually deteriorating to RENAL FAILURE and END-STAGE RENAL DISEASE (ESRD). INFECTION, AUTOIMMUNE DISORDERS, NEPHROPATHY of DIABETES, and nephropathy of HYPERTENSION (high BLOOD PRESSURE) are the most common identified causes of glomerulonephritis. As often as not, however, the nephrologist cannot determine the cause and focuses instead on treatment.

Symptoms and Diagnostic Path

The symptoms of glomerulonephritis may be minimal and difficult to detect or obvious and debilitating, depending on whether the condition is chronic or acute. Common symptoms of glomerulonephritis include

- fatigue
- edema (swelling or puffiness) of the face, hands and wrists, and feet and ankles
- discolored URINE (commonly described as tea-colored or cola-colored)
- hypertension
- foamy urine (ALBUMINURIA)

The diagnostic path begins with urinalysis, which typically reveals HEMATURIA (blood in the urine) and albuminuria (excessive ALBUMIN, or protein, in the urine). In many people, urinalysis done as part of a ROUTINE MEDICAL EXAMINATION provides the first indication of glomerulonephritis. Blood tests help the nephrologist assess the ability of the kidneys to remove toxins and wastes from the blood. Imaging procedures such as abdominal ULTRASOUND or COMPUTED TOMOGRAPHY (CT) SCAN can show the damage to the glomeruli. Needle biopsy of the kidney tissue allows microscopic examination of the glomeruli, providing the definitive diagnosis.

Treatment Options and Outlook

Treatment targets either the underlying condition or the resulting symptoms. Because hypertension is nearly always either a cause or a consequence of glomerulonephritis, the doctor is likely to prescribe medications that lower blood pressure (antihypertensives) such as beta blockers, angiotensin-converting enzyme (ACE) inhibitors, or calcium channel blockers. The doctor may also prescribe medications to extract more water from the blood (diuretics), which lowers blood pressure as well as eases the workload of the kidneys. Bacterial infections require ANTIBIOTIC MEDICATIONS. Viral infections, which are fairly common, will run their course after which kidney function usually returns to normal.

Acute glomerulonephritis may result in renal failure, requiring short-term RENAL DIALYSIS to remove wastes and toxins from the blood until kidney function returns enough to resume this functions. CORTICOSTEROID MEDICATIONS and other immunosuppressive therapies are necessary when the cause of the glomerulonephritis is an autoimmune disorder. Once the cause of the inflammation resolves, the glomerulonephritis generally resolves as well, and kidney function returns to normal.

Chronic glomerulonephritis may require long-term medication therapy, and presents a significant risk for progression to ESRD despite treatment.

Risk Factors and Preventive Measures

Diabetes and hypertension are the leading risk factors for glomerulonephritis. Keeping these conditions under control with medications and lifestyle methods lowers the likelihood for damage to the kidneys and can slow the progression of chronic glomerulonephritis. Untreated or undertreated (failing to complete the full course of antibiotics) strep infections such as STREP THROAT or IMPETIGO remain a significant source of bacterial infection that causes glomerulonephritis. Though there are no methods for preventing glomerulonephritis, the doctor may recommend measures to slow its progression such as dietary modifications (less sodium, potassium, and protein; more water consumption).

See also GOODPASTURE'S SYNDROME; MEDICATIONS TO TREAT CARDIOVASCULAR DISEASE; NEPHRITIS; NEPHRON; NEPHROTIC SYNDROME; POLYARTERITIS; SYSTEMIC LUPUS ERYTHEMATOSUS (SLE).

glomerulosclerosis The formation of SCAR tissue (fibrosis) within the glomeruli, the coiled capillary networks within the nephrons of the KIDNEYS. The most common presentation of glomerulosclerosis is focal segmental glomerulosclerosis in which the fibrosis is scattered throughout the glomeruli, affecting only parts of the GLOMERULUS in various nephrons. The damage permanently blocks the affected glomeruli, however. Because the kidneys have millions of nephrons, glomerulosclerosis may be under way for a significant time before it causes enough damage to manifest symptoms. Some forms of glomerulosclerosis are familial (have a hereditary component) and others arise in conjunction with INFECTION such as HIV/AIDS. Most often, however, the glomerulosclerosis is idiopathic—the nephrologist can find no cause for the scarring. Though some researchers believe the cause is autoimmune, glomerulosclerosis does not respond to IMMUNOSUPPRESSIVE THERAPY.

Symptoms and Diagnostic Path

Early symptoms of glomerulosclerosis are vague and may not appear to be symptoms at all. They include

- poor APPETITE in combination with weight gain
- edema (swelling) of the face, hands and wrists, and feet and ankles
- foamy URINE, indicating ALBUMINURIA (excretion of ALBUMIN, a form of protein, in the urine)
- discolored urine, indicating HEMATURIA (BLOOD in the urine)

The diagnostic path begins with urinalysis, which typically reveals the albuminuria as well as hematuria. Needle biopsy of the kidney shows the fibrosis among the glomeruli and may also show the presence of immunoglobulins characteristic of the condition. HYPERTENSION (high BLOOD PRESSURE) is also often present, a consequence of damage that affects the parts of the NEPHRON that produce a key HORMONE essential for blood pressure regulation (RENIN). Because the kidneys also produce ERYTHROPOIETIN (EPO), the hormone that stimulates the BONE MARROW to produce erythrocytes (red blood cells). Erythrocytes carry oxygen in the blood circulation. Progressive glomerulosclerosis often results also in ANEMIA (insufficient oxygen in the blood circulation).

Treatment Options and Outlook

There is no cure for glomerulosclerosis, which in most people progresses over about 10 years to END-STAGE RENAL DISEASE (ESRD). Treatment includes medications to control blood pressure. As CHOLESTEROL BLOOD LEVELS also tend to be high (HYPERLIPIDEMIA), the doctor may prescribe medications and lifestyle changes to help bring them down. These therapies may slow the progression of the fibrosis. The progressive loss of protein further damages the nephrons. At the point of ESRD, long-term RENAL DIALYSIS or KIDNEY TRANSPLANTATION is necessary to sustain life.

Risk Factors and Preventive Measures

Glomerulosclerosis, particularly focal segmental, tends to develop in people who are in their 20s and 30s and is about three times more common among African American males. There are no measures to prevent glomerulosclerosis. Managing the symptoms as effectively as possible may delay the onset of ESRD. Kidney transplantation becomes the treatment option that offers the greatest opportunity for a return to normal activities.

See also GLOMERULONEPHRITIS; MEDICARE COVERAGE FOR PERMANENT RENAL FAILURE; NEPHROTIC SYNDROME.

glomerulus The coiled capillary network within the NEPHRON of the kidney through which BLOOD passes for filtration. Glomeruli are abundant within the KIDNEYS as each kidney contains more than a million nephrons. The walls of the glomerulus are only a few cells in thickness. The glomerular walls are semipermeable, allowing smaller molecules such as water, metabolic wastes, GLUCOSE, and electrolytes to pass through and collect in the capsule (called Bowman's capsule) that surrounds the glomerulus. Together the glomerulus and Bowman's capsule are the renal corpuscle. The fluid and its contents, called filtrate, passes into the tubules of the nephron, which further filter and concentrate the filtrate. The nephron eventually reabsorbs 99 percent of the filtrate back into the blood; the remaining fluid drains into collecting ducts to move out of the kidneys as URINE. The glomerular filtration rate (GFR) is an important measure of kidney function. The GFR of a healthy adult kidney is 125 milliliters per minute.

For further discussion of the glomerulus within the context of the urinary system's structure and function please see the overview section "The Urinary System."

See also GLOMERULONEPHRITIS; GLOMERULOSCLEROSIS; RENAL FAILURE.

Goodpasture's syndrome An autoimmune disorder in which the IMMUNE SYSTEM produces antibodies that attack the glomeruli in the KIDNEYS, impairing kidney function, and the alveoli in the LUNGS, causing bleeding into the lung tissue. In most people who develop Goodpasture's syndrome the symptoms follow a viral INFECTION of the upper respiratory tract or exposure to environmental toxins, notably hydrocarbons. Because Goodpasture's syndrome tends to run in families, researchers believe a GENE MUTATION is likely responsible.

Siphoning gasoline and sniffing aerosols such as paints and glues are the most common exposures to hydrocarbons that can result in Goodpasture's syndrome.

Though the coughing up of bloody SPUTUM (HEMOPTYSIS) is the first and often the more distressing sign of Goodpasture's syndrome, GLOMERULONEPHRITIS is the more serious consequence, leading rapidly in many people to RENAL FAILURE. ANEMIA (insufficient erythrocytes in the blood) and HYPERTENSION (elevated BLOOD PRESSURE), consequences of the renal failure, may quickly become significant.

SYMPTOMS OF GOODPASTURE'S SYNDROME

Pulmonary (Lungs)	Renal (Kidneys)
HEMOPTYSIS (bloody SPUTUM)	HEMATURIA (bloody URINE)
DYSPNEA (shortness of breath)	foamy urine (indicates ALBUMINURIA)
COUGH	decreased urine volume
CHEST PAIN	edema (fluid retention)

The diagnostic path includes blood and urine tests to assess kidney function, chest X-RAY to detect accumulated fluid in the lungs, and biopsy of lung and kidney tissue to confirm the presence of antibodies. The course of Goodpasture's syndrome may run two months to several years. Early diagnosis allows aggressive interventions, including plasmapheresis to remove antibodies from the bloodstream and IMMUNOSUPPRESSIVE THERAPY to prevent the immune system from producing further antibodies. These interventions can mediate the syndrome's progression, minimizing damage to the kidneys. Though about 90 percent of those who develop this once-fatal syndrome now survive, many of them continue to experience progressive renal failure that results in END-STAGE RENAL DISEASE (ESRD).

See also ALVEOLUS; ANTIBODY; AUTOIMMUNE DISORDERS; HEMAPHERESIS; GLOMERULUS; RENIN.

H

hematuria BLOOD in the URINE. Hematuria may result from numerous circumstances and always requires medical evaluation to determine the underlying cause. Though BLADDER CANCER is uncommon, hematuria often is the earliest sign of its presence. Gross hematuria occurs when the amount of blood in the urine is sufficient to discolor the urine (typically pink, red, or brown). Occult, or microscopic, hematuria occurs when the amount of blood in the urine is very slight, detected during microscopic examination of the urine.

Urinalysis is the first step of the diagnostic path, with additional diagnostic procedures, depending on the findings and the symptoms. Treatment targets the underlying cause. Certain medications or foods may cause the urine to be pink or red, in which case the urinalysis shows there to be few erythrocytes (red blood cells) present in the urine. MENSTRUATION may also give the appearance of blood in the urine.

CONDITIONS FOR WHICH HEMATURIA IS A COMMON SYMPTOM

BENIGN PROSTATIC HYPERPLASIA (BPH)	BLADDER CANCER
BLUNT TRAUMA to the abdomen or back	CHLAMYDIA
CYSTITIS	EPIDIDYMITIS
GENITAL TRAUMA	GONORRHEA
PROSTATITIS	pyelonephritis
TRICHOMONIASIS	URETHRITIS
URINARY TRACT INFECTION (UTI)	UROLITHIASIS

See also ANURIA; DYSURIA; ENURESIS; NOCTURIA; OLIGURIA.

hemolytic uremic syndrome RENAL FAILURE that occurs as a rare complication in children after INFECTION with *Escherichia coli* O157:H7 acquired from contaminated food. *E. coli* O157:H7 causes hemorrhagic ENTERITIS, itself a life-threatening infection. Hemolytic uremic syndrome occurs when the toxins the *E. coli* O157:H7 release enter the bloodstream. The toxins destroy erythrocytes (red BLOOD cells) and platelets (clotting cells). Remnants of the destroyed blood cells clog the glomeruli within the KIDNEYS, preventing blood from flowing through these filtering structures. As more glomeruli become affected, the kidneys can no longer filter toxins from the blood.

Symptoms and Diagnostic Path

The symptoms of hemolytic uremic syndrome begin to emerge as the child appears to be recovering from the enteritis. The earliest indication of hemolytic uremic syndrome is the appearance of PETECCHIAE, pinpoint hemorrhages under the surface of the SKIN, in a child recovering from *E. coli* O157:H7 hemorrhagic enteritis. Other symptoms include reduced URINE volume, fatigue, irritability, and pale skin. Blood tests typically show the damaged blood cells and indications of diminishing kidney function. However, the child becomes life-threateningly ill very rapidly, requiring immediate hospitalization and intensive medical treatment.

Treatment Options and Outlook

There is no cure for hemolytic uremic syndrome. Treatment consists of intensive supportive care while the condition runs its course, including efforts to maintain the child's fluid and electrolyte balances as well as RENAL DIALYSIS to filter toxins from the blood. The renal failure disrupts all body systems and functions, often causing severe HYPERTENSION (high BLOOD PRESSURE), other cardiovascular problems, LIVER dysfunction, and neurologic dysfunction. With prompt and aggressive medical

care, 80 percent of children survive. About 70 percent of them recover fully with no residual health problems. Among the other 30 percent renal failure progresses to END-STAGE RENAL DISEASE (ESRD), often within months though sometimes over several years, requiring long-term renal dialysis and ultimately KIDNEY TRANSPLANTATION.

Risk Factors and Preventive Measures

Hemolytic uremic syndrome is a rare complication of *E. coli* O157:H7 hemorrhagic enteritis, so any child who acquires this infection incurs the risk for the syndrome. There are no measures to prevent hemolytic uremic syndrome as a complication of *E. coli* O157:H7 infection. Even with prompt and aggressive medical care for the hemorrhagic enteritis, hemolytic uremic syndrome remains a potential complication. The most effective preventive measures are precautions to protect against *E. coli* O157:H7 infection. Such measures include

- wash hands with hot, soapy water before and after handling meats
- do not handle other foods when preparing meats
- use separate, nonporous surfaces and utensils (not wooden) to prepare meats for cooking
- wash food preparation surfaces and utensils with hot soapy water immediately after preparing meats
- thoroughly cook all meats to the recommended temperatures for the kind of meat
- thoroughly rinse all fruits and vegetables in cold running water before eating or preparing them

See also FOOD-BORNE ILLNESSES; GLOMERULUS.

hepatorenal failure The progressive failure of the KIDNEYS in people who have chronic LIVER FAILURE. Doctors do not know what causes hepatorenal failure, also called hepatorenal syndrome, to develop though they do know the BLOOD supply to the kidneys becomes suddenly and severely restricted. Not enough blood flows through the kidneys for the kidneys to filter waste byproducts and toxins from the blood, and these substances accumulate in the blood. Because the kidneys play key roles in regulating BLOOD PRESSURE, HYPERTENSION (elevated blood pressure) may also develop.

The primary symptom of hepatorenal failure is diminished URINE production in a person who has chronic liver failure. Symptoms of liver failure are also often present and typically include ASCITES (fluid retention in the abdominal cavity), JAUNDICE (yellowish discoloration of the skin), and abnormal bleeding. Blood and urine tests help evaluate liver and kidney function, and diagnostic imaging procedures such as abdominal ULTRASOUND or COMPUTED TOMOGRAPHY (CT) SCAN demonstrate the extent of physical damage to the liver and the kidneys.

Treatment aims to improve both liver and kidney functions. RENAL DIALYSIS often becomes necessary. In some people the kidneys remain healthy and return to full function when the underlying liver disease improves, such as might occur with LIVER TRANSPLANTATION. When liver disease is severe, however, the progressive failure of the kidneys means the body loses nearly all of its ability to remove toxins and the risk of death is very high.

See also CIRRHOSIS; COAGULATION; ENCEPHALOPATHY; LIVER DISEASE OF ALCOHOLISM.

horseshoe kidney A random CONGENITAL ANOMALY in which a band of tissue fuses the KIDNEYS at the bottom, forming a shape resembling a horseshoe. The tissue band, called an isthmus, may be fibrous or the same tissue as the kidneys. In most people who have this anomaly, both kidneys are fully functional. However, the fusion distorts the normal structure of the kidneys, leading over time to conditions such as HYDRONEPHROSIS (dilation of the renal pelvis), NEPHROLITHIASIS (kidney stones), and VESICOURETERAL REFLUX (backflow of URINE from the BLADDER into the ureters and kidneys). The BLOOD vessels that supply the horseshoe kidney are often intertwined and anomalous, providing abnormal blood flow to the fused kidney that can affect its functions. The horseshoe kidney also resides lower in the abdominal cavity, placing it outside the protective enclosure of the rib cage. Horseshoe kidney increases the risk for some types of primary RENAL CANCER.

Two thirds of people who have horseshoe kidney learn of the anomaly during diagnostic proce-

dures for other health concerns. Doctors diagnose most others in the course of identifying the causes for conditions that affect the kidneys. When symptoms do occur, they generally represent a consequential condition such as nephrolithiasis. The diagnostic path includes blood and urine tests to assess kidney function. Diagnostic imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN or renal ULTRASOUND can provide visual evidence of the fused kidneys. Diagnostic prenatal ultrasound often detects horseshoe kidney in the unborn child.

For the most part horseshoe kidney of itself presents no unusual health risks. The fused kidneys are prone to the same conditions that affect kidneys in general. Treatment targets any conditions affecting the kidney. The urologist or nephrologist may suggest surgery (nephroplasty) to separate the kidneys and establish normal positioning of the ureters and the blood supply. Watchful waiting, with routine medical care to monitor kidney function and health, is appropriate for many people who have no symptoms of kidney disease. Researchers do not know what causes horseshoe kidney to occur. One child born with horseshoe kidney does not increase the likelihood that other children will also have the anomaly; the condition appears to be entirely random.

See also EPISPADIAS; HYPOSPADIAS; TURNER'S SYNDROME.

hydronephrosis A circumstance in which the renal pelvis, the portion of the kidney that collects URINE for passage from the kidney via the URETER, dilates and enlarges. Hydronephrosis results from conditions of the kidney that slow or block the flow of urine, causing urine to back up into or pool in the renal pelvis. Such conditions may include obstructive NEPHROLITHIASIS (kidney stones that block the ureter), NEUROGENIC BLADDER (in which the BLADDER fails to respond to the normal neurosensory signals that regulate URINATION and becomes overly full), and VESICOURETERAL REFLUX (urine washes back into the ureters from the bladder).

Unilateral hydronephrosis, which affects only one kidney, is the more common presentation. Bilateral hydronephrosis, which affects both KIDNEYS, often indicates CONGENITAL ANOMALY of kidney or ureteral structure though may develop as a consequence of conditions such as HYPERTENSION (high BLOOD PRESSURE), DIABETES and BENIGN PROSTATIC HYPERPLASIA (BPH) that constricts the urethra and slows the flow of urine during urination.

The symptoms of hydronephrosis may include

- abdominal or back PAIN
- DYSURIA (discomfort or burning with urination)
- URINARY FREQUENCY
- URINARY URGENCY
- signs of INFECTION such as FEVER and cloudy or bloody urine

Some people may have no symptoms, with the hydronephrosis showing up during evaluation of other medical concerns or in PREGNANCY. The diagnostic path begins with urinalysis and blood tests to evaluate kidney function and usually includes an abdominal X-RAY, ULTRASOUND, COMPUTED TOMOGRAPHY (CT) SCAN, INTRAVENOUS PYELOGRAM (IVP), or MAGNETIC RESONANCE IMAGING (MRI) examination to visualize the kidneys. Treatment targets the underlying disease process to restore the free flow of urine. Untreated hydronephrosis results in permanent damage to the kidney that may lead to RENAL FAILURE.

See also HEMATURIA; HORSESHOE KIDNEY; NEPHRITIS; NOCTURIA; URINARY TRACT INFECTION (UTI).

hypercalciuria Excessive excretion of calcium in the URINE. About 80 percent of people who have kidney stones (NEPHROLITHIASIS) or BLADDER stones (UROLITHIASIS) have hypercalciuria. In most people the circumstance appears a combination of factors that typically include high dietary calcium intake, insufficient water consumption (resulting in low urine volume), and physical inactivity. The water and citrate content of the urine normally allows most of the calcium the KIDNEYS extract from the BLOOD to dissolve and pass from the body. When urine volume and citrate concentration are low, calcium in the urine combines with other minerals (usually oxalate or phosphate) to form crystalline structures. Over time these structures harden or calcify (called calculi). Inactivity contributes to calculus formation because it allows mineral sediments to settle, facilitating their crystallization.

Other causes of hypercalciuria include endocrine disorders such as HYPERPARATHYROIDISM and ADDISON'S DISEASE, kidney dysfunction, and MALABSORPTION disorders of the gastrointestinal system. Many people who have hypercalciuria do not have nephrolithiasis or urolithiasis, though the presence of excess calcium in the urine raises their risk for developing either condition. Routine urinalysis often detects hypercalciuria. Doctors generally recommend increased water consumption, maintaining dietary calcium intake at recommended levels for BONE health, and daily physical activity. Many people also benefit from thiazide diuretic medications, which act to slow the extraction of calcium in the kidneys as well as to increase the volume of urine. Many stones that form as a consequence of hypercalciuria will pass through the urinary tract without medical intervention, though they require treatment when they cause significant pain or an obstruction in the kidney, URETER, bladder, or URETHRA.

See also CYSTINURIA; FANCONI'S SYNDROME; HYPEROXALURIA; RENAL TUBULAR ACIDOSIS.

hyperoxaluria Excessive OXALATE excretion in the URINE. Oxalate is a natural chemical that enters the body through dietary sources such as vegetables, fruits, and grains. The LIVER also metabolizes oxalate. Researchers do not know what benefits the body derives from oxalate. However, in the body oxalate attracts calcium, creating the insoluble compound calcium oxalate. About 80 percent of kidney stones are made of calcium oxalate. Deposits of calcium oxalate may also accumulate in tissues such as the KIDNEYS, liver, HEART, and bones, a circumstance known clinically as oxalosis.

Most hyperoxaluria is idiopathic (without a clearly identifiable cause). Doctors believe about 50 percent of people who have mild to moderate hyperoxaluria consume an abundance of foods high in dietary oxalate. In some people the binding between calcium and oxalate intensifies for reasons researchers do not understand though believe results from genetic factors. Less commonly, hyperoxaluria occurs as an autosomal recessive genetic disorder that results in the absence of an enzyme the body requires to break down oxalate into soluble components that are more easily excreted. Genetic hyperoxaluria generally causes symptoms (typically kidney or bladder stones) in early childhood. Rarely, hyperoxaluria is a secondary complication of MALABSORPTION disorders, such as SHORT BOWEL SYNDROME and INFLAMMATORY BOWEL DISEASE (IBD), that alter the gastrointestinal tract's absorption of dietary calcium and oxalate.

The most common symptoms are kidney stones (NEPHROLITHIASIS) or bladder stones (UROLITHIASIS). The diagnostic path includes laboratory tests to measure the levels of oxalate in the urine and the BLOOD, analysis of any stones, and family history. Dietary modifications (eating fewer foods with high oxalate content) are often treatment enough for mild idiopathic hyperoxaluria. Other therapeutic approaches include medications to increase the ability of the urine to dissolve calcium and oxalate salts, magnesium and pyridoxine (vitamin B_6) supplementation, and increasing water consumption to dilute the urine. Primary (genetic) hyperoxaluria typically results in RENAL FAILURE by early adulthood with the only definitive treatment being KIDNEY TRANSPLANTATION.

hypospadias A CONGENITAL ANOMALY in which the URETHRA is shorter than normal and exits along the underside of the PENIS in a boy or into the VAGINA in a girl. Though uncommon overall, hypospadias is very rare in girls. In boys, CHORDEE (severely curved penis) often accompanies hypospadias. The preferred treatment is surgery to extend the urethra to its normal length and path. In boys, such surgery also includes correction of the chordee. The surgery establishes normal URINATION and, in boys, restores structural integrity to the penis that will permit sexual function and FERTILITY later in life. The urologist typically performs the OPERATION when the child is between 6 and 12 months of age. More than 90 percent of such corrective surgery produces a functionally and cosmetically acceptable repair. Some children may need more than one operation, notably boys in whom the urethral opening is near the base of the penis.

interstitial cystitis See CYSTITIS.

intravenous pyelogram (IVP) A diagnostic imaging procedure to evaluate the flow of BLOOD and URINE through the KIDNEYS, ureters, BLADDER, and URETHRA. IVP requires moderate preparation that typically includes taking a laxative the night before the scheduled procedure to empty the intestines so the IVP provides clear visualization of the renal structures and then consuming nothing by mouth until after the IVP. An IVP takes about an hour to complete though does not require any recovery time after the procedure.

A radiologist performs IVP by injecting an iodine-based contrast medium into a VEIN in the arm. Some people experience a mild burning sensation with the contrast medium's injection. The person lies on the X-RAY table, and the radiologist takes X-rays at timed intervals as the contrast medium travels through the bloodstream and into the kidneys.

Sometimes the radiologist uses an inflatable compression belt, applied around the abdomen and back, to slow progress of the contrast medium through the kidneys. Near the end of the procedure the person urinates to empty the bladder, after which the radiologist takes a final series of X-rays.

It is important to drink plenty of water after an IVP to help flush the residual contrast medium from the body. Complications and side effects are rare, the most common being an allergic reaction to the contrast medium. People who have allergies to iodine or shellfish should discuss the possibility of sensitivity to the contrast medium with the radiologist or urologist before undergoing the IVP. The IVP provides an abundance of information about the structure and functions of the urinary system that is useful for the urologist in reaching or confirming diagnosis of numerous conditions affecting the kidneys.

Kegel exercises A series of exercises to strengthen the pubococcygeal muscle, a figure-eight double loop of MUSCLE that forms the pelvic floor. Arnold H. Kegel, MD, an American gynecologist who practiced in Los Angeles, California, popularized the pelvic muscle exercises that now bear his name when he developed a BIOFEEDBACK device called a perineometer in the 1940s. Though urologists and gynecologists had been instructing women in the procedure of these exercises for over a decade as treatment for URINARY INCONTINENCE, most women had no idea whether they were doing them correctly. The Kegel perineometer was the first device to measure the effectiveness of the cycles of contraction and relaxation of the pubococcygeal muscle. In conjunction with biofeedback, Kegel exercises became highly successful in resolving mild to moderate urinary incontinence in many women.

PERFORMING KEGEL EXERCISES

- Identify the pubococcygeal muscle by stopping and starting the flow of URINATION or, for women, inserting a finger into the VAGINA. Women or men may benefit from BIOFEEDBACK methods.
- Begin with 10 repetitions of the complete cycle of contract, hold, and relax. Maintain each stage for 10 seconds. Repeat three times a day.
- As pubococcygeal muscle STRENGTH improves, increase the length of each stage to 20 seconds and the number of repetitions gradually to 50. Repeat three times a day.

Kegel exercises, also called pelvic floor exercises, today remain the most effective noninvasive treatment for urinary incontinence in women—and in men after surgery to treat BENIGN PROSTATIC HYPERPLASIA (BPH) or PROSTATE CANCER. Many obstetricians recommend Kegel exercises to speed recovery after CHILDBIRTH. Kegel exercises are also often helpful for treating premature EJACULATION in men. The exercises are very simple, consisting of cycles of contracting, holding, and relaxing the pubococcygeal muscle repeated several times a day. Once a person learns the exercises, he or she can perform them unnoticeably and when seated, standing, or lying down.

It is important to correctly identify the pubococcygeal muscle; the muscles of the buttocks, abdomen, and thighs should be relaxed when performing Kegel exercises. An easy way to learn to contract the pubococcygeal muscle is to consciously stop and start the flow of URINE when urinating. BIOFEEDBACK remains the most effective means for determining whether the person is performing the Kegel exercises correctly, and a variety of biofeedback devices are available for home use. Women may also use a simple device called a vaginal cone. Most people begin to experience results in about six to eight weeks. It is important to continue regularly with Kegel exercises to maintain optimal pubococcygeal muscle tone and STRENGTH.

kidney donor An individual who donates his or her KIDNEYS after death or who donates one kidney

for live donor transplantation. Kidneys are the organs most commonly transplanted in the United States (other than SKIN and corneas). At present, people waiting for donor kidneys outnumber available kidneys nearly four to one. Between 50,000 and 60,000 people currently await donor kidneys in the United States. A person becomes a potential candidate for KIDNEY TRANSPLANTATION with the onset of END-STAGE RENAL DISEASE (ESRD), a permanent state of renal failure in which the kidneys cannot perform their functions at a level that sustains life.

The donor and the recipient must match in BLOOD TYPE and human leukocyte antigen factors and be negative for antibodies (negative crossmatch). HUMAN LEUKOCYTE ANTIGENS (HLAS) are six inherited proteins (three from each parent) on the surfaces of leukocytes (white BLOOD cells). The more HLAs that match, the greater likelihood the recipient's body will accept the donor kidney. Even with blood type match and good HLA matching, some people's immune systems produce antibodies in reaction to the donor's blood. A negative crossmatch mixes small amounts of the prospective donor's blood and the recipient's blood to confirm that there is no ANTIBODY reaction.

Living Donor

A living donor may be a relative or a stranger to the kidney recipient. In general a living donor must be in overall good health and have two normally functioning kidneys. Some health conditions, such as HYPERTENSION (high BLOOD PRESSURE), chronic LIVER disease, and DIABETES, preclude a person from donating a kidney because the risk is high for developing kidney disease as a consequence of these conditions. People with chronic health conditions generally are not eligible to donate a kidney. There is no greater likelihood of developing kidney disease with only one kidney, and a single kidney can more than adequately accommodate the body's needs.

The transplant team selects a living donor on the basis of the match between the donor and the recipient. Typically, the recipient's health insurance pays for the donor's medical expenses related to the kidney donation, including surgery, hospitalization, and follow-up care. Once selected, the living donor undergoes NEPHRECTOMY, an OPERATION to remove a kidney. There are two options, open nephrectomy and laparoscopic nephrectomy. Either procedure is a major surgery that requires hospitalization and postsurgical recovery time. Though recovery is uneventful for most donors whether they undergo laparoscopic or open nephrectomy, donating a kidney does require time off from work and regular activities.

Laparoscopic nephrectomy requires several small incisions through which the team uses laparoscopy to remove the donor kidney. Though technically more challenging for the transplant team, laparoscopic nephrectomy significantly reduces scarring and recovery time for the donor. Laparoscopic nephrectomy takes three to four hours, with two to three hours in the recovery room while the person returns to full consciousness. Most people who undergo laparoscopic nephrectomy stay one to three days in the hospital after the surgery and require four to six weeks for return to regular activities. Within a year or two, the small scars remaining from the incisions are nearly invisible.

Open nephrectomy requires a single large incision and takes two to three hours, with two to three hours in the recovery room to return to full consciousness. Most people who undergo open nephrectomy stay three to five days in the hospital after the surgery and need six to eight weeks for return to regular activities. The SCAR from the incision begins to fade in about a year.

The transplant team immediately performs the transplantation surgery to place the donor kidney into the recipient. Only the intended recipient may receive the living donor kidney; there are no waiting list requirements for live donor kidney transplantations. Living donor kidney transplants have a higher long-term success rate than cadaver donor kidney transplants.

Cadaver Donor

Cadaver donor kidneys come from the bodies of deceased persons who died of causes not related to kidney function, had healthy kidneys at the time of death, and signed documents affirming their desires to donate their organs after their deaths. Family members may make the decision about organ donation when the person dies without organ donor documentation. Organ donation can

proceed only when the appropriate assessments certify the person has suffered BRAIN DEATH.

UNIVERSAL DONOR CARD

Most states honor the universal donor card, a wallet-size document affirming a person's intent to donate his or her organs upon death, as a legal document. Many states incorporate the universal donor card into the driver's license.

A transplant team removes donor kidneys using sterile surgical technique and a procedure similar to nephrectomy (surgical removal of a kidney such as to treat RENAL CANCER), carefully preserving the blood vessels and URETER. After removing the kidneys, called organ harvesting, the transplant team places them in a cold solution that can sustain them for 36 to 48 hours and sutures closed the incisions made to gain access to the kidneys. The organ-processing procedure includes screening of the donor kidneys for any diseases they could convey to the recipient. In the United States an independent organization called the United Network for Organ Sharing (UNOS) oversees the collection and distribution of all cadaver donor organs in compliance with strict guidelines intended to ensure equity in the process of matching donor organs with recipients. The transplant surgery must take place within 36 to 48 hours of the kidney's harvesting, sooner if possible.

See also ORGAN TRANSPLANTATION; QUALITY OF LIFE; SURGERY BENEFIT AND RISK ASSESSMENT.

kidney failure See RENAL FAILURE.

kidneys A pair of organs responsible for filtering wastes and excess water from the BLOOD, excreting both from the body as URINE. The kidneys maintain the body's fluid and electrolyte balances, and also produce hormones that regulate the production of new erythrocytes (ERYTHROPOIETIN [EPO]) and BLOOD PRESSURE (RENIN). With each heartbeat about 20 percent of the body's blood supply surges through the kidneys. The body's entire blood supply passes through the kidneys about two dozen times a day. Though the kidneys are essential for life, a single functioning kidney can adequately sustain life in most people. The kidneys are fully functional from birth.

Renal Structure

The kidneys are dark reddish brown in color, four to five inches long, and about two inches across. An adult kidney weighs five to six ounces, and is the same shape as the bean that bears its name. The kidneys rest against along the spinal column at the back of the abdominal cavity, one on each side of the SPINAL CORD and within the protective enclosure of the rib cage. The kidneys are retroperitoneal—that is, they lie outside the posterior layer of the peritoneum, the membrane that protects the abdominal structures. The left kidney is about an inch higher than the right. A cushion of fatty tissue surrounds each kidney, helping protect it as well as hold it in place. An adrenal gland resides atop each kidney though does not physically or functionally integrate with the kidney.

A thin but tough membrane called the renal capsule surrounds the kidney, helping contain and protect its blood-rich tissues. The outer layer of the kidney is the renal cortex and the inner layer the renal medulla. The renal ARTERY, renal VEIN, and URETER junction with the kidney where it indents, an area called the hilus. Deeper within the kidney at this junction is the renal pelvis, a deltalike region of the kidney that drains urine into the ureter. The functional unit of the kidney is the NEPHRON, a microscopic structure, a set of tubules that carry out the functions filtration, and a coil of capillaries, the GLOMERULUS, which brings in the blood for filtration. Each kidney contains over a million nephrons, each of which functions independently. The nephrons extend through the renal cortex and the renal medulla. The renal cortex contains the blood vessels that bring blood to the nephrons and the glomerulus for each nephron, as well as a portion of filtering tubule. The renal medulla consists of 8 to 12 wedge-shaped segments, called pyramids. The pyramids contain the filtering tubules, including the loop of Henle and the collecting tubule, for each nephron. Blood circulates primarily through the renal cortex, while the structures of the renal medulla direct water and waste products (urine) toward the renal pelvis and elimination via the ureter.

Renal Function

The pressure of the blood as it flows through the glomeruli helps force molecules of water and

other substances across the membranous glomerular walls and into an encapsulated structure called Bowman's capsule. Specialized proteins called transporters carry these substances across the capillary membranes. The collected mixture, called filtrate, funnels from the Bowman's capsule into the tubules. A separate capillary network, the peritubular capillaries, entwines the filtration tubules to allow water and other substances to return to the blood circulation (reabsorption). By the time a heartbeat's surge of blood completes its passage through the nephrons, about 99 percent of the water and electrolytes originally filtered from the blood (sodium, potassium, magnesium, calcium, and others) have returned to the circulation.

Kidney function remains at a fairly constant level for much of life. By the 40s, the kidneys begin to lose nephrons at a rate of about 10 percent per decade. As a single kidney can meet the body's needs having only about one third of its capacity, the kidneys are well structured to function the length of the lifespan. The primary threats to kidney function are diseases that affect other body systems or the body as a whole, such as DIABETES, HYPERTENSION (high blood pressure), and CARDIOVASCULAR DISEASE (CVD).

The kidneys also produce two vital hormones: RENIN, which controls blood pressure, and EPO, which regulates erythropoiesis (the synthesis of new erythrocytes in the BONE MARROW). Health conditions that damage the kidneys also affect their ability to produce these hormones. Interstitial cells (cells in the body of the kidney) produce both hormones.

The pressure of blood flowing through the glomeruli helps determine whether the kidney releases renin, which is a process of perpetual balance. Renin sets in motion the cascade of events through which the body produces angiotensin II, a potent vasoconstrictor (chemical that narrows and stiffens the blood vessels to raise blood pressure). The kidneys also respond to the release of ANTIDIURETIC HORMONE (ADH) from the HYPOTHALAMUS, another mechanism of blood pressure regulation that influences the amount of water the kidneys withhold in the blood or excrete in the urine. The hypothalamus releases ADH to cause the kidneys to withhold more water, which increases the blood volume and thus the blood pressure.

The kidneys also detect the level of erythrocytes that are in the blood as it passes through them, and release erythropoietin when the erythrocyte level drops. Erythropoietin stimulates the production of reticulocytes in the bone marrow and their release into the blood circulation, where they mature to become oxygen-bearing erythrocytes.

kidney stone See NEPHROLITHIASIS.

kidney transplantation A surgical OPERATION to place a healthy, functioning kidney into a person whose own kidneys have permanently failed. The first successful kidney transplantation took place between identical twin brothers in 1954. However, until the discovery of the immunosuppressive DRUG cyclosporine in 1983, the risk of organ rejection was very high, and kidney transplantation was a treatment of last resort. With current IMMUNOSUPPRESSIVE THERAPY the recipient of a transplanted kidney can expect to live 5 to 20 years or longer with relatively normal kidney function.

Since the mid-1980s kidney transplantation has become the standard of treatment for END-STAGE RENAL DISEASE (ESRD), also called permanent kidney failure (RENAL FAILURE). Transplant surgeons in the United States perform about 15,000 kidney transplant operations each year. However, a severe

shortage of donor kidneys limits the availability of kidney transplantation. Another 30,000 to 45,000 people are eligible for kidney transplantations and await donor organs. A donor kidney may be a cadaver organ donation (donated after a person's death) or come from a person who has two healthy kidneys and offers to donate one to the recipient.

In the United States, the federal health-care program Medicare pays for 80 percent of most expenses related to kidney transplantation for those who meet the qualification criteria. The U.S. Centers for Medicare and Medicaid Services Web site (www.cms.hhs.gov) provides comprehensive information about eligibility and covered services. Private health insurance and other public programs also provide coverage for kidney transplantation costs, though coverage varies among carriers and programs.

Donor Kidneys

The primary source of donor kidneys is cadaver donation—people who authorize the donation of their organs when they die. In the United States the United Network for Organ Sharing (UNOS) administers the nationwide cadaver donor organ collection and distribution program, the Organ Procurement and Transplantation Network (OPTN). People eligible for kidney transplantation register with OPTN through regional organ transplantation centers. OPTN follows strict guidelines intended to ensure equitable access to donor organs. People may wait several months to several years for a matched cadaver donor kidney, as the OPTN system distributes organs to matched recipients who are the sickest.

The wait time for a living donor kidney transplant is typically significantly shorter, often only several months, because as soon as the transplant team confirms the intended donor is a match the surgeries (donation and transplantation) can take place. Living organ donation does not fall within OPTN. Only the intended recipient may receive the kidney from the living donor. The living donor is often a family member though may be a stranger who is a strong match with the recipient.

Donor-Recipient Match

The donor kidney must match the recipient as closely as possible in three ways. First, the donor and the recipient must have the same BLOOD TYPE. Second, the donor and the recipient must match HUMAN LEUKOCYTE ANTIGENS (HLAS), which are proteins on the surfaces of leukocytes (white BLOOD cells), as closely as possible. Every person has six HLAs. The more HLAs that match between donor and recipient, the higher the likelihood that the recipient's body will accept the donor kidney (though all organ transplant recipients take lifelong immunosuppressive therapy). Transplant surgeons like to see a match of three or more HLAs. Third, the donor's blood must not initiate an ANTIBODY response with the recipient's blood (called a negative crossmatch), which the transplant team tests by mixing samples of blood from each in a test tube.

Surgical Procedure

The transplant surgery generally takes three to five hours. With the person under general ANESTHESIA, the transplant surgeon makes an incision in the lower abdomen, placing the donor kidney in the abdominal cavity below the native kidneys. The surgeon attaches the donor kidney's arteries and veins to the recipient's iliac ARTERY and iliac VEIN, respectively, and the donor kidney's URETER to the BLADDER. Depending on the reason for the ESRD, the surgeon may either leave or remove the recipient's nonfunctioning kidneys. After returning to full consciousness in the recovery room, the recipient typically remains in the hospital for three to five days. The transplanted kidney may begin functioning immediately or take several weeks. The recipient undergoes RENAL DIALYSIS until kidney function becomes adequate.

Risks and Complications

The risks of transplantation surgery include bleeding during or after the operation and postoperative INFECTION. Because the transplanted kidney is lower in the abdomen than the native kidneys it lacks the protection of the rib cage and is more vulnerable to traumatic injury. Rarely the recipient's body may immediately reject the donor organ, in which case the transplant team must operate again to remove it. Most people recover fully from the surgery without complications, though there is always the risk of organ rejection. Many kidney transplant recipients experience episodes of organ rejection that the transplant

doctor can treat with various medications. The IMMUNOSUPPRESSIVE THERAPY that is necessary for organ transplant recipients to take lowers the body's overall immune response, lowering resistance to infection. IMMUNOSUPPRESSIVE MEDICATIONS have numerous other side effects as well. People who take long-term immunosuppressive therapy do have an increased risk for LYMPHOMA, a type of cancer that affects the lymph nodes.

Outlook and Lifestyle Modifications

Most people who receive transplanted kidneys feel better immediately after surgery and enjoy relatively normal lifestyles after recovering from surgery; however, they must continue taking immunosuppressive medications and receive regular medical checkups to monitor the health of their transplanted kidneys. Doctors generally recommend that people who have transplanted kidneys avoid activities with increased risk for blunt trauma to the abdomen, such as contact sports. The doctor may further recommend specific dietary and lifestyle modifications to maintain optimal kidney function.

See also ORGAN TRANSPLANTATION; SURGERY BENEFIT AND RISK ASSESSMENT.

Medicare coverage for permanent renal failure Federal government funding in the United States that pays for medical treatment for people of any age who have END-STAGE RENAL DISEASE (ESRD), also called permanent RENAL FAILURE. Though for other health conditions an individual must be age 65 or older to qualify for Medicare coverage, the US Congress in 1973 passed legislation broadening Medicare coverage to include care for ESRD at any age. There are specific eligibility requirements and co-payments. Health-care providers that offer care for ESRD have information about the application and approval processes. The US Centers for Medicare and Medicaid Services Web site (www.cms.hhs.gov) also provides comprehensive information about eligibility and covered services.

See also KIDNEY TRANSPLANTATION; QUALITY OF LIFE; RENAL DIALYSIS.

micturition See URINATION.

minimal change disease A disorder of kidney function in which the structure of the KIDNEYS, notably the nephrons, appears normal with regular (light) microscope examination though slightly abnormal with electron microscope examination. Minimal change disease is primarily a condition of childhood (usually in children under age six) and seldom occurs in adults. Researchers believe the condition is one of immune dysfunction in which T-cell lymphocytes cause molecular damage to the delicate walls of the glomeruli. The damage allows ALBUMIN (protein) to leak from the BLOOD into the URINE (ALBUMINURIA).

Symptoms and Diagnostic Path

The symptoms of minimal change disease are often vague and include

- edema, often of the face
- fatigue
- MUSCLE-wasting
- impaired growth
- unexplained weight gain

The diagnostic path begins with urinalysis, which typically shows albuminuria (albumin excretion). Other laboratory tests are often normal. There is a high correlation between minimal change disease and NEPHROTIC SYNDROME, a constellation of symptoms that indicate kidney dysfunction. The urologist may recommend a trial of treatment before conducting further, more invasive diagnostic procedures.

Treatment Options and Outlook

Treatment for minimal change disease is IMMUNOSUPPRESSIVE THERAPY with CORTICOSTEROID MEDICATIONS such as prednisone. Most children improve remarkably within two weeks, and nearly all within six to eight weeks. The nephrologist may make dietary recommendations to maintain appropriate protein, sodium, and fluid intake. Minimal change disease fully resolves, without residual damage to the kidneys, with treatment in most children. About 10 percent of children experience periodic RECURRENCE of symptoms through ADOLESCENCE and sometimes into adulthood. Children taking corticosteroid medications have a somewhat increased risk for INFECTION during the course of therapy.

Risk Factors and Preventive Measures

Because researchers do not know what causes minimal change disease, there are no measures to prevent its occurrence. Prompt treatment mini-

mizes the risk for permanent damage to the kidneys.

See also GLOMERULONEPHRITIS; GLOMERULOSCLEROSIS; NEPHRON.

nephrectomy A surgical OPERATION to remove a kidney. The most common reasons for nephrectomy are to treat RENAL CANCER, to remove a kidney for live donor KIDNEY TRANSPLANTATION, and to remove a kidney that is severely injured due to trauma or malformed due to CONGENITAL ANOMALY. There are three kinds of nephrectomy:

- partial nephrectomy, in which the surgeon removes only a portion of the kidney
- simple nephrectomy, in which the surgeon removes the entire kidney though leaves the surrounding tissue intact
- radical nephrectomy, in which the surgeon removes the kidney, surrounding tissues, and adjacent lymph nodes

Nephrectomy may be an open surgery, in which the surgeon operates through a large incision in the flank (side of the back), or laparoscopic, in which the surgeon operates through multiple small incisions using a laparoscope.

Surgical Procedure

Nephrectomy takes place in a hospital operating room with the person under general ANESTHESIA. For open nephrectomy, the surgeon makes a large incision into the flank over the kidney. The incision gives access to the kidney without the need to penetrate the peritoneum, as the KIDNEYS lie behind this protective membrane. The surgeon sutures off the renal ARTERY and VEIN and the URETER, then carefully cuts the kidney away from the adipose tissue that surrounds it and holds it in place. When the operation is radical nephrectomy for renal cancer, the surgeon also removes the adipose tissue, nearby connective tissue, and adjacent lymph nodes. After removing the kidney the surgeon sutures closed the incision, which will heal into a SCAR. Open nephrectomy takes two to four hours.

For laparoscopic nephrectomy, also called minimally invasive nephrectomy, the surgeon makes four or five small incisions, called ports, in locations around the flank on the side where the kidney will be removed. The surgeon inserts the laparoscope through one of the ports, and uses another to inflate the interior of the abdomen with a gas. The surgeon inserts instruments through the remaining ports. The laparoscope has a light and camera on the tip that conveys the image of the interior abdomen to a closed-circuit television monitor. The surgeon operates by watching the monitor. When the kidney is free from its BLOOD supply and connecting tissues, the surgeon inserts a special bag through one of the ports and puts the kidney into it. The surgeon carefully delivers the bag through the port, enlarging the port if necessary. When the kidney is out, the surgeon removes the instruments and laparoscope from their ports and sutures them closed. The ports heal into small scars. Laparoscopic nephrectomy takes three to five hours.

After either type of surgery, the person remains in the recovery room until fully awakened from the anesthesia and then goes to a hospital room. The hospital stay for open nephrectomy is generally five to seven days and for laparoscopic nephrectomy is generally three to five days. A person who undergoes open nephrectomy typically returns to regular activities in 8 to 12 weeks. A person who undergoes laparoscopic nephrectomy typically returns to regular activities in five to six weeks.

Risks and Complications

The primary risks of nephrectomy are bleeding and INFECTION, along with the potential for complications arising from anesthesia. These are uncommon events. The doctor will prescribe ANALGESIC MEDICATIONS to relieve postoperative PAIN. Further risks depend on the reasons for the nephrectomy. Some people experience fluctuations in BLOOD PRESSURE during the first few days after the nephrectomy, as the kidneys are key to regulating blood pressure in the body. This nearly always stabilizes without the need for treatment.

Outlook and Lifestyle Modifications

Most people fully recover and return to their regular activities after nephrectomy. The remaining kidney, if healthy, can more than adequately sustain the body's needs. People who have renal cancer often undergo follow-up CHEMOTHERAPY or RADIA-

TION THERAPY after surgery. The doctor may recommend dietary changes and other lifestyle modifications, depending on the person's general health status. A single kidney provides more than adequate function for people who are otherwise in reasonably good health. Lifestyle factors such as nutritious EATING HABITS, daily physical exercise, and maintaining healthy weight reduce strain on the kidney as well as the risk for HYPERTENSION (high blood pressure) and DIABETES, the two health conditions that are most likely to cause kidney disease.

See also MINIMALLY INVASIVE SURGERY; POSTOPERATIVE PROCEDURES; PREOPERATIVE PROCEDURES; SURGERY BENEFIT AND RISK ASSESSMENT.

nephritis INFLAMMATION of the kidney. The most common causes of nephritis are bacterial INFECTION, which generally cause acute (sudden onset) nephritis, and AUTOIMMUNE DISORDERS, which tend to cause chronic or recurrent inflammation. Nephritis can be acute (come on suddenly), chronic (long-term), or recurrent (repeated episodes of acute nephritis). Chronic nephritis can lead to NEPHROPATHY.

Bacterial nephritis When infection involves the glomeruli, it is infectious GLOMERULONEPHRITIS. Infectious glomerulonephritis develops as a complication of untreated or undertreated STREP THROAT or other streptococcal infection elsewhere in the body. Occasionally another bacterial strain such as staphylococcus is responsible. Infection that travels up the ureters from the BLADDER as a complication of untreated or undertreated URINARY TRACT INFECTION (UTI) is pyelonephritis. In pyelonephritis the infection involves the pelvis of the kidney where URINE drains from the kidney into the ureters. VESICOURETERAL REFLUX, in which urine backflows from the bladder through the ureters to the kidneys, is a common cause of pyelonephritis.

Interstitial nephritis In interstitial nephritis the inflammation affects the spaces between the tubules in the nephrons. Such inflammation is nearly always a consequence of acute toxic nephropathy. Medications such as penicillin and penicillin-derived antibiotics, the diuretic medication furosemide and thiazide diuretics, and NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) are commonly responsible for acute interstitial nephritis. The nephritis generally resolves without lingering complications within a few weeks of stopping the medication.

Lupus nephritis The autoimmune disorder SYSTEMIC LUPUS ERYTHEMATOSUS (SLE) affects the KIDNEYS in about 40 percent of people who have SLE. In some people, lupus nephritis may be the only manifestation of SLE. Lupus nephritis can progress rapidly to RENAL FAILURE and END-STAGE RENAL DISEASE (ESRD). Because women who have SLE outnumber men who have SLE nearly nine to one, lupus nephritis far more commonly affects women.

Hereditary nephritis Hereditary nephritis is a genetic disorder that results from GENE mutations. The symptoms of hereditary nephritis are apparent at or shortly after birth, and the inflammation tends to be progressive. The most frequent presentation of hereditary nephritis is ALPORT'S SYNDROME, a disorder of protein encoding.

Symptoms and Diagnostic Path

The symptoms of nephritis may include

- HEMATURIA (bloody urine)
- OLIGURIA (diminished urine volume)
- edema (fluid retention that causes swelling in the tissues), notably of the face, hands and arms, and legs and feet
- loss of APPETITE, NAUSEA, and VOMITING
- FEVER (bacterial nephritis)

The diagnostic path begins with urinalysis and BLOOD tests that assess kidney function. Urinalysis may show the presence of BACTERIA, indicating the cause of the nephritis is infection. Other diagnostic procedures the nephrologist may choose to conduct include further blood and urine tests, ULTRASOUND, COMPUTED TOMOGRAPHY (CT) SCAN, and kidney biopsy. The biopsy shows the presence of inflammation and any damage that has occurred to the tubules or glomeruli.

Treatment Options and Outlook

Treatment depends on the underlying cause. Bacterial nephritis requires antibiotic therapy, often long term (up to six months). Severe infection requires hospitalization for intravenous ANTIBIOTIC MEDICATIONS. Most people recover fully and without residual damage from bacterial nephritis.

Because the kidneys play key roles in regulating BLOOD PRESSURE kidney disease that interferes with such functions can result in HYPERTENSION (high blood pressure), which requires treatment. The doctor may recommend dietary changes to limit sodium, protein, and water intake. Treatment for lupus nephritis often includes IMMUNOSUPPRESSIVE THERAPY.

Risk Factors and Preventive Measures

The primary risk factors for nephritis are the conditions that can cause it. Nephrotoxins are generally avoidable once the doctor identifies them as responsible for the nephritis. Bacterial infections nearly always migrate to the kidneys from elsewhere in the body. Early and appropriate treatment for the primary infection, particularly strep throat, helps prevent the infection from spreading to the kidneys.

See also GLOMERULONEPHRITIS; GLOMERULOSCLEROSIS; INHERITANCE PATTERNS; NEPHROPATHY; NEPHROTIC SYNDROME.

nephrolithiasis The formation of calcifications (also called calculi) in the KIDNEYS, usually called kidney stones. Kidney stones are common, with about 1 in 10 adults in the United States likely to have at least one over the course of adulthood. Some people pass kidney stones with little discomfort and may not even be aware of them, though for many people nephrolithiasis is extremely painful and debilitating. Kidney stones may lodge in the ureters or within the kidney, usually in the renal pelvis or a structure within the renal medulla called the calyx where the collection tubules empty their URINE.

Kidney stones that block the flow of URINE constitute a medical emergency that may require immediate treatment.

About 75 percent of kidney stones are made of calcium in combination with oxalate, phosphate, or carbonate. Calcium oxalate stones are the most common. About 10 percent of stones are made of uric acid and occur most frequently in men who have GOUT (a form of arthritis) or in people who are undergoing CHEMOTHERAPY. Other stones may form of cystine, an amino acid compound, or of struvite, a compound of magnesium, ammonia, and phosphate that tends to form in women who have frequent bacterial urinary tract infections (UTIs).

Symptoms and Diagnostic Path

Common symptoms of kidney stones include

- rapid onset of excruciating PAIN in the side (flank) or back
- persistent or colicky (wavelike) ABDOMINAL PAIN
- NAUSEA and VOMITING
- URINARY FREQUENCY and URINARY URGENCY
- FEVER and chills
- NOCTURIA (urination at night)
- groin pain in men or women or testicular pain in men

The diagnostic path may include abdominal X-RAY, ULTRASOUND, OR COMPUTED TOMOGRAPHY (CT) SCAN to detect the location of the stone. The doctor may also choose to conduct an INTRAVENOUS PYELOGRAM (IVP) to assess the extent to which a stone is blocking the flow of BLOOD or urine. Blood and urine tests may show elevated levels of calcium, uric acid, or oxalate.

Treatment Options and Outlook

Treatment for nephrolithiasis with severe pain begins with analgesic medication, often narcotic, to relieve the pain. Further treatment to move the stone out of the urinary tract may include EXTRACORPOREAL SHOCK WAVE LITHOTRIPSY (ESWL), a noninvasive method that effectively disperses stones up to 2 centimeters in diameter, or surgery such as percutaneous lithotomy in which the nephrologist uses laparoscopic surgery to snare and remove the stone. Most urologists prefer to take a course of watchful waiting with calculi that are not causing symptoms or that appear small enough to be able to pass through the urinary tract on their own, often recommending increased water consumption to increase the volume of the urine.

Kidney stones tend to recur, so often it is useful to determine the stone's composition, as this helps the nephrologist or urologist assess appropriate measures to reduce the risk for future stone formation. The doctor will likely recommend strain-

ing the urine to capture the stones or stone fragments when they pass, for laboratory analysis. Despite the pain they cause, kidney stones do not usually cause permanent damage to the kidneys.

People who have had kidney stones should make dietary modifications, such as calcium restriction, only if the doctor specifically recommends them. Though doctors once believed dietary calcium was a key culprit in the development of kidney stones, recent research shows that when blood levels of calcium are too high (HYPERCALCEMIA) the cause is more likely to be overabsorption from the gastrointestinal tract than excessive consumption. Cutting back on dietary calcium in such a situation can have the opposite and undesired consequence of increasing gastrointestinal absorption of calcium. Dietary calcium is essential for BONE STRENGTH and health, tissue HEALING, and proper NERVE and MUSCLE function.

Risk Factors and Preventive Measures

Men are more likely than women to develop kidney stones. As well, kidney stones appear to run in families, suggesting a genetic or hereditary component. People who have RENAL TUBULAR ACIDOSIS or INFLAMMATORY BOWEL DISEASE (IBD) have increased risk for developing nephrolithiasis. Lifestyle measures to reduce the risk for kidney stones include drinking six to eight 8-ounce glasses of water and getting physical exercise daily. These measures increase the volume of urine, helping dissolve minerals that might crystallize, and keeps the urine moving through the urinary system. The doctor may prescribe medication to reduce the risk of kidney stones in people who have history of RECURRENCE.

nephron The microscopic functional unit of the kidney. Each kidney contains more than a million nephrons, each of which extends from the renal cortex into the renal medulla in fairly linear fashion. Two elements make up the nephron: the renal tubules and the renal corpuscle. The renal corpuscle contains the GLOMERULUS, the coiled network of capillaries that bring BLOOD into the nephron, and Bowman's capsule, the podlike structure that encases the glomerulus. The pressure of the blood as it enters the glomerulus forces molecules of water, electrolytes, and other substances through the thin glomerular wall into Bowman's capsule. This mixture, called filtrate, collects in the capsule and drains into the renal tubule. Each segment of the tubule reabsorbs different substances from the filtrate as it passes through them. A second network of capillaries separate from the glomerulus, the peritubular capillaries, entwines the renal tubule to allow the reabsorbed materials to reenter the blood circulation.

The first portion of the tubule to exit Bowman's capsule, the proximal tubule (also called the proximal convoluted tubule), runs along the renal corpuscle, heading inward toward the renal medulla though it remains within the renal cortex. The proximal tubule reabsorbs about two thirds of the sodium and two thirds of the water the filtrate contains, and reabsorbs calcium when vitamin D is present. The next segment, the loop of Henle, drops deep into the renal medulla, makes a sharp loop, and rises back up into the renal cortex in somewhat of a hairpin appearance. Different portions of the loop of Henle reabsorb sodium, potassium, chloride, magnesium, calcium, and water. The loop of Henle plays a significant role in the concentration and dilution of the URINE, and is the target of some types of diuretic medications. The distal tubule (also called the distal convoluted tubule) continues up through the renal cortex and wraps around the renal corpuscle, ultimately joining with the collecting tubule (also called the collecting duct). The distal tubule reabsorbs sodium and bicarbonate and secretes potassium. The final segment of the renal tubule is the collecting tubule, which funnels the remaining filtrate toward the renal pelvis for excretion via the URETER as urine. Only water reabsorption takes place from the collecting tubule.

For further discussion of the nephron within the context of the urinary system's structure and function please see the overview section "The Urinary System."

See also BLADDER; FANCONI'S SYNDROME; KIDNEYS; URETHRA.

nephropathy Progressive, irreversible damage to the KIDNEYS that occurs as a result of systemic

health conditions or disease processes. Nephropathy is the main cause of END-STAGE RENAL DISEASE (ESRD) and the leading reason for KIDNEY TRANSPLANTATION. Doctors diagnose more than 100,000 Americans with nephropathy every year. DIABETES and HYPERTENSION (high BLOOD PRESSURE) are the leading cause of nephropathy in the United States. These conditions damage the delicate glomeruli, the capillary networks that feed BLOOD through the nephrons, the filtering structures of the kidneys. Each kidney contains more than a million nephrons and can tolerate the loss of about two thirds of them before symptoms of kidney failure become apparent. By such time, however, damage to the kidneys is usually profound.

Nephropathy of diabetes Diabetes accounts for 45 percent of kidney failure among Americans. The elevated GLUCOSE (sugar) levels in the blood that occur with diabetes are particularly damaging to the blood vessels and the nerves that serve them. For reasons researchers do not understand, African Americans, Hispanic Americans, and Native Americans who have diabetes are significantly more likely to develop nephropathy of diabetes (sometimes called diabetic nephropathy). About 40 percent of people who have diabetes develop some degree of nephropathy, half of whom eventually progress to ESRD. Nephropathy is more likely in type 1 diabetes.

Nephropathy of hypertension Hypertension accounts for 25 percent of nephropathy among Americans. Chronically elevated blood pressure places considerable stress against the walls of the glomeruli, causing microscopic ruptures and scarring (fibrosis). As with nephropathy of diabetes, nephropathy of hypertension (sometimes called hypertensive nephropathy) is significantly more likely to develop in African Americans, Hispanic Americans, and Native Americans. The progression to ESRD can be rapid in poorly controlled or untreated hypertension.

IgA nephropathy In IMMUNOGLOBULIN A (IgA) nephropathy, a dysfunction of the IMMUNE SYSTEM results in deposits of gA, a protein, accumulating within the tubules of the nephrons. The kidneys have no process for removing these deposits, which eventually clog the tubules and prevent them from transporting filtrate. IgA nephropathy typically is ongoing for 20 years or longer before causing enough damage to result in symptoms. Many people who have IgA nephropathy also have a systemic autoimmune disorder such as SYSTEMIC LUPUS ERYTHEMATOSUS (SLE), RHEUMATOID ARTHRITIS, or ANKYLOSING SPONDYLITIS. Treating the underlying autoimmune disorder often slows the progression of the nephropathy.

Toxic nephropathy Many drugs and chemicals are nephrotoxins, substances that damage the kidneys. Toxic nephropathy typically develops as a result of chronic exposure though can occur with limited though substantial exposure (such as DRUG overdose). Common nephrotoxins include heavy metals (such as lead and cadmium), organic solvents (such as benzene), and certain ANTIBIOTIC MEDICATIONS (notably gentamicin and streptomycin, which are sometimes the only antibiotics effective against life-threatening infections such as bacterial MENINGITIS).

Worrisome culprits are the NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS). DEHYDRATION in combination with NSAID use, which occurs among people who compete in ENDURANCE activities, is a particular risk. Long-term, daily use of other pain-relief medications, notably codeine and combination products that contain CAFFEINE with acetaminophen or aspirin, also can cause this form of toxic nephropathy, commonly called analgesic nephropathy. People who have conditions of chronic PAIN are most susceptible to analgesic nephropathy. People who have diabetes or congestive HEART FAILURE, have other kidney disease, engage in heavy ALCOHOL consumption, or are age 70 or older also have increased risk for analgesic nephropathy, in part because many people do not understand the danger regular analgesic use poses for the kidneys. These circumstances reduce kidney function, increasing the likelihood that further damage to the kidneys will result in kidney failure.

Symptoms and Diagnostic Path

Nephropathy generally does not show symptoms until damage to the kidneys is fairly advanced. One of the earliest indications of nephropathy is ALBUMINURIA, a consequence of protein leaking from the glomeruli into the filtrate. Doctors often detect albuminuria through urinalysis done as part of a routine medical examination. When symptoms do appear, they often include

- frothy URINE during URINATION (indicates albuminuria)
- edema (fluid accumulation in the tissues), most noticeable upon awakening and often affecting the face and the feet
- fatigue
- loss of APPETITE in combination with increased weight (weight gain results from edema)
- HEADACHE

Some forms of nephropathy also cause painless HEMATURIA (bloody urine). The diagnostic path includes further urine tests as well as BLOOD tests to assess kidney function. The nephrologist may perform a kidney biopsy to examine the nephrons under the microscope, which reveals the microscopic damage of nephropathy. The nephrologist may also conduct diagnostic imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN and INTRAVENOUS PYELOGRAM (IVP) to examine kidney structure and function.

Treatment Options and Outlook

Treatment targets the underlying condition with the aim of slowing progression of the nephropathy and preserving remaining kidney function. It is critically important for people who have diabetes or hypertension (or both) to maintain effective control of these conditions through medication therapy and lifestyle measures. Some people are able to successfully manage the underlying condition and the nephropathy to avoid ESRD, though often nephropathy progresses to require RENAL DIALYSIS. Whether kidney transplantation is a viable treatment option for ESRD resulting from nephropathy depends on multiple factors, including co-existing health conditions, age, and overall health status.

Risk Factors and Preventive Measures

Diabetes and hypertension combined cause more two thirds of nephropathy in the United States. The risk for nephropathy is particularly high for people who have both these conditions. Preventing these conditions and appropriately and diligently treating them when they develop mitigates the risk for nephropathy. People who take long-term NSAIDs to treat chronic conditions such as OSTEOARTHRITIS should have regular blood and urine tests to screen for early indications of nephropathy, and work with their doctors to find the lowest effective DOSE and least nephrotoxic medication to manage the condition and its symptoms.

See also HEAVY-METAL POISONING; HEPATORENAL FAILURE; NEPHRITIS; NEPHRON; NEPHROTIC SYNDROME; RETINOPATHY.

nephrotic syndrome A constellation of symptoms that result as a consequence of conditions that damage the glomeruli within the renal nephrons. The damage allows excessive protein to move through the walls of the glomeruli into the filtrate. The tubules are unable to reabsorb the large protein molecules, so the body ends up excreting the protein in the URINE (ALBUMINURIA). The excessive excretion of protein results in HYPOALBUMINEMIA, or low levels of ALBUMIN in the BLOOD circulation. The hypoalbuminemia allows fluid to leave the blood circulation and enter the interstitial tissues, where it accumulates to cause edema (swelling). Because the blood volume is now low, the KIDNEYS compensate by reabsorbing higher levels of water and sodium.

Most people who have nephrotic syndrome have diagnosed kidney disease so the underlying cause is clear. When indications of nephrotic syndrome occur in someone who does not have kidney disease, the diagnostic path begins with blood and urine tests to assess kidney function. Further diagnostic procedures then strive to identify the underlying renal condition. Treatment targets the underlying renal condition as well as symptoms such as HYPERTENSION (high BLOOD PRESSURE) and RENAL FAILURE. Treatment may include RENAL DIALYSIS when renal function is significantly impaired. The outlook depends on the underlying renal condition and its response to treatment. Symptoms of nephrotic syndrome generally resolve when the underlying condition improves.

See also GLOMERULONEPHRITIS; GLOMERULOSCLEROSIS; MINIMAL CHANGE DISEASE; NEPHRITIS; NEPHRON; UREMIA.

nephrotoxins Substances such as medications or environmental chemicals that damage the glomeruli and the tubules within the nephrons of

the KIDNEYS. Among those most commonly associated with altered kidney function and RENAL FAILURE are

- heavy metals such as lead, mercury, cadmium, and arsenic; exposure to these metals is most often occupational
- NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) such as ibuprofen, naproxen, and ketoprofen
- possibly acetaminophen
- Contrast dyes used in radiologic procedures
- certain ANTIBIOTIC MEDICATIONS, notably streptomycin and gentamicin
- organic solvents such as benzene

People who already have compromised kidney function or conditions such as DIABETES or HYPERTENSION (high BLOOD PRESSURE) are at greater risk for kidney damage resulting from nephrotoxins. Chronic DEHYDRATION, such as may occur with diuretic therapy or insufficient water consumption, increases the risk for kidney damage resulting from medications, especially NSAIDs.

See also HEPATOTOXINS; NEPHRON; NEPHROPATHY.

neurogenic bladder A condition in which the nerves that control the BLADDER do not work properly, allowing the bladder to be underactive (hypotonic) or overactive (spastic). Damage may occur to the SPINAL CORD AND SPINAL NERVES, BRAIN, or PERIPHERAL NERVES that serve the bladder. Conditions that can cause such damage include traumatic injury, STROKE, degenerative neurologic disorders such as MULTIPLE SCLEROSIS and PARKINSON'S DISEASE, NEUROPATHY of DIABETES and neuropathy of HIV/AIDS, and injury to the nerves of the bladder as a consequence of pelvic surgery (such as PROSTATECTOMY in men or HYSTERECTOMY in women). URINARY INCONTINENCE is the most common consequence of neurogenic bladder.

The diagnostic path includes urinalysis, BLOOD tests, and diagnostic imaging procedures such as CYSTOSCOPY, ULTRASOUND, or COMPUTED TOMOGRAPHY (CT) SCAN. The urologist may also perform a voiding CYSTOURETHROGRAM to evaluate the flow of URINE through the urinary system. Electromyogram (EMG) measures the response of the nerves and muscles of the bladder and urethra to mild electrical stimuli. Other tests can measure the capacity and rate of emptying of the bladder.

Treatment targets the underlying cause of the neurogenic bladder when possible. Other treatment measures aim to improve urinary incontinence. The success of the treatment often depends on the underlying cause. Various medications may increase or decrease the bladder's responses. Surgery is sometimes an option. Though it may take time and much trial and error, most people find acceptable measures for accommodating neurogenic bladder.

See also SPINAL CORD INJURY; TRAUMATIC BRAIN INJURY (TBI); URINARY TRACT INFECTION (UTI).

nocturia The need to get up from nighttime sleep to urinate. Nocturia is a significant cause of SLEEP DISORDERS though has numerous potential causes. Nocturia becomes more common with increasing age in both women and men, sometimes simply as a consequence of normal age-related changes that occur in the urinary tract. Key among these changes is the reduced ability of the BLADDER to distend because lost elasticity in the tissues, effectively shrinking the bladder's capacity.

Many people are unaware how much fluid they drink in the evening. The urinary system is still processing all this fluid when the person lies down to go to bed. Often, simply changing habits to minimize fluid consumption after dinner is enough to slow URINE production through the night. When nocturia persists despite such measures, the urologist may prescribe medications such as tolterodine or oxybutynin that slow the bladder's response.

CONDITIONS FOR WHICH NOCTURIA IS A COMMON SYMPTOM

BENIGN PROSTATIC HYPERPLASIA (BPH)	CYSTITIS
CYSTOCELE	HYDRONEPHROSIS
NEPHROLITHIASIS	NEUROGENIC BLADDER
PROSTATITIS	URINARY TRACT INFECTION (UTI)
UROLITHIASIS	VAGINITIS

See also AGING, URINARY SYSTEM CHANGES THAT OCCUR WITH; ENURESIS; URINARY INCONTINENCE.

oliguria Significantly reduced URINE production that occurs as a consequence of RENAL FAILURE, DEHYDRATION, hemorrhage (massive BLOOD loss), or SHOCK. Normal adult urinary output is 1500 milliliters to 3000 milliliters per day. In oliguria urinary output is 500 ml per day or less. Oliguria indicates that the KIDNEYS are not receiving enough blood or are not functioning to filter the blood. Unless urine output increases, toxins will accumulate in the blood and the circumstance may become life-threatening.

See also ANURIA; UREMIA.

P

percutaneous lithotripsy See EXTRACORPOREAL SHOCK WAVE LITHOTRIPSY (ESWL).

polycystic kidney disease An inherited disorder in which hundreds to thousands of cysts form in the KIDNEYS as well as in other organs and structures such as the LIVER, HEART, and BRAIN. The cysts greatly enlarge and deform the kidneys. The cysts arise from the nephrons, which they destroy as they grow. Polycystic kidney disease affects about 500,000 people in the United States and is the fourth-leading cause of END-STAGE RENAL DISEASE (ESRD). About 10 percent of people on long-term RENAL DIALYSIS have polycystic kidney disease.

The most common type of polycystic kidney disease is autosomal dominant, which affects more than 90 percent of people who have the condition. It occurs as the result of mutations in the PKD1 GENE located on CHROMOSOME 16 and the PKD2 gene on chromosome 4. GENETIC TESTING can detect the presence of these mutations, which confirms the diagnosis. The progression of kidney damage in autosomal dominant polycystic kidney disease typically takes place over decades, with symptoms beginning to manifest around age 30 to 40. A much less common type of polycystic kidney disease is autosomal recessive, which has a different clinical presentation and course of disease. Its symptoms are often present at birth or appear in early childhood.

Symptoms and Diagnostic Path

Autosomal dominant polycystic kidney disease typically shows no symptoms until the person is age 30 to 40. At that time the cysts become numerous enough and large enough to cause PAIN and disrupt kidney function. Urinary system symptoms that emerge include

- HEMATURIA (bloody URINE)
- frequent, recurrent URINARY TRACT INFECTION (UTI)
- kidney stones (NEPHROLITHIASIS)
- upper ABDOMINAL PAIN

Additional symptoms include HYPERTENSION (high BLOOD PRESSURE) resulting from damage to the kidneys and cysts in the liver and other organs. Diverticulosis, a gastrointestinal condition in which small pockets distend from the bowel, is also common. Some people may have deformed heart valves and deformities in blood vessels that cause aneurysms to develop.

Treatment Options and Outlook

Treatment focuses on relieving symptoms. ANTIBIOTIC MEDICATIONS are necessary to treat a UTI. Surgery may be necessary to repair any ANEURYSM and sometimes to reduce the size of the kidneys. Most people progress to ESRD within 10 years of the appearance of symptoms, at which time renal dialysis becomes necessary to sustain life. KIDNEY TRANSPLANTATION is often a viable treatment option. The transplanted kidney does not develop cysts. However, cysts do continue to develop in other organs.

Risk Factors and Preventive Measures

Polycystic kidney disease is both genetic and inherited. People who have this condition in their families may benefit from genetic testing to determine whether they carry the mutated genes, and to discuss their family planning options with a genetic counselor.

See also INHERITANCE PATTERNS; RENAL CYST.

proteinuria See ALBUMINURIA.

pyelonephritis See NEPHRITIS.

renal cancer The growth of a malignant (cancerous) tumor in the kidney. Doctors diagnose about 30,000 people in the United States with renal CANCER, also called kidney cancer, each year. Men are twice as likely as women to get renal cancer, and cigarette smokers (male or female) are two to four times as likely as nonsmokers to get renal cancer. The most common form of renal cancer is renal cell CARCINOMA (RCC), which accounts for more than 90 percent of RCC among Americans. RCC arises from the epithelial cells that line the tubules within the nephrons. A type of kidney tumor that occurs almost exclusively in children under age eight is WILMS'S TUMOR, also called nephroblastoma. Though Wilms's tumor also arises from the tubules, its cells, course of growth, and treatment options are unique. Cancer from other sites may metastasize to the kidneys.

Symptoms and Diagnostic Path

The earliest indication of renal cancer is HEMATURIA (BLOOD in the URINE), which may be gross (enough blood is present to discolor the urine) or microscopic (the laboratory detects erythrocytes in the urine during examination of the urine sample under the microscope). Other symptoms may include

- lump or swelling in the central abdomen
- fatigue
- abdominal or back PAIN not related to injury
- unexplained or unintended weight loss

STAGING OF RENAL CANCER

Renal Cancer Stage	Extent of Cancer Treatment	Protocols/Options
stage 1	tumor remains confined to one site in one kidney and is 7 cm or smaller	partial or simple NEPHRECTOMY
stage 2	tumor extends beyond the tissue capsule surrounding the kidney or is larger than 7 cm	radical nephrectomy
stage 3	tumor extends to adjacent lymph nodes or the veins that carry BLOOD from the kidney	radical nephrectomy biological therapy
stage 4	tumor extends to both kidneys or to other organs in the abdomen or to distant organs such as the LUNGS or BRAIN	palliative surgery palliative therapies
recurrent	tumor returns after treatment, appearing either in the same kidney (when first cancer was stage 1), the other kidney, or another location in the body	varies according to previous treatment

- edema (swelling due to retained fluid in the tissues), notably in the hands and feet

The diagnostic path begins with urine tests, blood tests, and abdominal ULTRASOUND or COMPUTED TOMOGRAPHY (CT) SCAN. Biopsy of the detected tumor confirms the diagnosis and provides information about whether the cancer has yet metastasized. The pathologist assigns the cancer a stage based on the appearance and behavior of its cells. The cancer's stage determines the appropriate treatment options and expected outcome of treatment.

Treatment Options and Outlook

Treatment depends on multiple factors including the person's age, overall health status, and location and stage of the cancer. Doctors generally prefer surgery (NEPHRECTOMY) to remove the tumor (stage 0) or the kidney (all other stages). The nephrectomy may be segmental (removal of only the tumor and a small margin of healthy tissue), simple (removal only of the kidney), or radical (removal of the kidney, surrounding tissue, and adjacent LYMPH NODES). CHEMOTHERAPY and RADIATION THERAPY are not very effective in treating renal cancer. Biological therapies such as INTERFERONS and INTERLEUKINS, which stimulate the IMMUNE SYSTEM to step up its attack against the cancer cells, are showing great promise in renal cancer. The oncologist may use biological therapy after surgery for renal cancers that are stage 3 and 4. Some studies suggest a combination of biological therapy and chemotherapy may be more effective than biological therapy alone in some people. Treatment for recurrent renal cancer depends on how and where the cancer returns as well as on previous treatment.

Risk Factors and Preventive Measures

Cigarette smoking is the most identifiable, as well as preventable, risk for renal cancer. Other lifestyle factors that raise an individual's risk for renal cancer include lack of physical exercise (sedentary lifestyle) and OBESITY. Researchers believe obesity alters hormonal activity in the body in ways that facilitate the growth of renal cell carcinoma. Other known risks for renal cancer include POLYCYSTIC KIDNEY DISEASE, exposure to asbestos, exposure to heavy metals such as arsenic and cadmium, and industrial chemicals such as benzene and trichloroethylene. Renal cancer is also more common in people between the ages of 50 and 70, and in people who have a family history of renal cancer. The latter suggests genetic involvement, though researchers have yet to confirm evidence of this.

See also ASBESTOSIS; BLADDER CANCER; KIDNEYS; NEPHRON; NEUROTOXINS; PROSTATE CANCER.

renal cyst An encapsulated, fluid-filled growth that occurs in the kidney. Simple renal cysts are common and nearly always benign (noncancerous). Complex renal cysts, which may contain calculi (stones) and BLOOD, may be benign or cancerous. Most renal cysts, simple or complex, do not cause symptoms. Rather, the doctor detects them during diagnostic procedures, such as abdominal ULTRASOUND or COMPUTED TOMOGRAPHY (CT) SCAN, to evaluate other health concerns. When symptoms do occur, they may include a sensation of pressure if the cyst is large enough to pressure other structures in the abdomen or interfere with kidney function. Occasionally, a renal cyst grows large enough or in a location to cause significant PAIN.

Ultrasound or CT scan generally provides enough information for the nephrologist to determine whether a renal cyst appears suspicious. A needle biopsy, which removes a small sample of tissue and fluid from the cyst, can show whether the cyst is cancerous. The nephrologist may recommend a course of watchful waiting for benign cysts that cause no symptoms. Surgery is necessary to remove symptomatic or cancerous cysts. Recovery from such surgery—which may be laparoscopic or open, depending on the size and location of the cyst—is generally complete and without complications. The presence of multiple cysts may indicate POLYCYSTIC KIDNEY DISEASE, a genetic disorder in which numerous cysts form in the KIDNEYS as well as in other organs. Recurrent cysts require further evaluation.

See also NEPHROLITHIASIS; RENAL CANCER.

renal dialysis Procedures to filter toxins from the BLOOD when the KIDNEYS are unable to perform this function. Renal dialysis can be short term or

long term. Though in theory renal dialysis could sustain life indefinitely, in practice most people experience a steady decline of overall health with long-term dialysis because artificial methods of cleansing toxins from the blood are not as effective, efficient, or thorough as the natural processes the kidneys perform. However, it is not uncommon for people to use renal dialysis for 10 to 20 years or longer. There are two general types of renal dialysis: hemodialysis and peritoneal dialysis.

Hemodialysis

Hemodialysis filters toxins directly from the blood. The person goes to a hemodialysis center for each dialysis treatment. A catheter inserted into a blood vessel, usually in the arm, routes the blood circulation externally through a machine that removes toxins. The cleansed blood then returns to the body through a second catheter. When hemodialysis is long term, the doctor places a permanent arteriovenous (AV) shunt that connects an ARTERY and a VEIN. The dialysis machine's cannulas then connect to the shunt.

The hemodialysis machine consists of a pump and a container, called the dialyzer with a semiporous membrane inside. The membrane looks somewhat like the filter inside a water purification canister. On one side of the membrane is a solution called the dialysate. The dialyzer pumps blood into the container on the other side of the membrane. The dialysate attracts certain substances—minerals, electrolytes, and waste byproducts—to cross the membrane from the blood. The dialysate absorbs these substances. Fresh dialysate circulates through the dialyzer at the same rate as the blood. The blood and the dialysate never come into direct contact with one another. Another type of filter traps any air bubbles that are in the blood before the blood returns to the body. The dialyzer holds only a few ounces of blood at a time. It takes three to five hours for the blood to circulate through the dialyzer enough times to remove an appropriate amount of waste and toxins. Most people need three hemodialysis sessions every week.

In the United States hemodialysis is the standard renal dialysis method. Many nephrologists feel it more thoroughly cleanses the blood. However, hemodialysis entails significant risks. Key among these risks are INFECTION with HEPATITIS and other bloodborne conditions, injury to the blood vessels used to shuttle blood between the person and the dialysis machine, and microscopic damage to the blood cells.

Peritoneal Dialysis

Peritoneal dialysis makes use of a natural membrane in the body, the peritoneum, which encloses the abdominal cavity. Peritoneal dialysis is a continuous process. Two catheters surgically inserted into the abdominal cavity serve as the portals through which dialysate enters and leaves the cavity. The doctor prescribes the dialysate, which comes premixed in single-DOSE bags.

The molecules of the dialysate are to large to pass through the peritoneum so the solution remains contained in the abdominal cavity. The blood's natural circulation carries blood through the blood vessels (capillary networks) within the peritoneum. As with hemodialysis, the dialysate attracts certain molecules to cross the membrane into the dialysate. A second catheter carries dialysate out of the abdominal cavity. There are two stages to peritoneal dialysis, the exchange (draining the dialysate into and out of the abdominal cavity) and the dwell (the time during which the dialysate remains in the abdominal cavity.

There are two types of peritoneal dialysis:

- Continuous ambulatory peritoneal dialysis (CAPD) instills dialysate into the abdominal cavity using gravity to pull the dialysate into the catheter. The dialysate remains in the abdominal cavity for about four hours, then the person drains it out through the second catheter. Most people who use this method need four treatments each day. Aside from the 30 minutes it takes to instill the dialysate and the 30 minutes it takes to drain the dialysate, the person is unencumbered and goes about his or her regular activities.
- Continuous cycler-assisted peritoneal dialysis (CCPD) uses a pump to rapidly infuse and extract the dialysate at night when the person is sleeping, with dwell times of about two hours. The person then infuses the abdominal cavity with dialysate upon awakening, and retains the solution all day for a single long dwell time.

The primary advantage of peritoneal dialysis is mobility. Most people are able to participate in regular activities, including work, while peritoneal dialysis is under way, provided the person can perform exchanges on the necessary time schedule and there is a hygienic, private location where the person can do the exchange. The success of peritoneal dialysis is more variable than that of hemodialysis because the permeability of the peritoneum varies among individuals. Some doctors believe peritoneal dialysis is less effective than hemodialysis at clearing toxins from the body.

Benefits and Risks of Renal Dialysis

Renal dialysis is the difference between life and death for people who have END-STAGE RENAL DISEASE (ESRD). For most people, the benefits clearly outweigh the potential risks and complications. The primary risks related to renal dialysis are infection, and, with hemodialysis, bleeding. Renal dialysis becomes less effective over time because it simply is not as effective as the body's natural mechanisms. A slow cascade of complications arises. Dialysis only cleanses the blood; it cannot restore kidney function or prevent further degeneration of the kidneys.

See also QUALITY OF LIFE.

renal failure The inability of the KIDNEYS to adequately filter toxins from the body. Generally the kidneys reach the point of renal failure when they have less than 15 percent functional capacity. Renal failure can be acute (occur suddenly) or chronic (develop slowly over time). Though the term *failure* implies the condition is permanent, but this is not necessarily the case. Most people who experience acute renal failure fully recover with appropriate treatment. When the deterioration of kidney function is progressive and irreversible, however, renal failure is not only permanent but also eventually becomes complete. This irreversible condition is END-STAGE RENAL DISEASE (ESRD). A person who has ESRD requires long-term RENAL DIALYSIS or KIDNEY TRANSPLANTATION to sustain life.

Acute renal failure Acute renal failure can occur in response to any circumstance that overwhelms the body, such as systemic INFECTION, severe BURNS, or a toxic assault such as a DRUG overdose or massive exposure to a nephrotoxin. DEHYDRATION and lack of BLOOD flow to the kidney (such as may occur with severe ATHEROSCLEROSIS or a blood clot) also can cause acute renal failure. Acute renal failure may require short-term renal dialysis to cleanse the blood while the kidneys recover as well as appropriate treatment for the cause of the renal failure.

COMMON CAUSES OF ACUTE RENAL FAILURE

acute NEPHRITIS	ALCOHOL poisoning
DEHYDRATION	DRUG OVERDOSE
extensive BURNS	gentamicin
HEART FAILURE	HEAT STROKE
HEMOLYTIC UREMIC SYNDROME	LIVER FAILURE
major surgery	multisystem failure
nephrotoxin exposure	reaction to contrast dye
renal ischemia	SEPTICEMIA
streptomycin	trauma

Chronic renal failure Chronic renal failure develops gradually over time, often years to decades. The most common causes of chronic renal failure are NEPHROPATHY of DIABETES and nephropathy of HYPERTENSION (high BLOOD PRESSURE). Other causes include long-term exposure to NEPHROTOXINS, long-term daily use of nephrotoxic drugs such as NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) and other ANALGESIC MEDICATIONS (PAIN relievers), notably codeine. Chronic renal failure may also consist of repeated bouts of acute renal failure that leave minor residual damage. Over time this damage becomes cumulative, causing scarring in the nephrons that impairs their ability to function. About 20 million Americans live with chronic renal failure.

COMMON CAUSES OF CHRONIC RENAL FAILURE

ALPORT'S SYNDROME	chronic HYDRONEPHROSIS
DIABETES	FANCONI'S SYNDROME
GLOMERULONEPHRITIS	GLOMERULOSCLEROSIS
GOODPASTURE'S SYNDROME	HEAVY-METAL POISONING
HYPERTENSION	lupus NEPHROPATHY
organic solvent exposure	POLYCYSTIC KIDNEY DISEASE
renal ARTERY ATHEROSCLEROSIS	RENAL CANCER

Symptoms and Diagnostic Path

Symptoms of renal failure depend on whether renal failure is acute or chronic. Acute renal failure typically causes neurologic symptoms. ANEMIA, hypertension (high blood pressure), congestive HEART FAILURE, and OSTEOPOROSIS (loss of BONE DENSITY and STRENGTH) often accompany chronic renal failure. The diagnostic path includes URINE and blood tests to assess kidney function, diagnostic imaging procedures such as ULTRASOUND and COMPUTED TOMOGRAPHY (CT) SCAN, and often kidney biopsy to microscopically examine the nephrons.

RENAL FAILURE SYMPTOMS

Acute Renal Failure	Chronic Renal Failure
edema	edema
gastrointestinal bleeding	fatigue
confusion	OLIGURIA (diminished URINE production)
loss of consciousness	headaches
seizures	NAUSEA, VOMITING, and loss of APPETITE

Treatment Options and Outlook

Treatment targets the underlying cause. Acute renal failure requires immediate and intensive medical care, often including hemodialysis. Dietary modifications (such as reduced sodium, protein, and fluid intake) and medications to control conditions such as diabetes and hypertension allow many people to live with chronic renal failure for years to decades. When chronic renal failure progresses to ESRD, renal dialysis or kidney transplantation become necessary to sustain life.

Chronic renal failure in children impairs growth because it interferes with the ability of the kidneys to maintain calcium balance within the body and to produce erythrocytes (red blood cells). Without adequate calcium the bones cannot grow, resulting in short stature. Erythrocytes are necessary to carry oxygen, GLUCOSE, and other NUTRIENTS to cells throughout the body. Without these nutrients, cells slow their rate of division. Doctors often prescribe calcitriol supplement, a form of vitamin D, for children who have chronic renal failure to improve the body's ability to retain calcium. Many doctors also prescribe HUMAN GROWTH HORMONE (HGH) SUPPLEMENT therapy to achieve normal growth patterns in children who have chronic renal failure, though not all doctors agree this is appropriate. Human growth HORMONE supplementation can have other deleterious effects on the body; it is important to balance such risks with the potential benefits.

Risk Factors and Preventive Measures

The major risk factors for chronic renal failure are diabetes and hypertension. Measures to reduce the risk for these conditions also lower the risk for kidney disease. Such measures include

- nutritious EATING HABITS
- daily physical activity
- SMOKING CESSATION
- maintenance of healthy body weight

Diligent control of diabetes or hypertension if these conditions are present can slow their effects on the kidneys. Because chronic renal failure tends to be progressive, it is important to address symptoms of deteriorating kidney function promptly and aggressively for optimal quality of life.

See also HEPATORENAL FAILURE; NEPHROTIC SYNDROME; NEPHRON.

renal tubular acidosis (RTA) A genetic disorder in which the renal tubule within the NEPHRON fails to release hydrogen ions into the filtrate. The consequence is a buildup of acid in the BLOOD (serum acidosis) that causes various symptoms and imbalances among the body's electrolytes. There are numerous forms of renal tubular acidosis (RTA), most of which are random (sporadic) though some types are familial. Common forms of RTA include

- type 1 RTA, which affects the distal tubule and may occur secondary to AUTOIMMUNE DISORDERS such as SJÖGREN'S SYNDROME or after KIDNEY TRANSPLANTATION
- type 2 RTA, which affects the proximal tubule and often accompanies conditions such as WILSON'S DISEASE, FANCONI'S SYNDROME, MULTIPLE MYELOMA, and HYPERPARATHYROIDISM as well as after kidney transplantation

- type 4 RTA, which may accompany NEPHROPATHY of DIABETES or HIV/AIDS, SYSTEMIC LUPUS ERYTHEMATOSUS (SLE), and SICKLE CELL DISEASE

The diagnostic path includes blood tests and URINE tests that measure acidity. Treatment is usually medication (pharmaceutical sodium bicarbonate) to maintain the blood's pH (acidity level) within the desired range and regular blood or urine tests to measure acidity.

See also GENETIC DISORDERS; GLOMERULUS; HYPERKALEMIA; INHERITANCE PATTERNS.

U

uremia A serious condition in which nitrogen-based toxins such as urea and creatinine, the primary waste products of METABOLISM, accumulate in the BLOOD because the KIDNEYS are unable to filter them out and pass them from the body via the URINE. Uremia indicates RENAL FAILURE. Urologists sometimes use the term azotemia to designate preclinical uremia—that is, rising levels of urea in the blood that have not yet reached a level at which they cause symptoms.

Symptoms of uremia include

- NAUSEA and VOMITING
- confusion
- HEADACHE
- loss of APPETITE
- lethargy and difficulty concentrating

Blood and urine tests to measure levels of blood urea nitrogen (BUN) and creatinine confirm the diagnosis. Treatment is generally RENAL DIALYSIS to filter metabolic wastes and toxins from the blood, to restore the body's electrolyte, chemical, and water balances. KIDNEY TRANSPLANTATION may be a viable treatment option when kidney failure becomes permanent, such as in END-STAGE RENAL DISEASE (ESRD).

See also NEPHROPATHY; NEPHROTOXINS.

ureter A tubular structure that carries URINE from the kidney to the BLADDER. Urine from the kidney's collecting tubules drains into the renal pelvis, which channels the urine into the ureter. The ureter exits the kidney at the hilus and parallels the inferior VENA CAVA (left ureter) or the AORTA (right ureter) through the abdomen to the pelvis. At the pelvis the ureter crosses over the respective iliac branches (ARTERY and VEIN) and enters the top back of the bladder. The ureter forms a short, flattened tunnel within the bladder wall before opening into the interior of the bladder. This tunnel functions as a valve to help keep urine from flowing back up the ureter from the bladder. Each ureter is about 12 inches long, though the left is slightly longer than the right as the left kidney sits about an inch higher in the abdomen. The structure of the ureters is the same in men and women.

A smooth epithelial membrane forms the inner lining of the ureter. Two layers of MUSCLE surround the ureteral epithelium, the first running more or less lengthwise (longitudinal) though spiraling widely around the epithelium, and the second wrapping around the ureter in a circular pattern. The outer layer of the ureter is fibrous tissue. The muscle layers of the ureter contract in rhythmic waves (PERISTALSIS) to move urine from the kidneys to the bladder. The ureter is fairly thick and rigid, with an inner diameter of only 3 or 4 millimeters.

For further discussion of the ureters within the context of the urinary system's structure and function please see the overview section "The Urinary System."

See also GLOMERULUS; KIDNEYS; NEPHRON; URETHRA; VESICOURETERAL REFLUX.

urethra A narrow, somewhat muscular tube that carries URINE from the BLADDER to the outside of the body. The point of exit is the urinary or urethral meatus. The urethral sphincter MUSCLE at the base of the bladder controls the release of urine into the urethra. Once the urethral sphincter relaxes to let urine pass, the urine flows to the outside of the body until the bladder empties and the urethral sphincter tightens. It may take a few seconds after the sphincter closes for the residual urine in the

urethra to make its way out the urethral opening. BLADDER CATHETERIZATION, CYSTOSCOPY, ureteroscopy, and intravesical therapies use the urethra to enter the urinary system (usually with sedation or ANESTHESIA, except catheterization).

In a woman the urethra is about an inch and a half long, extending from the base of the bladder to the external GENITALIA where it exits the body between the CLITORIS and the VAGINA. The urethra's only role in a woman is to carry urine from the body. In a man the urethra is about eight inches long and extends from the base of the bladder to exit the body at the tip of the PENIS. As it exits the bladder in a man the urethra passes through the PROSTATE GLAND, which encircles the neck of the bladder. The male urethra also carries SPERM during EJACULATION. The VAS DEFERENS, the tube that carries SEMEN from the male reproductive organs, enters the urethra at the prostate gland. A valve at the base of the urethra directs the flow of either urine or semen through the urethra.

For further discussion of the urethra within the context of the urinary system's structure and function please see the overview section "The Urinary System."

See also EPISPADIAS; HYPOSPADIAS; RETROGRADE EJACULATION.

urethral stricture Narrowing of the URETHRA, impeding the passage of URINE from the BLADDER to the outside of the body. Urethral stricture may be congenital (present at birth) or acquired such as through scarring resulting from repeated URETHRITIS, BLADDER CATHETERIZATION, and other irritations to the urethra. BENIGN PROSTATIC HYPERPLASIA (BPH) and PROSTATITIS also can cause urethral stricture in men.

Symptoms of urethral stricture include

- straining when urinating
- the sensation that the bladder does not empty with URINATION (URINARY RETENTION)
- diminished urine flow
- frequent URINARY TRACT INFECTION (UTI)

The diagnostic path begins with urinalysis to determine whether INFECTION is present. Further diagnostic procedures may include CYSTOSCOPY to examine the urethra and bladder, INTRAVENOUS PYELOGRAM (IVP) to assess the flow of BLOOD and urine through the urinary system, or COMPUTED TOMOGRAPHY (CT) SCAN or ULTRASOUND to visualize the structures of the lower pelvis. Treatment targets the identified cause and may include ANTIBIOTIC MEDICATIONS when infection is present in addition to other therapies. Such therapies often include cystoscopic surgery to cut away SCAR tissue within the urethra or open surgery (urethroplasty) to reconstruct a badly scarred or damaged urethra. These methods permanently restore the flow of urine through the urethra and have minimal complications or risks.

See also UROLITHIASIS.

urethritis INFLAMMATION of an URETER. INFECTION, typically a sexually transmitted disease (STD), is the most common cause of urethritis though urethritis may occur as a result of inflammation or irritation from trauma such as occurs with BLADDER CATHETERIZATION or CYSTOSCOPY. Traumatic urethritis improves rapidly when the source of the trauma is gone, often without further treatment. Urologists classify infectious urethritis as gonococcal urethritis (GU) or nongonococcal urethritis (NGU). Symptoms may be vague and transient (disappear in a few days) or nonexistent, though the infection remains. In about 40 percent of women, urethritis progresses to PELVIC INFLAMMATORY DISEASE (PID) and INFERTILITY. Repeated or untreated urethritis in men may destroy testicular tissue, resulting in sterility. As well, untreated urethritis in men or women remains contagious through sexual contact.

Symptoms and Diagnostic Path

Often urethritis does not have symptoms, particularly in women. When symptoms are present they typically include

- puslike or bloody discharge from the PENIS
- PAIN or burning with URINATION (DYSURIA)

Laboratory analysis of discharge or swabs of the interior of the urethra identify the responsible PATHOGEN. Generally no further diagnostic proce-

dures are necessary unless other health concerns coexist.

Treatment Options and Outlook

Treatment is the appropriate antibiotic medication to kill the pathogen. It is important to take the full amount of the antibiotic as prescribed. Though tempting to stop the medication when symptoms abate, incomplete treatment allows the BACTERIA to surge back to reinfect. It also can permit bacteria to develop resistance to commonly prescribed antibiotics, requiring more powerful antibiotics for subsequent treatment. Both GU and NGU can occur repeatedly when the person becomes reinfected. Each cycle of infection requires treatment. It is important (and in many states a legal requirement) to notify sexual partners so they also can receive treatment.

Risk Factors and Preventive Measures

The primary risk for GU and NGU infection is unprotected sex, particularly with multiple partners. Men who have sex with men are at highest risk. Safer sex methods, including the use of a new condom for each sex act, help reduce exposure to the bacteria that cause urethritis though are not foolproof. Traumatic urethritis sometimes becomes chronic in people who must use long-term bladder catheterization, such as those who have SPINAL CORD INJURY resulting in paraplegia. The urologist may prescribe prophylactic antibiotics and anti-inflammatory medications in such situations. Diligent PERSONAL HYGIENE further helps reduce irritation and infection.

See also CHLAMYDIA; CYSTITIS; EPIDIDYMITIS; GONORRHEA; PROSTATITIS; REITER'S SYNDROME; SEXUAL HEALTH; SEXUALLY TRANSMITTED DISEASES (STDS).

urinary diversion A surgical procedure to create a method for the storage and passage of URINE from the body after cystectomy (surgical removal of the BLADDER). Though most often necessary following cystectomy to treat BLADDER CANCER or invasive cancer of the pelvic region, urinary diversion may be necessary after traumatic injury to the bladder. Urinary diversion may also be a palliative treatment for inoperable bladder or pelvic cancer, diverting the flow of urine to overcome urinary obstruction. Urinary diversion may be continent (collects and contains urine within the body), which most people prefer when it is possible, or incontinent (collects a steady flow of urine in a bag outside the body).

Continent Urinary Diversion

When the urethra remains intact the urologic surgeon can fashion a substitute bladder, called a neobladder, from a segment of bowel (which has the ability to expand somewhat), attaching the ureters and the URETHRA. The neobladder allows the person to urinate naturally. However, the neobladder requires more frequent, and usually timed or scheduled, emptying as it lacks the distention ability and capacity of the native bladder as well as the nerves that activate the micturition REFLEX.

When the cystectomy also includes removal of the urethra, the surgeon generally chooses to craft a collection reservoir from a segment of SMALL INTESTINE that remains in the abdominal cavity, then create a valved opening through the abdominal wall into the reservoir. The person periodically inserts a catheter into the opening to drain the urine, usually every three to four hours, including through the night. Though not as natural as the neobladder, the catheter reservoir still permits urinary continence.

Incontinent Urinary Diversion

Incontinent urinary diversion is similar to the catheter reservoir, except the opening through the abdominal wall, called a stoma, lacks a valve. The person attaches an ostomy bag over the opening using special adhesive. Urine drains continuously into the bag, and periodically the person removes the full bag and replaces it with a clean, empty bag. The bags are small and unobtrusive beneath the clothing. The adhesive ensures there is no leakage of urine. A urostomy bag may require changing every six to eight hours. Surgeons use this method, called urostomy or ileal conduit, primarily when continent urinary diversion is not a viable option.

Outlook and Lifestyle Modifications

Urinary diversion requires diligent attention to hygiene and emptying collected urine. Though the neobladder is the most natural urinary diversion

method, it requires more frequent emptying than would the natural bladder. Likewise the catheter reservoir, which further requires the person to carry a catheter at all times. URINARY TRACT INFECTION (UTI) tend to be more frequent in people who have any form of urinary diversion, though are most common with urostomy. Urostomy also may cause irritation to the SKIN around the stoma. Many people who have urostomies or catheter reservoirs feel self-conscious about them. The urologist or hospital can provide information about support groups where people who have urinary diversions can share their concerns and experiences.

See also COLOSTOMY; ILEOANAL RESERVOIR; ILEOSTOMY; QUALITY OF LIFE; SURGERY BENEFIT AND RISK ASSESSMENT.

urinary frequency The need to urinate more often than normal. Urinary frequency is common in PREGNANCY, CYSTITIS, URINARY TRACT INFECTION (UTI), BENIGN PROSTATIC HYPERPLASIA (BPH) and PROSTATITIS in men, and DIABETES. Urinary frequency at night is NOCTURIA. Sometimes the cause is excessive fluid consumption, particularly in the evening when nocturia is a problem. The diagnostic path may include urinalysis, assessment of any symptoms that accompany the urinary frequency, and procedures such as abdominal ULTRASOUND or CYSTOSCOPY to evaluate the BLADDER and URETHRA. Treatment targets the underlying cause. The doctor may prescribe medications such as tolterodine or oxybutynin to slow the bladder's response when no clear-cut cause emerges and symptoms persist.

See also URINARY INCONTINENCE; URINARY URGENCY.

urinary incontinence The involuntary leakage of URINE from the URETHRA. Health experts estimate that as many as 12 million Americans experience some degree of urinary incontinence, which becomes increasingly common with advancing age. There are several types of urinary continence. They include

- stress incontinence, in which urine leaks with activities such as sneezing, coughing, or laughing
- urge incontinence, in which urine leakage accompanies a sudden and overwhelming desire to urinate
- overflow incontinence, in which the bladder fails to send or respond to the normal NERVE signals that direct urination and becomes overly full, eventually leaking urine because it can hold no more volume

Many people, particularly women past MENOPAUSE, experience a combination of stress and urge incontinence. This combination form of urinary incontinence develops when the pelvic muscles and ligaments that support the bladder weaken and stretch. Overflow incontinence is more common in older men who have BENIGN PROSTATIC HYPERPLASIA (BPH). The enlarged PROSTATE GLAND can constrict the urethra, preventing urine from leaving the bladder. Overflow incontinence may also develop in people who have NEUROPATHY of DIABETES, long-standing chronic ALCOHOLISM, or conditions of the NERVOUS SYSTEM that affect control of involuntary functions such as MULTIPLE SCLEROSIS.

The diagnostic path includes a careful history of the urinary incontinence, BLOOD and urine tests, and possibly diagnostic imaging procedures such as ULTRASOUND or CYSTOSCOPY to identify any underlying conditions that could be causing the urinary incontinence. Treatment may be lifestyle modification, such as altering fluid consumption habits or emptying the bladder on a schedule. Many people, especially women, regain continence with KEGEL EXERCISES to strengthen and tone the pubococcygeal MUSCLE that forms the pelvic floor. Incontinence pads and other items help protect clothing from leaking urine. Sometimes medications to slow the bladder's response, such as oxybutynin (Ditropan), help ease urge incontinence. In situations that do not improve the urologist may suggest surgery to tighten pelvic muscles or the urethral sphincter. Though finding the most effective solution may take time, most people are able to successfully manage urinary incontinence.

See also ENURESIS.

urinary retention The inability to completely empty URINE from the BLADDER with URINATION. Because urinary retention presents a risk for bacterial URINARY TRACT INFECTION (UTI) or NEPHRITIS (INFECTION of the KIDNEYS), it is important to find and treat its cause. The most common cause is an

obstruction that blocks or narrows the URETHRA such as a bladder stone (UROLITHIASIS), URETHRITIS or URETHRAL STRICTURE, BENIGN PROSTATIC HYPERPLASIA (BPH) or PROSTATITIS in men, CYSTOCELE (sagging of the bladder) or UTERINE PROLAPSE in women, and rarely a tumor. As well, STROKE, SPINAL CORD INJURY, or TRAUMATIC BRAIN INJURY (TBI) can damage the nerves that control urination. The diagnostic path may include urinalysis and CYSTOSCOPY or ULTRASOUND to evaluate the urethra and bladder. Treatment targets the underlying cause and may include BLADDER CATHETERIZATION to empty the bladder of urine, either as an emergency procedure for acute urinary retention or on a routine basis for chronic urinary retention. Often, the underlying cause is treatable and the urinary retention resolves.

See also URINARY FREQUENCY; URINARY URGENCY.

urinary urgency The overwhelming sensation of the need to urinate. Urinary urgency, also called overactive BLADDER, can cause a person to urinate dozens of times each day. Though a common symptom of conditions such as CYSTITIS and URINARY TRACT INFECTION (UTI), especially when urinary urgency occurs in combination with URINARY FREQUENCY, urinary urgency may indicate a blockage in the urinary tract or result from neurologic conditions or injuries. Urinary urgency may also result in URINARY INCONTINENCE (inability to hold the URINE), even when the amount of urine in the bladder is small. Other common causes include DIABETES, PREGNANCY in women and BENIGN PROSTATIC HYPERPLASIA (BPH) in men. The diagnostic path begins with an assessment of any symptoms that accompany the urinary urgency, urinalysis, and perhaps procedures such as CYSTOSCOPY and pelvic ULTRASOUND to examine the bladder and URETHRA. Treatment targets any identified underlying cause. The doctor may prescribe medications such as tolterodine or oxybutynin to slow the bladder's response.

See also NEUROGENIC BLADDER; URINARY RETENTION.

urinary tract infection (UTI) A bacterial INFECTION of the BLADDER and URETHRA. The most common bacterial culprit is *Escherichia coli*, which is normally present in the gastrointestinal tract. Other BACTERIA may also cause UTI. Typically UTI, commonly called bladder infection, refers to infection that remains in the bladder and urethra. UTI may be acute (come on suddenly) or chronic (occur repeatedly over time). Untreated or undertreated UTI can spread into the KIDNEYS (NEPHRITIS), causing significant illness and the potential for permanent damage to the delicate tubules and glomeruli of the nephrons.

Symptoms and Diagnostic Path

Symptoms of acute UTI tend to be more intense than symptoms of chronic UTI, though either can be highly uncomfortable. The general symptoms of UTI include

- DYSURIA (burning with URINATION)
- URINARY FREQUENCY and URINARY URGENCY
- HEMATURIA (bloody URINE)
- cloudy, foul-smelling urine
- aching or discomfort in the lower pelvis or lower back

Urinalysis shows the presence of bacteria in most UTIs, confirming the diagnosis. Urinalysis does not identify the kind of bacteria, however. The doctor may choose to obtain a urine sample via BLADDER CATHETERIZATION (to avoid contamination by bacteria normally on the SKIN's surface) and culture it in the laboratory to determine the kind of bacteria present. A urine culture is especially helpful in chronic UTI or when symptoms fail to respond to initial treatment. A urologist may recommend additional diagnostic procedures for chronic UTI to determine the underlying reasons for the frequency or persistence of infection.

Treatment Options and Outlook

ANTIBIOTIC MEDICATIONS are the standard treatment for UTI. The antibiotic and length of treatment depend on the bacteria causing the infection. Most UTIs in women respond to a 3-day course of the antibiotic TMP-SMX or an antibiotic in the fluoroquinolone family such as ciprofloxacin. Women who cannot take either of these antibiotics may instead take an antibiotic in the tetracycline family (tetracycline or doxycycline) or the cephalosporin family (such as cefaclor). Men take the same antibiotics though often require a longer course,

typically 7 to 10 days. It is important to continue taking all prescribed doses of the antibiotic, even when symptoms improve, to make sure the antibiotic kills all the bacteria. The doctor may prescribe low-DOSE antibiotic medications for long-term preventive therapy (six months to a year) in women who have recurrent UTIs.

The medication phenazopyridine, a topical anesthetic that numbs the inner lining of the bladder and urethra, relieves discomfort during the first 36 to 48 hours of the UTI until the antibiotic begins eliminating bacteria. Phenazopyridine colors the urine deep orange and stains clothing. Some people experience intense bladder spasms, for which the doctor may prescribe a short course of antispasmodic medications such as flavoxate or methenamine.

ANTIBIOTICS COMMONLY PRESCRIBED TO TREAT UTI

amoxicillin	cefaclor	cefixime
cefotaxime	cefpodoxime	cefprozil
cefuroxime axetil	ciprofloxacin	doxycycline
fosfomycin	levofloxacin	nitrofurantoin
norfloxacin	ofloxacin	sparfloxacin
sulfamethoxazole trimethoprim	tetracycline	TMP-SMX

Risk Factors and Preventive Measures

UTIs are common in girls and women though uncommon in boys and men because of differences in anatomy. The very short female urethra provides an easy route for bacteria to travel into the bladder. Health experts estimate that one in five women will have at least one UTI during her lifetime. Measures to reduce the risk for UTI include

- drinking enough water (six to eight 8-ounce glasses daily)
- urinating when the bladder signals it is full
- wiping with toilet tissue from front to back
- urinating soon after SEXUAL INTERCOURSE
- prophylactic antibiotics when UTI occurs three times in a year or more frequently

About 20 percent of women who have one UTI have another; recurrent UTI is rare in men. Though untreated or undertreated UTI can cause serious and permanent damage to the urinary system, people who have appropriately treated UTIs typically recover completely and without residual complications.

See also CYSTITIS; GLOMERULUS; NEPHRON; SEXUALLY TRANSMITTED DISEASES (STDS); URETHRITIS.

urination The act of passing URINE from the BLADDER, also called uresis or micturition. Urination occurs when the urethral sphincter relaxes at the same time the detrusor MUSCLE that forms the middle layer of the bladder wall contracts, squeezing urine into the URETHRA. The urethra carries the urine to the meatus, its opening on the outer surface of the body. In men the meatus is at the tip of the PENIS; in women the meatus is within the VULVA between the CLITORIS and the VAGINA. Urination ends when the bladder sphincter closes and the residual urine in the urethra passes from the body.

Urination is a blend of involuntary and voluntary control. At birth urination is completely under the control of the micturition REFLEX and the sympathetic NERVOUS SYSTEM, which regulates involuntary functions. The micturition reflex is the series of events that begins when the filling of the bladder with urine activates specialized nerves in the bladder wall called stretch receptors. The stretch receptors send NERVE signals out to the SPINAL NERVES (S2, S3, and S4) that control the urethral sphincter and the detrusor muscle. The spinal nerves send back the nerve signals that stimulate the detrusor muscle to contract and the urethral sphincter to relax. A structure within the pons of the brainstem, the pontine micturition center (PMC), coordinates these functions to occur simultaneously.

The ability to control urination becomes possible around the ages of three to five when the muscles and nerve paths mature. At this point of development the BRAIN can override the involuntary nerve processes and the pubococcygeal muscle, which is a voluntary muscle, can override the involuntary muscle functions of the bladder. The normal frequency of urination varies among individuals and with fluid consumption, which largely determines urine volume. A healthy adult produces between 1.5 and 3 liters of urine every 24 hours. Typically the stretch receptors respond when the bladder contains about 200 to 300 milli-

liters of urine; maximum capacity of the bladder is about 500 ml.

CONDITIONS OF ALTERED URINATION

ANURIA	DYSURIA
HEMATURIA	NOCTURIA
URINARY FREQUENCY	URINARY INCONTINENCE
URINARY RETENTION	URINARY URGENCY

See also NEUROGENIC BLADDER.

urine The liquid the KIDNEYS generate to pass wastes and excess fluid from the body. The typical adult makes and passes between 1,500 and 3,000 milliliters (1.5 to 3 liters) of urine every 24 hours. Numerous variables influence the volume and composition or urine, though in general urine is 95 percent water and 5 percent suspended or dissolved solids.

Most of the solids urine contains are organic wastes in the forms of urea, uric acid, creatinine, and ammonia. These are the nitrogen-based waste byproducts of METABOLISM that the kidneys filter from the BLOOD. The urine also contains minerals (electrolytes) the kidneys excrete to maintain the body's electrolyte and fluid balance. Excreted electrolytes include sodium, potassium, chloride, magnesium, phosphate, and calcium. Normal urine may contain small amounts of ALBUMIN (protein).

Urine of normal concentration is pale yellow and has no odor. Dilute urine is colorless; concentrated urine can appear dark yellow to orange. Dietary substances, certain medications, and certain health conditions can alter the color as well as the odor of the urine. Normal urine is slightly acidic and has a specific gravity of 1.010 to 1.025, slightly above that of water. Deviations from normal urine composition and concentration suggest various health conditions and may require diagnostic evaluation.

For further discussion of the urine within the context of the urinary system's structure and function please see the overview section "The Urinary System."

See also ALBUMINURIA; ANURIA; CYSTINURIA; HEMATURIA; OLIGURIA; UREMIA; UROLITHIASIS.

urolithiasis The formation of calcifications (also called calculi) in the BLADDER. Most bladder stones, like kidney stones, form of calcium in combination with oxalate (the most common combination), phosphate, or magnesium. Bladder stones are less common today than kidney stones (NEPHROLITHIASIS), though throughout recorded history bladder stones have been a common urologic condition. Bladder stones are most likely to form when URINE remains in the bladder for an extended time, particularly with URINARY RETENTION (in which the bladder fails to completely empty with URINATION). URETHRAL STRICTURE, CYSTOCELE, BENIGN PROSTATIC HYPERPLASIA (BPH), long-term BLADDER CATHETERIZATION, and NEUROGENIC BLADDER are among the conditions that contribute to the formation of bladder stones. Chronic DEHYDRATION, such as occurs with drinking too little water, further contributes to calcification. Bladder stones are also common during PREGNANCY.

In urinary stasis the minerals dissolved in the urine begin to settle out when the urine is static (not moving), forming crystals. The formed crystals attract more of their composite minerals, eventually hardening into calculi. Small stones often easily pass through the urethra in the urine without the person's awareness of them. Stones that are large enough to scrape the walls of the urethra, or sandlike clumps of calculi that surge through the URETHRA, may cause irritation such as DYSURIA (burning sensation) with urination. Other symptoms may include URINARY FREQUENCY, URINARY URGENCY, and urinary hesitation (difficulty starting urination, or start-and-stop urination).

A stone that completely blocks the urethra, often at the neck of the bladder, causes excruciating PAIN that may feel as though it arises in the groin or, in men, in the TESTES (testicles). Often a change in position relieves the pain, causing the urine to wash the stone from its point of occlusion. A stone that is larger than the diameter of the urethra will intermittently though persistently obstruct the passage of urine. It may also cause bleeding, resulting in HEMATURIA (blood in the urine).

The diagnostic path typically includes urinalysis, ULTRASOUND to detect the presence of stones in the bladder, and CYSTOSCOPY. Cystoscopy often is both diagnostic and therapeutic, allowing the urologist to confirm the presence of stones as well as remove them from the bladder. Larger stones may require treatments such as EXTRACORPOREAL SHOCKWAVE

LITHOTRIPSY (ESWL) or surgical procedures such as percutaneous lithotomy or open cystostomy to remove the stones. Most people recover fully. Bladder stones tend to recur, however.

See also CYSTINURIA; HYPERCALCIURIA; HYPEROXALURIA.

urostomy See URINARY DIVERSION.

V

vesicoureteral reflux A condition in which URINE backflows from the BLADDER into the ureters toward the KIDNEYS. Vesicoureteral reflux may result from congenital anomalies in the structure of the ureters, such as short ureters or ureters that enter the bladder wall in an unusual location or at an unusual angle. Normally the URETER forms a short, flattened tunnel within the bladder wall that functions like a valve to keep urine from reentering the ureter from the bladder. Structural anomalies may prevent the valvelike action of the ureter's entrance into the bladder from functioning properly, such that when the bladder fills with urine the ureter is open and allows urine to enter.

Vesicoureteral reflux may also develop secondary to an obstruction that blocks the flow of urine from the bladder, such as bladder stones (UROLITHIASIS) or an enlarged PROSTATE GLAND in a man. Such an obstruction causes the bladder to overdistend, which causes the ureteral tunnels to open and allow urine to enter the ureters. INFECTION that inflames and narrows the URETHRA also can obstruct the flow of urine out of the bladder. Vesicoureteral reflux presents a high risk for INFLAMMATION and bacterial infection of the kidneys

VESICOURETERAL REFLUX GRADING

Reflux Grade	Extent of Urine Reflux	Effect on Kidneys
grade 1	part way up URETER but not into the kidney	increased risk for NEPHRITIS
grade 2	completely up ureter to renal pelvis	increased risk for nephritis
grade 3	URINE backs up into the renal pelvis and renal calyces	mild dilation of renal pelvis and ureters mild nephritis likely
grade 4	urine distends the renal pelvis and renal calyces	significant dilation of ureters nephritis HYDRONEPHROSIS with mild to moderate impaired renal function risk of permanent kidney damage
grade 5	as much or more urine refluxes as passes from the URETHRA	extensive and persistent dilation of ureters, renal pelvis, and renal calyces nephritis hydronephrosis with significant impaired renal function secondary problems such as HYPERTENSION permanent kidney damage likely

(NEPHRITIS) by introducing into the kidneys BACTERIA that may be present in the urine. Vesicoureteral reflux also can cause HYDRONEPHROSIS, dilation of the renal pelvis that results from the accumulation of urine. Nephritis and hydronephrosis both can cause permanent and sometimes progressive kidney damage.

Symptoms and Diagnostic Path

The most common indication of vesicoureteral reflux is infection, the symptoms of which typically include

- flank or ABDOMINAL PAIN
- FEVER and chills
- HEMATURIA (BLOOD in the urine) or cloudy urine
- DYSURIA (discomfort with URINATION)
- urinary frequency and urinary urgency

As well, the person may strain when urinating and feel as though urine remains in the bladder (URINARY RETENTION) after urinating. The diagnostic path begins with urinalysis, which shows the presence of bacteria, leukocytes (white blood cells that fight infection), and erythrocytes (red blood cells) when there is an infection. The urologist may perform diagnostic imaging procedures, such as abdominal ULTRASOUND or COMPUTED TOMOGRAPHY (CT) SCAN, to visualize the structures of the urinary system and identify any anomalies. Radionuclide scan, INTRAVENOUS PYELOGRAM (IVP), and voiding CYSTOURETHROGRAM are additional diagnostic procedures that help the urologist assess the urinary system's structure and function. Diagnosis of vesicoureteral reflux includes the designation of grade, which denotes the severity of the urine reflux and the effect on the kidneys.

Treatment Options and Outlook

Infection requires immediate treatment with ANTIBIOTIC MEDICATIONS. When the vesicoureteral reflux occurs secondary to an obstructive condition, treatment targets the underlying cause as well as any consequential infection. Treatment for primary vesicoureteral reflux depends on the person's age and the grade of the reflux. Children are likely to outgrow grade 1 and grade 2 reflux when the cause is short ureters and often when the cause is unusual entry of the ureters into the bladder. Grade 3 reflux may require corrective surgery. Grade 4 and grade 5 refluxes require reconstructive surgery such as ureteroneocystostomy, in which the surgeon creates new insertion tunnels into the bladder for the ureters. Appropriate treatment reduces the risk for permanent damage to the kidneys and restores the normal flow of urine.

Risk Factors and Preventive Measures

In children the primary risk factors for vesicoureteral reflux are anomalies of structure within the urinary system; these are not preventable. In adults risk factors for vesicoureteral reflux include NEPHROLITHIASIS (kidney stones), urolithiasis, chronic URINARY TRACT INFECTION (UTI), and BENIGN PROSTATIC HYPERPLASIA (BPH) in men. Prompt and appropriate treatment for these conditions reduces the risk they will cause vesicoureteral reflux.

Wilms's tumor A malignant (cancerous) growth in the kidney. Wilms's tumor, also called nephroblastoma, nearly always affects children under age six. Though relatively rare, with doctors diagnosing about 500 children a year in the United States with this form of kidney cancer, Wilms's tumor is the most common cancer of the kidney that occurs in children. Current treatment approaches have much improved survival, with the five-year survival rate now exceeding 90 percent.

Symptoms and Diagnostic Path

Wilms's tumor may not show symptoms until it is quite large, at which point a parent or caregiver may see or feel the tumor as a lump in the child's belly. The pediatrician may discover Wilms's tumor during a routine well-child examination. When the tumor causes symptoms, they often include

- HEMATURIA (bloody URINE)

STAGING OF WILMS'S TUMOR

Wilms's Tumor Stage	Extent of Cancer	Treatment Protocols/Options
stage 1	tumor is small and remains localized in one kidney	partial or simple NEPHRECTOMY followed by CHEMOTHERAPY
stage 2	tumor extends beyond the kidney though remains confined to a single mass that surgery can completely remove	radical nephrectomy followed by chemotherapy
stage 3	tumor extends to adjacent structures and lymph nodes and surgery cannot completely remove it	chemotherapy before surgery radical nephrectomy followed by chemotherapy and possibly RADIATION THERAPY
stage 4	tumor has metastasized to distant sites	chemotherapy nephrectomy radiation therapy
stage 5	both KIDNEYS have tumors	partial nephrectomy of both kidneys to remove as much cancer as possible yet retain kidney function chemotherapy repeat partial nephrectomy radiation therapy
inoperable	tumor is very large or located too close to vital BLOOD vessels for surgery to be viable	chemotherapy, radiation therapy, or a combination to reduce the tumor's size

- decreased APPETITE and weight loss
- NAUSEA and VOMITING
- abdominal discomfort or PAIN
- generalized irritability and crankiness

The diagnostic path begins with a comprehensive physical examination, BLOOD tests, and urinalysis. Diagnostic imaging procedures such as ULTRASOUND, COMPUTED TOMOGRAPHY (CT) SCAN, or MAGNETIC RESONANCE IMAGING (MRI) can identify the presence, size, and location of the tumor. Biopsy of the tumor is necessary to confirm the diagnosis.

Microscopic examination of the biopsied tissue further allows the pathologist to determine whether the tumor's cells are anaplastic, which means they are highly irregular and divide both rapidly and erratically. Tumors of anaplastic cells may be diffuse through the kidney and are more difficult to treat than tumors of what pathologists call favorable cells (cancerous cells that are more pathologically normal). The pathologist also assigns the cancer a grade that identifies the extent to which the tumor has spread (metastasized), which helps determine the appropriate treatment options.

Treatment Options and Outlook

NEPHRECTOMY (surgery to remove the affected kidney) in combination with CHEMOTHERAPY is the standard treatment for Wilms's tumor cancers. Partial nephrectomy removes the tumor and a margin of kidney tissue around it; simple nephrectomy removes the entire kidney. Radical nephrectomy removes the kidney. The oncologist may also add RADIATION THERAPY when the cancer's stage is advanced or its cells are anaplastic regardless of stage.

When the tumor is very large or the cancer involves both KIDNEYS, the oncologist may recommend chemotherapy or radiation therapy (or a combination of both) before surgery to shrink the tumors as much as possible. The oncologist may suggest participation in a clinical trial for inoperable, stage 5, or recurrent Wilms's tumor.

Treatment success largely correlates to the stage of the Wilms's tumor (the size of the tumor and the extent to which it has metastasized) and the characteristics of the cancer cells (anaplastic or favorable) at the time of diagnosis. Wilms's tumor is among the childhood cancers doctors consider curable.

Risk Factors and Preventive Measures

Researchers have recently identified GENE mutations that account about 30 percent of Wilms's tumor cancers. Located on CHROMOSOME 11, these are the Wilms's tumor 1 (WT1) and 2 (WT2) genes and provide encoding for development of urinary and genital structures. Wilms's tumor also is associated with several rare genetic syndromes, making it likely that other gene mutations further contribute to the errant encoding that allows these primitive cells to thrive. Family history raises the risk for Wilms's tumor, as it appears the gene mutations are sometimes hereditary.

Researchers believe Wilms's tumor represents clusters of cells in the kidneys that remain primitive, a consequence of the WT1 and WT2 mutations. When these primitive cells divide, they continue to do so at the same rapid rate of cell division that was normal in the EMBRYO. In the older child's body, however, this is inappropriate and the cells grow out of control, some wildly (the anaplastic cells). Some researchers believe the cell growth continues from early developmental stages and ultimately manifests as a tumor when the cluster of cells achieves enough mass. Other researchers believe environmental factors, perhaps processes in the body related to growth, trigger the cells to resume dividing.

There are no measures to prevent Wilms's tumor. Families who have had children with Wilms's tumor should have any other children undergo regular routine medical examinations that include screening (such as ultrasound) for the cancer. Doctors do not yet know the long-term health implications for Wilms's tumor survivors as the treatments that make survival possible have not been available long enough for many survivors to have yet reached adulthood.

THE REPRODUCTIVE SYSTEM

The organs and functions of the reproductive system make possible the creation of new life. Physician specialists who treat health conditions of the male reproductive system are urologists. Physician specialists who treat health conditions of the female reproductive system are gynecologists. Health-care providers who provide care during PREGNANCY and CHILDBIRTH are obstetricians (physician specialists) and midwives (usually registered nurses). Nurse practitioners (registered nurses with advanced specialized training and credentials) often function as women's health-care specialists, providing routine wellness care and treatment for minor reproductive and SEXUAL HEALTH conditions.

This section, "The Reproductive System," presents a discussion of the organs and structures of the male and female reproductive systems, an overview of reproductive and sexual health and disorders, and entries about the health conditions that involve the male and female reproductive systems. "The Urinary System" contains entries about male organs and structures that share urinary and reproductive functions. "Genetics and Molecular Medicine" contains entries about the genetics of reproduction. "The Endocrine System" contains entries about the sex hormones.

TESTICLES

SPERM
- epididymis

VAS DEFERENS

PROSTATE GLAND
- seminal vesicle
- urethra

Functions of the Reproductive System

Human reproduction requires participation from both male and female, each of which contributes one half the genetic material necessary for human existence. The cells that carry this material are the gametes—the OVA, or eggs, from the female half and the spermatozoa, or SPERM, from the male half. Determining gender are the sex chromosomes, one from each gamete to form the pair that designates the gender of the new life. Though gender distinction is apparent at birth, functional characteristics of gender do not emerge until late childhood when hormonal shifts initiate the changes of PUBERTY. At puberty the levels of androgens and estrogens increase in the body, initiating the emergence of the secondary sexual characteristics that mark reproductive maturity.

From a common beginning: embryonic gender differentiation The glands that both represent and sustain gender are the gonads—the OVARIES in the woman and TESTICLES, or testes, in the man. In the embryo these structures arise from the same base cells in the mesoderm (the middle layer of germ cells in the embryo) called the gonadal ridge. Until seven weeks, the embryo is androgynous (has no gender characteristics; male and female appear the same) with rudimentary structures—the genital tubercle, labioscrotal swellings, and urogenital groove and folds—that will evolve into gender-appropriate organs as the embryo develops.

At seven weeks the gonadal ridge organizes into a two-layer structure. If the genetic composi-

tion of the embryo is male, the gonadal ridge begins to produce TESTOSTERONE and a hormone unique to embryonic development, müllerian-inhibiting hormone. In response to testosterone the inner layer, the medulla, begins to take shape as the testes and the outer layer, the cortex, degenerates. The genital tubercle becomes the glans PENIS, the urogenital groove and folds enlarge to form the rest of the penis, and the labioscrotal swellings fuse to form the SCROTUM.

If the embryo's genetic composition is female there is no secretion of testosterone and müllerian-inhibiting hormone. So instead the outer layer, the cortex, begins to develop into the ovaries and the medulla deteriorates. The genital tubercle becomes the CLITORIS, the urogenital groove and folds become the VAGINA and labia minora, and the labioscrotal swellings form the labia majora. Primordial germ cells from the yolk sac migrate into the evolving testes or ovaries to become gametes (ova or sperm) as development continues. By 12 weeks gender differentiation is complete, though gender does not become detectable with ULTRASOUND imaging until the 20th week or later.

THE MYTHOLOGY OF THE HYMEN

The hymen, a narrow ring of membranous tissue that extends across the opening of the VAGINA, derives from the Greek god of the wedding feast, Hymen (also Hymenaeus). Hymen was the progeny of Dionysus, the god of FERTILITY, and Aphrodite, the goddess of love. Though the belief persists today that an intact hymen is evidence of a woman's virginity, in truth numerous activities (tampon use, horseback riding, bicycling, and gymnastics to name a few) can rupture the hymen. As well, the structure of the hymen varies widely among women and may be so insignificant as to not impede the penetration of the erect PENIS.

Transition to fertility: puberty Despite genital differences, boys and girls are fairly much alike physiologically for a dozen years or so after birth. Then hormonal signals trigger the onset of puberty, the transition from childhood to sexual and reproductive maturity. Though researchers do not know what activates the hormonal signals, the consequences are very familiar: the emergence of SECONDARY SEXUAL CHARACTERISTICS. The ovaries and testicles again become active, initiating the anatomic and physiologic changes that transform boys to men and girls to women. With sexual and reproductive maturity complete, SEXUAL INTERCOURSE and pregnancy become possible.

New life: conception, pregnancy, and childbirth On the surface of it, reproduction is an astonishingly simple premise, and its organs uniquely suited to its purpose. During sexual intercourse the erect penis fits precisely within the vagina, reaching to the CERVIX. EJACULATION deposits millions of sperm in the upper vagina, a short swim from the cervical os (opening through the cervix into the UTERUS). When conditions and timing are right, the sperm make their way through the cervix and uterus and into one of the FALLOPIAN TUBES, encounter the ovum (egg), and one of the millions penetrates the ovum to fertilize it. The resulting ZYGOTE travels down the fallopian tube, tumbles into the uterus, and implants itself into the dense, spongy endometrium: CONCEPTION.

The woman's body nourishes and shelters the developing FETUS, expanding and changing to accommodate its needs. The uterus stretches up to 10 times its normal size, pushing the abdominal wall outward. Again it is hormones that facilitate and support these processes, and hormones that bring the pregnancy to its conclusion: childbirth.

In the process of it, of course, there is nothing simple about any dimension of reproduction. Reproduction represents one of the most intricately choreographed experiences the human body can accommodate. Hundreds of hormones direct countless interactions, each of which spurs other events. Numerous factors, internal and external, influence reproduction to make it possible or not possible. Among the most significant advances in reproductive medicine are technologies to assist the process at various points along the reproductive continuum, from fertilization through childbirth.

Completing the cycle: menopause Men remain fertile nearly the rest of their lives after puberty, though sperm production and quality tend to diminish in later life as testosterone levels decrease. FERTILITY ends for women with MENOPAUSE, the cessation of OVULATION and men-

strual cycles. The ovaries contain a finite number of ova, present at birth. From the onset of MENSTRUATION to midlife, each monthly cycle causes a half dozen to a dozen ovarian follicles to ripen. Usually only one ovum (egg) reaches full maturity and leaves the ovary; the others atrophy (shrink) and the ovary reabsorbs them. By midlife the ovaries have made it pretty much through their supply of ova, far fewer follicles activate with each MENSTRUAL CYCLE, and ovarian function begins to shut down. Over a period of five to eight years, menstrual cycles become irregular and eventually infrequent until they stop altogether.

Health and Disorders of the Reproductive System

The health of the reproductive system, male or female, experiences internal and external influences. Internally the reproductive system relies significantly on an intricate hormonal balance as hormones direct nearly all sexual and reproductive functions. Disorders are often endocrine in origin. The organs of reproduction are particularly vulnerable to cancers that thrive on hormones, such as BREAST CANCER, OVARIAN CANCER, ENDOMETRIAL CANCER, PROSTATE CANCER, and TESTICULAR CANCER. Externally the reproductive system is vulnerable to injury and illness, to great extent through sexual activity. SEXUALLY TRANSMITTED DISEASES (STDS) can cause serious and sometimes life-threatening health conditions. STDs are a leading cause of INFERTILITY in women and can cause illness in newborns who are exposed during birth. Other factors that can affect reproductive health include exposures to chemicals such as pesticides or to radiation, which can damage the DNA of sperm or ova.

External factors are particularly important during pregnancy, when certain exposures at vulnerable points of fetal development can cause permanent injury. INFECTION with common viruses such as RUBELLA (German MEASLES) or measles can cause devastating BIRTH DEFECTS, as can taking certain drugs and medications. Nearly any substance the woman takes into her body may cross the PLACENTA to enter the fetus's BLOOD circulation. FETAL ALCOHOL SYNDROME, a constellation of physical birth defects and developmental abnormalities that occurs as a result of fetal exposure to ALCOHOL, is entirely preventable.

HEALTH CONDITIONS OF THE REPRODUCTIVE SYSTEM

ADENOMYOSIS	AMENORRHEA
BALANITIS	BARTHOLIN CYST
BENIGN PROSTATIC HYPERPLASIA (BPH)	BREAST CANCER
CERVICAL CANCER	CANCER OF THE PENIS
CHORDEE	CERVICAL INTRAEPITHELIAL NEOPLASIA (CIN)
CRYPTORCHIDISM	DYSMENORRHEA
ECLAMPSIA	ECTOPIC PREGNANCY
ENDOMETRIAL CANCER	ENDOMETRIAL HYPERPLASIA
ENDOMETRIOSIS	EPIDIDYMITIS
ERECTILE DYSFUNCTION	fibroadenoma

Traditions in Medical History

The high rate of maternal deaths from "childbirth FEVER" (puerperal fever) at the dawn of the era of antisepsis motivated Hungarian obstetrician Ignaz Philipp Semmelweis (1818–1861) to change his habits. In so doing, he transformed the practice of obstetrics and saved countless lives. By the middle of the 19th century scientists knew of the existence of microbes and their role in causing disease, though their mechanisms of infection remained a mystery. An emerging recognition was of the danger of infection for pathologists who performed autopsies. The slight wound from a slip of the scalpel was all too often fatal, causing systemic infection known as pathologist's pyemia. Semmelweis was the first to connect the two apparently

disparate conditions—puerperal fever and pathologist's pyemia—together.

Semmelweis practiced and taught at Vienna General Hospital, a major medical mecca of its time. Its maternity ward was very busy. As was the custom of the time, women attended by physicians went to one ward and women attended by midwives went to another ward. In 1847, the year of Semmelweis's epiphanic recognition, 20 to 35 percent of women who received care from doctors during childbirth died within weeks from puerperal fever. Only 2 percent of women who received their childbirth care from midwives met with similar fate.

Another customary practice of the time was for doctors to immediately autopsy patients who died, partly to provide education for student doctors. After his close friend died of a massive infection resulting from a wound suffered while conducting an autopsy, Semmelweis began to observe the patterns of illness in the maternity ward. He soon concluded that the practice of doctors freely moving between performing autopsies and attending to deliveries was the likely cause.

Semmelweis began to cleanse his hands with chlorinated lime before entering the childbirth ward and required his students to do the same. Though the caustic solution left the doctors' hands somewhat raw, nearly immediately the infection rate on their maternity ward dropped to 3 percent—much the same as the rate of infection on the midwifery ward. Midwives, of course, did not participate in autopsies. The change was a turning point in medicine's approach to childbirth. Within a decade antisepsis converged with the discovery of ANESTHESIA to vastly improve the safety and comfort of childbirth. When England's Queen Victoria received chloroform anesthesia during childbirth in 1853, she established a standard of acceptability for both improvements.

CESAREAN SECTION (surgical childbirth) also became a reasonable option for difficult deliveries, allowing doctors to save both mother and baby. Though ancient Chinese medical texts allude to a surgical childbirth procedure, cesarean section was an action of desperation to save the infant, generally carried out only when it was clear the mother had no chance of survival or had already died. Though popular mythology attributes the procedure and its name to the surgical birth of Rome's Julius Caesar, most medical historians believe such a correlation is highly unlikely. More likely is the derivation of the name from the Latin word *caesones*, the term applied to the infants who survived surgical extraction from their dying or dead mothers. Historical records document that Julius Caesar's mother lived long after her son's birth.

Breakthrough Research and Treatment Advances

The final decades of the 20th century brought pivotal advances in reproductive medicine. The first in vitro fertilization (IVF) baby—"test tube baby"—was born in England in 1978. Since then ASSISTED REPRODUCTIVE TECHNOLOGY (ART) has brought thousands of babies into the world. Today IVF is the cornerstone of treatment for infertility. Nearly 45,000 ART babies are born in the United States each year.

The coupling of advances in diagnostic imaging procedures and surgical techniques gave birth to the new subspecialty of fetal surgery, in which surgeons can operate on the unborn fetus to correct potentially devastating or fatal birth defects such as severe SPINA BIFIDA and congenital diaphragmatic HERNIA (incomplete formation or absence of the DIAPHRAGM). Technologic advances have also vastly improved the survivability of premature (preterm) infants, with some measures targeting efforts to maintain the pregnancy as long as possible and others focused on supporting the still-developing baby after birth.

Among the flurry of advances in pharmaceuticals at the turn of the 21st century, none attracted quite so much attention or sales as the phosphodiesterase (PDE) inhibitor medication to treat ERECTILE DYSFUNCTION, sildenafil. The trade name product Viagra catapulted to record sales, becoming the highest selling DRUG of all time within six months of its release. Sildenafil was the first convenient treatment for physiologically based erectile dysfunction, which affects about 25 million men in the United States.

The start of the 21st century also marked the end of a more than 50-year tradition in medical history when extensive research studies concluded that routine hormone replacement therapy (HRT) to treat menopause did not provide the health benefits widely attributed to it but instead signifi-

cantly raised a woman's risk for certain cancers. As well, there was no evidence that HRT reduced a woman's risk for CARDIOVASCULAR DISEASE (CVD), though supplemental estrogen did improve BONE health and reduce OSTEOPOROSIS. However, new drugs are able to accomplish the same effect without the increased risk for cancer that comes with estrogen supplementation.

A

abortion The end of a PREGNANCY before the FETUS is viable (capable of independent life). Abortion may occur spontaneously (commonly called miscarriage) or be induced to end a pregnancy. In the United States, federal law mandates the availability of induced abortion, and state laws regulate the definition of viability as it applies to induced abortion. The range of legal viability is 20 weeks to 24 weeks of gestational age. The clinical border for viability is generally 20 weeks or a fetal weight of 500 grams (about 1 pound). It is uncommon for a fetus delivered between 24 and 20 weeks and unlikely for a fetus born before 20 weeks of gestational age to survive. A full-term pregnancy is 42 weeks.

Spontaneous Abortion

Numerous factors may initiate spontaneous abortion. The most vulnerable period of pregnancy for spontaneous abortion is between 7 and 12 weeks. Doctors believe that most abortions that occur within this early stage of pregnancy occur because the conceived EMBRYO has congenital or chromosomal defects that are not survivable. About 15 percent of known pregnancies end in spontaneous abortion before the 12th week of pregnancy. Regardless of the cause and the stage of pregnancy, spontaneous abortion is often a traumatic loss for the woman and her partner.

Induced Abortion

An induced abortion is a procedure a woman chooses to undergo to end a pregnancy and may be therapeutic (medically necessary for the woman's health or because the fetus has known, nonsurvivable defects such as anencephaly) or elective termination of pregnancy. An induced abortion may be a surgical procedure called dilation and evacuation (D&E), performed under ANESTHESIA in a hospital operating room or in an AMBULATORY SURGICAL FACILITY, in which the doctor dilates the CERVIX and withdraws the contents of the UTERUS via suction (also called vacuum aspiration abortion). Before seven weeks an induced abortion may be a medical procedure, brought about by taking medications such as mifepristone (RU486), methotrexate, or misoprostol. These drugs, called abortifacients, prevent cell division (methotrexate, a CHEMOTHERAPY DRUG used to treat cancer) or implantation, or initiate uterine contractions (mifepristone and misoprostol).

Complications of Abortion

Uncontrolled bleeding (hemorrhage) and INFECTION are risks with either spontaneous or induced abortion. The abortion may be incomplete (some of the contents of CONCEPTION remain in the uterus), causing persistent or occasionally heavy bleeding. Persistent or heavy bleeding often requires DILATION AND CURETTAGE (D&C), a surgical procedure in which the doctor dilates the cervix and uses a curette to gently scrape the interior walls of the uterus. Undiagnosed GONORRHEA and CHLAMYDIA are the most common causes of postabortion infection. Infection requires treatment with ANTIBIOTIC MEDICATIONS. Either bleeding or infection may be life threatening; both require immediate medical evaluation and appropriate treatment. Rarely, abortion results in complications that can affect future FERTILITY.

Abortion, whether spontaneous or induced, is often an emotional experience for the woman and her partner. Guilt, sadness, and anger are common feelings that may persist for some time or reemerge years later. Induced abortion often has additional religious or philosophical implications.

adenomyosis A condition in which the cells that make up the endometrium (the lining of the UTERUS) grow into the wall of the uterus (myometrium), forming benign (noncancerous) tumors that appear as thickenings or masses contained within the uterine wall. Adenomyosis nearly always occurs in women who have carried pregnancies to full term, causing doctors to believe the condition results from injury to the wall of the uterus as it stretches to accommodate the growth of the FETUS in the final weeks of PREGNANCY.

Adenomyosis may not cause symptoms; the doctor may discover its presence during evaluation for other health conditions affecting the uterus, such as DYSFUNCTIONAL UTERINE BLEEDING (DUB) or ENDOMETRIOSIS. The uterus may be tender to palpation (examination by touching) during PELVIC EXAMINATION. When symptoms do occur they may include PAIN during SEXUAL INTERCOURSE, unusually heavy menstrual bleeding, and intense menstrual cramping.

The diagnostic path may include ULTRASOUND, COMPUTED TOMOGRAPHY (CT) SCAN, or MAGNETIC RESONANCE IMAGING (MRI), though definitive diagnosis requires myometrial biopsy (laboratory examination of a tissue sample from the uterine wall). The gynecologist may use HYSTEROSCOPY to obtain the biopsy, or may examine tissue obtained through procedures to treat DUB such as DILATION AND CURETTAGE (D&C).

The monthly surge of hormones that cause the endometrium to thicken is responsible for symptoms; the engorged endometrial tissue causes pressure where it has infiltrated the myometrium. Because this hormonal cycle ends with MENOPAUSE (cessation of the menstrual cycle), adenomyosis then goes away. Treatment thus attempts to relieve symptoms until menopause occurs and may include NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) or oral contraceptives (birth control pills) to regulate the hormonal balance that controls the MENSTRUAL CYCLE. When symptoms are severe and the woman does not desire further pregnancies, HYSTERECTOMY (surgery to remove the uterus) may be a treatment option. Because the infiltration into the myometrium is diffuse (spread out), it is not possible to surgically remove only the sites of adenomyosis. Adenomyosis does not affect FERTILITY or the capability of the uterus to again expand in pregnancy.

See also CONTRACEPTION; DYSMENORRHEA; ENDOMETRIAL CANCER; ENDOMETRIOSIS; UTERINE FIBROIDS.

adoption Accepting or relinquishing legal, social, and family responsibilities for a nonbiologic child. Adoption is an option within FAMILY PLANNING for people who desire children. Placing a child for adoption also an option in a circumstance of an unplanned PREGNANCY. About 150,000 adoptions take place in the United States each year. Adoptions may be open, in which there is direct or indirect contact between the biologic parents and the adoptive parents, or closed, in which the court seals the adoption records and biologic and adoptive parents do not know each other or anything about each other.

Each state in the United States has its own laws and procedures that regulate both sides of the adoption process. However, all states recognize and honor legal adoptions made in other states. Adoption laws regulate factors such as what information may be (or in some states, must be) made available to adult adopted children, the legal rights of biologic and adoptive parents, and the rights of biologic fathers who do not know their children were relinquished for adoption.

Countries around the world have their own laws and procedures for adoption that may or may not be consistent with practices in the United States. Though the United States generally recognizes foreign adoptions, federal immigration laws require specific evidence of legal adoption and other documentation. The US Department of State handles such matters. No matter the state or country, the legal issues of adoption are complex. It is prudent to obtain advice from a qualified adoption attorney before proceeding.

Health Concerns in Adopting a Child

Many adopted children come to their adoptive families with health concerns. Though it is ideal to have a full health history, including family history, for the adopted child, this does not often happen.

As a matter of course many adoptive families have the child undergo a comprehensive medical examination. Children adopted from other countries often have parasitic infections and other health conditions uncommon in the United States. FETAL ALCOHOL SYNDROME, congenital INFECTION with SEXUALLY TRANSMITTED DISEASES (STDS), HEPATITIS, RICKETS, TUBERCULOSIS, and hearing loss and VISION IMPAIRMENT are also common, especially with international adoptions. Though these are often treatable conditions, they do require prompt medical attention. Children older than one year may have emotional and psychologic problems as well. Sometimes, even in a closed adoption, the intermediary (adoption agency or attorney) is able to obtain more specific health information about the child to pass onto the adoptive parents. Conditions that require ongoing care, such as fetal ALCOHOL syndrome or developmental disabilities, are special needs.

Placing a Child for Adoption

Women have varying and often deeply personal reasons for placing their biologic children for adoption. Common reasons for being unable to retain parental rights include

- serious DRUG or alcohol abuse problems
- extreme youth or immaturity
- pregnancy that was the result of rape or incest
- health or disability issues that prohibit properly caring for a child

As well, mothers sometimes abandon their children without known reason. A woman who desires to place her child for adoption can notify her doctor, a community service agency, an adoption service, or an attorney. Typically there are no expenses to the relinquishing parent. Depending on circumstances the biologic mother may choose the adoptive family, especially if she is pregnant at the time she makes the decision to place the child for adoption.

The decision to place a child for adoption, which on the surface may appear straightforward, has lifelong emotional consequences for mother and child. The mother may feel guilty for "giving up" her child. The child, when old enough to understand what adoption means, may feel abandoned regardless of the circumstances of the adoptive family. It is important for adoptive families to be loving yet as open as possible about questions adoptive children may ask. Many communities have SUPPORT GROUPS for adoptive parents, adopted children, and people who placed their children for adoption. Support groups can help people share their concerns, feelings, and solutions to common problems.

Parenting and family are life experiences that have challenges and accomplishments, perils and joys, no matter what their configurations. For many adults who adopt, adoption brings to fruition a lifelong dream to raise and parent a child, either starting or adding to a family. And for many children who are adopted, adoption is daily evidence that someone wants them and loves them very much.

aging, reproductive and sexual changes that occur with The reproductive system, male or female, is intact but immature at birth and remains immature until the onset of PUBERTY around age 12. Researchers do not know what triggers the physiologic events that take place to initiate reproductive and sexual maturity. However, these events result in the development of SECONDARY SEXUAL CHARACTERISTICS, sex drive and interest, and the ability to produce new life. Male FERTILITY extends from puberty to the end of life, though may diminish somewhat in late old age. Female fertility is finite, starting at MENARCHE (the onset of the MENSTRUAL CYCLE) and ending with MENOPAUSE (the conclusion of the menstrual cycle). Only for a few days each month is a woman capable of CONCEPTION.

The hormones of sexual and reproductive maturity have numerous and far-reaching effects in the body. Men and women alike have the spectrum of sex hormones: ESTROGENS and ANDROGENS. Androgens dominate in men; estrogens dominate in women. These hormones account for secondary sexual characteristics and reproductive ability as well as MUSCLE mass and STRENGTH, BONE DENSITY, lipid metabolism, aspects of cardiovascular function, cognitive clarity, BRAIN function, mood, and emotion.

Age-related hormonal changes are most prominent in women, who experience significant transformation in their bodies with menopause. The cessation of OVULATION means a pronounced drop in estrogen within the body, affecting not only reproductive capability but also the functions of nearly every system in the body. Health concerns that arise from these changes include increased risk for OSTEOPOROSIS, CARDIOVASCULAR DISEASE (CVD), and certain types of cancer. Men also experience age-related changes in sexuality and reproductive function. A man's testosterone level peaks when he is in his early 20s and gradually declines with each decade of life. By age 60 most men have about half the testosterone they had at age 25. This decline results in changes such as diminished muscle mass and strength and male pattern baldness (ALOPECIA). A man's risk for PROSTATE CANCER significantly increases after age 60. Though a man can still father children even into his 80s, declining testosterone affects LIBIDO (sex drive) and erectile function.

alpha fetoprotein (AFP) A protein the LIVER produces. In PREGNANCY the amount of AFP in the woman's BLOOD circulation increases, reflecting the activity of the FETUS's liver as it develops and becomes functional. A blood test measures AFP in the woman's blood circulation early in the second trimester, between 15 and 22 weeks of pregnancy.

Elevated AFP levels in pregnancy may indicate a multiple pregnancy, NEURAL TUBE DEFECTS or defects in the structure of the abdominal wall that allow the organs of the gastrointestinal system to form outside the body. Chronic liver disease, such as HEPATITIS or CIRRHOSIS, also elevates AFP. Excessive ALCOHOL consumption and cigarette smoking are common causes of falsely high measures. Low AFP levels may indicate a pregnancy that is not as advanced as the woman believes or suggest the chromosomal disorder DOWN SYNDROME.

Other health circumstances elevate AFP blood levels in nonpregnant women and in men. Among them are liver disease, including LIVER CANCER, TESTICULAR CANCER in men, and OVARIAN CANCER in women. Deviations from normal AFP levels in pregnancy suggest circumstances that may warrant further medical evaluation such as ULTRASOUND, AMNIOCENTESIS, and CHORIONIC VILLI SAMPLING (CVS).

See also ALCOHOLISM; CHROMOSOMAL DISORDERS; GENETIC DISORDERS; PRENATAL CARE.

amenorrhea The absence of menstrual periods. Primary amenorrhea occurs when a young woman does not begin menstruating by age 16; secondary amenorrhea occurs in women who have been menstruating and then stop (miss six or more consecutive periods).

Primary amenorrhea may result from GENETIC DISORDERS such as TURNER'S SYNDROME or from hormonal disorders such as pituitary ADENOMA (a tumor of the PITUITARY GLAND) or HYPOTHYROIDISM (underactive THYROID GLAND). PREGNANCY is the most common cause of secondary amenorrhea. Other factors that may cause either primary or secondary amenorrhea include intense physical exercise, excessive body weight (OBESITY), and extreme underweight such as may result from EATING DISORDERS.

Amenorrhea is a symptom of underlying conditions that affect the function of the OVARIES rather than itself a health condition. Because the hormones the ovaries produce affect many other functions within the body, it is important to identify its cause. Unresolved primary amenorrhea may have consequences such as permanent INFERTILITY and failure to develop SECONDARY SEXUAL CHARACTERISTICS.

amniocentesis A diagnostic procedure to withdraw a sample of AMNIOTIC FLUID from the UTERUS of a pregnant woman to obtain information about the health status of the FETUS. Obstetricians use amniocentesis, typically performed during the second trimester of PREGNANCY, to help diagnose GENETIC DISORDERS and health conditions of the developing fetus such as DOWN SYNDROME or SPINA BIFIDA and other NEURAL TUBE DEFECTS. Amniotic fluid contains cells from the fetus that can provide a KARYOTYPE (representation of CHROMOSOME pair-

ings) and other genetic information about the fetus. The amniotic fluid may also provide information about the woman's health, such as whether any INFECTION is present, and help doctors determine whether the fetus's lungs are mature.

To perform amniocentesis, the obstetrician first numbs a small area on the surface of the woman's abdomen, either with a topical anesthetic spray or an injection of local anesthetic. The obstetrician then inserts a long needle through the woman's abdominal wall into the amniotic sac and withdraws about 20 milliliters (less than an ounce) of amniotic fluid for laboratory analysis. ULTRASOUND helps determine the position of the fetus and the ideal insertion and placement of the needle so as to avoid injury to the fetus. Because the laboratory must first cultivate cells from the amniotic fluid, GENETIC TESTING results take two to three weeks.

Risks of amniocentesis include bleeding, infection, injury to the fetus, and spontaneous ABORTION (loss of the pregnancy). Some women feel temporary discomfort during the procedure, and many women find the requisite full BLADDER (necessary for the ultrasound) causes pressure and other discomforts. Some women experience mild cramping and slight bleeding for a day or two after the amniocentesis.

See also ALPHA FETOPROTEIN (AFP); ANESTHESIA; CHORIONIC VILLI SAMPLING (CVS); CHROMOSOMAL DISORDERS; CONGENITAL ANOMALY; PRENATAL CARE.

amniotic fluid The liquid that surrounds the developing FETUS within the amniotic sac, a membranous structure that forms inside the UTERUS in PREGNANCY. The amnion, the inner membrane of the amniotic sac, begins producing amniotic fluid at about two weeks of gestation. The amniotic fluid, which is mostly water, cushions the fetus against changes in temperature as well as jarring and bumps from outside the womb. The composition of amniotic fluid changes somewhat over the duration of pregnancy though typically includes, in addition to water, electrolytes, lipids, proteins, metabolic byproducts, and cells that the fetus sheds. These cells provide the DNA that AMNIOCENTESIS uses to assess the health of the fetus.

Amniotic fluid is essential not only to protect the fetus but also for proper fetal development. In the second trimester the fetus swallows and "breathes" to take amniotic fluid into its STOMACH and LUNGS, which is necessary for development of the structures and functions of the pulmonary and gastrointestinal systems. The fetus also begins contributing URINE to the composition of the amniotic fluid. By the third trimester the amniotic fluid replenishes itself about every three hours and reaches a volume of approximately 500 milliliters. The amniotic sac ruptures when CHILDBIRTH is imminent, sending a flood of amniotic fluid from the woman's VAGINA. This process is the "breaking water" that often heralds the onset of pregnancy's final stages, labor and delivery.

A lower than normal volume of amniotic fluid is oligohydramnios, which may constrict the movement of the fetus to an extent that causes abnormal musculoskeletal development, intrauterine growth retardation, and other problems. A greater than normal volume of amniotic fluid is polyhydramnios, which may indicate NEURAL TUBE DEFECTS or BIRTH DEFECTS of the KIDNEYS or gastrointestinal structures. Polyhydramnios is sometimes present when the mother has diabetes. It presents increased risk for UMBILICAL CORD problems such as umbilical cord prolapse (the umbilical cord enters the vagina before the fetus's head as birth begins, a potentially life-threatening scenario for the fetus), as well as large for gestational age or macrosomia (birth weight significantly higher than normal).

For further discussion of amniotic fluid within the context of the structures and functions of reproduction and sexuality, please see the overview section "The Reproductive System."

See also CESAREAN SECTION.

andropause A term sometimes used to describe the physical and emotional changes men experience at midlife. The amount of TESTOSTERONE, the primary male sex HORMONE, in a man's BLOOD circulation begins to slowly and steadily decline after reaching its peak in the early to middle 20s. By age 75, testosterone levels are typically about half of what they were at age 25. Though this is still an adequate level of testosterone to maintain masculinity, the decline accounts for some of the physical changes characteristic of midlife in men: conversion of MUSCLE to fat, redistribution of body

fat, and sometimes diminished energy and LIBIDO (sex drive). Some men experience clinical DEPRESSION, loss of BONE mass, ERECTILE DYSFUNCTION, and other symptoms as a consequence of lower testosterone levels. Some researchers believe the decline in testosterone levels contributes to the increased risk for HEART ATTACK as a man gets older.

Doctors may recommend prescription hormone supplementation with ANDROGENS (testosterone or testosterone precursors) for men who have unacceptable symptoms. However, the long-term therapeutic value and possible risks of such treatment remain uncertain. Some men take the over-the-counter product DEHYDROEPIANDROSTERONE (DHEA), available in the United States as a dietary supplement, as an androgen precursor (a substance the body converts to testosterone during its METABOLISM). There are few clinical studies to provide clear evidence of whether this is effective or safe. Some doctors believe as long as the DHEA does not push testosterone levels beyond the normal range, the risk for adverse health effects is minimal. However, other doctors worry that sustained increases in blood testosterone levels in men over age 50 may increase the risk for PROSTATE CANCER and CARDIOVASCULAR DISEASE (CVD).

Apgar score A standardized measure of an infant's health status, typically assessed one minute and five minutes after birth. Anesthesiologist Virginia Apgar (1909–1974) developed the scoring system that bears her name in 1953, assigning a point value of 0, 1, or 2 to each of five categories of vital function (BREATHING, HEART RATE, REFLEX response, MUSCLE tone, and SKIN color) and reporting their sum as the overall Apgar score. Today the Apgar score is an international standard to assess whether a newborn needs resuscitation (lifesaving measures) and to evaluate the success of resuscitative efforts. The highest score possible is 10; doctors consider a score between 7 and 10 to reflect good health in the infant. A score between 4 and 7 bears monitoring and perhaps supportive care such as suctioning of the airways or supplemental oxygen. A score of 3 or lower indicates a life-threatening or critical circumstance for the infant.

See also CHILDBIRTH; PREMATURE BIRTH.

assisted reproductive technology (ART) Medical interventions to produce PREGNANCY. The US Centers for Disease Control and Prevention (CDC), which has a mandate under federal law to report the success rates of ART at FERTILITY clinics in the United States each year, defines ART as any method that involves manipulation of both SPERM and OVA (eggs). Other methods to aid fertility may use interventions such as HORMONE therapies to stimulate OVULATION (the release of ova) in the woman or techniques such as intrauterine artificial insemination (placement of sperm within the UTERUS) to improve sperm viability. ART typically

APGAR SCORES

Apgar Score	0	1	2
BREATHING	not breathing	slow or irregular breathing	20 to 50 breaths per minute, regular rhythm
HEART RATE	no heart rate	< 100 beats per minute	100 to 104 beats per minute
REFLEX response	no response to nasal stimulation	facial grimace with nasal stimulation	sneeze or cough with nasal stimulation
MUSCLE tone	flaccid	some flexing of the arms and legs	active movement
SKIN color	cyanotic (bluish gray)	cyanotic limbs	pink

becomes an option to treat INFERTILITY when less invasive approaches fail to result in pregnancy or when health factors compromise fertility in both partners.

Methods of ART

Most methods of ART involve uniting sperm and ova outside the body and returning the results to the woman's body. There are four commonly used methods of ART:

- In vitro fertilization (IVF) is the most common method of ART. The technologist mixes sperm and several ova together in a laboratory container. The sperm penetrate and fertilize the ova. After the zygotes form, the fertility specialist transfers two to four zygotes into the woman's uterus. IVF eliminates issues of sperm motility, sperm antibodies, and blocked FALLOPIAN TUBES. It may be an appropriate choice for male factor infertility, female factor infertility, or combined factor infertility and may use donor eggs, donor sperm, or eggs and sperm collected from the woman and her partner.
- GAMETE intrafallopian transfer (GIFT) mixes ova and sperm in a thin catheter and transfers the mixture directly to the woman's fallopian tube. Fertilization takes place within the fallopian tube and the ZYGOTE travels to the uterus to implant. GIFT may be the ART method of choice when the woman has healthy fallopian tubes and male factor infertility is the primary issue. GIFT is also an acceptable method of assisted CONCEPTION within cultures and belief systems in which fertilization must take place inside the woman's body.
- Intracytoplasmic sperm injection (ICSI) is somewhat like IVF though leaves less to chance. The technologist extracts a single sperm from the collected sperm and injects it into an ovum to fertilize the ovum. The fertility specialist then transfers the zygote into the woman's fallopian tube or uterus. ICSI is often the ART method of choice for male factor infertility, especially when the man's sperm count is very low.
- Zygote intrafallopian transfer (ZIFT) begins with IVF though the fertility specialist then uses laparoscopy to place two to four zygotes into the woman's fallopian tube. ZIFT is a common ART choice for male factor infertility and may be appropriate when IVF has not succeeded. Fertility specialists believe the embryos that result from IVF may be more fragile than those that develop within the fallopian tube.

Before any of these methods can occur, the fertility clinic must obtain ova and sperm, either from the woman and man undergoing ART or from donors. Ova retrieval begins with injection of a hormone, human chorionic gonadotropin (hCG). Then, 36 hours later, the fertility specialist aspirates (gently suctions away) the ripened ova using a catheter inserted into the pelvic cavity through the vagina with ULTRASOUND to visualize and guide the process. Sperm retrieval may occur through EJACULATION or the fertility specialist may extract sperm, using needle and syringe, directly from the man's testicle (EPIDIDYMIS). Sperm extraction does not require hormones.

Success of ART

About 45,000 births occur in the United States each year as a result of ART, representing about a 25 percent success rate overall for ART. However, many couples undergo multiple ART attempts, and the rate of pregnancy correlates to the woman's age with a precipitous drop after age 35. Nearly a third of ART conceptions are multiples (twins or higher), a consequence of the practice of implanting multiple embryos to improve the likelihood of a viable pregnancy (pregnancy that carries to full term with delivery of a healthy baby). Some ART methods are more successful than others, depending on the infertility circumstances. As well, the ART may succeed in generating a pregnancy but the pregnancy does not carry to term. The CDC reports annual ART success rates for pregnancies and live births according to ART method and by fertility center. The report is available at the CDC's Web site (www.cdc.gov/art).

Concerns and Risks of ART

Despite significant advances in understanding and technology, much about fertility remains a mystery. The long-term risk associated with hormone use to stimulate ovulation for egg retrieval in

women is probably negligible but remains unknown. Risks for chromosomal and genetic damage also remain unknown. However, since the first successful IVF in 1978, hundreds of thousands of babies born through ART methods have reached adulthood and many now have children of their own with both parent and child healthy. It is important for people considering ART to know as much as possible about their family health histories and to fully understand the possible complications and risks for the methods of ART they are considering, because knowledge in this area changes rapidly.

B

balanitis INFLAMMATION of the glans, the tip of the PENIS, usually the consequence of a bacterial or fungal (yeast) INFECTION. Balanitis is more likely to occur in uncircumcised men, as the foreskin can provide the moist, warm environment that supports the growth of pathogens. Diligent PERSONAL HYGIENE is especially important in uncircumcised men to keep the area beneath the foreskin clean and dry to prevent irritation and infection. The diagnostic path may include laboratory culture of a sample swabbed from the inflamed area to determine the cause of the infection, with appropriate ANTIBIOTIC MEDICATIONS or ANTIFUNGAL MEDICATIONS to treat the infection. Medications may be oral (taken by MOUTH), topical (applied to the penis), or both.

Most balanitis clears with treatment and hygienic measures. A potentially serious complication is PHIMOSIS, in which the foreskin forms adhesions to the glans and becomes unretractable. Phimosis further complicates balanitis and may require CIRCUMCISION (surgical removal of the foreskin).

Bartholin's cyst A fluid-filled enlargement of a Bartholin's gland. There are two Bartholin's glands, one on each side of the entrance to the VAGINA. Normally undetectable, the Bartholin's glands produce secretions that lubricate the vaginal opening. A cyst may form when the duct that allows the secretions to drain from the gland becomes blocked (occluded). The secretions continue to accumulate but have no exit, causing the gland to gradually enlarge. The enlargement may become quite large before a woman can detect it, and often causes no symptoms until its size causes discomfort.

The gynecologist can diagnose a Bartholin's cyst on the basis of its appearance. Treatment is to drain the cyst, after which the gland returns to normal function. The gynecologist may place a tiny tube temporarily into the cyst to allow the accumulated fluid to drain, or may make a small incision to release the fluid, then suture the incision open to maintain drainage. These procedures are usually performed in the gynecologist's office with local ANESTHESIA to first numb the area. Occasionally an INFECTION develops within a Bartholin's cyst, which requires a course of treatment with ANTIBIOTIC MEDICATIONS.

See also VAGINITIS.

benign prostatic hyperplasia (BPH) A noncancerous enlargement, also called benign prostatic hypertrophy, of a man's PROSTATE GLAND. BPH is common in men over age 60 and is a condition of aging. Though BPH is not cancer, some men who have BPH do develop PROSTATE CANCER. Researchers do not know what causes BPH though believe the changes in HORMONE levels and ratios that naturally occur with aging probably are key.

BPH develops when the number of cells in the prostate gland increases, causing the gland to grow. The prostate gland encircles the URETHRA like a cuff at the neck of the BLADDER. BPH typically constricts the urethra, either by compressing it from the outside or blocking it from the inside if prostate cells invade the urethral walls. The resulting occlusion interferes with URINATION.

Symptoms and Diagnostic Path

The symptoms of BPH develop gradually over time and may include

- hesitation when urinating (stopping and starting during the flow)
- URINARY URGENCY and URINARY FREQUENCY, especially at night (NOCTURIA)
- dribbling URINE after the man finishes urinating
- HEMATURIA (bloody urine)
- URINARY INCONTINENCE

The diagnostic path includes a BLOOD test to measure the PROSTATE-SPECIFIC ANTIGEN (PSA) level and a DIGITAL RECTAL EXAMINATION (DRE), which allows the doctor to palpate (feel) the prostate gland through the wall of the RECTUM. This examination helps determine whether the enlargement of the prostate gland is likely benign (the gland feels soft to palpation) or suspicious (the gland feels hard or irregular). Further diagnostic procedures may include measurement of postvoiding urine (urine that remains in the bladder after urination), ULTRASOUND of the bladder, and occasionally CYSTOURETHROGRAM to rule out other causes of the symptoms.

Treatment Options and Outlook

Treatment depends on the nature of the prostate gland's overgrowth, the severity of symptoms, and the man's preferences. Treatment options include

- MINIMALLY INVASIVE SURGERY to remove excess prostate gland tissue
- transurethral resection of the prostate (TURP), an OPERATION in which the urologist removes portions of the prostate gland using an endoscopic instrument inserted through the urethra
- PROSTATECTOMY, an operation to entirely remove the prostate gland
- alpha blocker medications, which relax smooth MUSCLE tissue to improve the flow of urine
- 5-alpha reductase inhibitor medications such as finasteride and dutasteride, which block the conversion of TESTOSTERONE to dihydrotestosterone (DHT) to slow the growth of prostate gland cells
- herbal remedies such as SAW PALMETTO, stinging nettle extract, SOY protein and soybean products, and flaxseed oil

MEDICATIONS TO TREAT BENIGN PROSTATIC HYPERPLASIA (BPH)

alfuzosin	doxazosin
dutasteride	finasteride
prazosin	tamsulosin
terazosin	

Prostatectomy is the only cure for BPH, though it has significant risks and potential complications. Most men are able to achieve long-term relief of symptoms through medication or minimally invasive procedures.

Risk Factors and Preventive Measures

Age is the primary risk factor for BPH. BPH is rare in men under age 50 and nearly always present in men over age 70. There are no known methods for preventing BPH. It is important for men over age 50 to undergo recommended preventive screening and examination for prostate cancer, as the risk for prostate cancer also increases with age and its early symptoms are indistinguishable from those of BPH.

See also AGING, REPRODUCTIVE AND SEXUAL CHANGES THAT OCCUR WITH; BLADDER CANCER; ENDOSCOPY; HORMONE-DRIVEN CANCERS; SURGERY BENEFIT AND RISK ASSESSMENT; URETHRAL STRICTURE.

birth control See CONTRACEPTION.

breast The mammary gland. Both men and women have breasts. Each person's two breasts are close to but not exactly the same size and shape. Breasts vary widely in appearance among both men and women.

At PUBERTY the female sex hormones (primarily ESTROGENS) in girls cause the glandular components of the breast to enlarge, establishing the potential to produce milk. The nipple also enlarges as does the glandular tissue surrounding it, the areola. Enlarged breasts are among the female SECONDARY SEXUAL CHARACTERISTICS. Female breasts fill out with adipose (fatty) tissue and connective tissue in addition to its glandular structures, becoming rounded, and extend out from the chest. The male sex hormones (primarily TESTOSTERONE) have the opposite effect in boys, causing the glandular components to all but disappear. In adulthood the male breasts remain relatively flat against the chest.

The glandular components of the adult female breast are the lactiferous glands, which can produce and secrete milk, and the lactiferous ducts, which store milk. Fatty tissue accumulates around these structures, called lobules. Supportive connective fibers called Cooper ligaments group the lobules into lobes. Each breast contains between 15 and 20 lobes. Milk production, called lactation, occurs under the stimulation of PROLACTIN, a HORMONE the PITUITARY GLAND begins to secrete after CHILDBIRTH. Lactation may continue for as long as the woman continues BREASTFEEDING. Another hormone, OXYTOCIN, stimulates the release of milk from the breast. The breasts may become significantly larger (up to three times their prepregnancy size) while the woman is breastfeeding. When breastfeeding stops the lactiferous structures (glands and ducts) shrink and the breasts return to their normal size.

The breasts are also sources of sexual stimulation and arousal for women and for men, both by touch and visually. During sexual arousal and at ORGASM the nipples become firm and erect. A woman's breasts may become uncomfortably tender and sometimes swollen during the luteal phase of the MENSTRUAL CYCLE, in response to the elevation of estrogens in the BLOOD circulation.

At MENOPAUSE the glandular tissue in the breast shrinks and the breast structure becomes much less dense. At this time a woman's risk for BREAST CANCER increases significantly. Current preventive health guidelines recommend routine MAMMOGRAM (X-RAY of the breast) beginning at age 40 for most women, and beginning earlier and occurring more frequently in women who have high risk for developing breast cancer. Health experts recommend that all women, beginning at the conclusion of puberty, perform monthly BREAST SELF-EXAMINATION as a method of early detection for BREAST HEALTH concerns, including lumps that may be cancerous.

HEALTH CONDITIONS THAT CAN AFFECT THE BREASTS

BREAST CANCER	fibroadenoma
FIBROCYSTIC BREAST DISEASE	GYNECOMASTIA
INTRADUCTAL PAPILLOMA	MASTALGIA
MASTITIS	PAGET'S DISEASE OF THE BREAST

For further discussion of the breast within the context of the structures and functions of reproduction and sexuality, please see the overview section "The Reproductive System."

See also LIGAMENT; PREMENSTRUAL SYNDROME (PMS); TURNER'S SYNDROME.

breast cancer A malignant (cancerous) tumor that arises in the BREAST. There are many types of breast cancers, some of which are HORMONE driven (draw sustenance from ESTROGENS or PROGESTERONE) and others that are not. Primary breast cancer originates in the breast; secondary breast cancer metastasizes (spreads) to the breast from an origin elsewhere in the body. Breast cancer may also metastasize to other sites in the body such as the LUNGS or bones.

Breast cancer is the most common cancer among American women; doctors in the United States diagnose breast cancer in about 200,000 women each year. Breast cancer is currently second to LUNG CANCER as the leading cause of deaths due to cancer among women. However, significant advances in the early 2000s in understanding the mechanisms of breast cancer cells and the resulting development of new treatments are changing the landscape of breast cancer.

Genetic factors The genes BRCA-1/BRCA-2 were the first genes conclusively linked to cancer. Inherited mutations in these genes significantly increase a woman's risk for breast cancer and OVARIAN CANCER. Researchers continue to study these mutations for ways to take advantage of them for preventing or treating cancers in women who have either or both mutations.

Other mutations are not hereditary but instead occur over time, the consequence of molecular damage that becomes cumulative over time. Researchers have identified nearly two dozen genes that influence cell proliferation (cell growth and division) in some way. One of the most significant is the *her-2* GENE (human epidermal growth factor receptor 2, also called HER-2/neu) gene, located on CHROMOSOME 17. The *her-2* gene expresses (directs the production of) certain protein receptors on the surfaces of cell membranes. The receptors allow binding with the HER-2/neu protein, a protein that instructs the cell to grow and divide. Mutations in the *her-2* gene cause increased numbers of HER-2/neu receptors on cells, allowing greater HER-2/neu binding. This

process, called overexpression, alters the way in which the cells grow and divide.

Hormonal factors Breast cancer cells may have receptors on the surfaces of their cell membranes for estrogen, progesterone, or both. These are hormone-positive cancer cells—designated as estrogen positive (ER+) or progesterone positive (PR+), with an accompanying percentage or numeric value that identifies the relative proportion or number of positive hormone receptors.

Immune factors The risk for breast cancer, like most types of cancer, increases with age. As immune function diminishes with age, so does the body's ability to protect itself against health conditions such as cancer. Researchers are exploring the roles foods and NUTRIENTS play in supporting the IMMUNE SYSTEM's ability to identify, contain, and eliminate cancer cells that develop. Immune dysfunction appears to play a direct role in one rare but aggressive type of breast cancer, inflammatory breast cancer (IBC). In IBC the breast cancer cells collect in the LYMPH vessels, causing INFLAMMATION within the breast rather than forming a discreet tumor.

TYPES OF BREAST CANCER

ADENOCARCINOMA	infiltrating comedocarcinoma
infiltrating intraductal CARCINOMA (IDC)	infiltrating lobular carcinoma
intraductal carcinoma	inflammatory BREAST cancer (IBC)
lobular carcinoma in situ (LCIS)	mucinous (colloid) carcinoma
noninfiltrating intraductal carcinoma	noninfiltrating comedocarcinoma
papillary carcinoma	PAGET'S DISEASE OF THE BREAST
	tubular carcinoma

Breast cancer in men Though people think of breast cancer as a woman's condition, men also can develop breast cancer. Breast cancer in men is rare, occurring in 1 man for every 100 women who develop it. Men develop fewer types of breast cancers as well, because their breasts do not have the glandular tissue prevalent in the breasts of women. The types of breast cancers that occur in men are ADENOCARCINOMA, ductal carcinoma in situ (DCIS), and infiltrating ductal carcinoma (IDC). Men can also develop PAGET'S DISEASE OF THE BREAST, a condition in which cancer cells migrate into the SKIN around the nipple, though this uncommon type of cancer is even more rare in men than in women. Symptoms of male breast cancer are the same as symptoms breast cancer in women. Many treatment options are also the same. Doctors diagnose about 1,700 men with breast cancer each year in the United States.

Symptoms and Diagnostic Path

In most situations the only symptom of breast cancer is a lump that the woman, her health-care provider, or a mammogram detects. Most breast cancer tumors do not hurt. Other symptoms of breast cancer may include

- nipple discharge, typically watery or sometimes blood tinged
- dimpling of the skin on the surface of the breast
- changes in the appearance of, or inversion of, the nipple
- changes in the shape or profile of the breast
- general sense of tiredness or lack of energy

The diagnostic path may include diagnostic mammogram, breast ULTRASOUND, fine-needle aspiration biopsy of the lump to obtain cell samples for laboratory examination, or excisional biopsy to remove the lump and provide tissue for laboratory examination. Excisional biopsy provides conclusive diagnosis. The pathologist determines the hormonal sensitivity of the cancer cells (estrogen or progesterone receptor positive) and whether they are *her-2* positive or negative. Many cancer centers conduct further testing to analyze the genetic composition of the cancer cells. Such testing provides insights into how the cancer cells grow and often reveals their vulnerabilities, allowing precisely targeted treatments. As well, the pathologist evaluates the size and characteristics of the tumor to determine its grade (level of abnormality in the cells) and stage (extent of the tumor). These factors in combination are crucial for determining appropriate CANCER TREATMENT OPTIONS AND DECISIONS.

Treatment Options and Outlook

Primary treatment for early stage breast cancer of any type is surgery to remove the cancer, which may be lumpectomy (removal of the lump and a

safe margin of normal tissue), segmental MASTECTOMY (removal of the one quarter segment of the breast that contains the tumor), simple mastectomy (removal of the breast), or modified radical mastectomy (removal of the breast and some surrounding tissue along with SENTINEL LYMPH NODE DISSECTION).

Nearly all women who have surgery for breast cancer also receive adjuvant (follow-up) therapy, which may include RADIATION THERAPY, CHEMOTHERAPY, HORMONE THERAPY, or MONOCLONAL ANTIBODIES (MABS) therapy, either singularly or in combination. These therapies also may be primary treatment for later stage and recurrent breast cancers. In the late 1990s hormone therapy and MAbs therapy (also called biological response modifier therapy or IMMUNOTHERAPY) became the frontrunners in adjuvant therapy for HORMONE-DRIVEN CANCERS—tumors sensitive to estrogen (ER+) or progesterone (PR+)—and HER-2/neu-positive tumors, respectively. In late 2005 the National Comprehensive Cancer Network (NCCN) issued revised treatment guidelines for breast cancer in which the cancer's hormone and *her-2* status are the primary factors for deciding the type and course of adjuvant therapy, with the traditional practice of evaluating tumor size and the degree of METASTASIS being a secondary step.

Hormone therapy for breast cancer Hormone therapy targets suppression of estrogen and progesterone in the woman's body. Among the therapies to achieve this goal are

- selective estrogen receptor modulators (SERMs), drugs that bind with estrogen receptors to keep estrogen from doing so; SERMs have some estrogen-like qualities that help maintain BONE DENSITY and lipid METABOLISM
- estrogen receptor downregulators (ERDs), which first bind with estrogen receptors and then destroy them
- aromatase inhibitors, which block the action of aromatase, an enzyme that converts ANDROGENS naturally occurring in body tissues such as fat into estrogen

Hormone therapy for breast cancer is effective in women who are past MENOPAUSE or who have no ovarian function due to surgical removal of the OVARIES (OOPHORECTOMY) or chemical suppression of ovarian function (medications such as goserelin and leuprolide). Blocking estrogen production cuts off the supply of estrogen to cancer cells that require it, preventing the cells from growing. Side effects that may occur with hormone therapy include JOINT PAIN, NAUSEA, DIARRHEA, HEADACHE, and HOT FLASHES.

SERMs were the first effective hormone therapy drugs (tamoxifen came on the market in the 1980s). They generally have therapeutic value for about five years, after which their ability to bind with estrogen receptors diminishes. Oncologists may recommend taking a SERM for five years and then switching to an aromatase inhibitor, which does not appear to have time-limited usefulness. Aromatase inhibitors and ERDs are too new in clinical practice to know their long-term effectiveness.

HORMONE THERAPY DRUGS TO TREAT BREAST CANCER

Selective Estrogen Receptor Modulators (SERMs)

raloxifene (Evista)
tamoxifen (Nolvadex)
toremifene (Fareston)

Aromatase Inhibitors

anastrazole (Arimidex)
exemestane (Aromasin)
letrozole (Femara)

Estrogen Receptor Downregulators (ERDs)

fulvestrant (Faslodex)

Trastuzumab (Herceptin) Trastuzumab, a monoclonal antibody, specifically targets *her-2* receptors on breast cancer cells. First produced in the early 1970s, trastuzumab demonstrated its effectiveness against *her-2* positive breast cancer in the 1980s and became the cornerstone of treatment for *her-2* positive metastatic breast cancer in the 1990s. Because trastuzumab so narrowly targets breast cancer cells, it causes few side effects. However, one significant, though rare, SIDE EFFECT is HEART FAILURE. In the first decade of the 2000s, oncologists began administering trastuzumab for *her-2* positive stage 2, stage 3, and stage 4/metastatic breast cancers along with combination chemotherapy.

CHEMOTHERAPY AGENTS TO TREAT BREAST CANCER	
capecitabine	cyclophosphamide
docetaxel	doxorubicin
epirubicin	5-fluorouracil (5FU)
gemcitabine	paclitaxel
vinorelbine	

Risk Factors and Preventive Measures

Age is the primary risk factor for breast cancers of all types, with the likelihood of developing breast cancer reaching one in two for women 85 and older. Hereditary factors (such as BRCA-1/BRCA-2) influence about 5 percent of breast cancers. Lifestyle factors that contribute to nonhereditary breast cancers include EATING HABITS that feature high-fat foods, lack of physical exercise, cigarette smoking, and excessive ALCOHOL consumption.

There is a strong correlation between OBESITY and breast cancer, though researchers do not know whether this is a circumstance of excess body fat or the consequence of eating habits and physical inactivity. Fat cells convert androgens to estrogen, raising the level of estrogens in the blood circulation. Continued exposure to elevated levels of estrogen is a risk factor for breast cancer as well as other hormone-driven cancers.

It is not possible at present to completely prevent breast cancer. However, lifestyle improvements can significantly reduce the risk of developing breast cancer. Regular breast examination from a health care provider, breast self-examination, and mammograms make possible early detection of breast cancer, which establishes the most ideal circumstances for successful treatment.

breastfeeding The process of nourishing an infant with milk the mother's breasts produce. Health experts recommend breastfeeding at least for the first six months of life when possible. BREAST milk provides the ideal nutritional balance for the infant. It also conveys important antibodies to the infant, helping provide immune protection while the infant's own IMMUNE SYSTEM is developing. Breastfeeding, also called nursing, further supports a strong physical and emotional connection between mother and baby.

Though breastfeeding suppresses a woman's normal hormonal cycle to some extent, breastfeeding is not a reliable method of CONTRACEPTION (birth control). It is still possible for a nursing mother to get pregnant.

First Milk: Colostrum

The first milk the mother's breast produces after birth is colostrum, often called premilk. Colostrum is more concentrated than mature breast milk and contains primarily carbohydrate and protein with little fat. This composition is very easy for the infant to digest in the first use of the gastrointestinal system; its concentration delivers more nutrition with less volume. Colostrum also contains a higher concentration of antibodies than mature breast milk. The infant should breastfeed about every two hours in its first few days of life, both to provide sufficient nutrition and to encourage adequate milk production.

Milk Production

The hormones of PREGNANCY establish the initial environment for milk production. The stimulation of the infant's sucking induces the hormonal responses that cause the lactiferous glands of the breasts to produce milk. The lactiferous ducts store some breast milk, though the lactiferous glands actively produce milk as the infant nurses. The breasts will continue producing milk after pregnancy for as long as the baby nurses regularly.

The breast releases mature milk in two surges. The first surge, the foremilk, is thin, bluish, and contains primarily lactose (a simple carbohydrate) and proteins. The second surge, which releases after the infant has nursed for three to five minutes, is hindmilk. Hindmilk is thicker, yellowish, and contains a higher concentration of fats that are essential to supply the infant with a source of energy. The infant may nurse 10 to 30 minutes on hindmilk.

Let the Infant Take the Lead

Lactation and nutrition experts currently recommend that the mother allow the infant to nurse

completely at one breast before switching to the other, even if the infant becomes satiated before switching or before finishing the second breast. The infant generally will pull away from one breast when ready to switch. Following the infant's lead in this way, rather than breastfeeding by the clock, allows the infant to receive maximum nutritional benefit from breastfeeding. Though conventional wisdom has long held that the mother should switch the infant from one breast to the other to provide equal time at each breast under the premise that this practice would to stimulate and sustain the most ideal milk production, recent research suggests the infant may not receive balanced nutrition with such an approach. As well, sucking provides emotional comfort for the infant.

Though breastfeeding is a natural process, the process of breastfeeding does not come naturally for most women. It takes time and patience for the mother to synchronize with the baby's needs and preferences. Birthing centers have lactation specialists who can help new mothers establish effective breastfeeding. New mothers often worry the infant is not receiving enough nourishment. The most accurate measure of this is the infant's steady and appropriate weight gain and development. The breasts seldom drain completely of milk, and the infant may nurse more aggressively at some feedings than others.

Care of the Breasts

The mother's breasts, especially the nipples, are often tender during the first few weeks of breastfeeding. It is important for the infant to latch around a good portion of the areola as well as the nipple when nursing, which properly stimulates the lactiferous glands as well as eases CHAFING and soreness of the nipples. A lactation specialist can help a new mother find the nursing positions that are most effective.

Washing the breasts with warm water after breastfeeding and allowing them to air dry helps prevent irritation and chafing. A nursing bra provides extra support for the breasts, which are quite heavy and enlarged during breastfeeding. Nursing pads inserted inside the bra protect leaking milk from staining clothing. Because many substances pass from the mother's body into the breast milk, the woman should check with her health-care provider before taking over-the-counter (OTC) medications. Certain foods appear to bother some infants, probably altering the taste or smell of the breast milk.

Expressing and Storing Breast Milk

Many women express (pump) milk from their breasts to store for feeding the baby when breastfeeding is not possible, such as after the woman returns to work. This allows other people to use a bottle to feed breast milk to the baby. Expressed breast milk will remain fresh for one week when refrigerated and for four months when frozen. Breast pumps simulate the rhythmic pressure of nursing, initiating the letdown REFLEX and releasing milk. It may take longer to express full breasts when pumping than when the baby nurses, though it is important to get as much milk as possible so milk production remains constant. The breasts adjust how much milk they produce according to the demand for milk.

See also ANTIBODY; BREAST HEALTH; MASTITIS.

breast health Measures a woman can take throughout her life to maintain the best possible health for her breasts. Because there is such wide variation around what is "normal" when it comes to breasts, health experts urge women to become familiar with the appearance and feel of their own breasts so they can easily and quickly detect changes that warrant further medical evaluation. A comprehensive approach combines lifestyle habits that support BREAST health with monthly BREAST SELF-EXAMINATION, regular breast exams from a health-care provider, and MAMMOGRAM (when age appropriate).

A woman's breasts are somewhat dynamic in that they undergo cyclic changes that follow the MENSTRUAL CYCLE. The glandular tissues respond to ESTROGENS and PROGESTERONE in the woman's BLOOD circulation. The same hormonal patterns that prepare the UTERUS for PREGNANCY also prepare the breasts to produce milk. They also cause cyclic changes in the breasts. Many women find their breasts become tender and somewhat swollen during the week before their menstrual periods—the luteal or secretory phase of the menstrual cycle when estrogen levels are especially high.

Women who have fibrocystic breasts may experience increased symptoms during this time. Knowing these cyclic patterns makes it easier to distinguish normal from unusual changes.

Lifestyle factors that influence breast health include EATING HABITS, physical exercise, and cigarette smoking. Some research studies suggest a diet high in saturated fat (animal fat) raises the risk for FIBROCYSTIC BREAST DISEASE and BREAST CANCER. The findings of other studies are inconclusive. There is increased risk for breast cancer with OBESITY, however, which may be a consequence of diet and exercise or a function of increased estrogen in the blood circulation as a result of aromatase conversion of stored estrogen in adipose (fat) cells. Numerous studies associate cigarette smoking with increased risk for fibrocystic breast disease, fibroadenoma (noncancerous breast tumor), breast cancer, and cancer overall.

See also DIET AND HEALTH; EXERCISE AND HEALTH; MASTITIS; OBESITY AND HEALTH; SMOKING AND HEALTH; SMOKING CESSATION.

breast self-examination A method a woman can use to examine her breasts for changes such as lumps and irregularities in the BREAST tissue. The primary purpose of breast self-examination (BSE) is to familiarize a woman with the normal appearance and feel of her breasts so she can detect changes that may warrant medical evaluation. Though most lumps and irregularities a woman detects through BSE are benign (noncancerous), BSE can result in early discovery of BREAST CANCER. The risk for breast cancer increases with age and is highest after MENOPAUSE.

The ideal time to perform BSE is at the end of the menstrual period when the breasts are least sensitive. BSE takes only a few minutes, following these steps:

1. Stand in front of a mirror, unclothed, with arms at the sides. Look at the breasts for any indentations, irregularities, or distortions to the shape of the breast.
2. Raise the arms and repeat the visual examination.
3. With the flat surfaces of the fingers of the left hand, gently feel the right breast starting at the nipple and moving outward in a circular pattern to cover the entire breast. Also feel into the armpit area, which contains breast tissue.
4. Gently squeeze the nipple to detect any discharge.
5. Repeat steps 3 and 4 for the left breast.
6. Lie on the back on a flat surface with the right hand behind the head. Repeat steps 3 and 4.
7. Switch to put the left hand behind head and repeat steps 3 and 4 for the left breast.

Though BSE primarily targets women, it is good preventive health for men to also become familiar with the appearance and feel of their breasts. Breast cancer is rare but can occur in men. Though lumps in the breast are easier to detect in men, men are more likely to disregard them as insignificant. A doctor should evaluate any lump that develops in a man's breast.

C

cancer of the penis A malignant (cancerous) tumor that arises from the tissues of the PENIS. Cancer of the penis is rare and usually occurs in men over age 50. Men who are uncircumcised and men who have HUMAN PAPILLOMAVIRUS (HPV) infection have increased risk for cancer of the penis. Early symptoms include a painless growth, bump, or sore at the tip of the penis. In an uncircumcised man such a growth most commonly appears beneath the foreskin, which often delays the cancer's detection. Early diagnosis and treatment allow the least invasive treatment. Surgery is the preferred treatment to remove the cancerous tumor and a safe margin of healthy tissue. Follow-up surgery to reconstruct the penis is sometimes necessary. Depending on how advanced the cancer is, the oncologist may recommend RADIATION THERAPY or CHEMOTHERAPY in addition to surgery.

See also CANCER TREATMENT OPTIONS AND DECISIONS; CIRCUMCISION; METASTASIS; PROSTATE CANCER; SEXUALLY TRANSMITTED DISEASE (STD) PREVENTION; PLASTIC SURGERY; SURGERY FOR CANCER; TESTICULAR CANCER.

cervical cancer A malignant (cancerous) tumor that originates in a woman's CERVIX. The cervix is a thick neck of tissue that joins the VAGINA and the UTERUS. INFECTION with the HUMAN PAPILLOMAVIRUS (HPV) accounts for nearly all cervical cancer, though only about 15 of the 100 or so strains of HPV are connected with cervical cancer and only a small percentage of women who have HPV infection with one of those strains actually develops cervical cancer.

Cervical cancer tends to follow a predictable path of development that takes many years to evolve, typically 10 years or longer. Because of this, with early detection cervical cancer is one of the most curable forms of cancer. The path of development for cervical cancer begins with slight changes in the cells of cervical tissue, called cervical DYSPLASIA. Though not cancer, dysplasia is a circumstance of irregular cell growth. All cervical cancer begins as cervical dysplasia. Because of this, even though only a small percentage of cervical dysplasia become cancer doctors consider cervical dysplasia a broad classification of cell abnormalities that range from precancerous to cancerous.

Doctors call moderate to severe cervical dysplasia, which is precancerous, CERVICAL INTRAEPITHELIAL NEOPLASIA (CIN). Doctors believe about two thirds of untreated cervical dysplasia progresses to cancer. The PAP TEST, a laboratory examination of cells swabbed from the cervix, can detect cervical dysplasia, CIN, and other changes in cervical tissue. A Pap test is part of a routine PELVIC EXAMINATION.

Symptoms and Diagnostic Path

Cervical cancer often shows no symptoms until it spreads outside the cervix, which is why routine Pap tests are so crucial in its detection. When symptoms are present they may include

- watery, sometimes blood-tinged discharge
- vaginal bleeding between menstrual periods or after MENOPAUSE
- vaginal bleeding during or after SEXUAL INTERCOURSE
- unusually heavy or prolonged menstrual periods
- low back discomfort
- unexplained tiredness, lack of energy, or fatigue
- URINARY URGENCY or URINARY FREQUENCY

The diagnostic path begins with pelvic examination, Pap test, and HPV testing, including HPV DNA. COLPOSCOPY (examination of the cervix with a special lighted microscope) provides additional information about the location and extensiveness of the cancer. Cervical biopsy (laboratory examination of tissue samples taken from the cervix) provides definitive diagnosis. Diagnostic imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) may show the extent to which the cancer has metastasized to locations within or distant from the pelvis. The pathologist determines the grade (degree of abnormality of the cells) and stage (extent of the tumor) from the biopsy tissue samples. STAGING AND GRADING OF CANCER is important for determining appropriate CANCER TREATMENT OPTIONS AND DECISIONS.

BASIC STAGING OF CERVICAL CANCER

Stage	Meaning	Treatment Options
cervical intraepithelial neoplasia (CIN2/CIN3)	cells are abnormal but precancerous and confined to a localized area of the CERVIX	cryosurgery, laser surgery, loop electrosurgical procedure (LEEP), or excisional conization to remove abnormal cells frequent and regular PAP TEST and COLPOSCOPY
CIN4/stage 0/carcinoma in situ	cancer remains confined to the cells of its origin	cryosurgery, laser surgery, LEEP, or excisional conization to remove abnormal tissue frequent and regular Pap test and colposcopy
stage 1	cancer remains confined to a small, clearly defined area of the cervix stage 1A is microscopic; stage 1B is barely visible to the unaided eye	stage 1A: total HYSTERECTOMY frequent and regular Pap test and colposcopy stage 1B: modified radical HYSTERECTOMY with SENTINEL LYMPH NODE DISSECTION and adjuvant RADIATION THERAPY and/or CHEMOTHERAPY *or* high-dose external beam radiation combined with internal seeding
stage 2	cancer has spread to other structures within the pelvis but not to distant organs stage 2A involves the upper VAGINA; stage 2B involves parametrial tissue	high-dose external and internal radiation therapy in combination with platinum-agent chemotherapy
stage 3	cancer has spread widely within the pelvis and may involve the lower vagina and ureters stage 3A involves the lower vagina but not the pelvic wall; stage 3B involves the pelvic wall or the pelvic LYMPH nodes	combination chemotherapy palliative radiation therapy clinical trials
stage 4	cancer has spread to distant organs or recurred (come back) after treatment stage 4A involves lower abdominal organs; stage 4B involves distant organs	combination chemotherapy palliative radiation therapy clinical trials

Treatment Options and Outlook

Cervical cancer is almost always curable with minimally invasive treatment when doctors detect it as CIN or stage 1. Stage 2 and stage 3 cervical cancers require more invasive treatments and have lower potential for cure. The primary treatment of choice for most stage 1 cervical cancers is surgery to remove the tumor, the entire cervix, or, in more advanced stages, the cervix and adjacent tissues such as the upper vagina and often the uterus (total or modified radical HYSTERECTOMY). Adjuvant (follow-up) treatment may include CHEMOTHERAPY or RADIATION THERAPY. High-dose radiation therapy (external beam and internal seeding) in combination with chemotherapy, is the primary treatment of choice for most stage 2 and stage 3 cervical cancers as these have usually spread beyond the scope of surgery, though surgery may be an option for stage 2 cervical cancer that remains confined to the upper vagina. The treatment of choice for stage 4 cervical cancer is combination chemotherapy with palliative radiation therapy to relieve symptoms of obstructive tumors.

CHEMOTHERAPY AGENTS TO TREAT CERVICAL CANCER	
carboplatin	cisplatin
gemcitabine	paclitaxel
topotecan	vinorelbine

Risk Factors and Preventive Measures

The key risk factors for cervical cancer are HPV infection with one of the few strains of HPV linked to cervical cancer, multiple sexual partners, and cigarette smoking. The HPV vaccine prevents infection with HPV types 6, 11, 16, and 18, the strains of HPV associated with genital warts and cervical cancer. Health experts recommend HPV vaccination for girls beginning at age 12, though women to age 26 can receive the vaccine. Because HPV accounts for nearly all cervical cancer, measures to reduce exposure to HPV infection (such as condom use and mutual monogamy) are also crucial. Routine pelvic examination with Pap test can detect cervical cancer in its earliest, curable stages.

See also BREAST CANCER; CONTRACEPTION; ENDOMETRIAL CANCER; HIV/AIDS; SEXUAL HEALTH; SEXUALLY TRANSMITTED DISEASE (STD) PREVENTION; SURGERY BENEFIT AND RISK ASSESSMENT.

cervical intraepithelial neoplasia (CIN) The growth of abnormal cells within the tissue of the CERVIX. Because without treatment CIN often progresses in severity and is the foundation of CERVICAL CANCER, doctors consider CIN a precancerous condition and grade it according to the extent to which it infiltrates the cervix. The four grades, or levels of severity, of CIN are

- grade 1, or CIN1, in which the abnormal cells infiltrate only the first layer of tissue; CIN1 often goes away on its own though merits careful observation until it is clear that it has done so
- grade 2, or CIN2, in which the abnormal cells penetrate to the second or third layer of tissue; standard treatment is surgical removal of the affected tissue using the loop electrosurgical excision procedure (LEEP)
- grade 3, or CIN3, in which the abnormal cells penetrate through the third layer of tissue and involve a fairly substantial area of cervical tissue; standard treatment is surgical removal of the affected tissue, usually using LEEP and sometimes using conization
- grade 4, or carcinoma in situ, in which the abnormal cells completely penetrate all epithelial layers using conization

Though CIN often follows an orderly progression from grade 2 to grade 4, culminating with cervical cancer, it does not always do so. About a third of CIN2 and CIN3 progresses to the next level and three fourths of women who have CIN4 or carcinoma in situ eventually develop cervical cancer. However, CIN1 progresses to cervical cancer in only 1 percent of women.

Symptoms and Diagnostic Path

Often a woman has no symptoms of CIN; the doctor detects the condition during routine PELVIC EXAMINATION and PAP TEST. COLPOSCOPY (examination of the cervix with a lighted surgical microscope) can sometimes confirm the diagnosis. However, excisional biopsy (removal of the abnormal area and laboratory examination of the tissue) is the definitive diagnostic procedure.

Treatment Options and Outlook

Standard treatment for CIN is removal of the abnormal cells with follow-up pelvic exam, Pap test, and other pathologic tests. The procedures for removal include

- LEEP, an office procedure in which the gynecologic surgeon inserts a wire loop through the VAGINA to the cervix and removes slices of tissue by sending a mild electrical current through the wire loop; LEEP is the standard treatment for CIN2 and some CIN3
- conization, also called excisional conization or cone biopsy, in which the gynecologic surgeon removes larger areas of tissue with instruments inserted through the vagina; the woman usually undergoes general ANESTHESIA, and the procedure is performed in an operating room

These treatments usually cure the CIN, though doctors recommend regular follow-up Pap tests, colposcopy, and other laboratory tests for up to five years after the initial treatment.

Risk Factors and Preventive Measures

The strongest risk for CIN is INFECTION with HUMAN PAPILLOMAVIRUS (HPV). CIN is more common in women who smoke and in women who have HIV/AIDS. A Pap test can detect CIN in its early, easily treatable stages. Preventive measures include safer sex methods (such as abstinence, condom use, or mutually monogamous sexual relationships) to prevent HPV infection. In 2006 the first vaccine to prevent HPV infection in women became available. The vaccine protects against infection with HPV types 6, 11, 16, and 18, the types associated with genital warts and cervical cancer. Health experts recommend HPV vaccination for girls beginning at age 12, though women to age 26 can receive the vaccine.

See also CANCER TREATMENT OPTIONS AND DECISIONS; CELL STRUCTURE AND FUNCTION; SURGERY BENEFIT AND RISK ASSESSMENT.

cervix The neck of the UTERUS, a thick cuff of muscular tissue about one inch in length that joins the VAGINA to the uterus. A narrow channel through the cervix, the cervical canal, allows menstrual material to leave and SPERM to enter the uterus. The opening of the cervix within the uterus is the internal os; the opening of the cervix within the vagina is the external os. The cervix has the ability to thin and dilate to permit CHILDBIRTH.

HEALTH CONDITIONS THAT MAY AFFECT THE CERVIX

CERVICAL CANCER	cervical DYSPLASIA
cervical erosion	CERVICAL INTRAEPITHELIAL NEOPLASIA (CIN)
cervical polyps	GONORRHEA
CHLAMYDIA INFECTION	incompetent cervix during PREGNANCY
HUMAN PAPILLOMAVIRUS (HPV) infection	
trauma	

For further discussion of the cervix within the context of the structures and functions of reproduction and sexuality, please see the overview section "The Reproductive System."

See also COLPOSCOPY; DILATION AND CURETTAGE (D&C); FALLOPIAN TUBES; GENITAL TRAUMA; HYSTERECTOMY; OVARIES; PAP TEST; PELVIC EXAMINATION.

cesarean section Surgical CHILDBIRTH. In cesarean (spelled caesarean in countries other than the United States) section, the obstetrician makes an incision through the abdominal wall and the wall of the UTERUS to extract the FETUS. Doctors in the United States perform cesarean section, also called c-section, to deliver 90 percent of breech presentations (fetus is bottom down rather than head down in the uterus) and about 25 percent of pregnancies overall. Most cesarean sections are unplanned though nonemergency, performed because of the mother's health status, the size of the baby, or the failure of labor to progress. Emergency cesarean section may be necessary when the fetus is in distress.

Though some women feel disappointed or even dismayed to need cesarean delivery, the outcome of healthy baby and healthy mother is the overarching objective. A woman who feels rushed into surgical delivery should discuss alternatives with her obstetrician. Ideally the woman and the obstetrician have had discussions during the course of PRENATAL CARE about the circumstances under which the obstetrician may recommend cesarean section and are in agreement about them.

COMMON REASONS FOR CESAREAN SECTION

cephalopelvic disproportion	ECLAMPSIA
erratic fetal heartbeat	GENITAL HERPES outbreak
higher order multiples (triplets or more)	known serious BIRTH DEFECTS
	known SPINA BIFIDA
macrosomia (very large baby)	maternal CARDIOVASCULAR DISEASE (CVD)
maternal HIV/AIDS	nonprogressive labor
maternal DIABETES	placenta previa
PLACENTA abruptio	previous CESAREAN SECTION
PREECLAMPSIA	prolapsed UMBILICAL CORD
previous uterine surgery	

Most hospitals allow the woman's partner to be present in the operating room during nonemergency cesarean delivery. The partner must change into sterile clothing (scrubs) and remain outside the sterile field, usually seated beside the woman's head; the delivery team will provide clear and specific instruction for the partner. A draped sheet provides a screen to block the woman's view of the OPERATION as it is taking place. Except in emergency situations when time is crucial, ANESTHESIA is nearly always epidural (injection of the anesthetic DRUG into the space around the SPINAL CORD) or spinal. These forms of anesthesia provide complete PAIN relief for the mother but do not affect the infant. General anesthesia, because the drugs enter the mother's BLOOD circulation, affects the infant and may suppress BREATHING and HEART RATE.

Surgical Procedure

After the anesthesia takes effect, the obstetrician makes an incision through the SKIN and abdominal muscles to expose the uterus, then makes an incision through the wall of the uterus to deliver the baby. The most common incision is the low transverse (also called the bikini cut), running horizontally across the lower abdomen just above the pubic BONE about at the pubic hair line. An alternative incision for rapid delivery is the vertical incision, which extends from the umbilicus (belly button) to just above the pubic bone.

The obstetrician first delivers the baby's head and thoroughly suctions the secretions from the NOSE, MOUTH, and upper THROAT. The pressures and forces of a vaginal delivery would squeeze these secretions from the infant as it passed through the birth canal. Removing the secretions is essential to prepare the airways for breathing. The obstetrician then delivers the rest of the baby and clamps the umbilical cord. The pediatrician examines the baby to assess its breathing and overall health. Often the obstetrician allows the woman's partner to cut the cord and show the baby to the mother. To this point, the cesarean section takes about 10 minutes.

The rest of the cesarean section takes about 40 minutes and consists of delivering the placenta, repairing the incision into the uterus, and repairing the incision through the abdominal muscles and the skin. The anesthesiologist may administer a sedative to help the mother relax and sleep during this part, after which she goes to the recovery unit until the epidural anesthesia wears off and sensation returns.

Risks and Complications

The risk for serious complications is very low with cesarean section. Among them are unusual bleeding, blood clots, and INFECTION in the immediate postoperative period, injury to the BLADDER or ureters, and URINARY TRACT INFECTION (UTI). There is also risk, comparable to that of vaginal birth, of injury to the infant.

The path of recovery is substantially longer for cesarean section than for vaginal birth. Most women spend three to five days in the hospital for initial recovery. The doctor will prescribe ANALGESIC MEDICATIONS to relieve pain that are safe for the woman to take while she is BREASTFEEDING. During the first two weeks at home the woman needs to take care of her incision as the doctor instructs. Full recuperation takes six to eight weeks, during which the woman needs help lifting and caring for the baby. However, walking and other physical activities are necessary and important for HEALING as well as to keep the LUNGS clear and to help prevent blood clots.

Long-term complications are rare and are most likely to occur when the cesarean section was an emergency and the obstetrician made a vertical incision. This incision creates weakness in the abdominal wall, the muscles of which have already stretched as a consequence of the pregnancy. Proper care is essential for optimal healing. The risk of incisional HERNIA is higher with the vertical incision than the transverse incision.

Outlook and Lifestyle Modifications

While the incision is healing the woman needs substantial help carrying and lifting the infant as well as with daily activities. After healing is complete the woman may and should return to full activities, including SEXUAL INTERCOURSE as she desires. Cesarean section does not affect the ability to breastfeed for as long as the woman desires or the potential for becoming pregnant again. Vaginal delivery with subsequent pregnancies (VBAC, or vaginal birth after cesarean) is possible for about two thirds of women who had transverse incisions on the uterus. Most obstetricians consider a vertical incision on the uterus too risky for VBAC because the stress of labor may cause the incisional SCAR on the uterus to rupture.

For further discussion of cesarean section, please see the overview section "The Reproductive System."

See also APGAR SCORE; POSTOPERATIVE PROCEDURES; PREOPERATIVE PROCEDURES; SURGERY BENEFIT AND RISK ASSESSMENT.

childbirth The passage of the FETUS from the UTERUS to independent life outside the woman's body as PREGNANCY culminates. The physiologic processes that establish this passage are labor and delivery (vaginal birth); childbirth may also occur as a surgical procedure (CESAREAN SECTION). Labor refers to the progressively intense contractions of the uterus that dilate and efface (stretch and thin) the CERVIX, then push the fetus into and through the VAGINA (birth canal).

Though labor and delivery occur in predictable and sequential stages, their timing varies widely. Early labor may last a few to 36 hours. Active labor generally lasts 2 to 8 hours. Delivery, the passage of the baby through the birth canal, may take 15 minutes to 2 hours. A woman's first delivery typically takes longer than subsequent deliveries. Though childbirth is a natural process, in the United States most childbirth takes place in hospitals or birthing centers with medical professionals (doctors, nurses, midwives) providing care and assistance.

Stage 1: Labor

Labor is the work of the uterus and abdominal muscles to ready the woman's body for birth and ultimately push the infant out. For more than 40 weeks the body's focus has been on maintaining the pregnancy within it. As the time for birth approaches, hormonal signals initiate the sequence of events that will make delivery possible. Researchers do not know what starts the hormonal cascade that ultimately results in childbirth, though these changes begin some time before actual labor starts.

Though the most intense experience of labor is in the hours that lead to delivery, the preparations actually begin several weeks before birth. One of the earliest signs of impending birth is the dropping of the presenting part of the fetus, usually the head, into the start of the cervix. Called engagement or lightening, this movement indicates the cervix is beginning to efface. It also signals changes that are occurring within the fetus to prepare it for life outside the womb, notably expansion of the LUNGS.

As the cervix continues to efface and begins to dilate the plug of mucus that formed in the cervical canal comes loose and slides out, which the woman may notice as a brownish discharge (sometimes called bloody show). This may occur a week or longer before birth. The characteristic experience of labor begins with sensations of tightening and relaxing in the lower abdomen, somewhat similar in experience to menstrual cramps. Many women feel these sensations in the lower back as well. The woman may feel restless and want to walk around; walking helps strengthen and coordinate contractions as they progress. Labor becomes more intense and focused when the membranes rupture, often called water breaking.

There are many ways women cope with the discomfort of labor, which intensifies as the labor progresses. Methods such as relaxation BREATHING, massage, acupuncture, and visualization often help a woman feel calm and centered. Some women become intensely active in the early stages of labor, cleaning house and otherwise "nesting." Doctors believe this behavior harkens to primal instincts of preparedness. In early labor contractions may be 10 to 15 minutes apart and last about 30 seconds and may become less intense with certain positions or activities. As early labor progresses to active labor, contractions are about 5 minutes apart and last for 45 to 60 seconds.

In active labor contractions continue to increase in frequency and intensity, and discomfort progresses to PAIN. Many women feel the need for pain relief during active labor. Common methods include narcotic ANALGESIC MEDICATIONS and regional ANESTHESIA such as epidural block. Active labor dilates the cervix to 7 or 8 centimeters.

The final stage of labor is transition, during which contractions come in waves often without more than seconds between them. Transition consumes the woman's attention and focus; she often is not aware of activity taking place around her. Many women feel the urge to push, though should not do so because the cervix is not yet ready. Transition is usually complete within three hours. The cervix finishes dilating to a wide-open 10 centimeters, and birth is imminent.

Stage 2: Delivery of the Baby

Delivery requires much conscious effort from the woman to push with contractions. The birthing team coaches and guides the process. The urge to push may be overwhelming; going with it is usually the most efficient approach unless the doctor or midwife advises to wait. Sometimes the baby's position in the birth canal becomes awkward such that waiting a few moments allows a turn or movement that then responds better to pushing. An epidural for pain relief tends to extend delivery somewhat because the woman does not as strongly feel the urge to push.

The head emerges first, with the shoulders and then the rest of the body following. The doctor or midwife suctions any mucus and BLOOD from the baby's NOSE and MOUTH. The baby begins breathing as soon as his or her body clears the birth canal and the chest can expand. When all is well, the doctor or midwife places the baby on the mother's chest for her to hold and clamps the UMBILICAL CORD in two places. The partner, the mother, an older sibling present for the birth, or the birthing attendant may cut between the clamps to sever the cord.

Stage 3: Delivery of the Placenta

After a brief pause contractions resume to separate the PLACENTA from the endometrium and push it from the body. It takes about 10 minutes to deliver the placenta, which sometimes requires the woman to bear down to help push it out. The uterus then continues mild contractions, which are important to restore its firmness and to stop bleeding. A member of the birthing team may massage the mother's lower abdomen to further stimulate these contractions. BREASTFEEDING the infant at this time is also helpful because the sucking at the BREAST releases OXYTOCIN, a HORMONE that continues the uterine contractions as well as releases colostrum (premilk) for the infant.

For further discussion of childbirth, please see the overview section "The Reproductive System."

See also POSTPARTUM DEPRESSION; PRENATAL CARE; VBAC.

chordee A congenital (present at birth) downward curvature of the PENIS. Chordee results from extra connective tissue that contracts the ventral surface of the penis, pulling the tip of the penis downward. Chordee typically occurs in conjunction with HYPOSPADIAS, a CONGENITAL ANOMALY in which the opening of the URETHRA (the meatus) is on the underside of the penis rather than at the tip. Chordee may be apparent only during ERECTION or may contract the penis significantly enough to prevent normal URINATION. Mild chordee that does not interfere with urination or SEXUAL INTERCOURSE does not require treatment. For more severe chordee, surgery to release the connective tissue and, if necessary, to correct the hypospadias relieves the curvature.

See also CIRCUMCISION; PEYRONIE'S DISEASE; PHIMOSIS; SURGERY BENEFIT AND RISK ASSESSMENT.

chorionic villi sampling (CVS) A diagnostic procedure, also called chorionic villus sampling, in which the obstetrician removes small clusters of cells from the hairlike edges of the PLACENTA, the chorionic villi, during PREGNANCY. The cells in this sample provide genetic information about the FETUS that can rule out or diagnose GENETIC DISORDERS such as CYSTIC FIBROSIS and TAY-SACHS DISEASE, NEURAL TUBE DEFECTS such as SPINA BIFIDA, or CHROMOSOMAL DISORDERS such as DOWN SYNDROME. The obstetrician can perform CVS in the first trimester, usually around the 11th week, providing information about potential health concerns early in the pregnancy to allow the woman and her partner to consider possible treatment options as well as

whether, with severe disorders or deformities, to continue the pregnancy.

To withdraw the sample of cells the obstetrician may insert a needle through the abdominal wall and into the UTERUS, similar to AMNIOCENTESIS, or may guide a very small catheter through the VAGINA and CERVIX into the uterus. The obstetrician first numbs either the site on the abdomen or the cervix with a local anesthetic, then uses ULTRASOUND to help place the needle or the catheter. After the procedure the woman may feel mild cramping or experience slight bleeding, which are the main risks associated with CVS. Rarely CVS can cause spontaneous ABORTION (loss of the pregnancy), though the risk with CVS less than the risk with amniocentesis, another prenatal diagnostic procedure, because CVS does not require penetration of the amniotic sac.

The findings available through CVS are not always as definitive as the results of amniocentesis. The advantages of CVS over amniocentesis, however, are twofold. First, the obstetrician can conduct CVS in the first trimester though cannot perform amniocentesis until well into the second trimester. Second, the risk for complications, including injury to the fetus and spontaneous abortion, is lower with CVS. It is important to discuss and thoroughly understand the reasons for either procedure.

See also ALPHA FETOPROTEIN (AFP); CONGENITAL ANOMALY; PRENATAL CARE.

circumcision The surgical removal of the foreskin (prepuce), the thin hood of SKIN that covers the end of the PENIS. The reason for circumcision may be therapeutic, religious, ceremonial, hygienic, cultural, or social. About two thirds of newborn boys in the United States are circumcised shortly after birth for nontherapeutic reasons. Nontherapeutic circumcision should take place within three weeks of birth when done in infancy. Circumcision at an older age, and particularly in adulthood, becomes a more significant surgical procedure with increased risk for complications.

Infant (Neonatal) Circumcision

For infant circumcision, the doctor applies an anesthetic cream or injects a local anesthetic to numb the penis, then applies a circumcision clamp and cuts away the end of the foreskin. The procedure takes about 10 minutes. Some methods leave a plastic ring around the penis that seals the edge of the wound; the ring falls off when the wound heals (within 7 to 10 days). There are no sutures (stitches). Minor bleeding for a day or so after the procedure is common.

Adult Circumcision

Adult circumcision is a minor surgery OPERATION generally performed in a hospital operating room or an AMBULATORY SURGERY FACILITY; it requires regional anesthesia (anesthetic injected into the NERVE that serves the penis) and a general sedative. The circumcision operation takes about 30 minutes; typically a urologist performs the operation. Sutures remain in place for five to seven days after the operation. It is important to try to avoid erections and sexual activity for four to six weeks to allow the surgical wound to heal properly. There is often mild to moderate discomfort during HEALING; the doctor may prescribe or recommend ANALGESIC MEDICATIONS for PAIN relief.

Risks and Complications

Risks associated with circumcision include excessive bleeding, injury to the penis, too much or too little foreskin removed, and postoperative INFECTION. Infants who have a CONGENITAL ANOMALY of the penis such as HYPOSPADIAS or CHORDEE should not undergo circumcision. Health conditions for which circumcision is therapeutic include PHIMOSIS and PARAPHIMOSIS, conditions in which the foreskin does not properly retract or return to its normal position, and chronic or persistent BALANITIS (an infection of the glans that develops under the foreskin).

Medical Debate about Routine Infant Circumcision

Despite its frequency, routine infant circumcision is a matter of considerable debate among health professionals. In 1999 the American Academy of Pediatrics issued a position statement that there are no medical or health reasons for routine circumcision of newborns. Numerous studies have attempted to determine whether circumcision provides health benefits. The findings are mostly inconclusive, with the exception of a significantly increased risk in uncircumcised boys for URINARY

TRACT INFECTION (UTI) during early childhood. Uncircumcised men are more likely to acquire infections such as balanitis and perhaps SEXUALLY TRANSMITTED DISEASES (STDS) such as HUMAN PAPILLOMAVIRUS (HPV) and HIV/AIDS. Circumcision does not provide protection against such infections, however.

See also CANCER OF THE PENIS; CULTURAL AND ETHNIC HEALTH CARE PERSPECTIVES; SURGERY BENEFIT AND RISK ASSESSMENT.

clitoris An organ of the female GENITALIA, located at and partially beneath the junction of the upper folds of the labia. Made of erectile tissue and nerves, the clitoris arises from the same embryonic cells as the male PENIS and, though much smaller, contains parallel structures. Two fused corpora cavernosa (spongy, tubelike channels) form the body of the clitoris, which is about an inch long. During sexual arousal the corpora cavernosa engorge with BLOOD and cause the clitoris to enlarge and become erect. At the end of the clitoris is a small bulb of highly sensitive NERVE tissue, the glans. A thin sheath, the prepuce (analgous to the male foreskin), covers the clitoral glans except during sexual stimulation when it retracts to expose the glans. The only known purpose of the clitoris is sexual stimulation, which increases vaginal lubrication and other physiologic changes to facilitate penetration during SEXUAL INTERCOURSE.

See also ERECTION; GENITAL TRAUMA; SEXUALITY.

colposcopy A diagnostic procedure in which the gynecologist examines a woman's external GENITALIA and the interior VAGINA using a lighted magnifying instrument called a colposcope. The gynecologist may also visualize the CERVIX though the colposcope remains outside the vagina. The colposcope allows the gynecologist to more closely examine the surface of the genital tissues when a PELVIC EXAMINATION or a PAP TEST reveals possible abnormalities. Colposcopy helps the gynecologist determine whether biopsy (removing a small sample of tissue) or another diagnostic procedure is necessary. The gynecologist performs colposcopy as an office procedure that requires no special preparation or anesthetic. Most women find colposcopy no more uncomfortable than a routine PELVIC EXAMINATION though any associated biopsy may cause minor discomfort and slight bleeding for a day or two after the biopsy. There are no aftereffects or risks for complication with colposcopy alone.

See also HYSTEROSCOPY.

conception The culmination of fertilization (union of a SPERM and an ovum) and implantation of the resulting blastocyst into the endometrium (lining of the UTERUS). Conception marks the onset of PREGNANCY.

Numerous factors, internal and external, influence conception. Internal factors include a woman's HORMONE levels and OVULATION patterns, the viability of the man's sperm, and circumstances that occlude the FALLOPIAN TUBES to keep sperm and ovum from meeting, such as scarring from PELVIC INFLAMMATORY DISEASE (PID). External factors that influence conception include cigarette smoking and birth control methods intended to block conception, such as condoms, the intrauterine device, and oral contraceptives (birth control pills).

Health conditions such as ENDOMETRIOSIS and UTERINE FIBROIDS may prevent the pregnancy from proceeding after implantation takes place, resulting in early spontaneous ABORTION (commonly called miscarriage) often before the woman realizes she has conceived.

See also ASSISTED REPRODUCTIVE TECHNOLOGY (ART); CONTRACEPTION; FAMILY PLANNING; FERTILITY; INFERTILITY; OVA; ZYGOTE.

contraception Any of various methods, also called birth control, intended to prevent PREGNANCY. Contraception allows sexually active women and their partners to prevent as well as plan pregnancies.

The US Food and Drug Administration (FDA) approved the first oral contraceptive in 1960. Thirteen years later the US Supreme Court legalized elective ABORTION. Though they remain controversial even today, these two events were pivotal in the arena of reproductive choice and planning because they were the first methods that placed contraception in the control of women. Now, nearly all forms of contraception are for the woman's use.

COMMON METHODS OF CONTRACEPTION

Method	Male or Female	Availability	Ease of Use	Effectiveness When Used Correctly
cervical cap	female	prescription only; health-care provider must measure and fit	must insert before SEXUAL INTERCOURSE must use with spermicide must remove after specified time	85 percent when woman has not had vaginal CHILDBIRTH 70 percent when woman has had vaginal childbirth
cervical shield	female	prescription only	must insert before sexual intercourse must use with spermicide must remove after specified time	85 percent
condom	male most common; female available	over the counter (OTC)	must put on before each sexual act must withdraw from partner and remove condom for disposal while PENIS remains erect female condom may be difficult to insert	male condom: 85 to 98 percent female condom: 80 to 95 percent
continuous abstinence	both	personal commitment	challenging	100 percent
contraceptive patch	female	prescription only	woman applies once a month	99.9 percent
contraceptive ring	female	prescription only	woman inserts during MENSTRUATION, leaves in place 3 weeks, then removes	98 percent
contraceptive sponge	female	OTC	must insert before sexual intercourse must remove after specified time	65 to 90 percent
depot medroxyprogesterone acetate (DMPA) injection	female	prescription only; health-care provider must administer	received every 12 weeks	99.9 percent
diaphragm	female	prescription only; health-care provider must measure and fit	must insert before sexual intercourse must use with spermicide must remove after specified time	85 to 94 percent

Method	Male or Female	Availability	Ease of Use	Effectiveness When Used Correctly
fertility awareness methods (FAMs)	both	personal commitment	requires diligent effort from both partners	75 to 99 percent
intrauterine device (IUD)	female	prescription only; health-care provider must insert	requires no attention once inserted can stay in the UTERUS for 5 to 12 years, depending on type	99 percent
oral contraceptives	female	prescription only	daily or weekly pill	99 percent
spermicide	female	OTC	must apply before each sexual act	70 to 85 percent
tubal ligation	female	requires surgery	requires no effort after OPERATION permanent	nearly 100 percent (1 in 300 failure rate)
vasectomy	male	requires in-office operative procedure	requires no effort after operation permanent	nearly 100 percent (1 in 500 failure rate)

Common forms of contraception include barrier methods, hormonal methods, mechanical methods, chemical methods, surgical methods, timing methods, and continuous abstinence. Some methods, such as oral contraceptives (birth control pills) and diaphragms, require a doctor's prescription. Others are invasive, such as intrauterine devices (IUDs), TUBAL LIGATION, and VASECTOMY. Still other methods of contraception are available for purchase without prescription or physician approval, sold in locations from grocery and drugstores to dispenser machines in public bathrooms. Most public health departments freely hand out over-the-counter (OTC) methods of contraception, notably condoms.

Contraceptive effectiveness relies primarily on proper use of the method and varies widely among methods as well as within a particular method. The most reliable methods of contraception are those that are in place or effective without any effort at the time of sexual activity. Methods that have the ability to provide nearly 100 percent prevention of pregnancy may actually result in much lower prevention when not used properly. Only about 40 percent of women take oral contraceptives precisely as the label instructions direct, for example, raising the risk for unintended pregnancy.

Many people combine methods to optimize protection from pregnancy, for example using barrier contraception (condom or diaphragm) with chemical methods (spermicides). Only condoms (male or female) also provide protection against SEXUALLY TRANSMITTED DISEASES (STDS). A woman who takes oral contraceptives to prevent pregnancy but has more than one sexual partner also needs the protection of a condom. Partners also should wear condoms for sexual activity during outbreaks of GENITAL HERPES and if they are HIV positive or have HUMAN PAPILLOMAVIRUS (HPV) or HEPATITIS B or C.

Emergency contraception is available through pharmacies in the United States without a doctor's prescription. Emergency contraception, also called the "morning after pill," is a high DOSE of an oral contraceptive. The hormones in the medication

alter the environment within the UTERUS such that a fertilized ovum (egg) cannot implant. The woman must take emergency contraception no later than 72 hours after unprotected SEXUAL INTERCOURSE.

See also CONCEPTION; FAMILY PLANNING; FERTILITY; INFERTILITY; OVA; SEXUAL HEALTH; SEXUALLY TRANSMITTED DISEASE (STD) PREVENTION; SPERM.

cryptorchidism Undescended testicle. The TESTICLES form within the abdominal cavity early in fetal development and normally descend through the inguinal canal at the floor of the pelvis into the SCROTUM during the third trimester of PREGNANCY. In some boys the testicle may spontaneously descend during the first year of life; after one year of age, however, this is unlikely. Numerous factors contribute to cryptorchidism, key among them being genetic and hormonal influences.

Treatment to bring the testicle outside the body is essential to preserve FERTILITY and because a testicle retained within the abdominal cavity has a high risk for TESTICULAR CANCER.

Treatment options are hormonal therapy, in which GONADOTROPIN-RELEASING HORMONE (GNRH) administration may stimulate the testicle to descend on its own, and surgery (ORCHIOPEXY) to shift the testicle from its abdominal position into the scrotum. Orchiopexy is the more common therapeutic route. Surgery sometimes involves procedures to repair related structures such as the arteries and veins that supply the testicle and the VAS DEFERENS, the tubular structure that transports SPERM from the testicle. Bilateral cryptorchism, in which both testicles are undescended, often results in sterility (permanent inability to father a child) because normal body temperature destroys the ability of the testicle to produce sperm.

Even after treatment the risk for testicular cancer remains higher than normal; boys and men who have had cryptorchidism should perform monthly TESTICULAR SELF-EXAMINATION. Most men who had successful treatment for cryptorchidism early in childhood have full fertility. Cryptorchidism does not affect sexual function.

See also FERTILITY; HYPOGONADISM; HYPOSPADIAS; SURGERY BENEFIT AND RISK ASSESSMENT.

D

dilation and curettage (D&C) A surgical procedure, also called dilatation and curettage, in which the gynecologist widens the opening of the CERVIX enough to allow passage into the UTERUS of a narrow scraping instrument called a curette. The gynecologist uses the curette to gently scrape the inside wall of the uterus, removing accumulated BLOOD and tissue that may be causing DYSFUNCTIONAL UTERINE BLEEDING (DUB) or that remains after a spontaneous ABORTION (miscarriage) or an induced abortion using abortifacients (drugs that terminate PREGNANCY).

The doctor performs a D&C in a hospital operating room or AMBULATORY SURGICAL FACILITY with the woman under general ANESTHESIA. The procedure itself takes about 15 minutes; most women are able to go home a few hours after, when they have completely emerged from the effects of the anesthesia. Discomfort similar to moderate menstrual cramps and mild bleeding may occur for up to two weeks after the D&C. Uncommon complications include unusual bleeding during or after the procedure, postoperative INFECTION, and uterine perforation, in which the curette penetrates the wall of the uterus (a small wound that typically heals without intervention). Most women are able to return to normal activities (except SEXUAL INTERCOURSE) within a few days though may feel discomfort for up to a week.

Before undergoing a D&C, a woman should confirm with her gynecologist that the benefits of the procedure outweigh the discomfort and potential complications compared to noninvasive procedures such as ULTRASOUND for diagnostic purposes or medications to treat DUB. Minimally invasive procedures such as endometrial sampling (in which the gynecologist inserts a very thin catheter through the cervix, without dilation, and into the uterus to withdraw a small sample of tissue from the uterine wall) and HYSTEROSCOPY often can provide the same diagnostic information as would D&C but with less risk and discomfort for the woman.

See also SURGERY BENEFIT AND RISK ASSESSMENT.

dysfunctional uterine bleeding (DUB) Bleeding from the UTERUS through the VAGINA that occurs outside the hormonal bleeding normally associated with the MENSTRUAL CYCLE. Doctors believe DUB results from an imbalance between ESTROGENS and PROGESTERONE, the hormones that regulate the menstrual cycle, which allows the endometrium (lining of the uterus) to grow unchecked. The excess tissue dies and sloughs away, producing clotty bleeding.

Vaginal bleeding that saturates more than eight pads in 24 hours for longer than two days may signal a health concern other than DUB and requires prompt medical evaluation.

Symptoms and Diagnostic Path

Because there are numerous causes for abnormal vaginal bleeding, DUB is a diagnosis of exclusion: The doctor concludes the situation is one of DUB after ruling out other possible causes for the bleeding. The essential symptom of DUB is excessive vaginal bleeding. Though the bleeding often has the characteristics of a heavy menstrual period, it may not follow the timing of the woman's menstrual cycle. Some women experience DUB as episodes of bleeding that occur between menstrual periods and for other women the bleeding may be fairly constant or occur with no predictable pattern. Further symptoms of DUB

may include HOT FLASHES and mood swings. Cramping and PAIN are uncommon; these symptoms suggest a diagnosis other than DUB.

Because doctors consider DUB as a diagnosis of exclusion—that is, a diagnosis the doctor reaches after ruling out other possible causes for the bleeding—the diagnostic path may include tests for SEXUALLY TRANSMITTED DISEASES (STDS), BLOOD test to check for PREGNANCY, and other blood tests to measure estrogen, progesterone, and LUTEINIZING HORMONE (LH). A key factor in establishing the diagnosis of DUB is the absence of OVULATION, which characterizes most DUB. The doctor may also check other HORMONE blood levels such as thyroid hormones.

Treatment Options and Outlook

For most women the first course of treatment for DUB is HORMONE THERAPY to restore the body's natural estrogen–progesterone balance. For women of childbearing age this might mean oral contraceptives (birth control pills); for women near MENOPAUSE this might mean a hormone medication such as conjugated estrogens with progesterone or progesterone supplementation. The general therapeutic approach is to take hormone therapy until the menstrual cycle returns to normal, typically three to six months. Nonhormonal medications that may relieve mild DUB include NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS). Because long-term excessive bleeding commonly results in iron-deficiency ANEMIA, the doctor may also prescribe an iron supplement.

When the medication path is not sufficient, the gynecologist may choose to perform endometrial ablation, in which the gynecologist uses electrocautery, hot balloon, or surgical laser to burn away the endometrial lining and the thin layer of uterine tissue beneath it. This restores the inside of the uterus to its base level so it can resume its natural cycle of thickening and sloughing. Other surgical options include DILATION AND CURETTAGE (D&C), to gently scrap away the endometrial lining, and HYSTERECTOMY (removal of the uterus). Though DUB is one of the most common reasons for hysterectomy, hysterectomy is generally the treatment of final choice for DUB, the treatment gynecologists turn to when other treatment options are not practical or are not successful. Because hysterectomy is a major surgery with numerous potential risks and permanently ends a woman's ability to become pregnant, it is an option that requires careful consideration.

Risk Factors and Preventive Measures

DUB occurs most often during the first and last years of the menstrual cycle. Progesterone-only methods of CONTRACEPTION may also precipitate DUB. However, there are no known measures for preventing DUB.

See also AMENORRHEA; DYSMENORRHEA; ECTOPIC PREGNANCY; ENDOMETRIAL HYPERPLASIA; HYPERTHYROIDISM; HYPOTHYROIDISM; MENSTRUATION; POLYCYSTIC OVARY DISEASE (PCOD).

dysmenorrhea Cramping, PAIN, abdominal bloating, and other discomforts associated with MENSTRUATION. Primary dysmenorrhea occurs without underlying health conditions that cause such symptoms and generally begins within two or three years of MENARCHE (the onset of menstruation). Secondary dysmenorrhea occurs because of underlying health conditions such as ENDOMETRIOSIS or UTERINE FIBROIDS and typically begins later in a woman's life as these conditions develop. Congenital anomalies that affect the way menstrual material flows from the body may also cause secondary dysmenorrhea that is present from menarche.

Doctors believe primary dysmenorrhea, which is the more common form of dysmenorrhea, results from the combination of hormonal actions that reduce BLOOD flow to the endometrium (lining of the UTERUS that thickens in the first half of the MENSTRUAL CYCLE to prepare the uterus for possible PREGNANCY) and initiate menstruation. As the body's balance of estrogen and progesterone shifts, the uterus releases PROSTAGLANDINS and vasopressin. These hormones cause the smooth MUSCLE tissue of the uterus to contract, helping expel the sloughed endometrial tissue that forms the menstrual discharge. Prostaglandins also play a key role in INFLAMMATION and sensitize NERVE endings to pain signals.

Symptoms and Diagnostic Path

Dysmenorrhea presents a characteristic spectrum of symptoms that occur in varying degrees among

different women though are usually consistent from period to period in an individual woman. These symptoms may include

- crampy pain in the lower abdomen, often extending into the lower back and sometimes occurring in a combination of steady cramps with intermittent spasms or outright pain
- sensation of heaviness in the lower abdomen
- bloating (fluid retention)
- HEADACHE
- NAUSEA and VOMITING
- bowel disturbances (CONSTIPATION or DIARRHEA)
- fatigue

Symptoms often vary in severity over the course of the menstrual period, typically being more severe during the first two to three days of menstrual bleeding. About 10 percent of women who have dysmenorrhea have symptoms severe enough to prevent their participation in regular daily activities. The diagnostic path begins with a medical examination that includes a comprehensive health history (including history of sexual activity), PELVIC EXAMINATION, PAP TEST, and laboratory tests for SEXUALLY TRANSMITTED DISEASES (STDS). Any abnormal findings suggest secondary dysmenorrhea and require additional assessment and appropriate diagnostic procedures. Normal findings establish a presumed diagnosis of primary dysmenorrhea.

Treatment Options and Outlook

Medications are the first choice of treatment for primary dysmenorrhea. Those that provide the greatest level of relief are NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS), which block the release of prostaglandins, and oral contraceptives (birth control pills), which regulate the estrogen–progesterone balance as well as reduce prostaglandin release. Some women obtain adequate relief from over-the-counter NSAIDs; other women require stronger prescription NSAIDs. For severe dysmenorrhea that does not improve with these treatments, the gynecologist may recommend extended cycle oral contraceptives, a therapy that reduces the frequency of menstrual periods to every three months, or HORMONE THERAPY to suppress menstruation up to 12 months. Lifestyle and complementary methods for relief of symptoms include ACUPUNCTURE, thiamine supplementation, herbal therapies, dietary changes to decrease inflammation, heat to the lower abdomen or back, progesterone cream, and daily physical exercise. Treatment for secondary dysmenorrhea targets the underlying condition as well as symptom relief.

MEDICATIONS TO TREAT DYSMENORRHEA

diclofenac	ethinyl estradiol and norethindrone
ethinyl estradiol and norgestimate	ibuprofen
ketoprofen	meclofenamate
mefenamic acid	naproxen

Risk Factors and Preventive Measures

Menstrual cramps and associated discomforts are very common among menstruating women. Women who have a heavy menstrual flow, who have not carried a pregnancy to term, or who smoke cigarettes are more likely to have dysmenorrhea. Physical inactivity, OBESITY, and chronic PELVIC INFLAMMATORY DISEASE (PID) may also influence dysmenorrhea. Health conditions that may exacerbate dysmenorrhea include DYSFUNCTIONAL UTERINE BLEEDING (DUB), endometriosis, and uterine fibroids. Because dysmenorrhea occurs only among menstruating women, the end of menstruation brings the end of dysmenorrhea. Circumstances that end menstruation include MENOPAUSE (the natural cessation of the menstrual cycle that occurs with aging), HYSTERECTOMY (surgical removal of the uterus), and some treatments for cancer such as CHEMOTHERAPY or RADIATION THERAPY to the abdomen.

See also AMENORRHEA; CONTRACEPTION; EXERCISE AND HEALTH; HYPERTHYROIDISM; HYPOTHYROIDISM; PREMENSTRUAL SYNDROME (PMS); SEXUALLY TRANSMITTED DISEASE (STD) PREVENTION; SMOKING AND HEALTH.

E

eclampsia A potentially life-threatening complication of PREGNANCY in which the woman experiences tonic–clonic seizures, extreme HYPERTENSION (high BLOOD PRESSURE), and periods of unconsciousness or COMA. Eclampsia threatens the well-being of the FETUS because it so dramatically affects the mother's health that prompt delivery is usually necessary, risking preterm birth when eclampsia occurs before 37 weeks gestation.

Routine PRENATAL CARE, which allows early detection of problems such as hypertension in the pregnancy, and aggressive treatment for PREECLAMPSIA, which is often though not always the precipitating condition, make eclampsia relatively uncommon in the United States. When it does occur, eclampsia usually develops between the 20th week of pregnancy and the first week after CHILDBIRTH (though sometimes occurs up to several weeks later).

Doctors do not know what causes eclampsia or what causes some women who have preeclampsia (sometimes called toxemia of pregnancy or gestational hypertension) to progress to eclampsia and others not. The treatment of choice for eclampsia is intravenous magnesium sulfate to stop the seizures with delivery of the baby as rapidly as possible. When eclampsia occurs before fetal viability (generally 24 weeks), doctors may attempt to control the hypertension and seizures in the mother to allow the fetus to further mature. However, the best outcomes for mother and baby occur with the earliest intervention possible. There are no known measures to prevent eclampsia.

See also GESTATIONAL DIABETES; SEIZURE DISORDERS.

ectopic pregnancy A life-threatening circumstance in which a fertilized ovum (ZYGOTE) implants in a location outside the UTERUS, usually in one of the FALLOPIAN TUBES though sometimes elsewhere in the abdominal cavity. A woman's body cannot support such a PREGNANCY; if an ectopic pregnancy continues beyond the very early stages of development it will cause the structure supporting (such as the fallopian tube) it to rupture. The resulting hemorrhage (uncontrolled bleeding) becomes life-threatening without treatment.

Symptoms and Diagnostic Path

Early symptoms of ectopic pregnancy typically occur before the woman realizes she may be pregnant and mimic those of the onset of MENSTRUATION. They may include

- cramping in the lower abdomen
- aching or PAIN in the lower back
- NAUSEA
- slight vaginal bleeding (spotting)

Many women do not experience early symptoms, however. The symptoms of ectopic pregnancy rapidly worsen, often over a period of hours, progressing to sharp pain in the lower abdomen and often shock and loss of CONSCIOUSNESS. Bleeding is usually internal, into the abdominal cavity, and consequently not apparent. The diagnostic path typically includes PELVIC EXAMINATION, BLOOD test for pregnancy, and abdominal ULTRASOUND. The ultrasound can detect abnormal tissues and bleeding.

Emergency medical care is essential for symptoms of ectopic pregnancy. Ectopic pregnancy cannot survive and is life-threatening for the woman.

Treatment Options and Outlook

Abortifacient medications (drugs that cause ABORTION, or loss of a pregnancy) such as methotrexate may terminate an ectopic pregnancy detected very early, avoiding the need for surgery and minimizing the risk for damage to the fallopian tubes and other structures. Such medications work by stopping cell division, affecting rapidly dividing cells such as those of the zygote. These medications were first developed, and are still used, to treat cancer, in which cells also rapidly divide.

Ectopic pregnancy that becomes at all advanced requires surgery that terminates the pregnancy and removes the tissues that have developed to support it. There may be damage to the structure where the pregnancy implanted, such as the fallopian tube or less commonly the CERVIX or ovary, that requires surgical repair. With prompt treatment most women recover fully from ectopic pregnancy though the experience of an ectopic pregnancy is often emotionally traumatic because the pregnancy cannot survive. Damage to or loss of the involved fallopian tube or ovary, if it occurs, may subsequently impair FERTILITY.

Risk Factors and Preventive Measures

Ectopic pregnancy occurs when there is a mechanical or hormonal impediment that prevents or slows the zygote's movement through the fallopian tube to the uterus after fertilization as is the normal process in establishing pregnancy. Risk factors for ectopic pregnancy include

- PELVIC INFLAMMATORY DISEASE (PID), which often results in scarring and blockage of the fallopian tubes
- congenital abnormalities of the fallopian tubes
- progesterone-only contraceptives, which work by impeding the implantation process
- TUBAL LIGATION in which the fallopian tube partially reopens and allows SPERM to escape into the abdominal cavity, or surgical reversal of tubal ligation to restore fertility
- use of an intrauterine device (IUD) for contraception
- ENDOMETRIOSIS
- abdominal adhesions (SCAR tissue), resulting from abdominal surgery such as APPENDECTOMY, that pull the fallopian tubes out of their normal positions
- previous ectopic pregnancy

Though there are no measures to prevent ectopic pregnancy, prompt medical attention to early symptoms of ectopic pregnancy allows treatment before life-threatening complications arise. Early treatment also helps preserve fertility.

See also CHEMOTHERAPY; CONTRACEPTION; OVA.

ejaculation The forceful contractions that expel SEMEN from the erect PENIS during the male ORGASM. Though ejaculation occurs as a result of sexual stimulation, the muscular contractions that produce ejaculation are not within voluntary control. Ejaculation moves semen (SPERM and seminal fluid) from the seminal vesicles, VAS DEFERENS, and PROSTATE GLAND into the URETHRA, and then ejects it from the urethra. In a man who has had a VASECTOMY, the semen does not contain sperm. A tiny valve at the urethral entrance to the BLADDER closes across the bladder opening, directing the flow of semen through the urethra to the outside of the penis. In a man who has had a PROSTATECTOMY (surgery to remove the prostate gland), ejaculation is retrograde (the semen enters the bladder instead of exiting through the urethra) because the OPERATION also involves removal of this valve.

For further discussion of ejaculation within the context of the structures and functions of reproduction and sexuality, please see the overview section "The Reproductive System."

See also RETROGRADE EJACULATION.

embryo The stage of prebirth development from the 15th day after CONCEPTION to 8 weeks of gestational age. The embryo arises from the three germ layers of the ZYGOTE:

- The ectoderm is the outermost layer. It is the foundation for the SKIN and mucous membranes, the TEETH, and the structures of the nervous system.
- The mesoderm is the middle layer. It is the foundation for the organs and structures of the musculoskeletal, cardiovascular, pulmonary,

gastrointestinal, urinary, and reproductive systems.

- The endoderm is the innermost layer. It is the foundation for the tissues that line the inside of the gastrointestinal, urinary, pulmonary, and reproductive organs and structures.

These layers differentiate into their respective structures and organs during the embryonic stage. When this differentiation is complete, the developing life becomes a FETUS.

For further discussion of the embryo within the context of the structures and functions of reproduction and sexuality, please see the overview section "The Reproductive System."

See also PREGNANCY.

endometrial cancer A malignant (cancerous) tumor, sometimes called uterine cancer, that arises from the tissues of the endometrium, the lining of the UTERUS. Often endometrial cancer is HORMONE driven, which means it requires ESTROGENS to grow. Doctors in the United States diagnose endometrial cancer in about 40,000 women each year; it is the fourth most common cancer among women. With early detection and treatment, endometrial cancer is highly treatable. Endometrial cancer tends to develop slowly, typically over years, and most commonly occurs in women over age 60.

Endometrial cancer develops when the cells that form the endometrium become disordered, often as a consequence of chronic ENDOMETRIAL

BASIC STAGING OF ENDOMETRIAL CANCER

Stage	Meaning	Treatment Options
stage 0/carcinoma in situ	cancer remains confined to the cells of its origin	total HYSTERECTOMY with optional bilateral salpingo-OOPHORECTOMY
stage 1	cancer remains confined to the body of the UTERUS	total hysterectomy with bilateral salpingo-oophorectomy and SENTINEL LYMPH NODE DISSECTION adjuvant RADIATION THERAPY
stage 2	cancer involves the uterus and the CERVIX	preoperative radiation therapy total hysterectomy with bilateral salpingo-oophorectomy and sentinel lymph node dissection
stage 3	cancer has spread beyond the uterus though remains confined to the pelvic area cancer may involve the VAGINA and LYMPH nodes adjacent to the uterus	preoperative radiation therapy radical hysterectomy adjuvant HORMONAL THERAPY
stage 4	cancer has spread to other organs in the abdomen such as the RECTUM or BLADDER cancer has spread to distant sites	radiation therapy hormonal therapy clinical trials
stage 4 recurrent	cancer has returned after treatment	radiation therapy hormonal therapy clinical trials four to six cycles of two-drug (doxorubicin and cisplatin) or three-drug (doxorubicin, cisplatin, and paclitaxel) combination CHEMOTHERAPY IMMUNOTHERAPY

HYPERPLASIA (overgrowth of the endometrium). Endometrial hyperplasia occurs when there is an imbalance between estrogens and PROGESTERONE in the woman's BLOOD circulation. Researchers do not know what sets the stage for this imbalance. Elevated estrogens cause the endometrium to thicken and engorge with blood, and diminished progesterone fails to initiate adequate sloughing of the endometrial tissue (such as during MENSTRUATION). The tissue continues to accumulate, and over time its cells become abnormal.

Symptoms and Diagnostic Path

Because endometrial cancer usually develops later in life, its symptoms sometimes blend with those of MENOPAUSE. Because of this a doctor should evaluate symptoms that persist, even when the symptoms do not seem especially serious. Early symptoms of endometrial cancer include

- unusually long or severe menstrual periods
- spotting or bleeding between menstrual periods
- watery, blood-tinged vaginal discharge
- PAIN during SEXUAL INTERCOURSE
- pelvic or lower abdominal pain

The diagnostic path includes a comprehensive medical examination with PELVIC EXAMINATION, during which the doctor often can palpate (feel) a growth within the uterus or detect abnormalities in the uterus's size or shape. Diagnostic imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN or ULTRASOUND may provide further information. However, only endometrial biopsy can provide a certain diagnosis. The doctor may obtain a tissue sample for biopsy by inserting a narrow catheter through the VAGINA and CERVIX into the uterus and aspirating (suctioning) cells from the endometrium. HYSTEROSCOPY or the surgical OPERATION DILATION AND CURETTAGE (D&C) may also provide endometrial cells for pathology analysis.

When confirming the diagnosis, the pathologist assigns a grade and stage to the cancer that characterize its aggressiveness and the extent to which it has grown or metastasized (spread to other locations in the body). Additional pathology tests determine whether the cancer cells have estrogen receptors (are estrogen positive). CANCER STAGING AND GRADING and estrogen reception provide guidance for CANCER TREATMENT OPTIONS AND DECISIONS.

Treatment Options and Outlook

Total HYSTERECTOMY, a surgical operation to remove the uterus and cervix, is nearly always the first treatment of choice for stage 0, 1, and 2 endometrial cancers. Women who have stage 1 or stage 2 endometrial cancer subsequently undergo adjuvant (follow-up) treatment such as HORMONE THERAPY or RADIATION THERAPY. Very early endometrial cancer (stage 0, also called carcinoma in situ, and stage 1) is nearly always curable.

For stage 3 and 4 endometrial cancer, the first treatment of choice is radiation therapy to shrink the cancer, with follow-up surgery and hormonal therapy (stage 3) or hormonal therapy alone. Surgery may be total hysterectomy with salpingo-oophorectomy (removal of the uterus, cervix, FALLOPIAN TUBES, and OVARIES) or radical hysterectomy (removal of all the organs of reproduction, the fatty layer covering them called the omentum, and nearby LYMPH nodes). Radiation therapy may be external beam (targeted at the pelvis from a machine outside the body) or brachytherapy (implanted radioactive pellets). Though other treatment options are more effective for stage 0, 1, and 2 endometrial cancers, combination CHEMOTHERAPY becomes a treatment option for metastasized endometrial cancer (stage 3 and stage 4).

Most endometrial cancers are hormone sensitive. Hormonal therapy, such as progestins or estrogen antagonists, effectively shrinks cancer tumors in women by depriving their cells of the hormones they need to thrive. Progestin causes endometrial atrophy (shrinkage of the endometrium) and is an option for younger women with stage 0 or stage 1 endometrial cancer who wish to preserve their FERTILITY. Among the estrogen antagonists currently available are aromatase inhibitors and tamoxifen; these therapies require the cessation of ovarian function. Most women who have stage 2 and more advanced endometrial cancer undergo oophorectomy (surgical removal of the ovaries). Aromatase inhibitors block the conversion of TESTOSTERONE to estrogen in adipose (fat) cells throughout the body, the primary means of estrogen production in a woman's body after MENOPAUSE.

Risk Factors and Preventive Measures

Endometrial cancer is most common in women over age 60. Unopposed estrogen therapy (estrogen without progestin, except in women who have had hysterectomies) and long-term tamoxifen use are additional risk factors. OBESITY, INSULIN RESISTANCE, and type 2 DIABETES also increase the risk for endometrial cancer because these conditions result in higher levels of estrogens in the blood circulation. Endometrial cancer follows a predictable path of evolution from endometrial HYPERPLASIA to full-blown cancer, a path that generally takes years or even decades to manifest. This characteristic makes endometrial cancer fairly easy to detect in women who have regular routine medical examinations with pelvic examination.

See also BREAST CANCER; CERVICAL CANCER; HORMONE-DRIVEN CANCERS; METASTASIS; OVARIAN CANCER; PAP TEST; PREVENTIVE HEALTH CARE AND IMMUNIZATION.

endometrial hyperplasia An overgrowth of the endometrium, the tissue that lines the UTERUS. The thickened endometrium fails to slough during MENSTRUATION, thus continuing to accumulate. Often menstruation is minimal or intermittent. Endometrial HYPERPLASIA in which cell DNA remains normal nearly always remains benign (does not become cancerous). Endometrial hyperplasia that consists of both abnormal cells and abnormal cell organization (architecture), though itself benign, is precancerous.

There are four types of endometrial hyperplasia:

- Simple endometrial hyperplasia (also called cystic glandular or mild hyperplasia) is the earliest stage of endometrial hyperplasia. There is excessive growth of the cells of the endometrium in confined locations though the cells and their architecture (structure and arrangement) are normal. The risk for progression to endometrial cancer is minimal; simple endometrial hyperplasia often resolves (goes away) without treatment.
- Complex endometrial hyperplasia features excessive growth of normal cells with irregular architecture, presenting a somewhat higher, though still relatively low, risk for developing into endometrial cancer without treatment. For most women, doctors recommend treatment with progestin, a synthetic form of PROGESTERONE, to halt the actions of estrogen and cause the endometrium to wither and slough. The endometrium generally returns to normal within two or three MENSTRUAL CYCLES.
- Simple endometrial hyperplasia with atypia is a moderate stage of endometrial hyperplasia in which patches of endometrial cells are not only replicating more frequently than normal but have also become abnormal in their DNA (called nuclear atypia). However, the cellular architecture still follows the normal pattern for endometrial tissue. Untreated simple endometrial hyperplasia with atypia progresses to endometrial cancer in about 10 percent of women. Treatment with progestin often resolves the hyperplasia.
- Complex endometrial hyperplasia with atypia is the most serious stage of endometrial hyperplasia. The endometrial cells have abnormal DNA, instructing them to replicate in unstructured and dysfunctional ways. As well, the endometrial tissue that contains the atypical cells is disorganized and erratic. Without treatment, this stage of endometrial hyperplasia progresses to endometrial cancer in a third or more of women. Treatment with progestin usually, though not always, resolves the hyperplasia.

Symptoms and Diagnostic Path

Symptoms of endometrial hyperplasia may include bleeding between menstrual periods, anovulatory periods (menstrual cycles without OVULATION), heavy or prolonged menstrual periods, and PAIN during SEXUAL INTERCOURSE. Some women may experience AMENORRHEA (absence of menstrual periods). Endometrial biopsy, as an independent procedure or after DILATATION AND CURETTAGE (D&C), confirms the diagnosis. Imaging procedures are not usually helpful as they cannot conclusively distinguish between noncancerous and cancerous tumors in the uterus.

Treatment Options and Outlook

In addition to progestin therapy, other treatment options include the surgical operations D&C and HYSTERECTOMY. In D&C the surgeon gently scrapes

away the overgrown endometrium; in hysterectomy the surgeon removes the uterus. In most situations, hysterectomy is appropriate only when complex endometrial hyperplasia with atypia recurs after other treatments or when the risk for endometrial cancer is high for other reasons, though women who are past menopause and have persistent symptoms may opt for hysterectomy to permanently end the hyperplasia.

Risk Factors and Preventive Measures

Any circumstance that increases the presence of estrogen in the BLOOD circulation underlies the development of endometrial hyperplasia. The risk for endometrial hyperplasia is highest in women who have anovulatory periods (menstrual cycles without ovulation), who take unopposed estrogen therapy (estrogen alone), or who take long-term tamoxifen to treat BREAST CANCER. Other factors that increase estrogen within the body are OBESITY, INSULIN RESISTANCE, and type 2 DIABETES. Nutritional EATING HABITS that emphasize foods low in fats, especially saturated fats, and daily physical exercise are the key lifestyle measures that reduce the risk for endometrial hyperplasia.

endometriosis A condition in which endometrial tissue (the tissue that forms the lining of the UTERUS) grows abnormally in areas outside the uterus. The most common sites are the OVARIES, FALLOPIAN TUBES, peritoneal (abdominal) cavity, gastrointestinal tract (particularly the COLON), and BLADDER, though endometrial tissue may appear in other locations throughout the body. Endometrial growths, also called implants or tumors, respond to the body's changing hormonal environment through the MENSTRUAL CYCLE in the same ways as endometrial tissue within the uterus: They engorge with BLOOD, atrophy, and slough (bleed). Because there is no pathway for bleeding from these distant endometrial implants to leave the body, the blood accumulates in the surrounding tissues. INFLAMMATION develops as part of the IMMUNE RESPONSE, initiating a HEALING process that results in the formation of SCAR tissue.

The growth of endometrial tissue in the fallopian tubes or ovaries blocks the ability of these structures to properly function, a primary consequence of which is impaired FERTILITY. Endometriosis also appears to instigate an abnormal immune response in which phagocytic cells (cells that engulf and consume cellular debris), primarily macrophages, target and kill SPERM and OVA (eggs). About 40 percent of women who seek treatment for INFERTILITY have endometriosis. Endometriosis affects more than five million women in the United States.

Researchers do not know what causes endometriosis or how endometrial tissue arises in sites other than the uterus. Many women who have endometriosis often also have AUTOIMMUNE DISORDERS such as atopic DERMATITIS, ASTHMA, and allergies, giving rise to the suspicion of a dysfunction within the immune system. Some researchers believe endometrial cells escape from the uterus via the fallopian tubes, then migrate through the LYMPH or blood circulation to implant and grow in other locations. Endometriosis tends to progressively worsen over time because the endometrial implants grow under the influence of ESTROGENS, though this growth usually abates with MENOPAUSE. For most women menopause, natural or induced, ends endometriosis.

Symptoms and Diagnostic Path

The primary symptoms of endometriosis are PAIN and infertility. Pain is typically cyclic, following the pattern of the menstrual cycle, and may be moderate to debilitating, especially during MENSTRUATION. Distant endometrial implants also cause pain as they swell and then bleed. The diagnostic path includes comprehensive medical examination with pelvic examination and often pelvic ULTRASOUND. Exploratory laparoscopy provides the definitive diagnosis, allowing the gynecologist to directly visualize the endometrial implants. Diagnostic imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN or MAGNETIC RESONANCE IMAGING (MRI) often can detect distant endometrial implants.

Treatment Options and Outlook

At present there is no cure for endometriosis, though various treatment approaches, medical

and surgical, can control symptoms and improve fertility. NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS), which block the inflammatory response as well as relieve pain, are often adequate to treat mild symptoms in women who wish to become pregnant. HORMONE THERAPY is highly effective to treat moderate to significant symptoms in women who do not desire to become pregnant. Common hormone therapies include

- estrogen and progestin in combination, such as oral contraceptives (birth control pills)
- progestin alone, such as in progestin oral contraceptives or DepoProvera injections
- danazol, an androgen analog (synthetic, weak male HORMONE) that suppresses the menstrual cycle
- GONADOTROPIN-RELEASING HORMONE (GNRH) antagonists such as leuprolide, which shut down the ovaries to prevent them from producing estrogen

Laparoscopic surgery to remove endometrial implants from pelvic structures and the peritoneal cavity may be the only treatment that effectively mitigates symptoms in women who have severe, disabling endometriosis. Therapeutic laparoscopy for endometriosis can provide long-term relief. However, it does not remove distant endometrial implants, which often continue to produce symptoms. As well, endometrial implants will regrow if a few endometrial cells remain.

Risk Factors and Preventive Measures

Factors that increase a woman's risk for endometriosis are unclear. Because endometriosis tends to run in families, researchers believe it may be the result of GENETIC PREDISPOSITION in combination with other, undetermined factors. However, any woman who menstruates can develop endometriosis. There are no measures to prevent endometriosis.

epididymitis INFLAMMATION of the EPIDIDYMIS, nearly always due to INFECTION. The epididymis is a tightly coiled tubule that begins at the base of the testicle and ends at the VAS DEFERENS. The epididymis incubates newly formed SPERM, bringing them to maturation as they migrate through its coils on their journey to the vas deferens. *ESCHERICHIA COLI* INFECTION, CHLAMYDIA, and GONORRHEA are the most common causes of epididymitis—*E. coli* in young boys and men over age 60; chlamydia and gonorrhea in men between ages 25 and 50. Repeated infections may result in permanent INFERTILITY.

Symptoms typically include scrotal PAIN and swelling, discharge from the PENIS, and difficulty urinating. Some men also experience FEVER, NAUSEA, and pain extending into the sides of the abdomen (the flank area). The diagnostic path includes examination to rule out TESTICULAR TORSION and culture of the discharge to identify the responsible PATHOGEN. Treatment is a course of the appropriate ANTIBIOTIC MEDICATIONS when the infection is bacterial. As with all infections, it is essential to complete the entire prescribed course of antibiotics even when symptoms improve. Less commonly, viruses (such as the MUMPS VIRUS) may cause epididymitis. Viral epididymitis resolves without treatment (antibiotic medications cannot treat viral infections).

The doctor may recommend ANALGESIC MEDICATIONS such as acetaminophen or NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) such as ibuprofen to relieve discomfort and fever; NSAIDs can also relieve inflammation. Ice packs or cold cloths applied to the SCROTUM and supporting the scrotum such as by wearing an athletic supporter may also provide relief.

episiotomy A surgical incision through the tissues of the PERINEUM to extend the opening of the VAGINA during CHILDBIRTH. The most common types of episiotomy are the midline (median) incision, which extends from the vaginal opening toward the ANUS, and the mediolateral incision, which extends from the vaginal opening diagonally to either side. The obstetrician numbs the tissues of the perineum with an injected local anesthetic (if the woman does not already have epidural anes-

thesia), then makes the incision. After delivery of the baby and the PLACENTA, the obstetrician sutures (stitches) the incision closed.

Though once commonplace as a routine measure to prevent tearing of the vagina and surrounding tissues, episiotomy is now a procedure most obstetricians perform only when it appears that a natural tear will penetrate into the muscles of the perineum or RECTUM. The prevailing belief supporting preventive episiotomy had been that the clean cut of a surgical incision healed more rapidly and with fewer complications than the often jagged wound that occurred with a natural tear (also called a laceration). However, numerous studies have failed to support this premise, and the American College of Obstetricians and Gynecologists (ACOG) now advises against routine episiotomy.

Most episiotomies heal in four to six weeks though some women experience discomfort or PAIN for up to several months, especially with SEXUAL INTERCOURSE. Typically the obstetrician uses sutures the body absorbs as the incision heals. Risks of episiotomy include excessive bleeding, INFECTION, and weakening of the muscles of the pelvic floor that may result in URINARY INCONTINENCE, FECAL INCONTINENCE, and painful sexual intercourse. Many practitioners who provide care for women during PREGNANCY and childbirth advocate prenatal efforts, such as perineal massage to increase tissue elasticity and KEGEL EXERCISES to strengthen and tone the pelvic muscles; perineal massage during labor may also reduce the risk for natural tears and thus lower the likelihood for episiotomy.

See also CESAREAN SECTION; PRENATAL CARE; SURGERY BENEFIT AND RISK ASSESSMENT.

erection The enlarged and hardened PENIS. Erections begin in the male fetus before birth and continue throughout life. An erection is necessary for SEXUAL INTERCOURSE and in an adult man usually occurs as a result of sexual arousal. Erections also occur spontaneously during sleep, usually during rapid eye movement (REM) sleep. A man typically has up to a half dozen nocturnal erections each night. Doctors do not know what causes nocturnal erections though believe they are a consequence of electrical activity in the BRAIN, not of sexual stimulation.

An erection during sexual arousal occurs as a result of interactions between the thoughts and physical stimulation of the penis. The sequence of interactions triggers the release of nitric acid, acetylcholine, EPINEPHRINE, and other neurotransmitters (biochemicals that conduct NERVE impulses). These substances cause the smooth MUSCLE tissue supporting the corpora cavernosa, the two tubelike channels along the top of the penis, to relax. BLOOD flows into the corpora cavernosa. Some of the layers of tissue within the penis contract to help hold the blood within the corpora cavernosa, and valves in the veins that normally carry blood from the penis close. These events cause the size of the penis to increase in length and circumference.

An erection may come to fullness within a few seconds to several minutes, depending on numerous factors such as the man's age and lasts generally until EJACULATION. Some men can sustain an extended erection during sexual activity. Nearly as quickly as the tissues of the penis release nitric acid, they also release the enzyme phosphodiesterase (PDE), which counters the actions of nitric acid and other neurotransmitters to allow blood to flow out of the penis. This action gains momentum after ejaculation or other culmination of sexual activity, serving to reverse the actions of these neurotransmitters. The penis again goes limp (becomes flaccid).

erectile dysfunction The reduced ability or inability for a man's PENIS to become erect or sustain an erection adequate for SEXUAL INTERCOURSE. Erectile dysfunction, sometimes called impotence, may occur as a physiologic condition, psychologic or emotional condition, or combination. Most commonly, however, all of these factors contribute to the condition. About 25 million men in the United States have chronic (long-term) erectile dysfunction.

Physiologic causes of erectile dysfunction include

- NERVE damage that occurs as a complication of PROSTATECTOMY (surgery to remove the PROSTATE GLAND)

- DIABETES, which progressively damages the body's arteries and nerves
- peripheral NEUROPATHY, which may damage the nerves that supply the penis
- MULTIPLE SCLEROSIS, a degenerative neurologic disorder that causes loss of nerve function in various areas of the body
- ATHEROSCLEROSIS, which may occlude the arteries that serve the penis and slow the flow of BLOOD to the penis
- chronic LIVER disease or chronic kidney disease
- SPINAL CORD INJURY or TRAUMATIC BRAIN INJURY (TBI), either of which may interrupt the flow of nerve impulses between the CENTRAL NERVOUS SYSTEM and the PERIPHERAL NERVOUS SYSTEM

Cigarette smoking is a key contributing factor for neuropathy and atherosclerosis, compounding the effect these conditions have throughout the body. Numerous medications may cause erectile dysfunction as an undesired SIDE EFFECT. The most common culprits are ANTIDEPRESSANT MEDICATIONS, antihypertensive medications to treat HYPERTENSION (high BLOOD PRESSURE), and ANTIHISTAMINE MEDICATIONS to treat seasonal allergies. Fear, stress, anxiety, and DEPRESSION are among the psychologic and emotional causes of erectile dysfunction.

ERECTILE DYSFUNCTION AND HEART DISEASE

Studies suggest erectile dysfunction in otherwise healthy men is a harbinger of HEART disease, notably ATHEROSCLEROSIS and CORONARY ARTERY DISEASE (CAD). The small arteries that flood the PENIS with BLOOD during ERECTION appear to show the effects of accumulated arterial plaque earlier than other arteries in the body. Though other arteries of similar size likely occlude to similar extent, men are more likely to notice and pay attention to circumstances that interfere with erection.

Symptoms and Diagnostic Path

The inability to get or sustain an adequate erection is the symptom of erectile dysfunction. The diagnostic path begins with a thorough physical examination, including DIGITAL RECTAL EXAMINATION (DRE) to assess the status of the prostate gland and blood tests to measure the levels of lipids (cholesterol and triglycerides), TESTOSTERONE, GLUCOSE (fasting blood glucose), and liver enzymes. The doctor may desire additional diagnostic procedures, depending on the results of these preliminary tests. Such procedures may include Doppler ULTRASOUND to assess the flow of blood to and within the penis, testing of nerve function and reflexes, and other factors of function. Because a man normally experiences multiple erections during sleep, some tests are done when the man is sleeping (such as the nocturnal penile tumescence test), to measure the characteristics of nocturnal erections.

Treatment Options and Outlook

Treatment targets the underlying cause when it is identifiable. About 85 percent of erectile dysfunction results from physiologic causes. Sometimes treatment is straightforward and relatively easy, such as changing to a different medication when the cause of erectile dysfunction is medication side effect. Often, however, the most effective treatment addresses multiple contributing factors and encompasses medical interventions, lifestyle modifications, and psychologic therapy or counseling.

Medical interventions Phosphodiesterase (PDE) inhibitors, also called selective enzyme inhibitors, are the least intrusive and often most successful medical treatment for erectile dysfunction. The best known of these oral medications to treat erectile dysfunction is sildenafil, first marketed under the trade name Viagra. Other medications in this classification include vardenafil (Levitra) and tadalafil (Cialis). These drugs work by delaying the enzyme-initiated process through which an erection subsides, extending the erection. The erection still requires sexual stimulation to develop; these medications do not cause spontaneous erection. Men who take certain medications to treat HEART disease, such as some antihypertensive medications to treat high blood pressure, cannot take PDE inhibitors because the actions of the drugs are similar and combining them can cause fatally low blood pressure. PDE inhibitors are most effective in men who have mild to moderate vascular disease (such as atherosclerosis) or arterial damage due to diabetes.

Prescription-strength preparations of the herb-derived product YOHIMBE/YOHIMBINE also may extend erections though work through a different

mechanism. Yohimbe (the herb) and yohimbine (the active ingredient derived from the herb) products require a doctor's prescription in the United States because they act on the parasympathetic NERVOUS SYSTEM (a division of the autonomic nervous system that regulates certain involuntary functions). Yohimbe/yohimbine products are most effective in men who have mild to moderate neuropathy (nerve damage). The supplement arginine may also decrease erectile dysfunction by increasing nitric oxide.

Other medications that cause erection are self-injected into the penis or inserted as tiny suppositories (about the size of a grain of rice) into the urethral meatus (opening of the URETHRA at the tip of the penis). These medications contain alprostadil, a formulation of PROSTAGLANDINS, that instigates the sequence of events within the penis that cause it to engorge and stiffen. Unlike oral PDE inhibitors, these medications do cause erection regardless of sexual stimulation because they act directly on the smooth MUSCLE within the penis that causes the corpora cavernosa to relax and fill with blood. The primary drawback to these medications is their form of administration, which limits their appeal as well as the frequency with which a man may use them (no more often than once every five days).

Surgery to repair damaged blood vessels or insert penile implants is an option for erectile dysfunction that does not respond to medications. The most commonly used penile implants are a combination of inflatable tubes, a tiny pump, and small reservoirs that contain a sterile fluid. The man activates the pump, usually placed in the SCROTUM or at the base of the penis, to fill the tubes to acquire an erection. A valve releases the fluid back into the reservoir.

Lifestyle modifications Lifestyle modifications such as weight loss, daily physical exercise, SMOKING CESSATION, and reduced ALCOHOL consumption can improve circulation and nerve function. Exercise in particular also helps reduce stress.

Psychologic therapy Counseling or sex therapy may be helpful when there are emotional factors at play. These factors may cause erectile dysfunction or develop because of it and then perpetuate it. Therapy may be individual or involve the sexual partner.

Risk Factors and Preventive Measures

Erectile dysfunction becomes more common after age 50. The key health risks for erectile dysfunction are cigarette smoking, OBESITY, diabetes, long-term ALCOHOLISM, CARDIOVASCULAR DISEASE (CVD), prostate disease, and kidney disease. Lifestyle significantly influences these factors. Lifestyle measures to reduce these risks include smoking cessation, nutritious EATING HABITS, daily physical exercise, moderation in or cessation of alcohol consumption, and weight management. Medical measures include management of blood lipid levels (cholesterol and triglycerides) and diligent control of blood glucose and INSULIN levels in men who have diabetes through appropriate medication therapy.

F

fallopian tubes A pair of narrow enclosed channels that transport OVA (eggs) from the OVARIES to the UTERUS. The fallopian tubes extend from the top of the uterus, one on each side, curving downward to end just short of the ovaries. The ovary end of the fallopian tube is somewhat fluted with fringelike edges called the fimbriae. The fimbriae float in fluid. At OVULATION the ovary releases an ovum (egg) into the fluid. The fimbriae undulate, drawing the ovum into the fallopian tube. Tiny cilia (hairlike structures) project from the cells that form the tube's inner lining. The cilia move in wavelike motions that pull the ovum along the fallopian tube toward the uterus. If SPERM are present, they may fertilize the ovum on its journey through the fallopian tube. If no sperm are present, the ovum passes into the uterus and out of the body with MENSTRUATION.

A TUBAL LIGATION is a form of permanent CONTRACEPTION (birth control) in which the gynecologist ablates (destroys, such as by electrocautery) or cuts and ties the fallopian tubes to block passage for ova. Rarely, a tubal ligation may spontaneously reconnect. Recurrent infections such as SEXUALLY TRANSMITTED DISEASES (STDS) may affect the fallopian tubes, causing salpingitis or PELVIC INFLAMMATORY DISEASE (PID). Either may result in permanent loss of FERTILITY through scarring that obstructs (blocks) the fallopian tubes.

For further discussion of the fallopian tubes within the context of the structures and functions of reproduction and sexuality, please see the overview section "The Reproductive System."

See also INFERTILITY; SEXUALLY TRANSMITTED DISEASE (STD) PREVENTION.

family planning The process of intentional decision making around having children. Family planning encompasses choices in regard to PREGNANCY, ADOPTION, and not having children. Factors that influence family planning include general health, FERTILITY, personal preferences, religious beliefs, and lifestyle matters such as partnership status and work or career demands. In the United States about half of all pregnancies are intended. One million unintended pregnancies occur in teens. The US government's program of health goals HEALTHY PEOPLE 2010 calls for the availability of appropriate resources (such as education and contraceptive methods) so that all pregnancies are intended.

Planning pregnancy prevention (CONTRACEPTION) and pregnancy (conception) are equally important. More than a half dozen methods of contraception are available, from abstinence and cyclic timing (rhythm method) to sustained-release HORMONE regulation. The choice of contraception should consider availability, ease of use, rate of success, and personal preferences of sexual partners. The most common reason for failure of any given contraceptive method is failing to use it. However, the only certain method for preventing pregnancy is abstinence (not having SEXUAL INTERCOURSE). No other method of birth control is 100 percent certain to prevent pregnancy, though methods such as TUBAL LIGATION and VASECTOMY (operations to produce permanent sterilization) come close.

A key aspect of pregnancy planning is birth spacing—the amount of time between the births of children. From a health perspective, three years or more between births is optimal for both maternal and child health. This spacing allows the mother to fully recuperate between pregnancies as well as to provide the attention that each child needs. Siblings who have three or more years

between them are in different developmental stages for most of their childhood years, requiring different kinds of attention. Providing adequate attention to each child is more difficult when their ages are so close together that their needs are similar. Birth spacing requires either abstinence or some form of contraception between pregnancies to prevent unintended pregnancy.

People may choose adoption (acquiring legal responsibility for a nonbiologic child) as an option for resolving INFERTILITY or because they feel it is a personally desirable or socially responsible approach to creating a family. Other people may choose to have no children, opting instead to define family in other ways.

See also ABORTION; GESTATIONAL SURROGACY.

fertility The ability to conceive a PREGNANCY, and in women to also carry the pregnancy to term. Men and women both become fertile during PUBERTY, when sexual maturity results in the development of SECONDARY SEXUAL CHARACTERISTICS. Men remain fertile all of their lives and are fertile on a continuous basis; women remain fertile through their late 40s or until MENOPAUSE and are fertile on a cyclic, monthly basis.

Female Fertility: Ovulation, Conception, and Pregnancy

Within a narrower context, fertility is the period of time within a woman's MENSTRUAL CYCLE when she is physiologically capable of CONCEPTION. This period of time is the approximately 48 hours before and 24 hours after OVULATION (release of an ovum). The ovum remains receptive to fertilization during the time it travels through the fallopian tube on its way to the UTERUS. SPERM can survive 48 to 72 hours after entering the woman's reproductive tract (such as with SEXUAL INTERCOURSE). A woman can conceive when viable sperm are present in her body when she ovulates.

Knowing the precise timing of ovulation is difficult because it varies somewhat from one menstrual cycle to another. As well, physical illness, trauma, or surgery can affect ovulation and fertility. Several methods may help a woman estimate when she is ovulating. The easiest, though the least precise, is counting 14 days back from the anticipated first day of MENSTRUATION. The days fertility is most likely are 12, 14, and 16 days before the onset of menstruation. This method is imprecise because many women ovulate earlier or later than 14 days and experience variation from one menstrual cycle to another. Other methods may detect when ovulation occurs but cannot predict it before the fact.

The simplest device-oriented measure to estimate a woman's fertile time is basal body temperature. This is the first temperature of the day, taken before getting out of bed and with minimal movement. A woman's body temperature is up to one degree higher after ovulation than before ovulation. The beginning of the rise marks ovulation. Either a regular oral thermometer or a basal body thermometer (which registers only between 96°F and 100°F) works for this purpose. Combining basal body temperature with calendar timing is more accurate than either method alone.

Home ovulation tests may examine saliva or URINE. The urine test, which has been available since the mid-1980s, detects the presence of LUTEINIZING HORMONE (LH) in the urine. The PITUITARY GLAND releases LH to stimulate the luteal, or secretory, phase of the menstrual cycle and the ultimate release of the ovum. The LH test is similar to a home pregnancy test in that the sample of urine causes a change in the indicator when LH is present in the urine. The saliva test, which became available in 2002, allows examination of the saliva for changes in the concentration of potassium chloride. The amount of potassium chloride in the saliva increases during the luteal phase, a reaction to the surge of ESTROGENS that precedes ovulation. The saliva test uses a small microscope, which comes with the test kit, to examine a drop of saliva on a slide for the pattern of potassium chloride. Small spots are normal; fernlike patterns suggest ovulation.

The final element of fertility in women is the ability to sustain pregnancy through birth. Some conceptions are unable to implant, perhaps because of extensive UTERINE FIBROIDS, excessively tipped uterus, malformation of the uterus, and other circumstances in which the uterus cannot support the blastocyst. As many as a third of pregnancies spontaneously abort (miscarry) within the first eight weeks. Spontaneous ABORTION becomes less common after the 14th week.

Though a woman retains fertility for as long as she ovulates and has menstrual cycles (even if irregular), her fertility diminishes as she approaches menopause. Menstrual cycles and ovulation often become irregular in timing, and anovulatory cycles (menstrual cycles without ovulation) become more common. Other factors that influence fertility in women include

- oral contraceptives (birth control pills), which override the body's hormonal regulation of the menstrual cycle, or estrogen suppression therapy, such as to treat severe uterine fibroids or ENDOMETRIOSIS
- TURNER'S SYNDROME
- PREMATURE OVARIAN FAILURE (POF), in which the OVARIES stop functioning before natural menopause
- TUBAL LIGATION (surgery to "tie" or cut the FALLOPIAN TUBES as a permanent form of CONTRACEPTION)
- HYSTERECTOMY (surgery to remove the uterus)
- chronic PELVIC INFLAMMATORY DISEASE (PID), which may SCAR and block the fallopian tubes
- CHEMOTHERAPY or RADIATION THERAPY to treat cancer anywhere in the body

Male Fertility and Conception

Male fertility relies on the motility (movement and thrust), morphology (physiologic form), and volume of sperm present in the ejaculate (SEMEN that leaves the man's PENIS with EJACULATION). Laboratory examination of a sperm sample measures these and other factors; there are no home tests for sperm viability. Sperm can live about 72 hours in the woman's reproductive tract, though the environment of the VAGINA is particularly hostile, and about half of the 500 million or so sperm typically present in a fertile man's ejaculate die during their passage through the it. However, dead and dying sperm are important to fertility because they provide protection and support for living, motile sperm. Dead sperm help form a protective barrier around surviving sperm. The movement of dying sperm helps propel onward the cluster of sperm that remain viable.

One healthy, functioning testicle is adequate to produce enough sperm for fertility. Though a man remains fertile all his life the quality of his sperm (motility, morphology, and other characteristics) tends to decline in his later years (age 70 and older). This may become an issue in regard to fertility if the woman's fertility is marginal. Other factors that influence male fertility include

- inflammatory damage to the TESTICLES due to bacterial or viral INFECTION
- RETROGRADE EJACULATION (semen enters the BLADDER instead of leaving the penis during ejaculation)
- PROSTATECTOMY (surgery to remove the PROSTATE GLAND)
- VASECTOMY (surgery to clip or cut the VAS DEFERENS as a means of permanent contraception) or ORCHIECTOMY (surgery to remove a testicle)
- CRYPTORCHIDISM (undescended testicle), particularly bilateral or delayed diagnosis
- ERECTILE DYSFUNCTION
- chemotherapy or radiation therapy for cancer anywhere in the body

Body temperature also affects male fertility. Normally the SCROTUM (saclike structure that contains the testicles) rises and lowers to maintain ideal temperature for spermatogenesis (production of new sperm). FEVER, sitting in a hot tub, and wearing clothing that holds the scrotum tight against the body are factors that can raise the temperature in the testicles to one at which sperm cannot survive. Though these often are temporary factors, they may be permanent.

fetus The stage of prebirth development from nine weeks of gestation to birth. The organ systems and major structures take form during the EMBRYO stage, which encompasses the second to the eighth weeks of gestation. During the fetal stage, which is 32 weeks in a full-term PREGNANCY, the systems, organs, and structures grow and develop further sophistication in preparation for independent life. The fetus reaches viability (possibility of surviving on its own) at around 24 weeks of gestation.

HIGHLIGHTS OF FETAL GROWTH

Fetal Age (Gestational Weeks)	Fetal Size	Key Developments
14	3 inches in length	face clearly formed LIVER produces erythrocytes
18	6 inches in length	lanugo (fine HAIR) on head movement may be detectable sucking gastrointestinal tract produces meconium
24	11 inches in length one pound in weight	viability possible with intensive medical care movement apparent eyebrows and eyelashes fingerprints and footprints heartbeat detectable with stethoscope gender detectable with ULTRASOUND startle REFLEX
28	15 inches in length two to three pounds in weight	viability possible eyelids open and close increasing level of BRAIN and NERVOUS SYSTEM functions alveoli in LUNGS
32	17 inches in length four pounds in weight	viability probable body fat BREATHING movements in lungs
36	19 inches in length five to six pounds in weight	viability likely fingernails completely cover fingertips head hair replaces lanugo on head
40	20 to 21 inches in length seven to eight pounds in weight	viable, full term body lanugo disappears lungs mature

fibroadenoma A benign (noncancerous) tumor of the BREAST composed of a mix of fibrous and glandular tissues. Fibroadenoma is the most common benign breast tumor and most often develops in women under age 30. Researchers do not know what causes fibroadenoma. Many women who develop fibroadenomas have higher than normal levels of ESTROGENS in their BLOOD circulation, though researchers do not know the extent to which this contributes. Fibroadenomas tend to grow during PREGNANCY and shrink after MENOPAUSE, supporting at least some level of hormonal involvement.

Most often the woman detects fibroadenoma as a lump she feels in her breast during BREAST SELF-EXAMINATION (BSE) or the doctor finds the fibroadenoma during the breast exam portion of the

woman's ROUTINE MEDICAL EXAMINATION. Fibroadenomas are characteristically firm, smooth, oval or round, and rubbery in texture. They move freely (are not attached to any surrounding tissues). Biopsy is the only means of definitive diagnosis. MAMMOGRAM is often not helpful in women under age 30 because their breast tissue is quite dense, which makes it difficult to distinguish growths within the breast. As well, the radiologic characteristics of fibroadenoma are very similar to those of breast cysts and BREAST CANCER. ULTRASOUND imaging is sometimes useful to visualize the growth though does not provide definitive diagnosis either.

Some doctors recommend surgery to remove a fibroadenoma because although fibroadenoma does not evolve into cancer, there is a slight possibility cancer may develop within the epithelial cells the fibroadenoma contains. Other doctors suggest a course of watchful waiting when the diagnosis is certain and the fibroadenoma is small. About 10 percent of fibroadenomas spontaneously disappear within a year or two of their discovery. Should the fibroadenoma grow or change, the doctor may biopsy it again or remove it.

See also FIBROCYSTIC BREAST DISEASE.

fibrocystic breast disease A chronic condition in which multiple noncancerous cysts develop in the breasts. As the cysts rupture and heal, they cause clusters of scarlike tissue that form palpable lumps in the BREAST. Though called a disease, this condition is benign (harmless and noncancerous) and very common, affecting more women than not; doctors consider it a normal process associated with the fluctuation of hormones during the MENSTRUAL CYCLE. Fibrocystic breast disease commonly affects both breasts though may affect only one breast.

The health concerns of fibrocystic breast disease are twofold. First, the cysts often cause PAIN and swelling of the breasts, particularly in the week before and the first day or two of the menstrual period. Second, it is not possible to be certain a breast lump is a cyst, raising concerns about BREAST CANCER. As well, though the cysts themselves do not become cancerous, when they are abundant their presence can delay detection of a breast cancer tumor. Fibrocystic breasts are more dense, decreasing the effectiveness of the MAMMOGRAM.

Symptoms and Diagnostic Path

Fibrocystic breasts are typically painful. The discomfort may be persistent, having the quality of dull aching or a sensation of fullness, or cyclic tenderness that intensifies the week before and first few days of the menstrual period. Other symptoms may include

- bumpy or lumpy texture to one quadrant, one side, or all of the breast
- itching or tingling of the nipples
- premenstrual swelling of the breasts

Fibrocystic lumps are characteristically rubbery, smooth, and rounded. With palpation they move within the breast; they are not anchored to the underlying structure of the breast. The diagnostic path includes comprehensive palpation of the breasts. Depending on the woman's age, health history, risk for breast cancer, and other factors, the doctor may use diagnostic imaging procedures such as mammogram and breast ULTRASOUND to obtain additional information about the shape, size, and pattern of the fibrocystic tissue. The doctor may also biopsy several lumps to evaluate their pathology (cell structure and organization) and rule out other causes for the symptoms.

Treatment Options and Outlook

Lifestyle treatments that help mediate discomfort include wearing a supportive bra when symptoms are most significant. Some women get relief by limiting their intake of dietary fats and CAFFEINE, though clinical studies of the correlations between these factors and fibrocystic breasts so far have produced inconclusive and sometimes conflicting findings. Others find that vitamin E, vitamin B_6 (pyridoxine), and the herbal preparation evening primrose oil reduce tenderness and swelling. Medical interventions that may provide relief include NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS), which reduce INFLAMMATION, and oral contraceptives (birth control pills), which regulate the hormonal cycle. Nearly always the discomforts of

fibrocystic breasts abate with MENOPAUSE and the lumpiness of the breasts diminishes, though some fibrocystic tissue remains.

Risk Factors and Preventive Measures

There are no clear risk factors or measures to prevent fibrocystic breast disease. It is important for women who have fibrocystic breasts to be diligent in performing monthly BREAST SELF-EXAMINATION and to see their health-care providers when they detect any changes in their breasts.

G

genitalia The collective term for the organs and structures of reproduction, also called the sex organs or the genitals.

Male genitalia The external male genitalia are the PENIS and SCROTUM; the internal male genitalia are the URETHRA, TESTICLES, VAS DEFERENS, bulbourethral glands (also called Cowper's glands), ejaculatory ducts, seminal vesicles, spermatic cords, and PROSTATE GLAND. All structures of the internal male genitalia occur in pairs except the prostate gland and urethra.

Female genitalia The female external genitalia are the mons pubis, labia majora, labia minora, CLITORIS, Skene's glands, Bartholin's glands, hymen, and vaginal introitus. Collectively the female external genitalia are the VULVA or pudendum. The female internal genitalia are the OVARIES, FALLOPIAN TUBES, UTERUS, CERVIX, and VAGINA.

For further discussion of the genitalia within the context of the structures and functions of reproduction and sexuality, please see the overview section "The Reproductive System."

See also CHILDBIRTH; CONCEPTION; PREGNANCY; SEXUAL HEALTH; SEXUAL INTERCOURSE.

genital trauma Injury to the GENITALIA (organs and structures of reproduction). Genital trauma may occur as the result of accidental injury, ritual genital mutilation, or SEXUAL ASSAULT and may affect the external or internal genitalia. Genital trauma may result in PAIN, structural damage, impaired genitourinary function, SEXUAL DYSFUNCTION, and INFERTILITY.

Male Genital Trauma

Common forms of genital trauma in young boys are in straddle injuries (such as falling onto the bar of a bicycle), blunt force injuries to the groin (such as being struck with a thrown or kicked ball), and toileting injuries (such as the toilet seat falling onto the PENIS or getting the penis or SCROTUM caught in the pants zipper.

In older boys and teens, blunt force injuries are more common. Most organized athletic activities and sports require boys to wear a protective cup to guard against such injuries. In adult men, genital trauma may occur as a result of blunt force and during sexual activity that places unusual or excessive pressure on the erect penis or on the scrotum and TESTICLES.

Some people and organizations that oppose routine male infant CIRCUMCISION (surgical removal of the foreskin) view its practice as a form of male ritualistic genital mutilation.

Female Genital Trauma

Straddle-type injuries are common in young girls, though less frequently from bicycles and more often from activities such as gymnastics and horseback riding. Activities that result in the "splits," whether intentional or accidental, can cause significant bruising and tearing of the external genitals and the PERINEUM (region between the opening of the VAGINA and the ANUS).

Sexual assault is a frequent cause of genital trauma in older girls and women, often resulting from rape (forced, nonconsenting, and violent SEXUAL INTERCOURSE). Health-care providers tend to view most circumstances of female genital trauma with the suspicion that they could represent sexual abuse or assault, in part because it is often the case and in part because the laws in many communities in the United States require them to do so. Hospitals and health-care providers must follow specific procedures to preserve potential evidence when treating sexual assault victims.

Women may experience genital trauma during CHILDBIRTH, particularly with vaginal delivery of a breech presentation (baby born bottom first) or a large baby. Some women have birth-related traumatic tearing of the perineum, and others have episiotomy in an attempt to limit the extent of trauma or enlarge the vaginal opening to allow the baby to pass. The resulting injuries may require surgical repair and sometimes result in long-term complications affecting urinary continence, fecal continence, and pleasure during sexual intercourse.

Female ritual genital mutilation, also called female circumcision, remains common in some cultures despite widespread opposition from the World Health Organization (WHO), Amnesty International, and other health and human rights organizations worldwide. Within such cultures ritual genital mutilation may be a rite of passage, a mark of ownership, or a religious practice conducted in early childhood by nonmedical practitioners, without ANESTHESIA and often under unsanitary conditions. Complications are common and often severe. WHO and other organizations have made it a goal to eliminate ritual genital mutilation worldwide.

See also PRIAPISM; TESTICULAR TORSION; VULVODYNIA.

gestational diabetes The development of INSULIN RESISTANCE or type 2 DIABETES during PREGNANCY. Gestational diabetes develops between 24 and 28 weeks of pregnancy. Doctors believe the rising levels of hormones the PLACENTA produces at this point in pregnancy interfere with the ability of the woman's body to properly metabolize INSULIN. Insulin production remains normal. Diabetes that manifests earlier than 24 weeks in pregnancy is nearly always diabetes that was undetected at the start of the pregnancy. Gestational diabetes goes away shortly after delivery, though women who have gestational diabetes have increased risk for developing type 2 diabetes later in life.

Untreated gestational diabetes poses a health risk primarily for the FETUS. The excessive GLUCOSE (sugar) that circulates in the mother's BLOOD crosses the placenta. When it reaches the fetus the excessive glucose fuels fetal growth, resulting in fetal size up to 20 percent greater than normal. This growth becomes problematic within the UTERUS as the fetus cannot move as freely. Adequate prenatal movement is important for proper muscular development. A fetus larger than about eight pounds often has difficulty passing through the birth canal. The circumstance of an overly large fetus, called macrosomia, often necessitates birth by CESAREAN SECTION (surgical delivery) to safeguard the health of both baby and mother. As well, the newborn infant may experience HYPOGLYCEMIA (low blood glucose) in the first hours after birth.

Symptoms and Diagnostic Path

Most often gestational diabetes has few noticeable symptoms. When symptoms do occur they may include frequent URINATION, increased thirst, and increased hunger. Because these are common in pregnancy, however, they are difficult to distinguish as symptoms of diabetes. Routine URINE tests at each prenatal doctor visit screen for the overflow of glucose in the urine, which indicates high blood glucose. Health-care providers routinely test for elevated glucose in the woman's blood circulation between the 24th and 28th weeks of pregnancy. The most common such test is the three-hour glucose tolerance test. Findings of an elevated blood glucose level at two or more of the four drawings of blood over the course of the test generally establishes the diagnosis of gestational diabetes.

Treatment Options and Outlook

Many women are able to manage gestational diabetes through nutritional EATING HABITS and daily exercise. Women for whom lifestyle measures do not maintain stable blood glucose levels typically require insulin injections through the remainder of pregnancy. The safety of oral antidiabetes medications in pregnancy remains undetermined, though some doctors offer this treatment. Diligent management of blood glucose levels helps maintain normal growth and weight of the fetus.

In nearly all women gestational diabetes goes away within a week of delivery and for a third of women diabetes is never again a health concern. However, in some women who have high risk for diabetes in the first place gestational diabetes may persist to become conventional diabetes. One in

five women who has gestational diabetes will develop conventional diabetes within five years of her baby's birth, and about two thirds of women will develop the condition later in life.

Risk Factors and Preventive Measures

Any pregnant woman can develop gestational diabetes. Factors that increase the risk for gestational diabetes include

- gestational diabetes in a previous pregnancy
- obesity
- African American or Hispanic heritage
- age 25 or older

Because gestational diabetes results from the effects in the woman's body of hormones the placenta produces, there are no certain measures to prevent its development. Lifestyle measures to maintain nutritious eating habits, daily exercise, and healthy weight help the body use glucose and insulin as efficiently as possible.

See also ECLAMPSIA; LIFESTYLE AND HEALTH; PREECLAMPSIA; WEIGHT LOSS AND WEIGHT MANAGEMENT.

gestational hypertension See PREECLAMPSIA.

gestational surrogacy A circumstance in which one woman carries a PREGNANCY for another woman who cannot carry it herself. Gestational surrogacy is among the possible solutions for INFERTILITY, typically in circumstances such as uterine malformation that prevent successful implantation or carrying the pregnancy to term.

The woman who carries the pregnancy is the gestational surrogate or gestational carrier; the woman to whom the pregnancy belongs is the intended parent. The gestational surrogate may be a relative of or a woman or couple desiring the pregnancy, may know the woman or couple desiring the pregnancy, or may make herself available to a FERTILITY clinic for the purpose of gestational surrogacy. The pregnancy takes place through some form of ASSISTED REPRODUCTIVE TECHNOLOGY (ART), typically in vitro fertilization. ART may use the intended mother's egg, a donor egg, or the gestational surrogate's egg fertilized with the intended father's SPERM or donor sperm. As with any pregnancy, multiple factors affect the success of these efforts.

Gestational surrogacy entails intense emotional and legal complexities as well as physical and health risks for the gestational surrogate. Women considering gestational surrogacy, whether as intended parent or gestational surrogate, should obtain legal advice before initiating the process. It is crucial for all participants to fully understand the risks and to agree, via written contract, to the conditions of the arrangements. In the United States each state determines the legal status of surrogacy; many states restrict financial arrangements with and payments to gestational surrogates as well as tightly regulate the myriad aspects of legal parentage and responsibility. Though gestational surrogacy is often a positive experience for all involved, the potential for complications and problems exists.

See also ADOPTION; FAMILY PLANNING.

gynecomastia BREAST enlargement in a man. Gynecomastia may be a symptom of OBESITY or hormonal imbalance such as may occur during PUBERTY or with various endocrine disorders that affect the production of TESTOSTERONE. Advanced CIRRHOSIS, LIVER CANCER, and chronic ALCOHOLISM often produce gynecomastia because the resulting dysfunction of the LIVER alters how the adipose (fat) cells metabolize ESTROGENS. Estrogen levels in the BLOOD circulation tend to rise with chronic liver disease or damage to the liver. Gynecomastia is also a characteristic SIDE EFFECT of HORMONE THERAPY to treat PROSTATE CANCER, again because the balance of estrogen in the blood circulation increases. Treatment for gynecomastia depends on the underlying cause.

See also MASTALGIA.

H

hematospermia BLOOD in the SEMEN that may be apparent with EJACULATION. Trauma and INFECTION are the main causes of hematospermia. SEXUALLY TRANSMITTED DISEASES (STDS), notably GONORRHEA and CHLAMYDIA, are common infections that irritate and inflame the URETHRA, often causing bleeding into both the URINE (HEMATURIA) and the semen as either passes through the urethra to leave the body. Less common causes of hematospermia include bleeding disorders (health conditions or medication induced); severe HYPERTENSION (high BLOOD PRESSURE); and, in men over age 50, PROSTATE CANCER. Diagnostic and therapeutic efforts focus on identifying and treating the underlying cause.

See also EPISTAXIS; URETHRITIS.

hot flashes Sudden episodes of flushing and sweating that occur with the fluctuating HORMONE levels that precede MENOPAUSE or as a consequence of HORMONE THERAPY such as to treat HORMONE-DRIVEN CANCERS. Though researchers do not know the precise mechanisms of hot flashes, they believe the sudden drops in ESTROGENS affect the thermoregulatory centers in the BRAIN that cause the body to function as though it must reduce body temperature. SKIN flushing and sweating are among the methods the body uses to accomplish such reduction. Hot flashes associated with menopause improve and usually go away when the body's estrogen levels stabilize.

Lifestyle measures to mitigate the discomfort of hot flashes include dressing in layers to allow rapid cooling, drinking cool fluids at the onset of a hot flash, minimizing CAFFEINE consumption, and avoiding foods that are high in tyramines, including red wine, aged cheese, smoked meats, and concentrated yeasts such as miso. Medical treatments for hot flashes include selective serotonin reuptake inhibitor (SSRI) medications, a classification of antidepressant medication that appears to reduce the frequency and intensity of hot flashes, or short-term hormone replacement therapy (HRT). Alternative and complementary approaches to relieve hot flashes include ACUPUNCTURE and botanical remedies such as BLACK COHOSH and SOY.

See also ANTIDEPRESSANT MEDICATIONS; MEDICINAL HERBS AND BOTANICALS; PREMATURE OVARIAN FAILURE (POF).

hydrocele A fluid-filled growth, similar to a cyst, that develops in the SCROTUM. Most hydroceles are congenital (present at birth) and occur as a result of incomplete closure of the channel through which the testicle descends from the abdomen to the scrotum. The defect allows peritoneal fluid to seep from the abdominal cavity into the scrotum. A congenital hydrocele, also called a primary hydrocele, appears as a variable and usually painless enlargement of the scrotum. The size of the enlargement may fluctuate with changes in abdominal pressure, increasing with activities such as bearing down (Valsalva maneuver), coughing, sneezing, or, in infants, vigorous crying. Secondary hydrocele may develop after viral INFECTION (more common in children) or trauma to the scrotum.

The preliminary diagnosis of hydrocele is clinical, based on the scrotum's transluminency. In this simple test the doctor holds a bright, focused penlight against the side of the scrotum. When the cause of scrotal swelling is hydrocele, the light passes uniformly through the tissues of the scrotum. Most other causes of scrotal swelling are not transluminent. An OPERATION to repair a primary hydrocele is the treatment of choice; surgical

examination of the swelling subsequently confirms the diagnosis. The operation closes the defect that allows fluid to seep into the scrotum. Complications after surgery are rare though could include anesthetic reaction, unusual bleeding, or infection. Secondary hydrocele generally heals on its own.

See also HERNIA; TESTICLES; VIRUS.

hypogonadism Dysfunction of the gonads resulting in inadequate production of sex hormones. In men the TESTICLES (also called testes) are the gonads that produce ANDROGENS and in women the OVARIES are the gonads that produce ESTROGENS. In primary hypogonadism the ovaries or testicles themselves fail. Genetic reasons for such failure are TURNER'S SYNDROME in females and KLINEFELTER'S SYNDROME in males. These genetic disorders result from errors in the sex chromosomes.

Hypogonadism may also be central, a result of problems with the endocrine mechanisms that regulate the function of the ovaries or testicles. The most common of such problems are traumatic injury, surgery, RADIATION THERAPY, and CHEMOTHERAPY. Tumors of the PITUITARY GLAND, untreated HYPOTHYROIDISM, and EATING DISORDERS such as anorexia nervosa that result in severe NUTRITIONAL DEFICIENCY, may also cause central hypogonadism.

Symptoms of hypogonadism depend on the developmental stage of the individual. Primary hypogonadism that occurs in childhood, such as resulting from Turner's syndrome or Klinefelter's syndrome, causes absence of PUBERTY and failure to develop SECONDARY SEXUAL CHARACTERISTICS. Hypogonadism that develops in adulthood results in menopausal symptoms such as HOT FLASHES in women and diminished LIBIDO, ERECTILE DYSFUNCTION, and sparsity of facial HAIR in men.

The diagnostic path includes BLOOD tests to measure blood levels of estrogen, TESTOSTERONE, FOLLICLE-STIMULATING HORMONE (FSH), LUTEINIZING HORMONE (LH), and thyroid hormones. Treatment for primary hypogonadism in most situations is HORMONE THERAPY to restore blood levels of the sex hormones to normal levels for the person's age. When hypogonadism is central, treatment targets the underlying cause. Hormone therapy initiates puberty when hypogonadism occurs in childhood. However, FERTILITY issues may remain even with treatment though other symptoms typically improve.

See also CHROMOSOMAL DISORDERS; CHROMOSOME; GYNECOMASTIA; HORMONE; SEX CHROMOSOME; THYROID GLAND.

hysterectomy A surgical OPERATION to remove the UTERUS. Hysterectomy may be treatment for ENDOMETRIAL CANCER or for noncancerous conditions that cause significant symptoms and do not respond to less invasive treatments. Among such conditions are UTERINE FIBROIDS, UTERINE PROLAPSE, DYSFUNCTIONAL UTERINE BLEEDING (DUB), and ENDOMETRIOSIS. Whatever its reason, a consequence of hysterectomy is immediate loss of FERTILITY. Hysterectomy is the second-most common operation women undergo in the United States; CESAREAN SECTION (surgical CHILDBIRTH) is the most common. Surgeons in the United States perform more than 600,000 hysterectomies each year.

Surgical Procedure

The ANESTHESIA for hysterectomy may be regional, such as epidural block, with sedation or general (deep sleep). The choice of anesthesia depends on the type of hysterectomy the woman is having, the woman's preferences, and the recommendations of the surgeon and anesthesiologist.

A simple hysterectomy removes only the uterus (sometimes called a supracervical hysterectomy); a total hysterectomy removes the uterus and CERVIX. Both operations leave the OVARIES in place to continue providing hormones that carry the woman to a natural MENOPAUSE if she has not already reached that stage of her life. Radical hysterectomy may be necessary when endometrial cancer or CERVICAL CANCER is the reason for the operation. In radical hysterectomy the surgeon removes the uterus, cervix, and upper VAGINA along with much of the tissue that supports these structures.

The operation may be an OPEN SURGERY, in which the surgeon makes a long incision through the SKIN and layers of MUSCLE to expose the uterus, or laparoscopically assisted vaginal hysterectomy, in which the surgeon removes the uterus through multiple small incisions in the abdomen and vagina and removes the uterus with the aid of a lighted, magnifying laparoscope that displays the pelvic structures on a monitor. A laparoscopically

assisted vaginal hysterectomy is somewhat more complex for the surgeon to perform though significantly faster recovery for the woman. It is an appropriate option when hysterectomy is to treat noncancerous conditions.

A laparoscopically assisted vaginal hysterectomy generally requires no more than an overnight stay in the hospital the night after the surgery. A woman often can return to regular activities in about six weeks with the laparoscopic operation. The typical hospital stay for open hysterectomy is three to five days, with full recovery and recuperation in about eight weeks.

Risks and Complications

The primary risks associated with hysterectomy are possible excessive bleeding, BLOOD clots, and INFECTION. Complications may include damage to the nerves that control the bowel or BLADDER that results in FECAL INCONTINENCE or URINARY INCONTINENCE or damage to the structure of the bladder or ureters (tubelike structures that drain URINE from the KIDNEYS to the bladder). These complications are uncommon though may have long-term consequences. When the surgeon leaves the FALLOPIAN TUBES and ovaries intact, these structures sometimes atrophy (shrink). Women who have total hysterectomies with removal of the cervix sometimes experience PAIN during SEXUAL INTERCOURSE for the first few months after surgery. Women who have hysterectomies tend to enter menopause somewhat earlier even when they retain their ovaries.

Outlook and Lifestyle Modifications

Most women return to full, regular activities within two months of surgery (and many sooner). Hysterectomy means the end of MENSTRUATION (though not necessarily the start of menopause), which is sometimes an emotional adjustment. The relief of symptoms related to the condition that necessitated the hysterectomy is sometimes profound, allowing the woman to return to a lifestyle and activities that she had long enjoyed but had stopped participating in because of the symptoms. In circumstances other than cancer, it is important for a woman to understand the nonsurgical options that are available to treat her condition so she can make a fully informed decision.

See also CANCER TREATMENT OPTIONS AND DECISIONS; OOPHORECTOMY; SEXUAL HEALTH; SURGERY BENEFIT AND RISK ASSESSMENT.

hysteroscopy A diagnostic or therapeutic procedure to examine the interior of the UTERUS using a lighted magnifying endoscope. Hysteroscopy is an outpatient surgical procedure that requires regional or general ANESTHESIA. After the administration of anesthesia the gynecologist dilates the CERVIX and inserts the lighted, flexible tube of the hysteroscope into the uterus and fills the uterus with carbon dioxide gas or sometimes liquid saline solution to push the uterine walls apart.

The hysteroscope allows the gynecologist to closely examine the entire endometrium (lining of the uterus) and the entries to the FALLOPIAN TUBES. The gynecologist may use the hysteroscope to obtain tissue samples for biopsy, remove UTERINE FIBROIDS or polyps, and repair minor injuries to the wall of the uterus and certain congenital malformations such as uterine septum.

The risks of hysteroscope include those of anesthesia as well as INFECTION, excessive bleeding, and uterine perforation (puncture of the uterine wall). These risks are uncommon though may require further treatment. Infection requires treatment with ANTIBIOTIC MEDICATIONS. Uterine perforation usually heals on its own. Excessive bleeding may require medications or follow-up surgery to control. Minor bleeding and discomfort (cramping) are normal after hysteroscopy and may continue for a few days.

See also COLPOSCOPY; ENDOSCOPY; SURGERY BENEFIT AND RISK ASSESSMENT.

I

infertility The inability to conceive or maintain a PREGNANCY. Infertility may be transitory (relate to a specific set of circumstances), treatable, or permanent. Infertility affects about 10 percent of Americans who attempt pregnancy.

There are numerous possible causes of infertility that can affect any of the various stages in the process of CONCEPTION. Causes may affect the woman, the man, or the couple in equal distribution. One of the most significant is the woman's age. An increasing number of women in the United States delay starting their families until completing their education and establishing their careers, the average age of first pregnancy is age 30. Though a woman can remain fertile into her late 40s, the likelihood of conception appreciably diminishes each year after age 35.

Infertility is highly emotional for most people. Infertility often comes as a shock, particularly for younger people who had no reason to suspect they were not fertile. Some people feel guilt or regret about choices made earlier in life in regard to CONTRACEPTION and FAMILY PLANNING. Diagnostic procedures and treatment approaches can be invasive and expensive and are without assurances. Though ASSISTED REPRODUCTIVE TECHNOLOGY (ART) is highly advanced and makes pregnancy possible for thousands of couples every year, it nonetheless is unable to help two thirds of couples who cannot conceive.

Female factor infertility In female factor infertility the reason for infertility rests with the woman. A third of infertility circumstances arise from female factors. Ovulatory dysfunction is the most common of them and may result from age, genetics, health conditions, or medical treatments. Blocked FALLOPIAN TUBES are also common. Previous ECTOPIC PREGNANCY, abdominal or pelvic surgery, and complications from untreated SEXUALLY TRANSMITTED DISEASES (STDS) may SCAR and otherwise damage the fallopian tubes. Congenital anomalies of the reproductive organs, such as malformations of the UTERUS, may prevent implantation. EATING DISORDERS such as anorexia nervosa and OBESITY influence the body's endocrine functions and OVULATION. Cigarette smoking, excessive ALCOHOL consumption, and substance abuse also affect FERTILITY.

FEMALE INFERTILITY FACTORS

age over 35	excessive ALCOHOL use
anorexia nervosa	CHEMOTHERAPY
cigarette smoking	CUSHING'S SYNDROME
DIABETES	ENDOMETRIOSIS
OBESITY	OVARIAN CYST
PELVIC INFLAMMATORY DISEASE (PID)	PITUITARY GLAND dysfunction
PREMATURE OVARIAN FAILURE (POF)	POLYCYSTIC OVARY SYNDROME (PCOS)
RADIATION THERAPY	previous ECTOPIC PREGNANCY
substance abuse	SICKLE CELL DISEASE
untreated HYPOTHYROIDISM	TURNER'S SYNDROME
uterine malformations	UTERINE FIBROIDS

Male factor infertility In male factor infertility the reason for infertility rests with the man. A third of infertility circumstances arise from male factors. Male infertility factors may result from problems with spermatogenesis (production of SPERM), SEMEN production, ERECTION and EJACULATION, sperm count, sperm morphology (structure), and sperm motility (movement). Body temperature and scrotal temperature are crucial for spermatogenesis and sperm survival. Circumstances that prevent the SCROTUM from dropping, such as tight clothing, or sustained exposure to heat, such

as sauna or hot tub use, may affect sperm viability. Such effects may be temporary or permanent. Viral infections such as the MUMPS and bacterial EPIDIDYMITIS may damage or destroy testicular tissue. CHROMOSOMAL DISORDERS such as KLINEFELTER'S SYNDROME and endocrine disorders may affect TESTOSTERONE production. Congenital absence of the VAS DEFERENS, which often occurs in men who have CYSTIC FIBROSIS, prevents sperm from leaving the TESTICLES.

MALE INFERTILITY FACTORS

agricultural pesticide exposure	ATHEROSCLEROSIS
CHEMOTHERAPY	chronic ORCHITIS
chronic PROSTATITIS	chronic URETHRITIS
cigarette smoking	CRYPTORCHIDISM
CUSHING'S SYNDROME	CYSTIC FIBROSIS
DIABETES	DOWN SYNDROME
ERECTILE DYSFUNCTION	excessive ALCOHOL consumption
HYDROCELE	KLINEFELTER'S SYNDROME
HYPOGONADISM	low SPERM count
low SEMEN volume	malformed sperm
low sperm motility	prolonged elevated body temperature
OBESITY	SICKLE CELL DISEASE
RADIATION THERAPY	substance abuse
RETROGRADE EJACULATION	testicular trauma
SPERMATOCELE	untreated HYPOSPADIAS
TESTICULAR CANCER	viral or bacterial EPIDIDYMITIS
untreated EPISPADIAS	
VARICOCELE	

Combined factor infertility In combined factor infertility the reason for infertility results from the unique combination of factors each partner brings to the couple. A third of infertility circumstances arise from combined factors or remain unknown in their origin. Combined factors may be elements that, on their own, would not be sufficient to prevent conception. In particular combinations, however, these elements result in infertility. The woman's IMMUNE SYSTEM may generate antibodies that attack the man's sperm. Combined factor infertility is often the most difficult to sort out and treat.

Symptoms and Diagnostic Path

The primary symptom of infertility is the absence of pregnancy after one year of unprotected SEXUAL INTERCOURSE when pregnancy is the desired outcome. The diagnostic path begins with comprehensive medical examination, including PELVIC EXAMINATION for women, and detailed history of attempts to conceive. Further diagnostic procedures depend on the preliminary findings and suspicions, though typically include laboratory tests for STDs, BLOOD tests for antibodies and HORMONE levels for the woman, and semen analysis for the man.

Additional diagnostic procedures for the woman may include

- basal body temperature journaling over several months to assess ovulation
- pelvic or transvaginal ULTRASOUND to examine the OVARIES and reproductive organs
- analysis of vaginal fluids to assess acidity (pH) and mucus
- hysterosalpingogram, a contrast medium X-RAY examination of the uterus and fallopian tubes
- karyotyping to detect chromosomal abnormalities such as TURNER'S SYNDROME
- exploratory laparoscopy to visually examine the internal pelvic structures

Additional diagnostic procedures for the man may include

- blood tests to measure hormone levels
- scrotal ultrasound to detect HYDROCELE, VARICOCELE, or SPERMATOCELE
- karyotyping to detect chromosomal abnormalities such as Klinefelter's syndrome

Treatment Options and Outlook

Treatment targets the identified or suspected cause. Basic approaches include frequent sexual intercourse, sexual positions that support conception, and timing sexual intercourse with ovulation. These basic measures result in conception within two years in about a third of couples. Other straightforward solutions may include treatment for infections or endocrine disorders (such as previously undiagnosed HYPOTHYROIDISM or ADRENAL INSUFFICIENCY).

Further treatment is more invasive. In men, such treatment may consist of surgery to repair hydrocele, varicocele, or spermatocele. Testosterone supplementation often improves sperm

production and erectile function in men whose blood testosterone levels are low. In women, further treatment may include surgery to correct or repair various situations that contribute to or cause female factor infertility such as abdominal adhesions, ENDOMETRIOSIS, UTERINE FIBROIDS, certain uterine malformations, blocked fallopian tubes, and OVARIAN CYST. Hormone supplementation may regulate the MENSTRUAL CYCLE to encourage or stimulate ovulation ("superovulation") in women. Some hormones used in this way are off-label (not approved for infertility treatment though approved for other uses) in the United States.

Fertility experts select hormone therapies according to the underlying cause for ovulatory dysfunction, the woman's age, and any existing health conditions. Hormone treatment for infertility may have serious side effects, risks, and complications, including HOT FLASHES, mood swings, ovarian cyst formation, increased risk for spontaneous ABORTION early in pregnancy (miscarriage), and high risk for pregnancy with multiples (twins or greater). The long-term risks associated with fertility drugs, for the women who take them as well as the children conceived with their assistance, remain uncertain because the drugs have not been in use long enough to allow comprehensive studies.

MEDICATIONS USED TO STIMULATE OVULATION

bromocriptine
cabergoline
clomiphene citrate
FOLLICLE-STIMULATING HORMONE (FSH)
GONADOTROPIN-RELEASING HORMONE (GNRH) analogs
human chorionic gonadotropin (hCG)
human menopausal gonadotropin (hMG)
letrozole
metformin

ART methods to combine sperm and OVA may be appropriate when there are no measures to correct the cause of infertility or attempted treatments have not succeeded.

Risk Factors and Preventive Measures

The primary risk factor for infertility is age. Though the time frame of fertility is clearly defined in women, fertility diminishes to some degree in men as they grow older. Lifestyle risk factors include cigarette smoking, alcohol consumption, environmental hazard exposure (such as pesticides), and obesity. Lifestyle also influences some health risks for infertility such as DIABETES, ATHEROSCLEROSIS, and infection with STDs. Risks for which there are no preventive measures include GENETIC DISORDERS and chromosomal disorders, CONGENITAL ANOMALY of the reproductive organs, POLYCYSTIC OVARY SYNDROME (PCOS), PREMATURE OVARIAN FAILURE (POF), endocrine disorders, and AUTOIMMUNE DISORDERS.

intraductal papilloma A benign (noncancerous) tumor that grows within a lactiferous duct (milk duct) of a woman's BREAST. Intraductal papilloma is the most common cause of nipple discharge, which is its primary symptom. The discharge may be milky, clear, or blood tinged. A woman may notice only slight staining on her clothing. There is usually no PAIN or discomfort associated with intraductal papilloma.

The tumor causing symptoms may be too small for the woman or her health-care provider to feel, though may appear on MAMMOGRAM and usually shows up on ULTRASOUND of the breast. Other diagnostic procedures may include a contrast X-RAY called a ductogram and laboratory analysis of the nipple discharge. Biopsy of the papilloma, usually in combination with its surgical removal, provides definitive diagnosis. Intraductal papilloma occasionally recurs.

See also BREAST CANCER; BREAST HEALTH; FIBROCYSTIC BREAST DISEASE.

K–L

Klinefelter's syndrome A chromosomal disorder affecting only males in which there is at least one extra X CHROMOSOME. The normal chromosomal configuration for a male is XY; the female configuration is XX. The extra X chromosome in a male, which doctors commonly designate as 47 XXY, dilutes the SECONDARY SEXUAL CHARACTERISTICS. Men who have Klinefelter's syndrome often do not produce SPERM and thus are infertile (unable to cause PREGNANCY).

Klinefelter's syndrome often does not become apparent until a boy enters (or fails to enter) PUBERTY. Secondary sexual characteristics are slow to develop and may appear effeminate, with small GENITALIA, enlarged breasts (GYNECOMASTIA), and little facial HAIR. LEARNING DISORDERS are also common in boys who have Klinefelter's syndrome, though researchers are uncertain of the reason for this. Adult men often experience SEXUAL DYSFUNCTION such as low LIBIDO, ERECTILE DYSFUNCTION, and INFERTILITY.

The diagnostic path includes BLOOD tests to measure the levels of TESTOSTERONE, LUTEINIZING HORMONE (LH), and FOLLICLE-STIMULATING HORMONE (FSH). Karyotyping, a representation of the chromosomal configuration of the cells, shows the extra X chromosome (and in some men, more than one extra X chromosome). Treatment is TESTOSTERONE supplementation to restore to normal the level of testosterone in the blood circulation. Testosterone supplementation generally results in increased masculinization (appearance of secondary sexual characteristics) such as thickened beard growth, deepened voice, enlarged PENIS and TESTICLES, and increased MUSCLE mass and definition. Treatment is generally lifelong.

See also CHROMOSOMAL DISORDERS; GENETIC DISORDERS; KARYOTYPE; TURNER'S SYNDROME.

letdown reflex The release of milk from the lactiferous glands and ducts to the nipple of the BREAST to initiate BREASTFEEDING (nursing). The first sucking motions the infant makes when attaching to the nipple are rapid and pulling. These motions stimulate the release of OXYTOCIN from the PITUITARY GLAND, which causes the tissues around the ducts to contract to push the milk to the nipple. The mother feels this release and the initial flow of milk as a tingling sensation. The more full of milk the breasts are the more intense the sensation. Letdown occurs multiple times during a breastfeeding session. Other events may also stimulate the letdown REFLEX, such as the sound of the infant's cry. Letdown affects both breasts, often causing milk to leak from the un-nursed breast.

See also PREGNANCY.

libido The level of sexual desire an individual feels, also called sex drive. Libido represents a complex interaction between the mind and the sex hormones. Low hormonal levels often result in reduced libido. In men the HORMONE associated with libido is TESTOSTERONE; in women both ESTROGENS and testosterone play roles in libido. Numerous medications, serious or chronic illness, long-term ALCOHOLISM, and substance abuse may also reduce libido. As well, libido typically slows with age.

Indications or symptoms of low libido may include

- lack of interest in sex
- lack of sexual arousal
- inability to reach ORGASM
- ERECTILE DYSFUNCTION in men
- reduced vaginal lubrication in women

Hormone supplementation often improves libido when hormone levels are the cause for its decline. Treating health conditions that may cause low libido, or changing medications that can affect libido, is sometimes all the treatment that is necessary. Libido also often has significant emotional and psychologic components. Treatment for low libido depends on its identifiable causes.

See also SEXUAL DYSFUNCTION; SEXUAL HEALTH; SEXUAL INTERCOURSE.

M–N

mammogram An X-RAY examination of the BREAST. The most common use of mammogram is for early detection of BREAST CANCER. However, mammogram may be a diagnostic tool in the evaluation of various conditions that affect the breasts. Most abnormal findings mammograms detect are not cancer.

Most often a woman stands for a mammogram. The technologist places one breast on a shelf on the X-ray machine, beneath which is the X-ray film. A moving shelf then compresses the breast against the shelf to somewhat flatten the breast tissue for better visualization. With routine screening mammogram the technologist takes two X-rays of each breast, one from the side and one from above. The entire procedure—positioning and taking the images—takes about 10 minutes. With diagnostic mammogram the technologist takes up to five images, in different positions, of each breast. The entire procedure for diagnostic mammogram takes about 15 minutes.

Though mammogram is generally quick and painless, some women experience discomfort with the compression of their breasts. Women who are still menstruating should have routine mammograms two weeks after the end of their menstrual periods to minimize discomfort, as the breasts are least sensitive at this time.

Most health-care providers recommend routine screening mammograms beginning at age 40 for women who have no unusual risks for breast cancer—every two years between ages 40 and 50 and once a year after age 50. Women who have had breast cancer or have three or more risk factors for breast cancer should talk with their doctors about the appropriate intervals for mammogram. Because the breast tissue of menstruating women is very dense it blocks visualization of abnormalities, making screening mammogram impractical in younger women. With MENOPAUSE the breast tissue becomes considerably less fatty and dense, so abnormal growths are readily obvious. Mammogram often can detect growths and tumors in the breast before they reach a size at which the woman or her health-care provider can feel them.

See also BREAST SELF-EXAMINATION; CANCER PREVENTION; FIBROCYSTIC BREAST DISEASE; PREVENTIVE HEALTH CARE AND IMMUNIZATIONS.

mastalgia Painful breasts. Cyclic mastalgia in women occurs commonly with MENSTRUATION. Noncyclic mastalgia in women may indicate MASTITIS (INFLAMMATION, often the result of bacterial INFECTION). Mastalgia in women is also common during PREGNANCY and BREASTFEEDING. Mastalgia is uncommon in men and signals an underlying condition that requires a doctor's evaluation.

Mastalgia is a symptom rather than itself a health condition. The diagnostic path attempts to pinpoint the cause of the PAIN. Diagnostic procedures the doctor may conduct include breast ULTRASOUND and MAMMOGRAM (X-RAY of the BREAST). Treatment targets the underlying cause.

See also GYNECOMASTIA.

mastectomy A surgical OPERATION to remove the BREAST. Mastectomy is most commonly a treatment for BREAST CANCER. Women who have extraordinarily high risk for breast cancer (such as because of family history or known MUTATION of the BRCA-1/BRCA-2 genes) may choose prophylactic mastectomy, also called risk-reduction mastectomy, to reduce the likelihood that they will develop cancer. Mastectomy is a major surgery that may require two to five days of hospitalization after the operation, depending on the extent

of the surgery. Women may choose to have immediate or follow-up breast reconstructive surgery, or no reconstruction.

Surgical Procedure

A woman undergoing mastectomy receives general ANESTHESIA. The operation generally takes two to four hours; mastectomy with reconstruction takes longer than mastectomy alone. There are three types of mastectomy:

- Segmental mastectomy is when the surgeon removes the tumor and the quadrant of breast that contains it. The surgeon may recommend this operation when the breast cancer tumor is small and localized though larger than would be appropriate for lumpectomy (removal of the tumor and a margin of the surrounding breast tissue).
- Subcutaneous mastectomy, also called SKIN-sparing mastectomy, is removal of the breast tissue with the nipple, areola, and surface skin of the breast remaining. Subcutaneous mastectomy affords the most ideal circumstance for breast reconstruction.
- Total mastectomy, also called simple mastectomy, removes all of the breast tissue including the nipple and areola. The surgeon may recommend total mastectomy when the cancer is diffuse (lacking clear boundaries) or in more than one location within the breast. The surgeon may also perform SENTINEL LYMPH NODE DISSECTION, a method that examines the first LYMPH NODE in the drainage path from the tumor. Whether the sentinel contains cancer cells is an accurate indicator of whether the cancer has spread from the breast.
- Modified radical mastectomy removes all of the breast, including the nipple and areola, as well as the axillary LYMPH nodes (lymph nodes under the arm), called axillary lymph node dissection. This is the operation of choice when the cancer tumor is fairly large or diagnostic scans show the lymph nodes contain cancer.

After removing the breast the surgeon places small tubes to drain fluid from the surgical site during the initial stages of HEALING and then sutures closed the surgical incision. The surgeon removes the drains three to seven days after the operation, usually before the woman leaves the hospital. The nature and extent of scarring and deformity depends on the type of mastectomy. If there are skin sutures, they are usually ready for removal in five to seven days.

Risks and Complications

As with any surgery, the risks of mastectomy include excessive bleeding, INFECTION, and reaction to the anesthesia. These risks are slight. The potential for complications increases with the complexity of the surgery. Women who undergo modified radical mastectomy with axillary lymph node dissection may have significant swelling in the arm on the side of the surgery in the immediate postoperative recovery period as well as intermittently over the long term. Many women undergo adjuvant therapy (follow-up treatment), such as RADIATION THERAPY or CHEMOTHERAPY, after mastectomy for breast cancer. These therapies carry their own risks and do not usually affect the course of healing from the surgery.

Outlook and Lifestyle Modifications

With early detection and treatment, recovery from both the mastectomy and the breast cancer is complete. Recovery from modified radical mastectomy can take several months, with restrictions on lifting and some physical activities until the area fully heals and swelling (LYMPHEDEMA) is under control. It is difficult to predict who will have ongoing lymphedema; this is a significant long-term risk for any woman whose surgery includes axillary lymph node dissection. Women who choose not to have reconstructive surgery may opt instead for prosthetic bras. Many women have concerns about body image and sexuality; these are potentially significant issues that can affect QUALITY OF LIFE. Some women find SUPPORT GROUPS helpful.

See also CANCER TREATMENT OPTIONS AND DECISIONS; HORMONE-DRIVEN CANCERS; PAGET'S DISEASE OF THE BREAST; PLASTIC SURGERY; SURGERY BENEFIT AND RISK ASSESSMENT.

mastitis INFLAMMATION of the BREAST, typically due to bacterial INFECTION. Mastitis usually begins as a combination of events: a blocked milk duct in

the breast of a woman who is BREASTFEEDING an infant and cracks or breaks in the SKIN, usually around the nipple, that allow BACTERIA to enter the milk duct. Mastitis due to infection is less common in women who are not breastfeeding. Mastitis may also occur as a result of viral infection or become chronic for reasons the doctor cannot identify though are likely hormonal.

Bacterial Mastitis

The symptoms of bacterial mastitis include PAIN, redness on the skin above the area of the infection, and swelling or hardness at the site of the infection. Many women also have FEVER, chills, bodywide MUSCLE aches, and fatigue. It is important for breastfeeding women to continue breastfeeding, as the infant's sucking helps massage the blockage from the duct. Warm compresses or a heating pad to the breast also may help.

A course of treatment with an antibiotic medication generally results in rapid improvement of bacterial mastitis. The small amount of the antibiotic that enters the breast milk is not enough to affect the infant. The doctor may recommend an analgesic medication to relieve pain and fever. A complication of bacterial mastitis is breast ABSCESS, in which the infection forms a pocket within the breast tissue that requires minor surgery to open and drain, as well as a more extended course of antibiotics, so HEALING can take place.

ANTIBIOTIC MEDICATIONS TO TREAT BACTERIAL MASTITIS

amoxicillin-clavulanic acid	cephalexin
ciprofloxacin	clindamycin
cloxacillin	flucloxacillin

Nonbacterial Mastitis

Mastitis may also result from viral infection, most commonly as a result of the MUMPS VIRUS. Nonspecific chronic mastitis sometimes occurs in a pattern that follows a woman's MENSTRUAL CYCLE, suggesting it is hormonal in nature. The diagnostic path for nonbacterial mastitis often includes MAMMOGRAM (X-RAY of the breasts) and sometimes biopsy of an area of inflammation to rule out BREAST CANCER or other causes for the symptoms. When such findings are negative, treatment is generally NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) to relieve inflammation and pain. NSAIDs also influence the production and release of PROSTAGLANDINS, hormonelike substances that fluctuate in the BLOOD circulation during the menstrual cycle. Chronic mastitis is a common symptom of FIBROCYSTIC BREAST DISEASE.

See also ANALGESIC MEDICATIONS; ANTIBIOTIC MEDICATIONS; HORMONE; MASTALGIA.

masturbation Touching one's own body, and in particular the genitals, for sexual pleasure and typically to reach ORGASM. Masturbation is a normal behavior most common among adolescents and young adults. Masturbation does not cause adverse health effects, either of the genitals or health in general. For several centuries myths have persisted that masturbation causes blindness, mental illness or insanity, HAIR growth on the palms of the hands, INFERTILITY, and other problems. These myths arise from social and cultural attitudes toward masturbation, not from medical science. Excessive masturbation may indicate underlying psychologic or emotional conditions. Inappropriate masturbation (notably public masturbation) is often an indication of serious mental illness, DEMENTIA, or BRAIN damage (such as due to STROKE or trauma), conditions that disturb the normal inhibitory mechanisms of conscious behavior.

See also SEXUAL DYSFUNCTION; SEXUAL INTERCOURSE.

menarche A woman's first menstrual period, the start of MENSTRUATION and the beginning of FERTILITY. The average age of menarche varies among cultures and countries throughout the world and largely correlates with nutritional well-being. In the United States the average age of menarche is 12½; in rural regions of South Africa the average age of menarche is near age 14. The age of menarche has declined worldwide by nearly a year over the past century, which health experts believe reflects improved nutrition and overall health status. Many cultures celebrate menarche as a rite of passage that ushers a girl into womanhood.

See also AMENORRHEA; MENOPAUSE; MENSTRUAL CYCLE.

menopause A woman's last menstrual period, the end of MENSTRUATION and the closure of a

woman's FERTILITY. Though researchers understand the cascade of physiologic events that results in menopause, the triggering factors remain a mystery though many researchers believe a key triggering mechanism is the loss of viable eggs (ova). Doctors consider a woman to have reached menopause when she has experienced one continuous year (12 contiguous months) without menstrual periods. However, the common perception of menopause encompasses the period of time, often years, preceding menopause. Some people call this time PERIMENOPAUSE ("around menopause").

Though menopause is a natural life shift, not a health condition or disorder, many women experience discomforts as their bodies rebalance after HORMONE levels shift. Most notable among these discomforts are HOT FLASHES, irregular menstrual periods or abnormal vaginal bleeding, and mood changes. Not all women experience all or even any of these discomforts; some women experience additional or different discomforts such as joint pain and HEADACHE. The transition of menopause is a uniquely individual passage.

Indications of Menopause

The most defining indication of menopause is the discontinuation of menstruation. In most women this occurs as a gradual process during which menstrual periods become increasingly irregular both in timing and quality. A woman may have three periods that are three weeks apart and last eight or nine days each, have one three-day period six weeks later, then not have another period for four months. This pattern may extend over three to five years, during which a woman typically experiences other indications that her hormone levels are fluctuating and dropping. Such indications commonly include

- vaginal dryness and painful sexual intercourse
- hot flashes and night sweats
- tendency to cry, mood swings, and irritability
- difficulty sleeping
- diminished ability to concentrate and memory difficulties
- decreased LIBIDO (sex drive)
- anxiety or DEPRESSION

Some women barely notice any of these indications and other women find that they interfere with nearly all aspects of their lives. There are few clinical answers to explain the broad range of experience, nor to predict what course a particular woman's menopause experience will take. There is some indication that a woman tends to have an experience similar to her mother's, though whether the reasons are cultural or physiologic remains unknown.

Relieving Menopause Discomforts

There are numerous approaches to relieving the discomforts of menopause, some of which are clinical and others that are alternative and lifestyle. The more a woman understands the changes that are occurring in her body and the natural course they represent, the more effectively she can cope with their effects and choose methods of relief that are appropriate for her health status and her degree of discomfort. Many women find the most effective solutions involve a mix of methods, and that the mix changes as menopause progresses.

Hormone replacement therapy (HRT) For the last half of the 20th century doctors treated menopause with hormone replacement therapy (HRT), hormone supplementation to elevate the levels of ESTROGENS and PROGESTERONE in the BLOOD circulation. The intent of HRT was to bring up these levels enough to relieve discomforts without restoring the menstrual cycle. Doctors also believed HRT helped protect a woman from CARDIOVASCULAR DISEASE (CVD) and OSTEOPOROSIS, two conditions that can have dire consequences as a woman ages. The foundation for this belief was the sharp rise in incidence of HEART ATTACK and the high rate of osteoporosis among women after menopause who did not take HRT. It seemed that women who took HRT were less likely to have either condition. Many American women took HRT for the last half of their lives.

However, extensive clinical studies began to show in the early 2000s that contrary to these popular perceptions, HRT did not have a protective effect against CVD and had perhaps a limited protective benefit for osteoporosis. Further, HRT significantly increased the risk for some types of HORMONE-DRIVEN CANCERS, such as BREAST CANCER and ENDOMETRIAL CANCER. In 2002 health agencies

withdrew recommendations for routine long-term HRT, advising that doctors instead prescribe time-limited hormone supplementation to relieve menopausal discomforts only when they interfered with a woman's QUALITY OF LIFE. Under the current standard of practice guidelines most women should not take hormone supplementation for longer than two years, with a trial off the supplementation every six months to assess whether it remains necessary. Each woman's individual health circumstances require her doctor's careful evaluation to determine whether hormone supplementation is appropriate.

There is a sizable group of health-care professionals who prescribe BIHRT (bio-identical hormone replacement therapy). BIHRT utilizes hormones such as estradiol, progesterone, and testosterone that are chemically identical to those found in the woman's body. It is felt by many that not only do they not pose the same health risks as were identified in the WHI study but do actually provide numerous health benefits.

Nonhormonal approaches Selective serotonin reuptake inhibitors (SSRIs), a class of ANTIDEPRESSANT MEDICATIONS, have emerged as effective therapies to relieve hot flashes. Doctors usually prescribe these medications at doses lower than those typically used to treat depression. Researchers do not know the precise mechanisms through which SSRIs relieve hot flashes.

There are numerous alternative or complementary approaches to relieve menopausal discomforts, some of which show evidence of their success through clinical studies. Among them include ACUPUNCTURE, SOY, and the medicinal herb BLACK COHOSH, all to relieve hot flashes, and wild yam cream to relieve vaginal dryness. Soy and black cohosh contain PHYTOESTROGENS, plant-based substances that are similar to human estrogens and bind with estrogen receptors in the body, though with less intensity than endogenous estrogens. Wild yams contain a plant-based form of progesterone.

Other remedies are widely believed to provide relief but lack evidence, either because studies have not been done or have produced inconclusive or conflicting results. Among these are black cohosh to relieve mood swings and irritability and DONG QUAI, soy, and red clover to relieve hot flashes and other discomforts. Evening primrose oil and vitamin E supplements appear to help with relaxation and sleep.

ALTERNATIVE REMEDIES TO TREAT MENOPAUSAL DISCOMFORTS

ACUPUNCTURE	BLACK COHOSH
DONG QUAI	evening primrose oil
red clover	SOY
vitamin E	progesterone cream

Changes That Occur with Menopause

Estrogen has multiple and powerful actions in a woman's body and the decline of its presence after menopause results in changes that affect all body systems. One such action is a diminished ability to repair collagen structures in the body such as ligaments, tendons, and the SKIN. The loss of collagen may affect the ligaments in the abdomen that support the UTERUS, particularly in women who have given birth, resulting in UTERINE PROLAPSE. A good number of women experience URINARY INCONTINENCE as a result of weakening of the muscles that control the flow of URINE; KEGEL EXERCISES often improve or prevent this. The skin thins and becomes less elastic, resulting in wrinkles. Sebaceous secretions also diminish, causing the skin to become dry. The mucous lining of the VAGINA thins as well, resulting in reduced vaginal secretions. The more fragile vagina may produce symptoms such as burning and itching (VAGINITIS) and discomfort during SEXUAL INTERCOURSE.

Changes in collagen also affect the walls of the arteries, causing them to become less flexible and less able to relax (dilate). As well, estrogen plays a key role in the METABOLISM of cholesterol and fatty acids. As estrogen levels drop the body handles these lipids less efficiently. Consequently HYPERLIPIDEMIA, ATHEROSCLEROSIS, and HYPERTENSION (high BLOOD PRESSURE) become more common after menopause. In addition, loss of estrogen (specifically estradiol) can contribute to HYPOTHYROIDISM and increased CORTISOL potentially leading to INSULIN RESISTANCE. Estrogen also acts as a natural selective serotonin reuptake inhibitor (SSRI) so its loss contributes to increased DEPRESSION. Nutritious EATING HABITS and daily physical exercise become especially important to maintain cardiovascular health in light of these changes.

Estrogen is also essential for maintaining the content of calcium and other bone-building minerals. After menopause calcium more easily leaves the bones and is less easily absorbed into the blood circulation from dietary sources, a double effect that can rapidly result in osteoporosis. More than two thirds of women over age 65 have some degree of osteoporosis. Calcium supplementation in combination with RESISTANCE EXERCISE (also called weight-bearing exercise) helps the bones to retain the calcium they require to remain dense and strong.

See also AMENORRHEA; BONE; BONE DENSITY; CHOLESTEROL, ENDOGENOUS; EXERCISE AND HEALTH; GENERAL ANXIETY DISORDER (GAD); HYSTERECTOMY; MEDICINAL HERBS AND BOTANICALS; MENARCHE; PREMATURE OVARIAN FAILURE (POF).

menstrual cramps See DYSMENORRHEA.

menstrual cycle The pattern of hormonal and physiologic changes that occur that occur in a woman's body in preparation for possible PREGNANCY. Though the average menstrual cycle spans 28 days, the frequency of MENSTRUATION varies widely among women and often within each woman individually. Menstrual cycles may be as short as 25 days or as long as 32 days and still be within the range of normal. Menstrual cycles outside these parameters may or may not be normal, depending on the woman's individual physiology and health status. The endocrine system directs the menstrual cycle.

Physiologic Phases of the Menstrual Cycle

There are four phases within the menstrual cycle that always occur in the same order:

1. The proliferative phase begins with the end of menstruation and the return of the endometrium (lining of the UTERUS) to its nonmenstrual state and culminates with OVULATION about 14 days after the onset of menstruation. During proliferation the level of ESTROGENS in the BLOOD circulation rises and the level of PROGESTERONE drops. The changing hormone levels stimulate the maturation of up to 20 ova within their ovarian follicles, called ripening. The follicle containing the first ovum to reach full maturity ruptures and releases the ovum into the fluid surrounding the fimbriae (fluted edges) of the fallopian tube. The other follicles that had started to develop then shrink; the ovary absorbs them and their ova.
2. The expelled ovum leaves behind the corpus luteum, a structure of endocrine tissue that begins secreting estrogens and progesterone. This period of activity by the corpus luteum is the luteal phase, also called the secretory phase. The increased blood levels of the hormones cause the endometrium to thicken and its blood vessels to enlarge. The glands that line the endometrium increase their secretions, and the inner endometrium becomes spongy and engorged in preparation to support implantation should CONCEPTION occur. The luteal phase lasts about 10 days.
3. When the ovum passes through the uterus without implanting, the corpus luteum involutes (turns in on itself) and the follicle absorbs it. The sudden drop in estrogens and progesterone causes the endometrial blood vessels to contract, called endometrial ischemia. The endometrial glands stop their secretions and the endometrium dramatically shrinks. This third phase of the menstrual cycle, called the ischemic phase, lasts 36 to 48 hours.
4. The culminating phase of the menstrual cycle is menstruation, during which the anemic (blood-deprived) tissue of the endometrium sloughs away and passes from the body. The menstrual flow contains tissue fragments, endometrial secretions, and blood. Menstruation lasts 3 to 5 days in 85 percent of women; about 15 percent of women menstruate for 7 days. Though menstruation is the last phase of the menstrual cycle, doctors consider the first day of menstrual bleeding to be the start of the menstrual cycle.

Endocrine Regulation of the Menstrual Cycle

The HYPOTHALAMUS, PITUITARY GLAND, and corpus luteum regulate the menstrual cycle. The hypothalamus initiates the proliferative phase of the menstrual cycle by releasing GONADOTROPIN-RELEASING HORMONE (GNRH). GnRH stimulates the pituitary gland to secrete a surge of FOLLICLE-STIMULATING

HORMONE (FSH), which induces an ovarian follicle to begin secreting estrogens. The estrogens cause the ovum within the follicle to begin ripening. The rising level of estrogens in the blood circulation triggers the hypothalamus to again release GnRH, which this time stimulates the pituitary gland to secrete LUTEINIZING HORMONE (LH). LH causes the ovarian follicle to produce progesterone, which brings the ovum to maturity and release (ovulation). Without pregnancy the blood levels of estrogens and progesterone both fall and menstruation takes place.

Disturbances of the Menstrual Cycle

Numerous factors may disrupt the menstrual cycle, the most common being pregnancy. When a fertilized ovum (ZYGOTE) implants in the endometrium, the menstrual cycle ends and pregnancy begins. The menstrual cycle does not return until six to eight weeks (and sometimes longer, up to months in women who are breastfeeding) after CHILDBIRTH. Hormonal imbalances may also disrupt the menstrual cycle. HYPOTHYROIDISM (underactive THYROID GLAND) or HYPERTHYROIDISM (overactive thyroid gland) is a common source of such hormonal disruption. Disorders of the pituitary gland, such as pituitary ADENOMA, or the ADRENAL GLANDS, such as ADRENAL INSUFFICIENCY, often alter the body's endocrine matrix in ways that affect the menstrual cycle.

Numerous medications and treatments such as CHEMOTHERAPY and RADIATION THERAPY may affect ovarian function. Menstrual disturbances may occur as a result of underlying health conditions such as POLYCYSTIC OVARY SYNDROME (PCOS), OBESITY, anorexia, and extreme emotional or physical stress. Though a normal menstrual cycle often occurs with a single functioning ovary, the absence or loss of both OVARIES ends the menstrual cycle. OOPHORECTOMY is the surgical OPERATION to remove an ovary. Women who participate in intense athletic activities, such as marathons and triathlons, may have irregular menstrual cycles or AMENORRHEA (absence of menstruation).

For further discussion of the menstrual cycle within the context of the structures and functions of reproduction and sexuality, please see the overview section "The Reproductive System." For further discussion of the menstrual cycle within the context of the structures and functions of the endocrine system, please see the overview section "The Endocrine System."

See also DYSFUNCTIONAL UTERINE BLEEDING (DUB); DYSMENORRHEA; FALLOPIAN TUBES; FERTILITY; INFERTILITY; MENARCHE; MENOPAUSE; PREMATURE OVARIAN FAILURE (POF); PREMENSTRUAL SYNDROME (PMS).

menstruation The final phase of the MENSTRUAL CYCLE, commonly called the menstrual period or simply the period. Menstruation is the discharge of BLOOD and excess tissue that build up within the UTERUS as endometrium (the lining of the uterus) thickens and engorges with blood in preparation for the implantation of a fertilized ovum (ZYGOTE). When PREGNANCY does not occur, hormonal changes cause the lining to slough away, passing from the uterus and out of the body via the VAGINA. Typically a woman passes two to three ounces of blood and other fluids over the course of the three to seven days she menstruates. The menstrual flow is generally heaviest on the second through the fourth days. About 85 percent of women menstruate for four to five days; about 15 percent menstruate for six to seven days.

Women typically use disposable sanitary napkins (commonly called pads) or tampons to capture the menstrual flow. Pads have adhesive strips that attach them to underwear; tampons fit inside the vagina. It is important to change either pads or tampons every four to six hours to prevent overflow and maintain appropriate PERSONAL HYGIENE. Tampons may irritate the vaginal walls. Because a tampon may carry BACTERIA into the vagina when the woman inserts, tampon use involves a slight risk for TOXIC SHOCK SYNDROME, a potentially life-threatening INFECTION. Doctors recommend using pads at night and during other times when it might not be possible or practical for a woman to change her sanitary protection every four to six hours.

There are no health reasons for women to avoid their regular activities, including sports, bathing, and sexual activity if desired, during menstruation. Women may prefer to shower when menstruating. Washing the GENITALIA with gentle soap and warm water is important to cleanse any accumulated menstrual fluids from the genital tissues, which reduces the presence of

bacteria as well as improves comfort. Many women wear tampons during athletic activities such as bicycling, swimming, dancing, and running. However, a woman should not sit in the bath tub or in a hot tub while wearing a tampon because the combination of heat and inactivity may draw bacteria into the vagina via the tampon's removal cord, which extends from the vaginal opening. A woman should also change her tampon immediately after water activities such as swimming.

For further discussion of menstruation within the context of the structures and functions of reproduction and sexuality, please see the overview section "The Reproductive System."

miscarriage See ABORTION.

mittelschmerz Discomfort a woman may feel on one side of her lower abdomen around the time she ovulates. The word is German for "middle PAIN," a reference to the occurrence of the discomfort midway through the MENSTRUAL CYCLE. The discomfort is often a sharp, achy pain that most commonly lasts from 2 to 12 hours though may continue up to 48 hours. Some women find the discomfort shifts sides from one menstrual period to another and some women have discomfort always on the same side. The side of the pain does not necessarily indicate which ovary is releasing an ovum as ovarian pain may refer to the opposite side of the lower abdomen.

Doctors believe mittelschmerz results from irritation the released ovum and the fluids that surround it create in the abdominal cavity, or from the pressure of the ovarian follicle immediately before its rupture to release the ovum. Mittelschmerz is a normal part of the menstrual cycle for many women and does not signal any underlying health concerns, though a doctor should evaluate any changes that may occur in the nature of the discomfort.

See also OVA; OVARIAN CYST; OVULATION.

morning sickness The NAUSEA and VOMITING that may occur during PREGNANCY, notably in the first trimester though it may continue through the second trimester and occasionally for the duration of the pregnancy. The term morning sickness is a misnomer as the nausea may occur at any time, day or night. However, many women do experience the nausea of pregnancy primarily in the morning when they first awaken. Many women find certain odors, tastes, or even appearances of food act as triggers for morning sickness.

Though doctors do not know for certain what causes morning sickness, they believe it is a reaction to the multitude of hormonal changes rapidly taking place in the woman's body as the pregnancy establishes itself. The onset of morning sickness, typically at about six weeks into the pregnancy, correlates with the surge of human chorionic gonadotropin (hCG) that emerges from the newly formed PLACENTA. Morning sickness, though disruptive, is not harmful for the pregnancy unless it prevents the woman from drinking enough water to remain hydrated. Most weight gain in pregnancy occurs in the second and early part of the third trimesters, and most women are able to eat enough to remain well nourished.

Nonpharmaceutical remedies for morning sickness include

- gingerroot shavings or tea
- flat GINGER ale (made with real ginger)
- cola syrup (available in drugstores) or flat cola soda
- soda crackers (such as saltines)
- not mixing solids and liquids
- small meals eaten frequently throughout the waking hours, and small snacks when awake during the night, so there is always something in the STOMACH
- ACUPUNCTURE or acupressure (including motion sickness wristbands that apply pressure to acupuncture points for nausea)

If these efforts are unsuccessful and morning sickness interferes with normal eating and drinking, the doctor may recommend or prescribe ANTIEMETIC MEDICATIONS that are safe to take during pregnancy. Some women experience relief with vitamin B_6 supplement, though doctors are unsure why this is. Because some medications may be

harmful to, or have unknown effects on, the developing FETUS, it is important to talk with the doctor before taking any medication or herbal remedy.

The doctor may consider intravenous fluids and nutrition for women who experience severe, extended morning sickness (called hyperemesis gravidarum), though the need for such intervention is uncommon. Morning sickness is more common in women who have a history of migraine HEADACHE, motion sickness, or morning sickness in previous pregnancies. Morning sickness is also more common in women who are pregnant with multiples (twins or higher).

See also PRENATAL CARE; VITAMINS AND HEALTH.

nabothian cyst A mucous-filled growth that develops within a nabothian gland. The nabothian glands are clusters of mucous-secreting cells on the surface of the CERVIX. Nabothian cysts are very common, cause no symptoms, and present no health risk. Typically the health-care provider discovers nabothian cysts, which are hard and pimplelike, during routine PELVIC EXAMINATION. Occasionally the doctor may choose to further examine nabothian cysts using COLPOSCOPY to confirm the diagnosis.

See also BARTHOLIN'S CYST; PAP TEST.

neonatal jaundice A condition in which the newborn infant's LIVER cannot yet properly destroy old erythrocytes (red BLOOD cells), resulting in the accumulation of BILIRUBIN in the blood circulation. The excessive bilirubin, a pigmented protein compound, gives the SKIN a characteristic yellowish orange hue. Neonatal JAUNDICE, also called physiologic jaundice of the newborn, is more common in infants born before 37 weeks gestational age because of the immaturity of their livers.

Mild neonatal jaundice clears on its own within a few days. The doctor may prescribe photolight therapy (also called PHOTOTHERAPY) for moderate neonatal jaundice, a treatment that exposes the infant's skin to short periods of ultraviolet light. Ultraviolet light expedites the chemical breakdown of the bilirubin so the body can excrete it.

Circumstances of jaundice in a newborn may result from numerous pathologic causes including BILIARY ATRESIA (absence of the BILE DUCTS), BOWEL ATRESIA (absence of the large intestine), hemolytic disease of the newborn (Rh incompatibility), and congenital HEPATITIS B.

See also ANEMIA; BLOOD TYPE; ERYTHROCYTE.

nocturnal emission ORGASM and EJACULATION that occur when a boy or man is asleep. Nocturnal emissions are natural and normal across the age spectrum from ADOLESCENCE through old age, though are most common during adolescence when SECONDARY SEXUAL CHARACTERISTICS are developing and HORMONE levels are rising. Researchers believe nocturnal emissions often occur during dreams (thus the casual term "wet dreams") though the man may not remember dreaming.

See also AGING, REPRODUCTIVE AND SEXUAL CHANGES THAT OCCUR WITH; MASTURBATION; PUBERTY; SEXUAL HEALTH.

oophorectomy A surgical OPERATION to remove one ovary (unilateral oophorectomy) or both OVARIES (bilateral oophorectomy) in a woman. Oophorectomy may be therapeutic (to treat a health condition) or prophylactic (to prevent a health condition).

The key health conditions for which therapeutic oophorectomy is an option include OVARIAN CANCER, severe ENDOMETRIOSIS, ovarian ABSCESS (INFECTION of the ovary), and large or multiple ovarian cysts. Prophylactic oophorectomy is an effort to lower the possibility for developing HORMONE-DRIVEN CANCERS (ovarian, breast, endometrial) in a woman who has unusually high risk for such cancers, either genetically or because of a prior such cancer. Removing both ovaries cuts a woman's estrogen production to almost nothing, mostly depriving hormone-sensitive cancer cells of the substance they require to thrive.

Unilateral oophorectomy often allows a woman to preserve her FERTILITY because the remaining ovary, if healthy, continues to produce hormones and OVA (eggs) that maintain the MENSTRUAL CYCLE. Bilateral oophorectomy entirely ends ovarian function and the menstrual cycle, resulting in abrupt MENOPAUSE in women who are still menstruating at the time of surgery. Such surgically induced menopause, because it is sudden, may thrust the body into significant symptoms such as HOT FLASHES.

The operation for either unilateral or bilateral oophorectomy may be OPEN SURGERY, in which the surgeon makes an incision in the lower abdomen large enough to expose the ovary, or MINIMALLY INVASIVE SURGERY, in which the surgeon makes several small incisions in the lower abdomen and visualizes the operative site using a laparoscope. The type of operation depends on multiple factors including the reason for the oophorectomy and the woman's general health status. Open oophorectomy requires three to five days of hospitalization and six to eight weeks for recovery. Laparoscopic oophorectomy is often an ambulatory (outpatient) surgery with rapid recovery and return to regular activities within a week or two. About half of total hysterectomies (operations to remove the UTERUS) also include removal of the ovaries (hystero-oophorectomy) or the ovaries and the FALLOPIAN TUBES (hysterosalpingo-oophorectomy).

The short-term risks of oophorectomy include excessive bleeding and postoperative infection. The key long-term complication of bilateral oophorectomy is OSTEOPOROSIS (loss of BONE DENSITY), the risk for which arises from the depletion of estrogen.

See also BRCA-1/BRCA-2; BREAST CANCER; CANCER TREATMENT OPTIONS AND DECISIONS; CA-125; ENDOMETRIAL CANCER; HYSTERECTOMY; LASER SURGERY; MINIMALLY INVASIVE SURGERY; ORCHIECTOMY; OVARIAN CYST; SURGERY BENEFIT AND RISK ASSESSMENT.

orchiectomy A surgical OPERATION to remove one testicle (unilateral orchiectomy) or both TESTICLES (bilateral orchiectomy) in a man. Unilateral orchiectomy is typically a treatment for TESTICULAR CANCER or severe TESTICULAR TORSION in which the testicle becomes gangrenous due to prolonged loss of BLOOD circulation. Bilateral orchiectomy is typically a treatment for advanced PROSTATE CANCER.

The testicles produce both TESTOSTERONE and SPERM. Many men who undergo unilateral orchiectomy retain their FERTILITY and full sexual function. However, other treatment such as CHEMOTHERAPY may affect sperm production and thus fertility. Bilateral orchiectomy ends produc-

tion of both testosterone and sperm, resulting in permanent INFERTILITY. The intent of bilateral orchiectomy is to cut the supply of testosterone that feeds prostate cancer cells, as prostate cancer is one of the HORMONE-DRIVEN CANCERS. The resulting precipitous decline in testosterone production often also diminishes LIBIDO (sex drive) and may cause ERECTILE DYSFUNCTION (difficulty achieving or sustaining an ERECTION).

For unilateral orchiectomy the surgeon removes the testicle through an incision in the lower abdomen, just above the pubic HAIR line. The incision exposes the inguinal canal, a passage of ligaments through which the testicles originally descended into the SCROTUM. The surgeon manipulates the testicle upward from the scrotum into the lower abdomen, extracting it through the incision. This procedure prevents damage to the scrotum that could allow cancer cells to escape into the LYMPH nodes; the testicles and the scrotum use different lymph networks so the surgeon does not want to disturb the scrotum or create a circumstance in which cells from the testicle can enter the lymph nodes that serve the scrotum. For bilateral orchiectomy as prophylactic treatment for advanced prostate cancer the surgeon may make the incision in the scrotum.

The key risks of orchiectomy include excessive bleeding and INFECTION. Unilateral orchiectomy sometimes lowers testosterone levels, which the doctor may treat with testosterone supplementation. Long-term complications that occur with bilateral orchiectomy include loss of BONE DENSITY and increased risk for OSTEOPOROSIS, GYNECOMASTIA (enlarged breasts), and erectile dysfunction.

See also GANGRENE; OOPHORECTOMY; ORCHIOPEXY; SURGERY BENEFIT AND RISK ASSESSMENT.

orchiopexy A surgical OPERATION to correct an undescended testicle (CRYPTORCHIDISM). Nearly always the operation takes place early in childhood, typically between ages six and 12 months. In many situations the operation is an outpatient procedure the surgeon can perform in an AMBULATORY SURGICAL FACILITY, usually with general ANESTHESIA.

The surgeon makes two incisions, one in the lower abdomen and one in the SCROTUM. The abdominal incision provides access to the undescended testicle, which the surgeon manipulates through the inguinal canal (a passageway through the ligaments supporting the pelvic floor) and into the scrotum. Through the incision in the scrotum the surgeon sutures (stitches) the testicle to the inside of the scrotum so it cannot reascend.

The primary risks of orchiopexy are excessive bleeding and INFECTION, both of which are uncommon. Recovery is typically rapid, with HEALING complete within two weeks. When done early in childhood, orchiopexy preserves FERTILITY. However, an increased risk for TESTICULAR CANCER remains, making TESTICULAR SELF-EXAMINATION an important screening procedure.

See also ORCHIECTOMY; SURGERY BENEFIT AND RISK ASSESSMENT; TESTICLES.

orchitis INFLAMMATION of one testicle or both TESTICLES, often due to INFECTION. Bacterial infection may result from SEXUALLY TRANSMITTED DISEASES (STDS) such as GONORRHEA or SYPHILIS. MUMPS, a viral INFECTION that primarily affects the SALIVARY GLANDS, is a common cause of orchitis, particularly when the mumps VIRUS infects adult men.

The symptoms of orchitis are PAIN and swelling of the involved testicle. The diagnostic path includes physical examination of the SCROTUM and testicles and sometimes ULTRASOUND to rule out other causes of similar symptoms such as TESTICULAR TORSION, HYDROCELE, or VARICOCELE.

Treatment with ANTIBIOTIC MEDICATIONS is necessary when the infection is bacterial. NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) relieve pain and inflammation regardless of the cause. Resting in a reclining position or wearing an athletic supporter also provides relief. A complication of orchitis may be testicular atrophy (reduced size of the affected testicle), which may affect SPERM production and FERTILITY. An atrophied testicle also presents an increased risk for TESTICULAR CANCER, making routine TESTICULAR SELF-EXAMINATION prudent.

See also BACTERIA; EPIDIDYMITIS.

orgasm Intense sensation of pleasure and excitement that occurs at the culmination of sexual stimulation. Involuntary contractions of the pelvic muscles typically accompany orgasm. In men these contractions result in EJACULATION, propelling SEMEN from the urethral opening (meatus) at the

tip of the PENIS. In women the contractions of orgasm occur as rhythmic waves along the walls of the VAGINA. Aside from being a source of intense pleasure, orgasm appears to serve as a mechanism to facilitate the movement of SPERM through the vagina. This is important from a reproductive perspective as the vagina presents a fairly hostile environment for sperm, which are not able to survive longer than an hour or two within it.

Though a man can have an orgasm without ejaculating, he cannot ejaculate without orgasm. After orgasm a man enters a refractory period during which his body recovers from the experience. During this time the mechanism of ERECTION does not respond to sexual stimulation and many men feel the overwhelming desire to fall asleep. The length of the refractory period varies with age and among men, ranging from 10 to 20 minutes for a man in his 20s to an hour or longer for a man 50 or older. A woman does not have a refractory period and may continue or revive sexual arousal indefinitely. The consistent inability to reach orgasm is a form of SEXUAL DYSFUNCTION that may have physiologic or emotional foundations.

See also ERECTILE DYSFUNCTION; MASTURBATION; RETROGRADE EJACULATION; SEXUAL INTERCOURSE.

ova The female cells of reproduction, also called eggs or gametes. An ovum, also called an oocyte (single egg cell), is a haploid cell; it contains one half of the genetic material necessary for human life. At birth the OVARIES contain about 400,000 follicles, each of which holds a single immature ovum. At PUBERTY the follicles begin to ripen, with usually one ovum coming to maturity with each MENSTRUAL CYCLE. Over the course of a woman's reproductive years her ovaries produce 400 to 600 ripened ova. About 10 to 20 times as many ova begin but do not complete the maturation process. The ovaries eventually absorb ova that fail to reach maturity.

Ovulation The sequence of hormonal and physiologic changes that bring an ovum to maturity is OVULATION, which takes place during the start of the menstrual cycle's luteal phase around day 14 of the menstrual cycle (day 1 being the first day of MENSTRUATION). The PITUITARY GLAND releases first a surge of FOLLICLE-STIMULATING HORMONE (FSH), which activates an ovarian follicle. The follicle secretes ESTROGENS, which begin the maturation process for the ovum the follicle contains. The pituitary gland then secretes LUTEINIZING HORMONE (LH), which induces the ovarian follicle to produce PROGESTERONE. The progesterone brings the ovum to full maturity and the follicle ruptures, releasing the ovum for capture into the fallopian tube.

Fertilization, implantation, and conception The smooth MUSCLE walls of the fallopian tube contract in a gentle, wavelike pattern that draws the ovum through the tube toward the UTERUS. When SPERM are also present in the fallopian tube, fertilization takes place. Typically, though many sperm attempt to penetrate the outer membrane of the ovum only one succeeds. The chemical composition of the ovum's membrane alters once the sperm is within the ovum, preventing other sperm from following. The nuclei of the gametes (ovum and sperm) fuse to form a single diploid cell, called a ZYGOTE. As the zygote moves along the fallopian tube toward the uterus it continues to grow and divide. By the time the zygote reaches the uterus it has become a two-layered mass of cells called a blastocyst. The outer layer of the blastocyst attaches to the endometrium; as pregnancy continues this layer becomes the PLACENTA and the inner layer develops into the EMBRYO. The completion of fertilization and implantation is CONCEPTION.

For further discussion of the ova within the context of the structures and functions of reproduction and sexuality, please see the overview section "The Reproductive System."

ovarian cancer A malignant (cancerous) tumor that develops in the tissues of the ovary. Ovarian cancer may arise from any of the ovary's three types of cells—germ, stromal, and epithelial—though about 90 percent of ovarian cancers arise from the ovarian epithelium (the membranous covering of the ovary). Ovarian epithelial cancer occurs most commonly in women over age 60 (after MENOPAUSE). Though tumors are typically noncancerous or cancerous, ovarian epithelial

tumors may straddle the border. Doctors classify such tumors as low malignant potential (LMP); though cancerous these tumors grow slowly, have little propensity to metastasize (spread) and usually respond very well to treatment. Ovarian epithelial cancer that develops in women under age 60 is often LMP. Ovarian germ cell cancer and ovarian stromal cell cancer are rare; they are more likely to occur in women under age 50 (before menopause).

Doctors in the United States diagnose ovarian cancer in about 22,000 women each year. Because ovarian cancer typically causes few symptoms until it has metastasized (spread), the prognosis (outlook) for ovarian cancer overall is rather bleak. However, early diagnosis allows successful treatment and a promising outlook. Any woman who has her OVARIES is vulnerable to ovarian cancer, even if she has had a HYSTERECTOMY (OPERATION to remove the UTERUS). Bilateral OOPHORECTOMY (operation to remove both ovaries) ends the risk for ovarian cancer, though it remains possible for epithelial cancer very much like ovarian cancer to develop in the peritoneum, the membranous lining of the abdominal cavity.

Symptoms and Diagnostic Path

Early symptoms of ovarian cancer are often generalized and vague. Both the woman and her doctor commonly mistake them for symptoms of gastrointestinal disorders. These early symptoms may include

- sensation of abdominal bloating
- abdominal swelling
- unexplained weight gain
- changes in bowel habits (CONSTIPATION or DIARRHEA)
- urinary urgency

As ovarian cancer progresses, symptoms become more specific and include

- pelvic, abdominal, or low BACK PAIN
- unexplained weight loss
- unusual vaginal bleeding
- fatigue and general sense of not feeling well (malaise)
- persistent gastrointestinal symptoms (NAUSEA, VOMITING, diarrhea, or constipation) that do not vary with eating patterns

The diagnostic path includes comprehensive medical examination including PELVIC EXAMINATION, BLOOD tests (cell count and differentiation as well as CA-125), abdominal ULTRASOUND or COMPUTED TOMOGRAPHY (CT) SCAN, and often COLONOSCOPY.

Blood levels of the protein CA-125 are often elevated in moderate to advanced ovarian cancer though not in early ovarian cancer. As well, numerous noncancerous conditions can elevate CA-125 blood levels. Though the doctor may consider the CA-125 level among the diagnostic indicators, it does not alone confirm or rule out diagnosis of ovarian cancer. Other tumor markers include ALPHA-FETOPROTEIN (AFP), HUMAN CHORIONIC GONADOTROPIN (hCG), and CARCINOEMBRYONIC ANTIGEN (CEA).

Because benign tumors and cysts of the ovaries are common, noninvasive diagnostic procedures often cannot determine whether an ovarian growth is cancerous or noncancerous. The only certain diagnostic procedure is laparoscopy or laparotomy, both of which are surgical operations to enter the abdominal cavity, to view the ovary and remove samples of tissue (biopsy). Laparoscopy is a MINIMALLY INVASIVE SURGERY in which the surgeon uses several small incisions through which he or she inserts an endoscope (flexible, lighted viewing instrument) and specialized instruments to visualize the ovary via display on a monitor. Laparotomy is an OPEN SURGERY in which the surgeon makes a substantial incision through the SKIN in the abdomen and examines the ovary directly.

The pathologist who examines the tissue samples determines the type of cancer cells that are present and assesses the extent to which they are likely to have spread to locations outside the ovary. The results of this assessment, called STAGING AND GRADING OF CANCER, help guide treatment decisions. The pathologist also may revise the stage or grade may change after surgery to remove the cancer, depending on the surgeon's findings and the character of the cancer cells within the tumor.

BASIC STAGING OF OVARIAN CANCER

Stage	Meaning	Treatment Options
low malignant potential (LMP)	tumor is borderline cancerous and slow growing	surgery to remove the involved ovary (unilateral OOPHORECTOMY)
stage 1	cancer remains confined to a local tumor in one ovary	surgery (bilateral salpingo-oophorectomy, total HYSTERECTOMY, omentectomy, and lymphadenectomy) intraperitoneal CHEMOTHERAPY, RADIATION THERAPY with follow-up single DRUG chemotherapy, or combination (multiple drug) chemotherapy
stage 2	cancer involves both OVARIES or has spread to the FALLOPIAN TUBES, UTERUS, or tissue within the pelvis	surgery (bilateral salpingo-oophorectomy, total hysterectomy, omentectomy, and LYMPH NODE dissection) combination chemotherapy, four to six cycles
stage 3	cancer has spread to other organs in the abdomen, the peritoneum, and abdominal LYMPH nodes	surgery (bilateral salpingo-oophorectomy, total hysterectomy, omentectomy, and lymph node dissection) and debulking surgery combination chemotherapy, four to six cycles
stage 4	cancer has spread to distant organs	debulking surgery combination chemotherapy, multiple cycles "second look" surgery to remove remaining cancerous tissue
stage 4/recurrent	cancer has returned after treatment	combination chemotherapy IMMUNOTHERAPY clinical trial of appropriate investigational new treatments high-DOSE chemotherapy with autologous bone marrow therapy (STEM CELL support) palliative surgery for symptom relief

Treatment Options and Outlook

The treatment of first choice for nearly all ovarian cancers is surgery to remove the ovary that contains the tumor. In all ovarian cancers except LMP, surgery also includes removal of the rest of the pelvic reproductive organs—both ovaries, both FALLOPIAN TUBES, uterus, and CERVIX—as well as the omentum (a layer of fatty tissue that covers the interior of the peritoneum) and nearby LYMPH nodes (lymphadenectomy). Because ovarian cancer tends to spread in layers of cells that cover the pelvic or abdominal structures, the surgeon removes as much of it as possible through a procedure called debulking. Debulking may also involve removing segments of the SMALL INTESTINE.

Most women also receive adjuvant therapy (follow-up treatment) with CHEMOTHERAPY, RADIATION THERAPY, or both. Treatment with a single chemotherapy agent is often sufficient to treat early stage 1 ovarian cancer, though many oncologists prefer combination chemotherapy or radiation therapy with single-agent chemotherapy after. Multiple cycles of combination chemotherapy are the current standard of treatment for stage 2 through stage 4/recurrent ovarian cancer. Some chemotherapy agents are available in oral forms

(pills), which a woman can take at home, and others are available only in intravenous injectable forms, which require administration at a chemotherapy center.

CHEMOTHERAPY AGENTS TO TREAT OVARIAN CANCER	
cisplatin	doxorubicin
etoposide	ifosfamide
melphalan	paclitaxel
topotecan	

High-dose chemotherapy with autologous BONE MARROW therapy, also called STEM CELL support, is often effective in providing short-term REMISSION in stage 4 ovarian cancer. However, many cancer experts question whether the high risk and cost of this treatment ultimately improves a woman's QUALITY OF LIFE and LIFE EXPECTANCY. For many women, investigational treatments provide equal or better results with significantly less severe side effects and complications.

Because the spread of ovarian cancer within the abdominal cavity is so diffuse, early detection and treatment are particularly essential. Surgery is most effective when the tumor remains confined to the ovary; treatment is most effective when the surgeon is able to remove all of the cancer. The outlook for remission with early treatment is very good. Later stage ovarian cancer is difficult to control because the surgeon cannot remove all of the cancer. Chemotherapy provides highly effective treatment though side effects can be significant. Later stage ovarian cancer has a tendency to recur after remission, though each period of remission may last three to five years.

Risk Factors and Preventive Measures

The primary risk factors for ovarian cancer are age greater than 60 years and family history of ovarian cancer, especially among first-degree relatives (mother, daughter, sister). Women who carry the BRCA-1/BRCA-2 GENE mutations have especially high risk, though not the certainty, to develop ovarian cancer. Some women who have such high risk choose prophylactic oophorectomy (surgery to remove the ovaries) when they reach the end of their childbearing years or menopause as a means for reducing their risk.

The causes of ovarian cancer are unclear, though there appear to be hormonal correlations. Women who carry at least one pregnancy to delivery, breastfeed, or take oral contraceptives (birth control pills) for longer than three years, or have a TUBAL LIGATION or a total hysterectomy (surgery to remove the uterus and cervix) for reasons other than cancer appear significantly less likely to develop ovarian cancer. Lifestyle factors such as the fat content of the diet and the frequency of physical exercise also correlate to the risk for ovarian cancer, with the risk much lower in women who eat a low-fat diet and get daily physical exercise (minimum 30 to 60 minutes). Cigarette smoking raises the risk for ovarian cancer, as it does for many cancers.

Though many ovarian tumors are difficult to palpate (feel), health experts recommend routine pelvic examination as a means of possible early detection of ovarian cancer. However, the PAP TEST that often accompanies a pelvic examination, while very effective for detecting early CERVICAL CANCER, does not detect ovarian cancer. The schedule of examination varies with age and health status, though women at high risk for ovarian cancer should have annual pelvic examinations.

ovarian cyst A noncancerous, fluid-filled growth that forms within an ovary. Ovarian cysts are common and many are transient (come and go). The most common type of ovarian cyst is a follicular cyst, which develops in an ovarian follicle. Typically the follicle fills with fluid. Over time the fluid reabsorbs into the follicle and the cyst goes away. Sometimes a follicular cyst ruptures, causing sudden PAIN. Cysts may also form in the corpus luteum, the structure of endocrine tissue that supports a ripened ovum. Such a cyst, called a luteal cyst, typically goes away when the corpus luteum involutes (turns in on itself) and becomes absorbed into the ovarian follicle immediately preceding MENSTRUATION. Follicular cysts and luteal cysts are usually functional—that is, they come and go with the hormonal shifts of the MENSTRUAL

CYCLE. Ovarian cysts are occasionally pedunculated (growing on the end of stalks). Such cysts may twist on their peduncles and become gangrenous, which is an emergency situation requiring surgery.

Dermoid cysts, also called teratomas or germ cell cysts, are much less common though more troublesome because they can grow quite large. The key characteristic of a dermoid cyst is that it consists primarily of epithelial tissue though may also contain fatty tissue and fragments of HAIR, CARTILAGE, BONE, and sometimes TEETH. Dermoid cysts are congenital (present from birth). Doctors do not know how they occur though believe they arise from cells that escape migration when the three layers of the early EMBRYO (mesoderm, ectoderm, and endoderm) develop.

The doctor detects most ovarian cysts incidentally during routine PELVIC EXAMINATION or ULTRASOUND of the lower abdomen done for other reasons. When a woman does have symptoms they are often nonspecific in nature, such as abdominal bloating or pressure, CONSTIPATION, URINARY INCONTINENCE or URINARY FREQUENCY, or pain during SEXUAL INTERCOURSE (dyspareunia). Abdominal or transvaginal ultrasound or abdominal COMPUTED TOMOGRAPHY (CT) SCAN help the doctor confirm the diagnosis. When these diagnostic imaging procedures are not conclusive, the doctor may perform diagnostic laparoscopy to look at the cyst and take a tissue sample for biopsy.

Most ovarian cysts go away without treatment or intervention. The gynecologist may recommend surgical removal of an ovarian cyst that is large, persistent, or symptomatic (causes discomfort, irregular menstrual periods, or bleeding) or when the cyst has suspicious features that cause the gynecologist to want to rule out OVARIAN CANCER. Though ovarian cysts are not cancerous and very seldom become cancerous, they can co-exist with cancerous tumors. As well, ovarian cancer tumors commonly have cystic characteristics. Often it is possible to remove the cyst without damaging the ovary. When the cyst is large or questionable the surgeon may need to remove the entire ovary (OOPHORECTOMY). As long as the remaining ovary is healthy and functional, removing a single ovary does not affect the menstrual cycle or FERTILITY.

See also OVARIES; SURGERY BENEFIT AND RISK ASSESSMENT.

ovaries The female organs of reproduction, also called the female gonads. The ovaries produce OVA (eggs) and sex hormones, predominantly ESTROGENS and PROGESTERONE as well as small amounts of ANDROGENS. A woman has two ovaries, one ovary on each side of the UTERUS in the lower abdomen. Ligaments suspend the ovaries in place within the abdominal cavity. Each ovary is about the size, shape, and consistency of a large olive. At birth it contains the full complement of ova that will supply a woman for all her years of FERTILITY.

The ovary has two distinct layers of structure, an outer cortex and an inner medulla. The ovarian cortex contains the ovarian follicles, each of which holds an immature ovum (egg), also called a GAMETE or germ cell. The fibrous tissue of the ovarian medulla, made up of stroma cells, contains the ovary's BLOOD vessels, LYMPH vessels, and nerves. The layer of cells covering the ovary is the epithelium; it is made up of epithelial cells (the same type of cell that makes up the SKIN and mucous membranes throughout the body).

Beginning during PUBERTY with the onset of MENSTRUATION, hormonal influences ripen one ovum (sometimes called an oocyte) each MENSTRUAL CYCLE. The ovary releases the ovum into a pocket of fluid that surrounds it. The fimbriae of the fallopian tube (fluted edges of the tube's open end) float in this fluid, extending toward but not touching the ovary. The undulating movements of the fimbriae pull the released ovum into the fallopian tube where, if SPERM are also present, fertilization may occur.

The PITUITARY GLAND releases FOLLICLE-STIMULATING HORMONE (FSH) and LUTEINIZING HORMONE (LH) at different phases of the menstrual cycle to stimulate the sequence of events that will cause the maturation of an ovum. Several ova typically begin the maturation process during each menstrual cycle though usually only one will complete it. The follicle expels the mature, or ripe, ovum. The cells of the follicle produce estrogens and proteins. The developing ovum is a haploid cell—that is, is contains precisely one half the complement of chromosomes (23) necessary to support human

life. When the ovum merges with the sperm, the resulting ZYGOTE contains the full complement of chromosomes (46).

HEALTH CONDITIONS THAT AFFECT THE OVARIES

ENDOMETRIOSIS	OVARIAN CANCER
OVARIAN CYST	POLYCYSTIC OVARY SYNDROME (PCOS)
PREMATURE OVARIAN FAILURE (POF)	TURNER'S SYNDROME

For further discussion of the ovaries within the context of the structures and functions of reproduction and sexuality, please see the overview section "The Reproductive System." For further discussion of the ovaries within the context of the structures and functions of the endocrine system, please see the overview section "The Endocrine System."

See also CELL STRUCTURE AND FUNCTION; CONCEPTION; CONTRACEPTION; PREGNANCY; TESTICLES.

ovulation The maturation and release of an ovum (egg) during a woman's monthly MENSTRUAL CYCLE. Ovulation establishes FERTILITY (the physiologic ability to conceive a PREGNANCY); only during ovulation may pregnancy occur. Ovulation marks the transition from the proliferative phase to the luteal phase of the menstrual cycle, during which the PITUITARY GLAND's release of LUTEINIZING HORMONE (LH) stimulates the ovarian follicle (sometimes called the graafian follicle) to rupture. The follicle expels the ripened ovum into a small pool of fluid that surrounds the ovary. The fimbriae (fluted edges of the fallopian tube) float in this fluid. As the fimbriae undulate they draw the ovum toward them and into the fallopian tube, where contractions of the tube's wall propel the ovum along the fallopian tube toward the UTERUS. FERTILIZATION, if it is to occur, takes place in the fallopian tube.

It is very difficult to calculate or determine the timing of ovulation. Though ovulation generally occurs within 10 to 15 days after the start of the previous menstrual period, its timing depends on numerous factors, most of which are hormonal. Body temperature rises slightly and the quality of cervical mucous changes during ovulation. Home ovulation testing kits can determine ovulation with fair accuracy; laboratory tests done through the doctor's office are more precise. Ovulation timing is important for women who are trying to conceive, and also for women who are trying to avoid conception. The rhythm method, also called periodic abstinence, relies on avoiding SEXUAL INTERCOURSE during ovulation as a means of CONTRACEPTION.

For further discussion of ovulation within the context of the structures and functions of reproduction and sexuality, please see the overview section "The Reproductive System."

P–R

Paget's disease of the breast A rare presentation of BREAST CANCER, also called Paget's disease of the nipple. Researchers believe Paget's disease of the BREAST occurs when disordered cells from a cancer within the breast migrate to the SKIN surface, most likely through the milk ducts, to infiltrate the tissues of the outer breast and the nipple. Paget's disease of the breast is most commonly associated with an underlying invasive breast cancer or ductal cancer in situ (DCIS).

The symptoms of Paget's disease of the breast may develop over months to years, and typically begin with a scaly RASH that may itch or burn. The skin of the nipple and the areola (the area around the nipple) may crack and bleed. Because skin conditions such as atopic DERMATITIS (also called eczema) and PSORIASIS commonly affect the breasts, early symptoms are often misdiagnosed as dermatologic. One subtle difference is that Paget's disease of the breast begins in the nipple and spreads to the areola, whereas dermatologic conditions begin in the areola and extend to the nipple. As Paget's disease of the breast advances, the nipple may invert or there may be bloody discharge from the nipple.

The diagnostic path typically includes MAMMOGRAM (X-RAY of the breast) and biopsy of the cells of the nipple and underlying breast tissue. ULTRASOUND of the breast may reveal tumors within the breast. Treatment begins with surgery to remove the cancer, which may be breast-conserving surgery when the cancer remains fairly localized and simple or radical MASTECTOMY when the cancer is widespread within the breast. RADIATION THERAPY, HORMONE THERAPY (such as with tamoxifen) when the underlying cancer is hormone sensitive, and CHEMOTHERAPY are common adjuvant (follow-up) treatments.

See also CANCER TREATMENT OPTIONS AND DECISIONS; PAGET'S DISEASE OF THE BONE.

Pap test A screening test for disorders of the CERVIX, notably CERVICAL INTRAEPITHELIAL NEOPLASIA (CIN) and CERVICAL CANCER. A Pap test, also called a Papanicolaou test, is the laboratory examination of cells swabbed from the cervix during a PELVIC EXAMINATION. The test derives its name from the doctor who developed it. Women over age 18 should have Pap tests every one to three years, depending on their health status. A woman who has had a total HYSTERECTOMY (surgical removal of the UTERUS including the cervix) for reasons other than cancer does not need Pap tests unless she has a history of HUMAN PAPILLOMAVIRUS (HPV). When the hysterectomy was for cancer or was a simple hysterectomy (removal only of the uterus), the woman needs Pap tests according to routine recommendations.

See also COLPOSCOPY.

paraphimosis A condition in which the foreskin retracts onto the shaft of the PENIS and will not return to its normal position to cover the glans (tip of the penis). Paraphimosis can only occur in an uncircumcised man. The foreskin swells and acts as a tourniquet, constricting the flow of BLOOD and causing the shaft of the penis to engorge while cutting off the blood supply to the glans. Paraphimosis requires immediate medical attention to prevent permanent damage, including GANGRENE that necessitates AMPUTATION, to the penis.

Treatment for paraphimosis includes measures to reduce swelling such as ice and compression dressings to the penis. Injection of hyaluronidase, an enzyme, often rapidly reduces the swelling (edema). Once the swelling goes down the doctor may then gently manipulate the foreskin back

PAP TEST RECOMMENDATIONS

Woman's Age	Health Status	Pap Test Interval
under 21	sexually active	every year
21 to 30	all women regardless of health status	every year
31 to 64	three consecutive normal Pap tests no SEXUALLY TRANSMITTED DISEASES (STDS)	every two to three years
31 to 64	multiple sex partners HUMAN PAPILLOMAVIRUS (HPV) INFECTION abnormal Pap test within three years has had treatment for cancer of the CERVIX or endometrium (UTERUS)	every year
65 to 70	normal Pap tests for the previous 10 consecutive years total HYSTERECTOMY	no longer necessary
any age	mother took diethylstilbestrol (DES) when she was pregnant HIV positive organ transplant recipient long-term corticosteroid therapy impaired immune function	every year

over the glans. When these measures are inadequate, the doctor may make an incision through the foreskin to release it. The definitive treatment for paraphimosis is CIRCUMCISION (surgical removal of the foreskin).

See also PHIMOSIS.

pelvic examination A manual and visual examination of a woman's VULVA, VAGINA, and CERVIX. A routine pelvic examination has three parts: visual examination of the external GENITALIA, bimanual palpation, and speculum examination of the inner vagina and the cervix. A pelvic examination is painless and is part of a ROUTINE MEDICAL EXAMINATION for women beginning around age 18 and continuing throughout life. For a routine pelvic examination a woman lies on her back on the examination table with her feet in stirrups and her knees spread apart. The doctor also performs pelvic examination during labor to assess the status of the cervix and progression of labor.

Visual examination The doctor visually examines the external genitalia to detect abnormalities such as growths, sores, discoloration, and other indications of INFECTION or disease.

Bimanual examination For the bimanual portion of the pelvic exam the doctor inserts two gloved and lubricated fingers into the vagina and with the other hand palpates the outside of the abdomen. This procedure allows the doctor to feel the size and placement of the UTERUS and the OVARIES, which may detect abnormalities such as swelling, hypersensitivity or PAIN, displacement (such as tipped uterus), and other indications of health concerns.

Speculum examination The doctor then inserts a lubricated speculum into the vagina. The speculum has two opposing blades that fit together to form a smooth, thin blade that easily enters the vagina. Once the speculum is in position the doctor gently opens the blades to spread apart the walls of the vagina, providing access to the cervix. The doctor visually examines the cervix and inner vagina with the aid of a bright light, and may take a cervical smear (sampling of cells and mucous from the cervix) for a PAP TEST or other laboratory

procedures. The doctor closes the speculum's blade to withdraw the speculum.

See also KEGEL EXERCISES; PREVENTIVE HEALTH CARE AND IMMUNIZATIONS.

pelvic inflammatory disease (PID) A bacterial INFECTION involving the UTERUS, FALLOPIAN TUBES, CERVIX, and VAGINA. Untreated PID has the potential to become life threatening if it spreads to involve the peritoneal membrane (PERITONITIS), the tissue that encloses the abdominal cavity. Because PID can cause scarring within the fallopian tubes that occludes them (blocks the tubes' openings), chronic or recurrent PID is a leading cause of INFERTILITY in women. PID is a significant health concern in the United States with doctors diagnosing more than one million women with it each year, about half of whom have permanently impaired FERTILITY as a consequence.

The most common cause of PID is recurrent or untreated infection with SEXUALLY TRANSMITTED DISEASES (STDS) such as CHLAMYDIA and GONORRHEA. Other causes include infection that occurs as a postoperative complication after a surgical procedure such as DILATION AND CURETTAGE (D&C) or elective ABORTION. A less common cause of PID is infection resulting from an intrauterine device (IUD), a form of long-term birth control.

Symptoms and Diagnostic Path

It is possible to have PID, especially chronic PID, with few or no symptoms. Many women who have PID typically appear quite ill, however, and may have FEVER and chills in addition to other symptoms. Such symptoms may include

- yellowish or greenish malodorous (foul-smelling) vaginal discharge
- lower abdominal tenderness, cramping, or PAIN
- NAUSEA, VOMITING, and DIARRHEA
- vaginal bleeding between menstrual periods
- irregular or unusually heavy menstrual periods

The diagnostic path includes PELVIC EXAMINATION with vaginal discharge and tissue samples for laboratory analysis and BLOOD tests to evaluate the presence of infection or INFLAMMATION within the body (such as elevated sedimentation rate, white blood cell count, and C-REACTIVE PROTEIN). The cervix and uterus are generally very tender to palpation during the pelvic exam, which is a key diagnostic criterion.

Treatment Options and Outlook

Treatment is prompt administration of ANTIBIOTIC MEDICATIONS, by intravenous (IV) or intramuscular injection for severe symptoms and orally otherwise. Antibiotic therapy may include two or more antibiotic medications, depending on the identified BACTERIA present in the vaginal and cervical cultures. It is essential to take the full course of all antibiotics as prescribed to completely eradicate the infection, which cures the PID. ANALGESIC MEDICATIONS relieve pain and reduce fever to improve comfort. Possible complications of PID include infertility, increased risk for ECTOPIC PREGNANCY, and chronic pelvic pain. The likelihood of these complications increases with each episode of PID, though prompt diagnosis and treatment helps mitigate their risk.

ANTIBIOTICS TO TREAT PELVIC INFLAMMATORY DISEASE (PID)

ampicillin/sulbactam	cefotetan
cefoxitin	ceftriaxone
ciprofloxacin	clindamycin
doxycycline	gentamicin
metronidazole	ofloxacin

Risk Factors and Preventive Measures

The primary risk factor for PID is untreated STD infection. Many people do not have symptoms of STDs yet are infected and pass the infections to their sex partners. Multiple sex partners and unprotected sex are high-risk behaviors for STDs and PID. Measures to prevent infection among sexually active adults include mutual monogamy and latex condom use with every sexual act.

See also HIV/AIDS; MENSTRUATION; SEXUALLY TRANSMITTED DISEASE (STD) PREVENTION.

penis The male organ for URINATION and SEXUAL INTERCOURSE. The penis is an elongated, cylindrical structure made of connective and erectile tissue that extends outside the body from the base of the pelvis. Ligaments attach the root of the penis (segment within the body) to the pubic bone at the

front of the pelvis and the ischial bones at the back of the pelvis. The shaft is the length of the penis that extends outward from the body, and the glans is the end or head of the penis. The URETHRA exits the glans through an opening called the urethral meatus. A loose fold of SKIN, the foreskin (also called the prepuce), covers the glans at birth; beginning around 8 years of age the foreskin retracts from the glans when the penis is erect and returns to drape the glans when the penis is flaccid. CIRCUMCISION is a surgical OPERATION to remove the foreskin.

The interior penis contains three channels: the corpus spongiosum runs along the underside of the penis and houses the urethra; the two corpora cavernosa run side-by-side along the top of the penis and engorge with BLOOD to stiffen and enlarge the penis during ERECTION. A wall of fibrous tissue, the septum, separates and supports the corpora cavernosa. The inside of each corpus cavernosum is a honeycombed network of spaces (called trabeculae) that fill with blood when the penis is erect. The erect penis is capable of penetrating the woman's VAGINA during SEXUAL INTERCOURSE, with sexual stimulation culminating in ORGASM and EJACULATION.

HEALTH CONDITIONS THAT CAN AFFECT THE PENIS

BALANITIS	CANCER OF THE PENIS
CHORDEE	EPISPADIAS
ERECTILE DYSFUNCTION	GENITAL HERPES
HUMAN PAPILLOMAVIRUS (HPV)	HYPOSPADIAS
HYPOGONADISM	KLINEFELTER'S SYNDROME
PARAPHIMOSIS	PEYRONIE'S DISEASE
PHIMOSIS	PRIAPISM

For further discussion of the penis within the context of the structures and functions of reproduction and sexuality, please see the overview section "The Reproductive System."

See also OVARIES; SEXUAL DYSFUNCTION; SEXUAL HEALTH.

perimenopause The period of time during which a woman's body transitions from FERTILITY to MENOPAUSE. The length of perimenopause varies widely though tends to be five to seven years. Perimenopause begins with the changes in the MENSTRUAL CYCLE that herald the approach of menopause. These changes include irregular spacing of menstrual periods (including skipped periods), unusually heavy or light menstrual flow, light breakthrough bleeding (bleeding between periods), and HOT FLASHES.

Bleeding between periods may indicate a health condition that requires treatment. A doctor should evaluate breakthrough bleeding to determine whether it is normal.

Because PREGNANCY is possible during perimenopause, as OVULATION may occur intermittently, a woman who has two consecutive skipped menstrual periods should have a pregnancy test. Women typically experience a range of fluctuating discomforts, notably hot flashes and sleep disturbances, during the menopausal transition. Menopause is a point in time identified in retrospect as the complete absence of menstrual periods for 12 consecutive months.

See also DYSFUNCTIONAL UTERINE BLEEDING (DUB); ENDOMETRIOSIS; MENSTRUATION; UTERINE FIBROIDS.

Peyronie's disease A condition in which a hardened, fibrous plaque forms within the connective tissue of the PENIS, causing a contracture that pulls the penis into a curved position. Researchers do not know what causes the plaque to form. Some believe it represents an autoimmune response (overreaction of the IMMUNE SYSTEM) and others that it occurs as a reaction to traumatic injury. Peyronie's disease generally affects men age 50 and older. The contracture often causes PAIN, particularly when the penis is erect, and interferes with or prevents SEXUAL INTERCOURSE.

The doctor can usually diagnose Peyronie's disease on physical examination of the penis. The plaque is both visible and palpable. The doctor may request an ULTRASOUND of the penis, which shows the extensiveness of the plaque. In about a third of men who have Peyronie's disease the plaque softens and goes away on its own. In other men the curvature progresses to a certain point and then remains stable. It is important to evaluate the potential risks compared to benefits for proposed treatments, which include injecting the plaque with a medication to dissolve the fibrous

tissue and surgery to remove the plaque. A key risk of either procedure is ERECTILE DYSFUNCTION (inability to obtain erections). Generally these treatments are most appropriate when the contracture completely prevents sexual intercourse.

See also CHORDEE; PARAPHIMOSIS; PHIMOSIS; PRIAPISM.

phimosis A condition in which the foreskin becomes fused to the glans of an uncircumcised PENIS and will not retract. Phimosis occasionally occurs as a congenital condition (present at birth) though more often develops later in life, typically as a consequence of poor PERSONAL HYGIENE. Phimosis is the leading cause of BALANITIS, a fungal INFECTION of the inner surface of the foreskin, and can interfere with URINATION and cause PAIN with ERECTION. Recurrent phimosis increases a man's risk for CANCER OF THE PENIS.

The doctor is sometimes able to gently free the adhered foreskin after anesthetizing the penis. Frequent retraction of the foreskin and diligent cleansing are necessary to prevent phimosis from recurring. When this is not effective or phimosis becomes chronic, the recommended treatment is CIRCUMCISION, an OPERATION to surgically remove the foreskin. Though in some men an unusually tight foreskin (congenital phimosis) is the primary cause of phimosis, diligent personal hygiene can prevent most phimosis. It is important for uncircumcised boys and men to clean beneath the foreskin every day by retracting the foreskin, washing the glans gently but thoroughly to remove any accumulated secretions, and allowing the foreskin to return to its natural position.

See also CHORDEE; CONGENITAL DISORDERS; PARAPHIMOSIS; PEYRONIE'S DISEASE.

placenta An organ of PREGNANCY that nourishes and sustains the FETUS. The placenta also secretes a number of hormones that maintain the biochemical environment within the woman's body to support the pregnancy. The placenta develops within the first two weeks after the blastocyst implants into the endometrium of the UTERUS, arising from the outer layer of the blastocyst's cells, the trophoblast. The amniotic sac, which encloses the developing fetus, and the UMBILICAL CORD also arise from the trophoblast.

PLACENTAL HORMONES

activin	chorionic adrenocorticotropin
CHORIONIC GONADOTROPIN	chorionic somatomammotropin
CORTICOTROPIN-RELEASING HORMONE (CRH)	CORTISOL
GONADOTROPIN-RELEASING HORMONE (GNRH)	ESTROGENS
INHIBIN	GROWTH HORMONE–RELEASING HORMONE (GHRH)
PROGESTERONE	placental actinogen
RELAXIN	PROLACTIN
	THYROTROPIN-RELEASING HORMONE (TRH)

The placenta uniquely belongs to both the mother and the fetus. Though the maternal BLOOD circulation delivers NUTRIENTS and oxygen to the fetal blood circulation and carries away fetal wastes, the two circulations do not normally mix with each other. The side of the placenta that faces the fetus is the chorion. Fringelike extensions called the chorionic villi permeate the tissue of the maternal portion of the placenta. Fetal blood circulates through the chorionic villi. Arterioles (tiny arteries) and venules (tiny veins) extend from the myometrium (muscular wall of the uterus) into the spaces between the chorionic villi. The arterioles carry maternal blood into the spaces where it circulates around the chorionic villi. Nutrients, oxygen, and wastes pass across the thin membranes that enclose the chorionic villi.

Problems that can arise with the placenta during pregnancy include

- placenta abruptio (also called placental abruption), in which the placenta partially or completely separates from the uterus; partial separation reduces nutrition to the fetus and complete separation is fatal to the fetus
- placenta accreta, in which the tissues that anchor the placenta to the wall of the uterus penetrate the myometrium too deeply, making it difficult for the placenta to separate after birth
- placenta previa, in which the placenta grows partially or completely across the CERVIX, necessitating CESAREAN SECTION to prevent hemorrhage during labor

After the fetus is born a second round of contractions separate the placenta from the uterine

wall and expel it through the VAGINA. The expelled placenta is the afterbirth.

For further discussion of the placenta within the context of the structures and functions of reproduction and sexuality, please see the overview section "The Reproductive System."

See also AMNIOCENTESIS; AMNIOTIC FLUID; CHILDBIRTH; CHORIONIC VILLI SAMPLING (CVS); CONCEPTION; HORMONE.

polycystic ovary syndrome (PCOS) A condition in which the OVARIES produce excessive ANDROGENS, the male sex hormones, resulting in irregular menstrual cycles and often anovulation (absence of egg maturation and release). A common characteristic of PCOS is the formation of multiple and often numerous cysts within the follicles of the ovaries. PCOS, sometimes called Stein-Leventhal syndrome or hyperandrogenic anovulation, is a common cause of INFERTILITY in women.

Researchers believe INSULIN RESISTANCE, an endocrine disorder in which the cells in the body do not appropriately respond to INSULIN, is a key factor in the development of PCOS though do not know the mechanisms of the relationship between the two conditions. PCOS commonly appears among a constellation of symptoms associated with insulin resistance including OBESITY, HYPERLIPIDEMIA (elevated levels of fatty acids in the BLOOD circulation), ATHEROSCLEROSIS (accumulations of fatty plaques within the walls of the arteries), CORONARY ARTERY DISEASE (CAD), and type 2 DIABETES.

Symptoms and Diagnostic Path

The symptoms of PCOS include

- irregular menstrual cycles
- AMENORRHEA (absence of MENSTRUATION) or frequent skipped menstrual periods
- excessive or male pattern body HAIR (HIRSUTISM)
- male pattern thinning of the hair on the head (ALOPECIA)
- pelvic discomfort or PAIN
- inability to conceive (infertility)
- excessive or persistent ACNE

In addition, many women who have PCOS also have HYPERTENSION (high BLOOD PRESSURE) along with other health conditions in the insulin resistance constellation (notably diabetes, hyperlipidemia, and obesity). Though some women who have PCOS have irregular menstrual cycles from MENARCHE (the onset of menstruation) or fail to start menstruating (primary amenorrhea), many women do not suspect they have PCOS until they are unsuccessful in their attempts to become pregnant.

The diagnostic path begins with a comprehensive medical examination including blood tests to measure HORMONE levels, GLUCOSE tolerance test, and PELVIC EXAMINATION, during which the doctor often can palpate (feel) the enlargement and irregular shape of the ovaries that is typical with multiple cysts. Transvaginal or pelvic ULTRASOUND provides visual representation of the ovaries that can confirm the diagnosis.

Treatment Options and Outlook

Though there is no cure for PCOS, medical treatments to regulate the balance of hormones in the body often can restore normal OVULATION and menstruation. For women who are not trying to become pregnant, the medication of choice is an oral contraceptive (birth control pills). Some oral ANTIDIABETES MEDICATIONS that affect how cells respond to insulin are also effective at improving symptoms.

For women who are trying to become pregnant, FERTILITY medications may stimulate ovulation though the risk for multiple pregnancy becomes significant. Some doctors recommend in vitro fertilization (IVF), a method of ASSISTED REPRODUCTIVE TECHNOLOGY (ART), rather than fertility medications for women who have PCOS and wish to become pregnant because IVF allows control over the number of potential fetuses. During pregnancy women who have PCOS have increased risk for spontaneous ABORTION, GESTATIONAL DIABETES, PREECLAMPSIA, and PREMATURE BIRTH, though diligent PRENATAL CARE keeps these risks to a minimum.

A surgical treatment option is ovarian drilling, a laparoscopic OPERATION in which the surgeon uses electrocautery to burn selected ovarian follicles to destroy the cysts they contain. Ovarian drilling typically restores normal ovulation for a limited time, which reduces symptoms overall. However,

the effectiveness of ovarian drilling eventually diminishes as cysts continue to grow in the remaining ovarian follicles.

Nonmedical approaches such as electrolysis or laser hair removal can improve excessive hair growth. Daily physical exercise improves cell sensitivity to insulin, as does maintaining appropriate body weight. Weight loss of 10 to 15 percent often is enough to restore normal menstrual cycles. Weight management also improves conditions that may co-exist with PCOS such as hypertension and diabetes. Women in whom hormonal balance continues such that amenorrhea persists long term (as may occur in untreated PCOS) have increased risk for ENDOMETRIAL HYPERPLASIA and ENDOMETRIAL CANCER (overgrowth and cancer of the endometrium, the lining of the UTERUS).

Risk Factors and Preventive Measures

The primary risk factor for PCOS appears to be insulin resistance. Lifestyle measures to maintain healthy body weight and regulate the insulin–glucose balance often reduce symptoms of PCOS, though there are no certain measures to prevent PCOS. PCOS does appear to run in families, suggesting a genetic role in its development.

See also CONCEPTION; CONTRACEPTION; EXERCISE AND HEALTH; MENSTRUAL CYCLE; OVA; PREMATURE OVARIAN FAILURE (POF); WEIGHT LOSS AND WEIGHT MANAGEMENT.

preeclampsia A complication of PREGNANCY in which a woman develops significant to severe HYPERTENSION (high BLOOD PRESSURE) and elevated protein in the URINE. Preeclampsia, sometimes called toxemia of pregnancy, is more common in a first pregnancy and in pregnant women who are under age 20 or over age 40 and in women who have DIABETES, kidney disease, or hypertension when they become pregnant. Preeclampsia also seems to run in families, suggesting a GENETIC PREDISPOSITION. For the most part, however, doctors do not know what causes preeclampsia to develop. In about 10 percent of women preeclampsia progresses to ECLAMPSIA, in which seizures occur and which is life-threatening for the woman and the FETUS she carries.

The primary symptoms of preeclampsia are

- HEADACHE
- edema (swelling due to fluid retention)
- NAUSEA and VOMITING
- disturbances of vision (blurred or double vision)
- ringing in the ears or other auditory disturbances

The elevation in blood pressure tends to occur as a surge, most commonly in the second and third trimesters. Most often the doctor detects preeclampsia in its early stages through regular PRENATAL CARE visits and monitoring. Prompt diagnosis and treatment with antihypertensive medications to lower blood pressure can often prevent complications from developing. The doctor may also recommend reduced activity or bedrest to help keep blood pressure down. CHILDBIRTH is the most effective treatment. When preeclampsia is moderate to severe and the pregnancy is 37 weeks or beyond, the doctor may induce labor or perform a CESAREAN SECTION (surgical childbirth). Many women who have preeclampsia are able to go through labor and delivery without additional risk to the fetus or themselves.

See also GESTATIONAL DIABETES.

pregnancy The series of events, extending from CONCEPTION to delivery (CHILDBIRTH), through which a blastocyst (the clump of cells that implants in the endometrium, the lining of the UTERUS) becomes a baby. A full-term pregnancy spans 266 days. However, doctors calculate the estimated date of delivery, commonly called the due date, to be 280 days from the start of the last menstrual period.

Confirming Pregnancy

Though a missed menstrual period is the classic first sign of pregnancy, URINE pregnancy tests are now sensitive enough to detect minuscule amounts of pregnancy-related hormones in the urine only a few days after conception and well before the woman misses a period. Home pregnancy tests are generally as accurate as the tests health-care providers use, though following the directions precisely is important. False results are common because of mistakes such as using a urine sample other than the first of the day (which is

the most concentrated) or not properly timing the duration of the test. Most health-care providers will do a pregnancy BLOOD test at the first prenatal visit to confirm the pregnancy. Pregnancy tests, urine or blood, measure the presence of human chorionic gonadotropin (hCG) or beta hCG.

Early signs of pregnancy a woman may detect include

- tender, swollen breasts
- unexplained nausea and vomiting
- aversions to or cravings for certain foods, including smells and sights of them
- profound tiredness
- sensation of lower abdominal bloating
- increased URINATION
- lightheadedness or dizziness

The health-care provider's examination also detects signs of pregnancy, including changes in the texture (by internal palpation) and appearance of the CERVIX and an enlarged, softened uterus. As pregnancy advances the uterus rises out of the pelvis and into the abdomen (beginning around 12 weeks). As part of the diagnostic process the provider uses terminology to identify how many pregnancies and how many deliveries the woman has had previous to the current pregnancy, designating them with the Latin words *gravida* and *para*. A woman who has been pregnant twice and delivered twice is a gravida 2 para 2, for example, and a woman who is pregnant for the first time is a primigravida nullipara or gravida 1 para 0.

Key Changes During Pregnancy

The woman's body undergoes profound changes during the course of pregnancy. Hundreds of hormones unique to pregnancy initiate and facilitate these changes, the most obvious of which are enlarged breasts and a steadily expanding belly. This biochemical flood is also responsible for the emotional swings that characterize early pregnancy. Nearly every body system modifies its functions in some fashion to support the pregnancy and the developing FETUS.

Uterus and abdomen The woman's uterus, pelvis, and abdominal structures flex and expand to accommodate the fetus as it develops and grows. The uterus, for example, can stretch up to 10 times its normal size during pregnancy. The numerous hormones unique to pregnancy act on connective tissue throughout the woman's body to soften ligaments and muscles, providing the pliability necessary to allow this expansion. This softening also accounts for the MUSCLE and JOINT aches, especially in the hips and knees, common in the last months of pregnancy.

The endometrium (lining of the uterus) remains spongy and vascular to support the PLACENTA. A plug of mucus collects in the cervix, helping block BACTERIA from entering the uterus. The tissues of the VAGINA and VULVA engorge with blood, softening in preparation for childbirth. As the pregnancy approaches term, the cervix softens and thins (effaces). With the contractions of labor the cervix dilates and the vagina expands to allow passage of the fetus.

Breasts Changes in the breasts, notably tenderness and swelling, are often the earliest indications of pregnancy as the breasts respond to the hormones. As pregnancy progresses a woman's breasts greatly enlarge and change in preparation for BREASTFEEDING (lactation) after birth. The mammary glands and ducts (milk glands and ducts) swell and around the seventh month begin producing colostrum, a fatty premilk that conveys important NUTRIENTS and antibodies for basic immunity to the infant.

Cardiovascular A woman's blood volume and cardiac output progressively increase as pregnancy advances. The heart enlarges somewhat, HEART RATE goes up, and blood pressure rises. In very early pregnancy the blood vessels dilate in anticipation of the increased blood volume, sometimes resulting in episodes of lightheadedness or dizziness. Some women also get vascular headaches in response to the changes taking place within the muscular walls of the arteries.

Gastrointestinal One of pregnancy's early hallmarks is MORNING SICKNESS, nausea and vomiting doctors believe results from the hormones that surge into the woman's blood circulation when the blastocyst implants. These same hormones are responsible for softening connective tissue and have similar actions on the muscular tissues of the gastrointestinal system, sometimes slowing peristalsis (movement of the intestines) enough to

cause CONSTIPATION. Drinking plenty of fluids, eating foods high in fiber, and walking for at least 30 minutes every day help keep the gastrointestinal system functioning at its best.

In the later months of pregnancy the enlarged uterus displaces the organs of the upper abdomen further upward against the DIAPHRAGM, pressuring the stomach to cause DYSPEPSIA (upset stomach and heartburn) and gastric reflux. These discomforts go away after the baby is born and the abdominal organs return to their normal positions.

Weight gain Weight gain is both normal and essential to support the pregnancy. Appropriate weight gain for a woman who is of healthy weight at the onset of pregnancy is 25 to 35 pounds; in OBESITY less weight gain, 15 to 25 pounds, is healthier for both mother and baby. About 15 to 18 pounds of the weight comes from the baby and organs that support it (uterus, placenta, AMNIOTIC FLUID). The changes in the breasts add 2 to 3 pounds; additional fluids (such as blood) and increased body fat account for the remainder. The most rapid weight gain typically occurs in the second trimester, 2 to 4 pounds per month.

Most women require only an additional 200 to 300 calories a day to meet their increased energy needs. Nutritious EATING HABITS are especially important to meet nutritional needs for vitamins and minerals. Pregnant women should take prenatal vitamins to make sure they receive adequate amounts of vital nutrients. Folic acid (folate) is particularly crucial for proper development of the BRAIN and SPINAL CORD. Supplemental iron boosts the ability of the woman's blood to carry oxygen, helping prevent ANEMIA.

Health Care During Pregnancy

Though pregnancy is a natural event, not a medical condition, routine PRENATAL CARE provides optimal circumstances for the health of the woman and of the fetus. Current medical knowledge and technology make possible high-risk pregnancies as well as early intervention to avert or manage medical complications that may arise in the woman or the fetus. Screening tests and procedures can detect congenital and genetic abnormalities (BIRTH DEFECTS) that may require special medical attention during or after birth.

For further discussion of pregnancy within the context of the structures and functions of reproduction and sexuality, please see the overview section "The Reproductive System."

See also ABORTION; ADOPTION; ECTOPIC PREGNANCY; FAMILY PLANNING; FERTILITY; GESTATIONAL SURROGACY; OVA; PREMATURE BIRTH; STILLBIRTH; ZYGOTE.

premature ovarian failure (POF) A health condition in which a woman's OVARIES stop functioning before age 40. POF is a leading cause of INFERTILITY in women. Though POF causes MENOPAUSE-like symptoms and people (including doctors) sometimes refer to it as premature menopause, women

THE WOMAN'S BODY THROUGH PREGNANCY

Gestational Week	Body Characteristics
4 to 6	UTERUS soft and enlarged; breasts tender and swollen
12	belly begins to bulge; 2 to 4 pounds weight gain
16	darkened nipples and areola; dark line down center of abdomen
20	top of uterus at the level of the belly button; pregnancy obvious; breasts enlarged
24	Braxton-Hicks contractions; top of uterus above belly button; VULVA enlarged due to blood engorgement
28	weight gain of about 1 pound a week; minor swelling of the ankles and feet; size of uterus pressures BLADDER and DIAPHRAGM
32	breasts begin to leak colostrum; fetal movements visible through the abdominal wall
36	top of uterus near the bottom of the sternum; CERVIX begins to soften and thin (efface); pelvic ligaments and muscles soften and stretch
40	Strong Braxton-Hicks contractions; uterus completely fills the abdominal cavity; cervix continues to efface and begins to dilate; breasts engorged and frequently leak colostrum; mucous plug dislodges from cervix; water breaks (amniotic membrane ruptures)

who have POF often have irregular menstrual cycles for years after the onset of POF symptoms and do retain the ability to conceive, whereas menstrual cycles completely cease with menopause, ending the potential for pregnancy.

The reasons for POF are unclear though likely are a mix of genetic, hormonal, and perhaps autoimmune factors. Women who have POF have lower than normal levels of ESTROGENS and higher than normal FOLLICLE-STIMULATING HORMONE (FSH) levels in the BLOOD circulation, suggesting depletion or dysfunction of the ovarian follicles. Doctors do not know whether the abnormal HORMONE levels cause or result from follicular factors. CHROMOSOMAL DISORDERS such as TURNER'S SYNDROME and GENETIC DISORDERS such as ACHONDROPLASIA (a form of SKELETAL DYSPLASIA, often called dwarfism) also are associated with POF.

Symptoms and Diagnostic Path

The symptoms of POF are similar to those of menopause and commonly include

- HOT FLASHES and night sweats
- vaginal dryness and irritation (nonbacterial VAGINITIS)
- painful SEXUAL INTERCOURSE (dyspareunia)
- diminished LIBIDO
- low energy or fatigue
- irritability and mood swings
- irregular menstrual periods

The diagnostic path begins with a comprehensive medical examination, including PELVIC EXAMINATION, and blood tests to measure blood hormone levels (usually including a PREGNANCY test). The doctor may desire genetic tests as well, such as a KARYOTYPE, to evaluate the possibility of a genetic or chromosomal disorder. Women who have very mild Turner's syndrome may first learn of this diagnosis during evaluation for POF, as other symptoms of the syndrome may be so nominal as to escape detection.

Treatment Options and Outlook

Treatment with estrogen and progestin supplementation until closer to the age for natural menopause may relieve many POF symptoms though does not usually improve FERTILITY. However, pregnancy remains possible and is something a woman should consider when her menstrual period does not occur as expected when she is taking hormone supplementation.

Women who have POF have increased risk for OSTEOPOROSIS and CARDIOVASCULAR DISEASE (CVD), and should follow lifestyle practices to support BONE and cardiovascular health. Such practices include calcium supplementation, daily physical exercise such as walking or running for cardiovascular health, resistance activities such as lifting weights to maintain MUSCLE mass and BONE DENSITY, nutritious EATING HABITS, and weight management. ASSISTED REPRODUCTIVE TECHNOLOGY (ART) methods using donor OVA (eggs) may provide pregnancy for a woman who has POF and desires to conceive.

Risk Factors and Preventive Measures

Known risk factors for POF are chromosomal or genetic disorders affecting the sex chromosomes or features of sexual development and ADDISON'S DISEASE (an autoimmune disorder affecting the ADRENAL GLANDS). Medical treatments such as CHEMOTHERAPY and RADIATION THERAPY may cause secondary POF. There are no known measures to prevent POF.

See also AUTOIMMUNE DISORDERS; POLYCYSTIC OVARY SYNDROME (PCOS); SEX CHROMOSOME; WEIGHT LOSS AND WEIGHT MANAGEMENT.

premature birth The delivery of an infant before 37 weeks gestational age, also called preterm birth. Though viability is possible after 24 weeks, many fetal organ systems do not reach maturity sufficient for independent life until near full term. Sometimes there are warning signs of premature birth that allow the doctor to attempt to delay CHILDBIRTH by administering medications to stop uterine contractions. The doctor may also help the FETUS prepare for independent life. Giving the mother injections of betamethasone, a corticosteroid, accelerates the fetus's lung development.

Though premature birth does not present any unusual risk for the woman, it often results in mild to moderate health challenges for the infant. Very early premature birth, between 24 and 32 weeks, presents grave health risks for the infant, who commonly requires extensive medical care

for several weeks to several months, depending on the gestational age at birth. About 10 percent of babies in the United States are born prematurely. The most common causes of premature birth are multiple PREGNANCY and PREECLAMPSIA. Women who have DIABETES, HYPERTENSION (high BLOOD PRESSURE), and chronic kidney disease have increased risk for premature delivery.

See also ABORTION; NEONATAL JAUNDICE; STILLBIRTH.

premenstrual syndrome (PMS) A constellation of symptoms that occurs in a regular pattern aligned with a woman's MENSTRUAL CYCLE. Doctors believe PMS results from the hormonal shift in the balance between ESTROGENS and PROGESTERONE that follows involution of the corpus luteum. This shift sets in motion the events that produce MENSTRUATION. PMS tends to begin during the last half of the luteal phase and continue to the onset of menstrual bleeding, typically spanning five to seven days. As many as 85 percent of women experience some symptoms of PMS; about 10 percent experience symptoms significant enough to interfere with daily activities. Some doctors call debilitating symptoms premenstrual dysphoric disorder (PMDD).

Symptoms and Diagnostic Path

The symptoms of PMS may vary from month to month in a woman and also vary widely among women. Common PMS symptoms include

- irritability, extreme emotions, and mood swings
- MASTALGIA (painful breasts)
- confusion, forgetfulness, and difficulty concentrating
- abdominal cramping and bloating
- low back ache or PAIN
- fluid retention and swelling of the hands, ankles, and feet
- weight gain (as much as two to four pounds)

The diagnostic path begins with a comprehensive medical examination, including PELVIC EXAMINATION. The doctor may ask the woman to keep a daily diary of her symptoms over three to six months, which helps to establish a clear pattern of symptoms and their severity. The doctor may request BLOOD tests and abdominal ULTRASOUND to rule out hormonal imbalances, ovarian conditions, and other possible causes for symptoms.

Treatment Options and Outlook

Mild to moderate PMS often improves with lifestyle modifications, including sufficient sleep, nutritious EATING HABITS, daily physical exercise, MEDITATION or other relaxation methods, and reduced CAFFEINE consumption (though some women find the diuretic and mild stimulant effects of caffeine helpful). BIOFEEDBACK and ACUPUNCTURE are also often effective. Supplementation with B vitamins, vitamin E, and calcium appear to reduce PMS symptoms, though it may take several months for the effect to become apparent. Evening primrose oil, SOY and other PHYTOESTROGENS, DONG QUAI, and BLACK COHOSH are among the herbal remedies that may relieve PMS symptoms. Over-the-counter (OTC) NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) relieve HEADACHE and mastitis, and may reduce other symptoms because of their actions to suppress the release of PROSTAGLANDINS (chemicals that increase the sensitivity of nerves to pain signals).

Selective serotonin reuptake inhibitors (SSRIs), a class of ANTIDEPRESSANT MEDICATIONS, are effective in relieving moderate to severe PMS symptoms and are the current standard of care for PMS as well as PMDD. Researchers believe SSRIs work so well because they influence the neurohormonal interactions that take place in the BRAIN. Though some women find their symptoms improve with oral contraceptives (birth control pills), recent research suggests progesterone (which appears in the synthetic form progestin in many oral contraceptive formulas) is a key factor in causing PMS. Current clinical guidelines recommend oral contraceptives as treatment for PMS only when the woman also desires to take them as a means of preventing PREGNANCY.

Risk Factors and Preventive Measures

PMS occurs only in menstruating women. However, though PMS is very common not all menstruating women experience it. Some research suggests that women may metabolize progesterone differently, accounting for differences in its effects during the menstrual cycle. Lifestyle meas-

ures, medications, or a combination of approaches can help mitigate symptoms for many women, though there are no methods for preventing PMS.

See also DYSMENORRHEA; MEDICINAL HERBS AND BOTANICALS; MENOPAUSE.

prenatal care Routine and preventive health care provided during PREGNANCY to safeguard the health and well-being of the woman and the FETUS. In the United States routine prenatal care consists of regular visits to the health-care provider (family practitioner, obstetrician, or nurse midwife), URINE and BLOOD tests, BLOOD PRESSURE checks, and additional diagnostic procedures as needed such as ULTRASOUND, AMNIOCENTESIS, or CHORIONIC VILLI SAMPLING (CVS). The schedule of visits varies according to the trimester of pregnancy and any specific concerns about the pregnancy.

Ideally, prenatal care begins before CONCEPTION with a focus on nutritious EATING HABITS, healthy weight, appropriate management of any health conditions (such as DIABETES, HYPERTHYROIDISM, and HYPERTENSION), and abstinence from cigarette smoking, ALCOHOL consumption, and substance abuse. The prospective father should share this focus, as the health of both parents contributes to FERTILITY and fetal health. Also ideally, a woman who is planning pregnancy already receives routine medical examinations, including PELVIC EXAMINATION and PAP TEST, according to the recommendations appropriate for her age, sexual activity, and health history. Lifestyle habits to maintain the health of the woman and the fetus remain significant for the duration of pregnancy.

Health experts strongly encourage all women of childbearing age, regardless of their intentions toward pregnancy, to take a folic acid supplement. Folic acid, also called folate, significantly reduces the risk for serious BIRTH DEFECTS called NEURAL TUBE DEFECTS. However, the neural tube (the rudimentary CENTRAL NERVOUS SYSTEM) develops very early, well before a woman suspects she might be pregnant. Taking 400 micrograms (mcg) of folic acid supplement daily provides protection even when pregnancy is unexpected (as is the case with half of pregnancies that occur in the United States) and provides nutritional benefit for the woman. Oral contraceptives (birth control pills) deplete folic acid.

Prenatal Care: First Trimester

Routine prenatal care visits occur monthly during the first trimester, which extends through the 12th week of pregnancy. The first prenatal visit is more extensive than subsequent visits because the health-care provider conducts a comprehensive medical examination, including pelvic exam, and collects detailed information about the woman's health history, including any previous pregnancies, SEXUALLY TRANSMITTED DISEASES (STDS), childhood diseases, and immunizations. At the first prenatal visit the health-care provider also establishes a baseline of vital data such as height, weight, blood pressure, and size of the pelvic opening and the UTERUS. Routine blood tests done on the first prenatal visit commonly check BLOOD TYPE including Rh factor, ANEMIA, and antibodies for MUMPS, MEASLES, CHICKENPOX, HEPATITIS B, RUBELLA, and SYPHILIS. The provider may also recommend a blood test for HIV/AIDS and screening of both parents for cystic fibrosis if not yet done.

Another priority on the first prenatal visit is estimation of the anticipated due date for birth, which is important to assess whether the pregnancy and fetal growth are progressing as they should. Adding seven days and subtracting three months from the date the last menstrual period started gives the approximate due date, which the provider compares to findings from the pelvic examination to assess the age of the fetus.

At each subsequent prenatal visit during the first trimester the health-care provider tests a urine sample for GLUCOSE and protein, obtains weight and blood pressure, and measures the growth of the uterus. Pelvic exams are not usually necessary. If there are concerns about GENETIC DISORDERS or CHROMOSOMAL DISORDERS the provider may offer CVS (chorionic villi sampling) between the 10th and 12th weeks. At the last visit of the first trimester the health-care provider is often able to detect the fetal heartbeat using Doppler ultrasound.

Prenatal Care: Second Trimester

Routine prenatal visits continue monthly during the second trimester, the 13th through the 26th weeks of pregnancy. The growth of the uterus is more apparent and measurements of it more precise, allowing the health-care provider to refine

the prospective due date. Weight, blood pressure, and urine sample for glucose and protein remain staples of prenatal visits in the second trimester.

Around the 18th week the health-care provider offers a set of screening blood tests, the triple screen or the quad screen. These tests measure certain hormones and proteins in the woman's blood that may suggest neural tube defects such as SPINA BIFIDA and chromosomal disorders such as DOWN SYNDROME. The results of these tests are specific to the gestational age so the provider will be as certain as possible about the due date before conducting them.

It is important for the woman, her partner, and the provider to discuss the implications of positive results from screening tests, and for the woman and her partner to consider what actions they might take. The provider typically recommends amniocentesis to further evaluate positive triple screen or quad screen results. The provider may recommend abdominal ultrasound around the 20th week if the due date is questionable or if there is reason to suspect abnormalities in fetal development. At the end of the second trimester the provider typically requests a glucose challenge test to check for GESTATIONAL DIABETES as well as blood tests to check for anemia.

MATERNAL SCREENING BLOOD TESTS

Triple Screen
ALPHA FETOPROTEIN (AFP)
beta human chorionic gonadotropin (beta-HCG)
unconjugated estriol (uE3)
Quad Screen
AFP
beta-HCG
uE3
pregnancy-associated plasma protein A (PAPP-A)

Prenatal Care: Third Trimester

Routine prenatal care visits shift to every two weeks between 28 and 36 weeks and weekly from 36 weeks until delivery. The health-care provider continues to check weight, urine, and blood pressure. Early in the third trimester the provider discusses the potential for delivery by CESAREAN SECTION if the fetus is in a breech position or there are other circumstances that might increase the risk to the fetus or the woman with a vaginal delivery.

At the 34th or 35th week the provider cultures swabbed samples from the VAGINA and rectum for group B streptococcus (GBS) BACTERIA, which some women harbor without harm to themselves but that can cause life-threatening INFECTION in the newborn. Women who test positive for GBS receive ANTIBIOTIC MEDICATIONS when they go into labor. The provider also monitors the status of GENITAL HERPES, when this STD is present, to be prepared for cesarean section should an outbreak occur near the anticipated time of delivery.

priapism A condition in which a man's PENIS remains erect for longer than four hours. Priapism is involuntary (not a function of sexual stimulation), painful, and requires immediate medical attention to prevent permanent damage to the penis and preserve sexual function. Priapism is most often a SIDE EFFECT of medication, notably medications to treat ERECTILE DYSFUNCTION and the antidepressant medication trazodone. It also may occur as a complication of SICKLE CELL DISEASE, GENITAL TRAUMA, and PROSTATE CANCER. Treatment may include evacuation of BLOOD from the corpora cavernosa, the tubular channels within the penis that fill with blood to establish an erection, via needle and syringe or intravenous catheter. The doctor may also inject the penis with vasoconstrictor medications. If medical interventions fail, surgery may be necessary to implant a shunt that allows blood to drain from the penis.

See also ANTIDEPRESSANT MEDICATIONS; PARAPHIMOSIS; PEYRONIE'S DISEASE.

prostate cancer A malignant (cancerous) tumor that arises from the glandular tissue of the PROSTATE GLAND, a walnut-size structure that encircles a man's URETHRA at the base of the BLADDER. Prostate cancer is one of the HORMONE-DRIVEN CANCERS that appears to have some genetic foundations as it tends to run in families. Prostate cancer also strongly correlates to increased age; it is rare among men under age 50 and affects more than half of men over age 70.

Prostate cancer is the most frequently diagnosed cancer among men in the United States and is primarily found in men over age 60. Though prostate cancer may take an aggressive path with widespread METASTASIS that leads to premature death, prostate cancer more often than not is a slow-growing cancer and runs a course that doctors can control through various treatments. Far more men die *with* prostate cancer than *from* prostate cancer. With early detection and treatment, prostate cancer may be curable.

The symptoms of prostate cancer are often difficult to distinguish from the symptoms of noncancerous conditions that affect the prostate gland, particularly BENIGN PROSTATIC HYPERPLASIA (BPH). All men eventually develop some degree of BPH as they grow older, enlargement of the prostate gland begins to occur as a natural dimension of aging. However, BPH is not and does not become prostate cancer, though a man may have both conditions concurrently.

Symptoms and Diagnostic Path

Early to moderately advanced prostate cancer may cause no symptoms, with diagnosis resulting from further investigation of an abnormally high PROSTATE-SPECIFIC ANTIGEN (PSA) BLOOD level or abnormal findings during DIGITAL RECTAL EXAMINATION (DRE) performed during a ROUTINE MEDICAL EXAMINATION. When symptoms are present they may include

- frequent URINATION, particularly at night (NOCTURIA)
- incomplete emptying of the bladder with urination, sometimes resulting in URINARY URGENCY, URINARY FREQUENCY, and URINARY TRACT INFECTION (UTI)
- reduced urinary flow, urinary hesitation (difficulty starting the flow of urine), and dribbling (difficulty stopping the flow of URINE)
- blood in the urine (HEMATURIA) or SEMEN (hematospermia)
- sensation of heaviness or fullness in the lower abdomen (pelvic area)
- low BACK PAIN or rectal pressure

The diagnostic path may include DRE to palpate the prostate gland, blood tests to measure PSA levels and detect the presence of other TUMOR MARKERS, urinalysis, transrectal ULTRASOUND (TRUS), and biopsy (multiple tissue samples) of the prostate gland.

STAGING AND GRADING OF CANCER are critical for identifying and selecting the most appropriate treatment options. Several systems exist for cancer staging and grading. Because prostate cancer cells typically invade different areas of the prostate gland at varying levels of what pathologists call architectural disorder—the extent to which the cell structure deviates from normal—conventional staging and grading methods often cannot accurately classify the prostate cancer overall. Some areas of invasion may be fairly advanced and others minimally involved. The Gleason system and the Jewett system are methods unique to prostate cancer and the ones most doctors use to guide treatment decisions. In addition, conventional staging methods provide further classification.

Gleason pattern and score The Gleason system allows the pathologist to select the pattern (sometimes called grade) of the two most predominant architectures (primary and secondary) among the biopsy samples and combine them into a score that represents the character of the prostate cancer overall. There are five patterns and nine scores possible within the Gleason system. The lower the Gleason score (also called the Gleason sum), the more likely the cancer is confined and will respond to treatment. However, the patterns that establish the score are also important. For example, a prostate cancer that has a Gleason score of 7 coming from 3 + 4 has a more positive prognosis than one with a Gleason score of 7 coming from a 4 + 3 because the first number indicates the primary pattern and pattern 3 is less aggressive than pattern 4. It is important to know both patterns as well as the score.

Jewett staging system The Jewett system, also called the Jewett-Whitmore system, assigns four alphabetic values to the extent of cancer metastasis, with numeric subvalues for more precise classification.

Conventional staging Some doctors additionally use conventional staging and grading systems

GLEASON PATTERNS AND SCORES FOR PROSTATE CANCER

Gleason Pattern	
pattern 1	cells and architecture nearly normal (well differentiated)
pattern 2	cells nearly normal though glandular cells beginning to invade MUSCLE tissue within the PROSTATE GLAND
pattern 3	cells still maintain glandular structure though invasion of muscle tissue within the prostate gland is significant; possible regional METASTASIS
pattern 4	significant cell abnormality with loss of normal architecture and distorted glandular structure; probable regional metastasis; possible distant metastasis
pattern 5	cells and architecture completely irregular and abnormal (undifferentiated); probable distant and multiple metastases

Gleason Score	
2	lowest possible score; very early cancer with excellent prognosis
3 to 4	slow growing tumor; early cancer with good prognosis
5 to 6	mildly aggressive tumor likely confined to the prostate gland
7	moderately aggressive tumor with possible regional metastasis
8 to 9	aggressive tumor with regional metastasis
10	highly aggressive tumor with multiple distant metastases

JEWETT STAGING SYSTEM CLASSIFICATIONS

stage A	very early, localized cancer; only indication is elevated BLOOD PROSTATE-SPECIFIC ANTIGEN (PSA) level
	A1: well-differentiated or single site within PROSTATE GLAND
	A2: clearly abnormal cells or multiple sites within prostate gland
stage B	localized cancer palpable via DIGITAL RECTAL EXAMINATION (DRE); may cause mild symptoms
	B1: single site
	B2: multiple sites
stage C	METASTASIS to adjacent tissue but not to LYMPH nodes
	C1: tumor is outside the prostate gland but nonobstructive
	C2: tumor obstructs the BLADDER or the URETHRA (urinary symptoms)
stage D	metastasis to lymph nodes or distant organs
	D1: regional LYMPH NODE involvement
	D2: distant lymph node or organ involvement (including BONE)
	D3: RECURRENCE after treatment

to further classify and understand the prostate cancer's characteristics to optimally tailor treatment approaches. The two main conventional staging systems are

- the numeric system, which identifies five levels of tumor aggressiveness (stage 0 through stage 4, or IV)
- the American Joint Committee on Cancer (AJCC) tumor, node, and metastasis (TNM) system, which assigns numeric values to the size of the tumor, invasion of LYMPH nodes, and spread to distant organs or structures

Treatment Options and Outlook

The treatment of choice for men under age 70 is nearly always PROSTATECTOMY, a surgical OPERATION to remove the prostate gland, with adjuvant (follow-up) CHEMOTHERAPY, RADIATION THERAPY, or HORMONE THERAPY as appropriate. Radiation therapy is most effective when the cancer remains confined to the prostate gland. For men over age 70, in

whom prostate cancer is likely to be slow growing and remain localized, the doctor may recommend less invasive approaches such as diligent monitoring (watchful waiting) or radiation therapy (external beam or internal seeding).

No matter his age at the time of diagnosis, a man must consider the many factors that contribute to the relative benefits and risks of treatment options for his stage and grade of cancer, prognosis, other health conditions, and personal desires. Treatments such as surgery and hormone therapy may affect sexual function and have other undesirable side effects. It is important to fully understand the potential implications of treatment options and their effects on QUALITY OF LIFE. Though prostate cancer is the second-leading cause of cancer deaths among men in the United States (LUNG CANCER being first), treatment provides long-term management and prostate cancer is not fatal in the majority of men who develop it.

Risk Factors and Preventive Measures

The most significant risk for prostate cancer is age. Prostate cancer is uncommon in men under age 50 though is present in about half of men over age 80. Other factors that increase the risk for prostate cancer are African American heritage and long-term EATING HABITS that feature foods high in saturated fat. There is some evidence that dietary consumption of SOY proteins, such as in soybean-based foods and in nutritional supplement products, and LYCOPENE, found in tomatoes and pink grapefruit, improve the ability of prostate glandular cells to resist cancerous changes. The medicinal botanical product SAW PALMETTO, available in the United States as a nutritional supplement, may help maintain overall PROSTATE HEALTH.

Health experts differ in their opinions about the value of routine screening procedures, such as DRE and PSA blood levels, for detecting prostate cancer and especially for improving the outcome of treatment. PSA in particular tends to generate a high percentage of false-positive findings, thrusting men into more invasive diagnostic procedures that have increased risks as well as heightened emotional stress. However, both DRE and PSA are components of a routine medical examination in the United States for men over age 50. It is important for a man and his doctor to carefully and comprehensively evaluate all aspects of the man's personal prostate health and to weigh the risks and benefits of further diagnostic assessment.

See also CANCER TREATMENT OPTIONS AND DECISIONS; CARCINOMA; DIET AND HEALTH; LIFESTYLE AND HEALTH; MEDICINAL HERBS AND BOTANICALS; SURGERY BENEFIT AND RISK ASSESSMENT.

prostate gland The gland in the male reproductive tract that produces most of the volume of SEMEN. About the shape and size of a walnut, the prostate gland wraps around the URETHRA at the neck of the BLADDER. The back of the prostate gland rests against the front wall of the RECTUM. A tough, fibrous membrane forms a single capsule enclosing the 30 to 50 clusters of glandular tissue that make up the prostate gland. There are three distinct structures of glandular tissue, which urologists refer to as zones—peripheral, transition, and central—though how the zones differ in function remains unknown. The prostate gland also contains nonglandular cells, primarily MUSCLE and connective tissue cells that help move prostatic secretions into the urethra.

Prostate gland cells produce their secretions under stimulation by TESTOSTERONE, which reaches them through the BLOOD circulation. The seminal vesicles, which lie just behind the prostate gland, store mature SPERM encased in a thick, jellylike solution that prevents them from motility. During ORGASM and EJACULATION, the seminal vesicles and the prostate gland each contract, mixing sperm and prostatic fluid in the urethra to form semen. The prostatic fluid contains an enzyme, PROSTATE-SPECIFIC ANTIGEN (PSA), that thins the semen to allow the sperm to become motile. Ejaculation then carries the semen through the urethra and out the tip of the PENIS.

As a man ages the prostate gland slowly enlarges, a condition called BENIGN PROSTATIC HYPERPLASIA (BPH). In most men BPH remains innocuous, causing no symptoms or even awareness of its presence. Other health conditions that can affect the prostate gland are PROSTATITIS (INFLAMMATION or INFECTION) and PROSTATE CANCER. The surgical OPERATION to remove the prostate gland is

PROSTATECTOMY. The doctor can palpate (feel) the prostate gland through the wall of the rectum during DIGITAL RECTAL EXAMINATION (DRE), which helps detect prostate enlargement as well as abnormalities that suggest other health concerns affecting the prostate gland. Because the risk for prostate cancer increases after age 40, DRE palpation of the prostate gland becomes part of the ROUTINE MEDICAL EXAMINATION for men age 40 and older.

HEALTH CONDITIONS THAT CAN AFFECT THE PROSTATE GLAND

bacterial PROSTATITIS	BENIGN PROSTATIC HYPERPLASIA (BPH)
nonbacterial prostatitis	prostadynia
PROSTATE CANCER	prostatic ABSCESS

See also AGING, REPRODUCTIVE AND SEXUAL CHANGES THAT OCCUR WITH; CANCER PREVENTION.

prostate health Measures a man can take throughout his life to maintain healthy function of his PROSTATE GLAND. The prostate gland, which wraps around the URETHRA at the base of the BLADDER, produces the primary volume of SEMEN, the fluid that carries SPERM out of the body during EJACULATION, and the enzyme PROSTATE-SPECIFIC ANTIGEN (PSA), which thins the semen to permit sperm motility. The prostate gland functions unobtrusively through most of a man's life. In early to mid-adulthood the most significant risk to prostate health is INFECTION (PROSTATITIS), which may be due to the spread of a sexually transmitted disease (STD) such as GONORRHEA or may result from non-STD causes.

In late midlife and beyond the prostate gland begins to slowly enlarge, a natural aspect of aging. Doctors call the enlargement BENIGN PROSTATIC HYPERPLASIA (BPH). For about half of men over age 60 BPH becomes significant enough to constrict or obstruct the urethra (the tubelike structure that drains URINE from the bladder), causing symptoms of urinary obstruction such as URINARY FREQUENCY and hesitation. With increasing age the risk for PROSTATE CANCER, the most serious health condition affecting the prostate gland, also increases.

Dietary and lifestyle measures may slow the progression of both BPH and prostate cancer. Foods that support prostate health include

- SOY (soybeans, soy protein, tofu, tempeh)
- tomatoes and tomato-based foods such as tomato sauce and tomato paste, which contain LYCOPENE
- pink grapefruit and watermelon, which also contain lycopene
- cruciferous vegetables (broccoli, cauliflower, cabbage, kale), which contain sulforaphane and other isothiocyanates, substances that appear to help prostate gland cells fight cancer

A number of studies show the herbal remedy SAW PALMETTO can improve the symptoms of mild to moderate BPH, apparently by shrinking the prostate gland tissues. Some studies show a correlation between high BODY MASS INDEX (BMI) and more aggressive prostate cancers, and other studies demonstrate a lower risk for cancer overall (as well as CARDIOVASCULAR DISEASE and DIABETES) with healthy body weight and regular physical exercise. In the United States, preventive health-care recommendations call for PSA BLOOD level measurements and DIGITAL RECTAL EXAMINATION (DRE) as part of a man's ROUTINE MEDICAL EXAMINATION beginning around age 50. These tests may detect abnormal function or size of the prostate gland that could be early indications of BPH or prostate cancer.

prostatectomy A surgical OPERATION to remove part or all of the PROSTATE GLAND. The prostate gland encircles the URETHRA at the base of the BLADDER. It produces the fluid that mixes with SPERM to form SEMEN and produces the enzyme PROSTATE-SPECIFIC ANTIGEN (PSA), which facilitates sperm motility after EJACULATION. Prostatectomy is primarily treatment for PROSTATE CANCER and BENIGN PROSTATIC HYPERPLASIA (BPH) that constricts the urethra to the extent that it interferes with URINATION. Removal of the prostate gland ends a man's FERTILITY though not necessarily his ability to have and ERECTION and ORGASM.

Surgical Procedure

Surgeons may choose from a number of operations to remove the prostate gland. The choice depends on the reason for the operation, the size of the prostate gland, and the man's overall health status. There are six commonly performed prostatectomy operations: transurethral retrograde prostatectomy (TURP), transurethral incision of the prostate (TUIP), three open prostatectomy operations (suprapubic, retropubic, and perineal), and radical open prostatectomy.

Transurethral retrograde prostatectomy (TURP) TURP has long been the standard, and remains the most common, surgical operation to remove obstructive prostate gland tissue due to BPH (noncancerous prostate gland enlargement) when the prostate gland remains relatively small. The surgeon uses an endoscopic instrument called a resecting cystoscope or resectoscope, inserted through the PENIS and urethra to the prostate gland.

The surgeon passes a cutting tool through the resectoscope to make an incision through the urethra and remove part or all of the prostate gland by shaving away layers of tissue. After removing the prostate gland the surgeon sutures the urethra back to the neck of the bladder. The removed shreds of tissue collect in the bladder and pass out with the URINE over the first few days after surgery. TURP generally requires three days in the hospital and two to four weeks recovery time until full return to normal activities. A man who has had a TURP usually retains erectile function though has RETROGRADE EJACULATION (ejaculation into the bladder).

Transurethral incision of the prostate (TUIP) TUIP is a cystoscopic procedure in which the surgeon makes a series of small incisions through the urethra into the prostate gland. The incisions relieve the pressure the enlarged prostate gland is exerting against the urethra, without removing prostate tissue, restoring the free flow of urine. TUIP is treatment only for noncancerous prostate enlargement, such as BPH, and is used only in limited circumstances that depend on the size and structure of the prostate gland. TUIP is often an AMBULATORY SURGERY procedure (a same-day surgery) with full return to normal activities in three to five days. Erectile and ejaculatory functions nearly always remain normal.

Open prostatectomy The three operations of open prostatectomy, sometimes called simple prostatectomy, involve making an incision through the surface of the SKIN to reach the prostate gland. The incision for suprapubic or retropubic prostatectomy extends from the navel (belly button). In the suprapubic approach the surgeon reaches the prostate gland through the bladder. In the retropubic approach the surgeon reaches the prostate gland without entering the bladder. The incision for perineal prostatectomy is between the SCROTUM and the ANUS. Open prostatectomy removes the prostate gland and seminal vesicles intact. The surgeon may also remove nearby LYMPH nodes (lymphadenectomy) when the operation is to treat prostate cancer.

Open prostatectomy is major surgery that requires a stay of up to eight days in the hospital and six to eight weeks recovery (sometimes longer) before return to regular daily activities. There is moderate risk for significant complications such as bleeding, URINARY INCONTINENCE, and damage to the nerves that supply the penis resulting in ERECTILE DYSFUNCTION.

Radical prostatectomy Radical prostatectomy is a treatment for prostate cancer in which the surgeon removes the prostate gland, seminal vesicles, and surrounding tissue (fat, MUSCLE, and connective tissue) during an operation that can take five hours or longer. Often the surgeon removes adjacent lymph nodes as well. Radical prostatectomy is major surgery that requires about 10 days in the hospital and up to four months for recovery. Radical prostatectomy is treatment for prostate cancer and has a high risk for complications such as urinary incontinence and erectile dysfunction, though these complications may improve over time.

In some circumstances the surgeon may opt to perform radical prostatectomy laparoscopically, inserting a laparoscope and surgical instruments through several small incisions in the abdomen. The laparoscopic approach significantly lessens the risk for complications and shortens recovery time, though the operation is nonetheless major surgery. Sometimes the surgeon may use laparoscopic surgery to remove pelvic lymph nodes while using the open perineal approach to remove the prostate gland.

Risks and Complications

Prostatectomy, particularly an open or radical approach, is extensive surgery with potential complications that require careful consideration. Among them are excessive bleeding during or after surgery that may necessitate BLOOD TRANSFUSION, INFECTION, retrograde ejaculation, urinary incontinence, bladder damage, rectal damage, and erectile dysfunction. Generalized risks include reaction to ANESTHESIA and blood clots. The risk for complications depends on the reason for the prostatectomy (cancer or noncancerous condition), the type of operation, age, and overall health status. Surgeons prescribe prophylactic antibiotics to help prevent infection and antiembolism therapies such as ANTICOAGULATION THERAPY and compression stockings or boots to help prevent blood clots.

Outlook and Lifestyle Modifications

For many men, prostatectomy ends the symptoms of the condition that necessitated the operation. Because the prostate gland continues to slowly enlarge as a man ages, about 20 percent of men who have TURP to treat BPH find their symptoms return in 10 to 15 years, requiring additional treatment. Many men are able to return to normal activities, including sexual activities, within a few months of their surgeries. However, prostate cancer may require adjuvant (follow-up or accompanying) treatment after surgery.

See also ANTIBIOTIC PROPHYLAXIS; CANCER TREATMENT OPTIONS AND DECISIONS; SURGERY BENEFIT AND RISK ASSESSMENT.

prostate-specific antigen (PSA) An enzyme PROSTATE GLAND cells produce. Prostatic fluid, the cumulative secretions of prostate gland cells, contains high levels of PSA. PSA acts on the jellylike substance that encases SPERM during their storage in the seminal vesicles, liquefying the substance when the sperm mix with prostatic fluid in the URETHRA during EJACULATION. This action restores motility to the sperm.

Measuring the BLOOD concentration of PSA provides information about the health status of the prostate gland. In the healthy prostate gland of a man under age 40, the prostate gland cells form a tight structure that directs nearly all PSA the cells produce into the prostatic fluid; only a small amount of PSA escapes to circulate in the blood. In certain health conditions, most notably PROSTATE CANCER, PSA blood levels rise. Prostate cancer disrupts the structure and organization of prostate gland cells, allowing much higher concentrations of PSA to enter the blood circulation. Other health conditions such as PROSTATITIS, BENIGN PROSTATIC HYPERPLASIA (BPH), and even URINARY TRACT INFECTION (UTI) can also cause PSA levels to rise.

As well, PSA also normally rises with increasing age because the prostate gland slowly enlarges beginning around age 40, a process that also alters the structure and organization of prostate gland cells. Because of this natural change, normal PSA blood values differ according to a man's age. Blood PSA concentrations above the value for age may suggest the presence of prostate disease, including prostate cancer. In general, a blood PSA level of 4 nanograms per milliliter (ng/mL) may indicate the need for further evaluation of the prostate gland's health.

NORMAL VALUES FOR BLOOD PROSTATE-SPECIFIC ANTIGEN (PSA) LEVELS

Age	PSA Blood Concentration
40 to 49	< 2.5 nanograms per milliliter (ng/mL)
50 to 59	< 3.5 ng/mL
60 to 69	< 4.5 ng/mL
70 to 79	< 6.5 ng/mL

However, health experts disagree about the value of blood PSA levels for prostate cancer screening and detection. There is limited consensus around what the values mean, there are several methods for measuring PSA that are not equivalent to one another, and there is a higher rate of false-positive PSA results—PSA levels that are elevated for reasons other than prostate disease—than many doctors find acceptable. These factors are of concern because the next step of diagnosis, biopsy, is invasive and carries risk for numerous complications. Many doctors find PSA blood tests more useful when treating disorders of the prostate gland, such as BPH and prostate cancer, as measures to help assess the effectiveness of treatment.

prostatitis INFLAMMATION, INFECTION, or PAIN of the PROSTATE GLAND. Prostatitis may be acute (come on suddenly) or chronic (persist or recur over time). Urologists classify five types of prostatitis:

- Acute bacterial prostatitis occurs as a result of infection with BACTERIA, usually URINARY TRACT INFECTION (UTI), that infiltrates the prostate gland. SEXUALLY TRANSMITTED DISEASES (STDS), notably GONORRHEA and CHLAMYDIA, may also cause acute bacterial prostatitis. Treatment with appropriate ANTIBIOTIC MEDICATIONS usually cures the infection.
- Chronic bacterial prostatitis occurs as a result of an underlying chronic health condition that allows continued or repeated bacterial access to the prostate gland. Treatment requires long-term, and sometimes repeated, antibiotic therapy as well as efforts to resolve the underlying condition.
- Chronic inflammatory prostatitis causes pain and exists when there is inflammation but no infection. Treatment is with NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) to reduce inflammation and relieve pain.
- Asymptomatic inflammatory prostatitis does not cause any symptoms and is sometimes a factor in male INFERTILITY that shows up during FERTILITY testing. NSAIDs may improve the inflammation.
- Prostadynia, also called chronic noninflammatory prostatitis, involves neither inflammation nor infection though pain is persistent and sometimes debilitating. Doctors do not know what causes prostadynia. Medications such as alpha blockers, used to treat BENIGN PROSTATIC HYPERPLASIA (BPH), and NSAIDs sometimes provide relief. BIOFEEDBACK, ACUPUNCTURE, and prostatic massage are other methods to relieve pain.

Symptoms and Diagnostic Path

The primary symptom of all but asymptomatic inflammatory prostatitis is pain in the lower pelvis. Men who have acute bacterial infection often have FEVER and feel quite ill. Men who have chronic bacterial prostatitis may feel intermittently fatigued. The diagnostic path for prostatitis may include DIGITAL RECTAL EXAMINATION (DRE) to palpate the prostate gland, measurement of BLOOD PROSTATE-SPECIFIC ANTIGEN (PSA) levels, urinalysis including urine culture, and SEMEN analysis to look for the presence of red blood cells (evidence of bleeding), white blood cells (evidence of inflammation), and bacteria (evidence of infection). When symptoms are chronic, additional diagnostic procedures may include transrectal ULTRASOUND (TRUS), COMPUTED TOMOGRAPHY (CT) SCAN, prostate biopsy, or CYSTOSCOPY.

Treatment Options and Outlook

Treatment and outlook depend on the identified underlying cause for the symptoms. Because the structure of the glandular tissue within the prostate gland is such that it prevents blood components from entering the prostate gland (a protective mechanism to prevent ANTIBODY formation and to keep the semen PSA concentration high), the course of antibiotic therapy for bacterial prostatitis is lengthy, typically four to eight weeks. A complication of untreated or undertreated bacterial prostatitis is prostatic ABSCESS (the formation of a contained pocket of pus), which may require a cystoscopic procedure under ANESTHESIA to drain the abscess.

Risk Factors and Preventive Measures

Prompt diagnosis and treatment of UTIs and STDs significantly reduce the risk for bacterial prostatitis. There are no clear preventive measures for other forms of prostatitis.

See also CHRONIC PAIN; CYSTITIS; MALDYNIA; SEXUALLY TRANSMITTED DISEASE (STD) PREVENTION; URETHRITIS.

puberty The transition from childhood to the sexual and reproductive maturity that marks adulthood. Puberty occurs under the influence of hormonal shifts. The path of puberty tends to start and end about two years earlier for girls than for boys. Puberty in most industrialized parts of the world begins between ages 10 to 15 and concludes between ages 17 to 19. SECONDARY SEXUAL CHARACTERISTICS emerge during puberty, coinciding with ADOLESCENCE, the emotional and psychologic changes that occur during the shift from childhood to adulthood.

Puberty begins with hormonal changes the HYPOTHALAMUS and the PITUITARY GLAND initiate that stimulate the gonads (ovaries in women and testicles in men) to begin producing gonadotropins (sex hormones)—ESTROGENS and ANDROGENS. The PINEAL GLAND, which regulates the body's circadian rhythms, also appears to play a role. Researchers do not know what triggers these changes. Because external factors such as nutritional status and illness can influence the timing of puberty, researchers suspect body mass (height and weight) may somehow signal the endocrine system. CHROMOSOMAL DISORDERS involving the sex chromosomes, such as TURNER'S SYNDROME, which affects girls, and KLINEFELTER'S SYNDROME, which affects boys, alter or prevent natural puberty.

In both sexes, the first indication of puberty is the growth of HAIR under the arms and around the GENITALIA. At first the hair is light and fine; as puberty progresses the hair darkens and thickens. Hair on the legs also darkens and becomes more dense. There is usually an accompanying growth spurt, which in boys particularly may amount to six inches or more of height within a year. Boys begin to broaden at the shoulders and girls at the hips during this surge of growth. The remaining changes that occur with puberty are gender specific.

Puberty in Girls

BREAST buds, firm bumps that form beneath the nipples, mark the onset of estrogen-driven changes occurring in the girl's body. In most girls breast budding occurs simultaneously with the development of pubic and axillary hair though one set of events may precede the other. Over the course of one to three years the breasts continue to grow and take form and the girl's body takes on a womanly appearance. Generally, about the time the pattern of body hair becomes adult-like the girl begins to menstruate, indicating her ovaries are mature and functional. Puberty concludes in girls when the MENSTRUAL CYCLE is regular and predictable. External factors that can influence the start of MENSTRUATION (MENARCHE) include OBESITY, which tends to cause earlier menarche, and intense physical activity such as athletic competition, which tends to cause later menarche. Both are within the range of normal.

Puberty in Boys

Enlargement of the SCROTUM and testicles marks the onset of TESTOSTERONE-driven changes occurring in the boy's body. The boy's voice lowers in register and deepens. Growth continues at a rapid rate. Over the course of one to three years the PENIS thickens and elongates, and the testicles begin producing SPERM. Sexually stimulated ERECTION and NOCTURNAL EMISSION ("wet dreams") are common. Toward the conclusion of puberty hair on the arms may also become darker, longer, and more dense, and hair begins to grow on the chest. Puberty concludes in boys when the genitalia reach adult proportions, which occurs at age 15 to 19.

Precocious Puberty

Occasionally disturbances of hormonal function may result in early, or precocious, puberty, which doctors define as the onset of puberty before age 8 in girls and age 9 in boys. Treatment for precocious puberty depends on the underlying cause of the hormonal disturbance when the doctor can identify it; a common cause is pituitary ADENOMA (noncancerous tumor in the pituitary gland). Often the cause remains unknown (idiopathic precocious puberty), in which case the doctor may administer GONADOTROPIN-RELEASING HORMONE (GNRH) to regulate the pituitary gland's release of LUTEINIZING HORMONE (LH), the hormone that stimulates estrogen and testosterone. There are usually no adverse effects of idiopathic precocious puberty.

See also AGING, REPRODUCTIVE AND SEXUAL CHANGES THAT OCCUR WITH; HYPOGONADISM.

retrograde ejaculation A circumstance in which a man's SEMEN enters the BLADDER instead of ejecting from the PENIS during EJACULATION. Semen and URINE share the URETHRA for their exit from a man's body. A tiny valve in the urethra at the neck of the bladder ordinarily closes across the entry to the bladder during ejaculation, directing the flow of semen through the penis. When this valve does not close, semen takes the path of least resistance and enters the bladder during ejaculation. A man may notice retrograde ejaculation as a "dry ORGASM" in which very little discharge leaves the penis with orgasm. Retrograde ejaculation does not present any health concerns for the man

though results in INFERTILITY when all semen enters the bladder. Analysis of the first urine after ejaculation shows the presence of SPERM. That first urine after ejaculation may also appear cloudy.

BENIGN PROSTATIC HYPERPLASIA (BPH), a noncancerous enlargement of the PROSTATE GLAND, is the most common cause of retrograde ejaculation. The prostate gland surrounds the neck of the bladder; in BPH the gland may compress the urethra in such a way as to prevent the valve from properly functioning. Surgery to treat BPH or PROSTATE CANCER may permanently damage or remove the valve. Retrograde ejaculation may also occur in men who have DIABETES, particularly when BLOOD GLUCOSE (sugar) regulation is poor. Some medications that affect smooth MUSCLE function may also cause retrograde ejaculation. When the cause is a medication SIDE EFFECT, ejaculation returns to normal when the man stops taking the medication. When the cause is a health condition such as BPH or diabetes, retrograde ejaculation is likely not reversible.

See also FERTILITY; PROSTATE HEALTH; SEXUAL HEALTH; URINARY TRACT INFECTION (UTI).

S

scrotum The saclike structure, a thin layer of MUSCLE and SKIN, suspended from the base of a man's pelvis that contains the TESTICLES. A pair of ligaments, the spermatic cords, extend from the lower abdomen to support the scrotum. The spermatic cords also serve as the conduits for the BLOOD vessels and nerves that supply the testicles. The abdominal and scrotal muscles contract or relax to raise or lower the scrotum, maintaining the appropriate temperature for spermatogenesis (SPERM production). Sperm production, which is a key function of the testicles, requires a temperature of 96°F to 96.5°F, about 2 degrees lower than body temperature. Pubic HAIR covers the outside of the scrotum after PUBERTY.

See also HERNIA; SPERMATOCELE; VARICOCELE.

secondary sexual characteristics The physical changes that distinguish the genders from each other. Secondary sexual characteristics emerge with PUBERTY and establish sexual and reproductive maturity: males produce viable SPERM capable of causing PREGNANCY, and females produce ripened OVA (eggs) capable of fertilization that results in pregnancy.

FEMALE SECONDARY SEXUAL CHARACTERISTICS

growth of pubic and axillary (underarm) HAIR
thickened and coarse or dark leg hair
enlarged breasts and broadened hips

MALE SECONDARY SEXUAL CHARACTERISTICS

growth of pubic, axillary, chest and facial hair
thickened, darkened, and coarse arm and leg hair
broadened shoulders and chest
increased MUSCLE mass and definition
deepened voice and prominent Adam's apple in the THROAT
enlarged TESTICLES, enlarged and elongated PENIS

See also CONCEPTION; CONTRACEPTION; FERTILITY; MENSTRUAL CYCLE; MENSTRUATION; PREGNANCY.

semen The fluid of a man's EJACULATION. In a fertile man about 5 percent of the semen content is SPERM; in a man who has had a VASECTOMY semen does not contain sperm. The seminal vesicles and the PROSTATE GLAND produce the milky fluid of semen, which is primarily a water base that contains proteins, sugars (notably fructose and some GLUCOSE), lipids (fatty acids), electrolytes, and PROSTAGLANDINS. The bulbourethral glands, also called Cowper's glands, add a gelatinous secretion to the semen that thickens it. Semen may flow back into the BLADDER rather than out of the PENIS (RETROGRADE EJACULATION) in a man with a PROSTATECTOMY (surgery to remove the prostate gland).

The electrolytes protect sperm on their journey through the VAGINA and into the UTERUS. The sugars, particularly fructose, and lipids provide nutrition for the sperm. Vaginal secretions are highly acidic and deadly to sperm. The thickness of semen helps contain and insulate sperm as they travel through the VAGINA, though the semen thins by the time it reaches the UTERUS to release the sperm. The electrolytes in semen make it highly alkaline, helping neutralize the vaginal environment to improve sperm survival. Prostaglandins help suppress the IMMUNE RESPONSE, the natural reaction of the woman's IMMUNE SYSTEM to the presence of the sperm. The semen also has the ability to carry various pathogens such as viruses and BACTERIA that can spread SEXUALLY TRANSMITTED DISEASES (STDS).

Semen analysis is a laboratory examination of a semen sample to measure the concentrations of its ingredients and the number and characteristics of the sperm. ALCOHOL consumption, cigarette smok-

ing, and frequency of ejaculation are among the factors that influence the volume and content of semen.

SEMEN NORMAL VALUES PER EJACULATION	
semen volume	1.5 to 6.5 milliliters
sperm count	20 to 250 million per milliliter
pH	7.1 to 8.0
fructose	30 milligrams per milliliter

See also CONTRACEPTION; HEMATOSPERMIA; HYDROCELE; PATHOGEN; SEXUAL INTERCOURSE; SEXUALLY TRANSMITTED DISEASE (STD) PREVENTION; VARICOCELE; VIRUS.

sexual dysfunction Physical or psychologic circumstances that interfere with sexual interest or sexual activity. Most people experience some degree of sexual dysfunction over the course of their lifetimes. The causes of sexual dysfunction are numerous; most are transient (improve or go away with time). Physical illness, injury, surgery, disability, medication side effects, emotional stress, job pressures, CHILDBIRTH and PARENTING responsibilities, GRIEF, DEPRESSION, and relationship discord are among the most common factors. People who have experienced SEXUAL ASSAULT or rape, in childhood or as adults, may also have difficulty establishing or maintaining healthy sexual relationships. As well, an individual's attitudes toward and understanding of sex affect the nature and quality of sexual interaction.

Painful SEXUAL INTERCOURSE, called DYSPAREUNIA, is the most common form of physical sexual dysfunction in women. Dyspareunia may result from insufficient vaginal lubrication (which becomes more common after MENOPAUSE), vaginal MUSCLE spasms (VAGINISMUS), INFLAMMATION or irritation of the VAGINA (VAGINITIS) or VULVA (vulvitis), PAIN in the external GENITALIA (VULVODYNIA), UTERINE PROLAPSE, ENDOMETRIOSIS, UTERINE FIBROIDS, or perineal injury (such as perineal tear or EPISIOTOMY repair). Chronic PELVIC INFLAMMATORY DISEASE (PID) may also cause pain during sex. Psychologic or emotional factors may also contribute to dyspareunia.

The most common form of physical sexual dysfunction in men is the inability to achieve or maintain an ERECTION (ERECTILE DYSFUNCTION), which may result from physical or psychologic factors. ATHEROSCLEROSIS (accumulation of plaque deposits in the arteries that narrows the channel for BLOOD flow), DIABETES, peripheral NEUROPATHY (damage to the small nerves that supply the penis), long-term cigarette smoking, and medication side effects are the leading physical causes of erectile dysfunction in men. Men may also experience pain with intercourse as a consequence of URETHRITIS, PEYRONIE'S DISEASE, and inadequate lubrication during penetration.

Excessive ALCOHOL use, ILLICIT DRUG USE, and heavy or long-term cigarette smoking contribute to sexual dysfunction in men and women. Alcohol and many drugs, prescription or "street," depress LIBIDO. Alcohol affects the health of blood vessels and nerves; long-term alcohol abuse is another cause of erectile dysfunction in men. Cigarette smoking also affects blood flow; NICOTINE is a powerful vasoconstrictor (narrows blood vessels) and the changes in blood oxygen levels that occur when smoking affect the function of cells throughout the body. These effects are most significant for NERVE cells, which require consistent levels of oxygen.

Symptoms and Diagnostic Path

The primary symptom of sexual dysfunction is the reduced ability to engage in or enjoy sexual activity. Men and women may experience difficulty achieving ORGASM (sexual climax); this is more common in women. Psychologic and emotional symptoms of sexual dysfunction in men or women may include diminished libido (sex drive), disinterest in sex, or excessive interest in sex. The diagnostic path begins with a comprehensive medical examination, including PELVIC EXAMINATION for women, and discussion about factors that might be contributing to the symptoms. The doctor may perform additional diagnostic procedures, depending on the findings of the medical examination, such as blood tests (men and women), cultures of vaginal fluids (women) or any discharges (men and women), or pelvic ULTRASOUND (women).

Treatment Options and Outlook

Treatment options depend on the identified causes of the symptoms. Treatment may be as straightforward as changing or stopping a medication that is causing the symptoms or treating an underlying physical condition. Often the symptoms of sexual

dysfunction resolve when the factors responsible for them go away, such as when a person changes from a high-pressure job to one that has a lower level of stress. Sometimes simply the process of discussing life circumstances in response to the doctor's questioning provides a connection between the circumstances and the symptoms that the person had not been able to see.

Sexual dysfunction can be a complex intertwining of physical and psychologic factors that benefits from a combination of treatment for the physical conditions and therapy (counseling) for the psychologic and emotional factors. Relationship or personal therapy may help a person come to insight and understanding about his or her attitudes and expectations about sex.

Risk Factors and Preventive Measures

The key risk factors for sexual dysfunction are physical or psychologic conditions or emotional issues that affect interest in and satisfaction with sexual activity. Appropriate treatment combined with open and compassionate communication can help partners address their concerns and achieve a level of sexual interaction that accommodates each partner's needs. Though it is not always possible to prevent health and life circumstances from resulting in sexual dysfunction, most causes of sexual dysfunction are treatable.

See also ALCOHOLISM; EJACULATION; FERTILITY; INFERTILITY; PARAPHIMOSIS; PELVIC INFLAMMATORY DISEASE (PID); PHIMOSIS; PRIAPISM; RETROGRADE EJACULATION; SEXUAL HEALTH.

sexual health Measures men and women can take to experience sexuality in ways that support their physical and emotional well-being. A key factor for sexual health is overall health—nutritional EATING HABITS, daily physical exercise, MEDITATION or relaxation, adequate sleep, and adequate time for leisure or recreational activities. Sexual health further incorporates measures to reduce the risk for health conditions specifically related to sexual activity such as INFECTION with SEXUALLY TRANSMITTED DISEASES (STDS) and undesired PREGNANCY (CONTRACEPTION).

In addition to the physical factors of sexual health are the psychologic, emotional, and social factors. Despite the tendency of health-care providers to focus on physical concerns such as STDs because of the health issues these infections entail, the emotional intimacy of sexual relationships is an essential component of sexual health. It is sometimes difficult to determine when a relationship is consenting and when it is abusive. Sexual health requires mutual appreciation for each partner's needs, physical and emotional.

Young people especially may face pressure to enter into sexual relationships yet are uncertain that they are ready or willing to do so. The consequences may be far reaching. One million teens become pregnant in the United States each year. STDs such as GENITAL HERPES, HEPATITIS B, and hepatitis C are treatable but not curable. Though treatment regimens now greatly extend life and improve quality of life, HIV/AIDS remains ultimately fatal. Other STDs may cause scarring and other damage that results in permanent INFERTILITY.

See also BREAST HEALTH; BREAST SELF-EXAMINATION (BSE); PROSTATE HEALTH; SEXUAL ASSAULT; SEXUALLY TRANSMITTED DISEASE (STD) PREVENTION; TESTICULAR SELF-EXAMINATION (TSE).

sexual intercourse Sexual activity that involves penetration between sexual partners. In conventional context sexual intercourse is the insertion of a man's erect PENIS into a woman's VAGINA and is the primary mechanism of human reproduction. Male EJACULATION propels SEMEN into the vagina, where the SPERM it contains may unite with an egg (ovum) if the woman is ovulating and conditions are conducive. In contemporary context the term more broadly encompasses vaginal sex, anal sex, and oral sex between partners of either gender as acts of intimacy and pleasure, physical and emotional, that may or may not include the intent to conceive a PREGNANCY.

See also CONCEPTION; CONTRACEPTION; ORGASM; OVULATION; SEXUAL ASSAULT; SEXUAL HEALTH; SEXUALLY TRANSMITTED DISEASE (STD) PREVENTION.

sexually transmitted diseases (STDs) Infections that spread from one person to another during sexual activity, causing illness or damage to the body. The pathogens that cause STDs may be BACTERIA, viruses, or parasites. STDs, also called sexually transmitted infections (STIs), are significant concerns worldwide, diminishing overall health

and QUALITY OF LIFE. STDs infect tens of millions of people in the United States and hundreds of millions of people throughout the world.

STDs may not have symptoms though the person continues to be infectious (capable of passing the STD to sex partners). Often a person has more than one STD at the same time, a circumstance called co-infection. It is possible for reinfection with the same STD to occur after treatment. ANTIBIOTIC MEDICATIONS are the mainstay of treatment for bacterial STDs. ANTIVIRAL MEDICATIONS may alleviate symptoms in viral STDs such as GENITAL HERPES and lessen the risk for transmitting the VIRUS to others, though the virus often remains in the body and symptoms recur.

Though all STDs are treatable, many are not curable. Some, such as HEPATITIS B and HUMAN PAPILLOMAVIRUS (HPV), are known causes of cancer (LIVER CANCER and CERVICAL CANCER, respectively). Hepatitis C may be fatal and at present HIV/AIDS is always fatal, though treatment and supportive lifestyle measures can manage both conditions for years to decades. STDs are a leading cause of PELVIC INFLAMMATORY DISEASE (PID) in women, a serious INFECTION that can result in INFERTILITY by causing scarring and occlusion (blockage) of the FALLOPIAN TUBES and sometimes the CERVIX.

Oral contraceptives (birth control pills), intrauterine devices (IUDs), cervical diaphragms, spermicides, VASECTOMY, TUBAL LIGATION, and HYSTERECTOMY, though effective methods of CONTRACEPTION, do not prevent INFECTION with SEXUALLY TRANSMITTED DISEASES (STDS).

Abstinence (no sexual partners) is the most effective means to prevent infection with STDs. Among people who are sexually active, key measures to reduce the risk for STD infection are

- long-term, mutual monogamy (one exclusive sex partner)
- male latex condom use with every sexual act (vaginal intercourse, anal intercourse, oral sex, partner MASTURBATION)

The effectiveness of these measures varies for the specific STD. Latex condoms are highly effective for preventing GONORRHEA and HPV, for example, though may be less effective for protecting against genital herpes and HIV/AIDS. The female condom is another barrier method of CONTRACEPTION that provides some, but more limited, protection from STD infection compared to the male condom. Unprotected contact with bodily fluids (pre-ejaculate or vaginal secretions), such as may occur during heavy petting and foreplay, carries the same risk for STD infection as does actual intercourse.

Infections not typically characterized as STDs, such as TUBERCULOSIS, may also pass between people during sexual activity. Conversely, some infections characteristically transmitted through sexual contact may also pass via other means such as shared needles among intravenous DRUG users (notably HIV/AIDS and hepatitis). An infant may acquire gonorrhea, CHLAMYDIA, and genital herpes during CHILDBIRTH (passage through the VAGINA). An infant may also acquire congenital herpes without passing through the birth canal if the mother first becomes infected when she is pregnant.

Because many STDs are highly contagious and prompt treatment can minimize their spread as well as prevent long-term health complications for infected individuals, health experts strongly encourage diagnostic testing and treatment for all sexual partners of everyone who acquires an STD. In the United States, community health centers and public health services provide low-cost or free STD testing and treatment. Private doctors and other health-care providers also diagnose and treat STDs.

See also ANTIBIOTIC RESISTANCE; SEXUAL HEALTH; SEXUALLY TRANSMITTED DISEASE (STD) PREVENTION.

sperm The male cells of reproduction, also called gametes. A spermatozoon (single sperm cell) is a haploid cell; it contains one half of the genetic material necessary for human life. The epididymis within the testicle (also called the testis) produces sperm, a process called spermatogenesis, at the rate of hundreds of millions each day from PUBERTY (the onset of sexual maturity) through the end of life. The tissues of the TESTICLES absorb sperm that remain in the epididymis for longer than six weeks, allowing the supply of sperm to remain fresh.

Spermatogenesis The production of new sperm cells begins with the division and differentiation of

SEXUALLY TRANSMITTED DISEASES (STDS)

STD	Cause	Symptoms	Treatment and Outlook
CHLAMYDIA	BACTERIA: *Chlamydia trachomatis*	often no symptoms; men may have discharge from PENIS and burning with URINATION; women may have vaginal discharge	treatable and curable with antibiotic medications
GENITAL HERPES	VIRUS: HERPES SIMPLEX 2 (HSV-2)	burning, itching, chancrelike sores; vaginal discharge in women; burning with urination in men	not curable but symptom relief with ANTIVIRAL MEDICATIONS
GONORRHEA	bacteria: *Neisseria gonorrhoeae*	often no symptoms; burning with urination and discharge from the penis in men; vaginal discharge in women	treatable and curable with antibiotic medications though some strains are resistant
HEPATITIS B	virus: hepatitis B virus (HBV)	JAUNDICE, FEVER, NAUSEA, VOMITING, swollen and tender LIVER	preventable with hepatitis B VACCINE postexposure prophylaxis
hepatitis C	virus: hepatitis C virus (HCV)	jaundice, fever, nausea, vomiting, swollen and tender liver	postexposure prophylaxis
HIV/AIDS	virus: human immunodeficiency virus (HIV)	flulike symptoms when INFECTION occurs; typically no symptoms until AIDS emerges	not curable and ultimately fatal; antiretroviral drugs can keep the virus in check for delay of disease manifestation and remission of symptoms
HUMAN PAPILLOMAVIRUS (HPV)	virus: human papillomavirus (HPV)	often no symptoms; may cause genital warts	not curable though infection often runs its course in several years; various methods to remove warts; some strains associated with CERVICAL CANCER
nongonorrheal URETHRITIS	bacteria: various	burning with urination; discharge from the penis in men	treatable and curable with antibiotic medications
SYPHILIS	bacteria: *Treponema pallidum*	painless chancre that may be unnoticeable; SKIN RASH; fever; late stage symptoms often systemic	treatable and curable with antibiotic medications
TRICHOMONIASIS	PROTOZOA: *Trichomonas vaginalis*	foul-smelling, discolored discharge; painful urination in men; vaginal or vulvar itching or burning in women	treatable and curable with metronidazole

germ cells in the seminiferous tubules. Specialized cells called Sertoli cells nourish and protect the new sperm cells, ushering them into the epididymis where they grow to maturity as they migrate through the 10 to 12 feet of tightly coiled tubule that makes up this testicular structure. Their journey takes sperm to the ejaculatory ducts, where they mix with SEMEN. A mature spermatozoon consists of a head (the cell body) containing genetic material and a whiplike tail that

provides mobility. ANDROGENS, notably TESTOSTERONE, and other hormones regulate spermatogenesis. Spermatogenesis is a continuous process.

Fertilization The role of the sperm is to fertilize the ovum (egg), the first step in establishing PREGNANCY. SEXUAL INTERCOURSE, in which the man's erect PENIS enters the woman's VAGINA, is the natural mechanism through which sperm gain access to the woman's reproductive tract. From 20 to 250 million sperm leave the testicles within the semen, the fluid that nourishes and protects the sperm, during each EJACULATION. The sperm swim through the fluids in the vagina, enter the UTERUS through the CERVIX, and continue to the entrance of the FALLOPIAN TUBES at the top of the uterus.

Of the millions of sperm that begin this journey, most die before reaching the fallopian tube. Surviving sperm continue through the fallopian tube; fertilization takes place if there is an ovum (egg) also in the fallopian tube and a sperm is able to penetrate its surface membrane. Multiple factors influence this ability, including the shape of the sperm head, the remaining motility of the sperm tail to thrust the head through the ovum's membrane, and the environment within the fallopian tube. Once a single sperm penetrates the shell of the ovum, the ovum closes itself to further penetration. Only the head of the sperm enters the ovum; the tail of the sperm drops off outside the ovum. Multiple pregnancies occur when two or more sperm simultaneously penetrate the ovum (identical multiples) or when two or more OVA are present in the fallopian tubes (fraternal multiples). Abnormalities of sperm structure or motility may interfere with the sperm's ability to reach or penetrate the ovum.

For further discussion of sperm within the context of the structures and functions of reproduction and sexuality, please see the overview section "The Reproductive System."

See also ASSISTED REPRODUCTIVE TECHNOLOGY (ART); CELL STRUCTURE AND FUNCTION; FERTILITY; INFERTILITY; SECONDARY SEXUAL CHARACTERISTICS; SEXUAL HEALTH.

spermatocele A cyst containing dead SPERM that forms in the epididymis. Doctors do not know what causes spermatoceles, also called epididymal cysts, to develop though suspect they result from some sort of obstruction that blocks their flow through the epididymis. A spermatocele is round, firm, and clearly defined. A man may discover a spermatocele during routine TESTICULAR SELF-EXAMINATION (TSE) or the doctor may find it during ROUTINE MEDICAL EXAMINATION. A large spermatocele may cause PAIN. ULTRASOUND of the SCROTUM confirms the diagnosis. No treatment is necessary for a small spermatocele that does not cause symptoms. For large spermatoceles or spermatoceles that cause pain, surgery to remove the spermatocele is the most effective treatment. However, surgery may impair FERTILITY because it usually involves removing a portion of the epididymis.

See also HYDROCELE; SURGERY BENEFIT AND RISK ASSESSMENT; VARICOCELE.

sperm donation The collection of a man's SEMEN, which contains SPERM, for use in FERTILITY treatments. The man obtains the semen for donation through MASTURBATION to produce EJACULATION. Sperm banks (facilities that collect and store donated sperm) have varying policies for qualifying sperm donors. In general a sperm donor must be between the ages of 18 and 45, have no known genetic or hereditary conditions, and have no exposure to infectious diseases such as HIV/AIDS, HEPATITIS, and SEXUALLY TRANSMITTED DISEASES (STDS). Sperm donors have no legal rights or responsibilities for children conceived with their sperm and typically remain anonymous.

See also ASSISTED REPRODUCTIVE TECHNOLOGY (ART); GESTATIONAL SURROGACY.

stillbirth The death of the FETUS after 24 weeks of gestation. There are numerous causes for stillbirth; often the reason remains unknown. Sometimes the obstetrician cannot detect the fetal heartbeat during a routine PRENATAL CARE visit; more often the woman notices the fetus has stopped moving. An ULTRASOUND can confirm the death, after which the doctor induces labor to deliver the baby. Death may also occur during CHILDBIRTH. The loss of a PREGNANCY through stillbirth is emotionally traumatic for parents, family members, and friends.

See also ABORTION; GRIEF; PREMATURE BIRTH; SUPPORT GROUPS.

T

testicles The paired male organs, also called the male gonads, that produce SPERM and ANDROGENS, notably TESTOSTERONE. Each egg-shaped testicle is about two inches long and an inch in diameter. A man's testicles may be slightly different from each other in size. The testicles reside side by side in the SCROTUM, a saclike structure suspended outside the body from the lower pelvis. The testicles are outside the body because spermatogenesis (the generation, or production, of sperm) requires a temperature two to three degrees below normal body temperature. A hollow ligament, the spermatic cord, extends from the abdomen to the testicle through the inguinal canal, carrying the ARTERY, VEIN, LYMPH structures, and nerves that supply the testicle.

The outer layer of the testicle is the tunica albuginea, a sheath of fibrous tissue that contains and protects the structures within the testicle. Tightly coiled tubules, the seminiferous tubules and the epididymis, make up the main mass of the testicle. The cells that fill the space between the tubules are the Leydig cells, also called the interstitial cells, which produce testosterone. The seminiferous tubules contain germ cells, from which new sperm cells (spermatozoa) arise, and Sertoli cells, which nourish and support the developing sperm cells. The Sertoli cells draw testosterone into the seminiferous tubules, which sperm cells require to come to maturation, and prevent antibodies in the BLOOD from entering the seminiferous tubules.

As the sperm cells develop, they travel from the seminiferous tubules to the epididymis, another coiled tubule. The epididymis incubates spermatozoa to maturity during the 12 days or so it takes for them to journey through the convolutions of the epididymis, during which they acquire tails and motility (the ability to move). The vas deferens then carries sperm from the epididymis to the ejaculatory duct, which is within the lower pelvis.

HEALTH CONDITIONS THAT CAN AFFECT THE TESTICLES

CRYPTORCHIDISM	EPIDIDYMITIS
GENITAL TRAUMA	HYDROCELE
HYPOGONADISM	INFERTILITY
KLINEFELTER'S SYNDROME	ORCHITIS
SPERMATOCELE	TESTICULAR CANCER
TESTICULAR TORSION	VARICOCELE

For further discussion of the testicles within the context of the structures and functions of reproduction and sexuality, please see the overview section "The Reproductive System." For further discussion of the testicles within the context of the structures and functions of the endocrine, system please see the overview section "The Endocrine System."

See also CONCEPTION; CONTRACEPTION; ORCHIECTOMY; ORCHIOPEXY; PROSTATE GLAND; SEXUAL HEALTH; VAS DEFERENS; VASECTOMY.

testicular cancer A malignant (cancerous) tumor that arises from the tissue of a man's testicle. Testicular cancer is usually unilateral (occurs only in one testicle), though sometimes occurs bilaterally (in both TESTICLES), and is most common in early adulthood (ages 20 to 34). With detection before the cancer metastasizes (spreads elsewhere in the body), the cure rate for testicular cancer is 99 percent. Doctors in the United States diagnose testicular cancer in about 8,000 men each year.

The two main types of testicular cancer are seminoma and nonseminoma, though some testicular cancers contain a mix of these types. Oncologists classify mixed testicular cancer tumors as nonseminoma because the nonseminoma cells

tend to be dominant in determining the tumor's behavior. The distinction is important because the types have different patterns of aggressiveness (rate and way in which the tumor grows), METASTASIS, and responsiveness to treatment.

Symptoms and Diagnostic Path

The most common symptom of testicular cancer is a painless though sometimes tender lump or swelling in the SCROTUM. The man may discover the lump or swelling during TESTICULAR SELF-EXAMINATION (TSE) or coincidentally, or the doctor may find it during ROUTINE MEDICAL EXAMINATION. Testicular cancer also may cause few symptoms until it has grown and spread outside the testicle, such as to organs in the abdomen. In such circumstances, symptoms may be more generalized and include low pelvic or low back heaviness or pressure, fatigue, and overall sense of not feeling well (malaise).

BASIC STAGING OF TESTICULAR CANCER

Stage	Meaning	Treatment Options
stage 0/carcinoma in situ	cancer remains contained in the cells of their origin	radical inguinal ORCHIECTOMY
stage 1	cancer remains confined to a local tumor in one testicle	radical inguinal orchiectomy seminoma: inguinal and retroperitoneal LYMPH NODE irradiation nonseminoma: retroperitoneal lymph node dissection or two cycles of chemotherapy
stage 2 nonbulky	cancer has spread to retroperitoneal LYMPH nodes and nodes are 2 inches or smaller	radical inguinal orchiectomy seminoma: inguinal and retroperitoneal lymph node irradiation nonseminoma: retroperitoneal lymph node dissection, then two cycles of chemotherapy
stage 2 bulky	cancer has spread to retroperitoneal lymph nodes and nodes are larger than 2 inches	radical inguinal orchiectomy seminoma: three cycles of chemotherapy nonseminoma: three or four cycles of chemotherapy
stage 3 nonbulky	cancer has spread to lymph nodes outside the abdomen and to the LUNGS though all metastasized tumors are ¾ inch or smaller	radical inguinal orchiectomy seminoma: three or four cycles of chemotherapy; RADIATION THERAPY for BRAIN METASTASIS nonseminoma: three or four cycles of chemotherapy; surgery to remove any remaining metastatic tumors
stage 3 bulky	cancer has spread to lymph nodes outside the abdomen and nonlung sites such as the LIVER or brain, and some metastasized tumors are larger than ¾ inch	radical inguinal orchiectomy seminoma: four cycles of chemotherapy; radiation therapy for brain metastasis nonseminoma: four cycles of chemotherapy; surgery to remove any remaining metastatic tumors clinical trials
stage 4/recurrent	cancer has returned after treatment	surgery for small, isolated metastases high-DOSE chemotherapy

The diagnostic path typically includes BLOOD tests to look for TUMOR MARKERS (proteins in the blood circulation that suggest the presence of cancer), such as ALPHA FETOPROTEIN (AFP) and lactate dehydrogenase (LDH), and ULTRASOUND of the scrotum, which may indicate whether the growth is fluid-filled (more likely a cyst or HYDROCELE) or solid (more likely a tumor).

Though biopsy (removal of a sample of the tumor's tissue for laboratory examination) is the means of establishing a cancer diagnosis in most other types of cancer, the risk that the biopsy will cause the release of cancer cells into the blood or LYMPH circulation is very high with testicular cancer because of the circulatory and lymphatic structures of the testicle. The urologist may consider biopsy when both testicles are involved or when a man has only one testicle. In such a circumstance the OPERATION begins as would an inguinal orchiectomy but the surgeon sends a tissue sample for the pathologist to examine and waits for the report of cancer or not cancer before proceeding. Otherwise laboratory analysis of the tumor occurs after removal of the testicle and its spermatic cord. The pathologist then identifies the type and stage of the cancer, which determines appropriate treatment options.

Treatment Options and Outlook

Surgery to remove the testicle containing the cancer is the first line of treatment. The operation of choice is radical inguinal ORCHIECTOMY, performed with the man under general ANESTHESIA. The surgeon makes an incision in the groin and pulls the testicle up from the scrotum to remove it, intact, along with its spermatic cord. The spermatic cord contains the blood and lymph vessels that supply the testicle; removing the entire testicular structure significantly reduces the risk for stray cancer cells entering the blood and lymph circulations to spread elsewhere in the body.

For seminomas or large tumors, the surgeon may also remove lymph nodes in the lower abdomen that are the path of lymph drainage from the spermatic cord (retroperitoneal LYMPH NODE dissection). Though a more extensive surgery, such an operation is very successful in preventing the spread of the cancer.

Most men then receive adjuvant (accompanying) treatment with RADIATION THERAPY or CHEMOTHERAPY, depending on the type and stage of the cancer. Tumors that contain only seminoma cells (pure seminoma) tend to stay contained longer and are very sensitive to radiation therapy. Tumors that contain nonseminoma cells tend to metastasize (spread) earlier and are more responsive to chemotherapy. Oncologists typically administer chemotherapy using combinations of drugs for several cycles (three or four) of treatment.

CHEMOTHERAPY AGENTS TO TREAT TESTICULAR CANCER

bleomycin	carboplatin
cisplatin	cyclophosphamide
etoposide	ifosfamide
vinblastine	

Testicular cancer is among the most treatable cancers. Testicular cancer detected and treated while it remains localized in one testicle (stage 0 or stage 1) has a current five-year survival rate of 99 percent; oncologists consider this a cure rate because the cancer rarely recurs. The RECURRENCE rate (likelihood for the cancer to return after treatment) is very low, though a man who has had testicular cancer has increased risk for cancer in the remaining testicle (usually a new cancer rather than a metastasis of the original cancer) or for other types of cancer.

Treatment for testicular cancer does not affect a man's sexuality though may affect his FERTILITY. Most people feel fatigued during cancer treatment, which often lowers LIBIDO (interest in sexual activity). However, most testicular cancer treatments do not affect a man's ability to obtain ERECTION, reach orgasm, or achieve EJACULATION. Extensive retroperitoneal lymph node dissection has a slight risk for NERVE damage that can result in RETROGRADE EJACULATION (in which SEMEN enters the BLADDER rather than exiting the PENIS during ejaculation). Many men retain fertility after testicular cancer, though doctors recommend sperm banking for men who may desire to father children because many factors influence fertility so it is not certain. A man may choose to have a testicular prosthesis implanted to restore the cosmetic appearance and feel of the scrotum.

Risk Factors and Preventive Measures

The most significant risk factor for testicular cancer is undescended testicle (CRYPTORCHIDISM), even after corrective treatment. Untreated cryptorchidism in which the testicle remains within the abdomen presents a very high risk as well as low potential for early detection of testicular cancer. Testicular atrophy, such as may occur after INFECTION with the MUMPS VIRUS, bacterial ORCHITIS, or SEXUALLY TRANSMITTED DISEASES (STDS), and family or personal history of testicular cancer also increase a man's risk for testicular cancer. Though there are no measures to prevent testicular cancer, monthly TSE is an effective means of early detection. Regular follow-up care, including blood tests to measure tumor markers and imaging procedures such as COMPUTED TOMOGRAPHY (CT) SCAN or POSITRON EMISSION TOMOGRAPHY (PET) SCAN, is important.

See also BREAST CANCER; CANCER TREATMENT OPTIONS AND DECISIONS; HORMONE-DRIVEN CANCERS; PROSTATE CANCER; SEXUAL HEALTH; STAGING AND GRADING OF CANCER; SURGERY FOR CANCER.

testicular self-examination A technique by which a man checks his TESTICLES for lumps, PAIN, and other abnormalities as a means of early detection of TESTICULAR CANCER and noncancerous conditions that may affect the testicles and a man's fertility, such as VARICOCELE and HYDROCELE. The primary purpose of TSE is to familiarize a man with the characteristics and anatomy of his testicles so he can detect changes that occur because it is these changes that may signal health conditions that require medical treatment. Though the main intent of TSE is early detection of testicular cancer, as mentioned, the technique also detects noncancerous conditions such as SPERMATOCELE, which can reduce fertility.

Health experts recommend TSE monthly, such as on the first day of every month, and suggest doing TSE in the shower when the SCROTUM is relaxed and lowered and the hands are soapy. TSE takes only a few minutes, following these steps:

1. Cup the testicles in one hand to support them.
2. Gently roll one testicle between the fingers, feeling for small lumps or unusual tenderness. The testicle should feel firm and smooth.
3. Use the fingers to feel the cordlike structure that runs from top to bottom, along the back of the testicle, the epididymis, exploring for hard lumps or areas of unusual tenderness. The epididymis is a tightly coiled structure that should feel somewhat lumpy or ropelike.
4. Use the fingers to feel the tubelike structure that runs from bottom to top along the side of the testicle, the VAS DEFERENS, checking for lumps or areas of unusual tenderness. The vas deferens should feel smooth and firm, and should move easily within the scrotum.
5. Repeat for the other testicle.

A doctor should promptly evaluate any changes or unusual findings such as lumps. It is normal for the testicles to be somewhat different in size and for one to hang lower than the other within the scrotum. Factors that increase a man's risk for developing testicular cancer include undescended testicle (CRYPTORCHISM), even after treatment to correct it, and family or personal history of testicular cancer. Testicular cancer is most common in men between the ages of 20 and 40, though can occur at any age. With early detection and treatment testicular cancer is highly treatable or curable, which is what makes TSE so important.

See also BREAST SELF-EXAMINATION (BSE); PROSTATE HEALTH; ROUTINE MEDICAL EXAMINATION; SEXUAL HEALTH.

testicular torsion A condition in which the spermatic cord twists within the SCROTUM, turning the testicle and jeopardizing its BLOOD supply. Testicular torsion is very painful and can result in loss of the testicle due to strangulation (cutting off the flow of blood to the testicle). Testicular torsion may occur as a result of injury or may occur spontaneously (without apparent cause) and is most common in boys between the ages of 8 and 14. Normally connective tissues firmly attach the epididymis to the SCROTUM; in testicular torsion this attachment either did not exist (congenital) or broke free with exertion or a blow to the TESTICLES.

Testicular torsion is a medical emergency that requires urgent treatment from a doctor.

The key symptoms of testicular torsion are PAIN, swelling, and discoloration (cyanosis) of the scrotum. Symptoms usually appear suddenly, though some boys or men have recurring symptoms over time. Because of the structure of the spermatic cord, testicular torsion most often affects the left testicle. Chronic symptoms suggest congenital detachment of the epididymis from the scrotum. The diagnostic path includes careful physical assessment of the testicles, usually by a urologist. ULTRASOUND (usually Doppler ultrasound) can confirm the diagnosis.

Treatment, when diagnosis comes within six to eight hours of the first symptoms, is emergency surgery to restore the testicle to its normal position and attach it to the scrotum (ORCHIOPEXY). The testicle cannot survive more than six to eight hours after symptoms emerge; after this time necrosis (death of the tissue) sets in and the only treatment is to remove the testicle (ORCHIECTOMY). With rapid and appropriate treatment the urologist can save the testicle about 80 percent of the time. However, testicular atrophy (wasting) and necrosis (tissue death) remain possible for up to six months after the surgery to remedy testicular torsion.

The longer the time between the onset of symptoms and surgery, the greater the likelihood for impaired FERTILITY even when the urologist can save the testicle. This is because the SPERM that escape into the tissues of the testicle establish or activate the IMMUNE RESPONSE, which produces antibodies to the man's own sperm that then attack the sperm as the testicles produce them.

tubal ligation A surgical OPERATION to sever (cut) or tie off a woman's FALLOPIAN TUBES to prevent PREGNANCY. Tubal ligation is a form of permanent CONTRACEPTION, sometimes called tying the tubes or sterilization. There are two fallopian tubes, one leading from each ovary to the UTERUS. Cutting or cauterizing the fallopian tubes prevents the union of OVA, which travel from the OVARIES to the uterus, and SPERM, which travel from the uterus toward the ovaries. This blocks fertilization and prevents pregnancy.

Surgical Procedure

The most common method of tubal ligation is an abdominal operation usually performed as a laparoscopic procedure in an AMBULATORY SURGICAL FACILITY (outpatient or same-day surgery). The doctor may also perform tubal ligation as an OPEN SURGERY at the conclusion of a scheduled CESAREAN SECTION, provided the woman has given informed consent for the procedure.

The woman first receives ANESTHESIA, which may be general anesthesia (deep sleep) or regional anesthesia such as an epidural block. The surgeon then makes a single incision (called a single puncture technique) or several small incisions near the area of the navel (belly button) to insert the laparoscope and operating instruments. The incisions give access to the fallopian tubes. The surgeon places surgical clips or uses cautery to close the tubes. There may or may not be SKIN sutures, depending on the method the surgeon uses. The operation typically takes 35 to 45 minutes.

The woman spends one to three hours in the recovery room after the operation, until she emerges from the effect of the anesthesia. Most women go home within four to six hours of the operation. There is some abdominal discomfort for one to three days, for which the doctor will prescribe or recommend appropriate ANALGESIC MEDICATIONS. Full recovery may take two to three weeks, though many women can return to most normal activities within a few days. INFERTILITY is immediate.

Risks and Complications

As with any surgery, tubal ligation carries the risk for excessive bleeding, INFECTION, and reaction to the anesthesia. However, these complications are uncommon. Also possible though uncommon is PELVIC INFLAMMATORY DISEASE (PID), in which infection becomes widespread within the fallopian tubes and uterus and may also involve other abdominal structures. Rarely a fallopian tube may spontaneously reanastomose (reconnect), resulting in unexpected fertility usually detected through pregnancy.

Complications that may occur months to years after the operation include abdominal adhesions (the formation of restrictive SCAR tissue within the abdominal cavity) and ECTOPIC PREGNANCY, a life-

threatening circumstance that typically occurs when a tube partially reanastomoses but the fertilized egg cannot pass through the tube to the uterus and instead begins to grow in the fallopian tube or the abdominal cavity.

Outlook and Lifestyle Modifications

Tubal ligation has no effect on a woman's LIBIDO (sex drive), and in fact may increase a woman's interest in sexual activity because she no longer worries about unintended pregnancy. However, tubal ligation does not protect against SEXUALLY TRANSMITTED DISEASES (STDS) or HIV/AIDS.

The intent of tubal ligation is to establish permanent infertility (sterility), and a woman should consider tubal ligation to be permanent though it is sometimes possible to reverse a tubal ligation through a second surgery. The operation to reverse tubal ligation is usually major abdominal open surgery; its success depends on multiple factors, including the woman's current age and the age at which she had the tubal ligation and the skill of the surgeon.

Turner's syndrome A spontaneous (nonhereditary) chromosomal disorder in which there are abnormalities of the X CHROMOSOME, the SEX CHROMOSOME that establishes female gender, resulting in various anatomic and physiologic anomalies. These abnormalities may include only a single X chromosome (X chromosome deletion) instead of the normal pair of X chromosomes, or one complete and one fragmented or partial X chromosome. As well, the pattern may be mosaic, with some cells in the body carrying the normal paired X chromosome complement and others carrying the abnormality. Turner's syndrome affects only females.

Though symptoms of Turner's syndrome vary depending on the severity of the chromosomal abnormality, characteristic traits include very short stature and loss or lack of ovarian function. An unusually short neck with webbed SKIN, and a broad, shield-shaped chest may be prominent at birth to suggest the presence of Turner's syndrome though often the diagnosis comes later in childhood or early ADOLESCENCE when SECONDARY SEXUAL CHARACTERISTICS fail to develop. GENETIC TESTING (KARYOTYPE) confirms the diagnosis. Anomalies of the HEART (coarctation of the AORTA) and KIDNEYS (HORSESHOE KIDNEY) are also common. As adults, women who have Turner's syndrome have increased risk for type 2 DIABETES, HYPOTHYROIDISM (underactive THYROID GLAND function), HYPERTENSION (high BLOOD PRESSURE), and OSTEOPOROSIS.

HORMONE THERAPY with ESTROGENS and progestin from PUBERTY through midlife (to the age MENOPAUSE would normally occur, around 50) is the standard course of treatment for Turner's syndrome. This treatment causes relatively normal development of secondary sexual characteristics and sometimes of ovarian function to produce hormones, though the OVARIES do not produce normal OVA. In mosaic Turner's syndrome, the woman's ovaries may function until early adulthood. ASSISTED REPRODUCTIVE TECHNOLOGY (ART) techniques can make PREGNANCY possible. There are no measures to prevent Turner's syndrome.

U

umbilical cord The entwinement of the two umbilical arteries, one umbilical VEIN, and nerves that extend from the PLACENTA to the developing FETUS during PREGNANCY. The length of the umbilical cord varies according to numerous factors. The flow of BLOOD through the umbilical arteries and vein holds the umbilical cord relatively rigid. A thick gelatinous coating, called Wharton's jelly, surrounds the umbilical cord to protect it as it floats in the AMNIOTIC FLUID.

The umbilical cord carries nourishment from the mother to the fetus and metabolic waste from the fetus to the mother via the blood circulation. The umbilical cord enters the fetus in the center of its abdomen. The umbilical arteries carry blood from the fetus to the placenta, which delivers oxygen and NUTRIENTS to the blood. The umbilical vein then carries the oxygenated blood back to the fetus.

The third stage of childbirth is delivery of the placenta, often called the afterbirth. When the woman delivers the umbilical cord the doctor or midwife clamps it in two places, cuts between the clamps, and seals the end attached to the baby with a plastic clip. Within two to three weeks the stump of the umbilical cord shrivels, hardens, and falls off. In its place remains the SCAR that forms to close off the umbilical portal into the infant's body, the umbilicus or navel (commonly called the belly button). The remnants of the umbilical arteries and umbilical vein become ligaments within the abdomen.

For further discussion of the umbilical cord within the context of the structures and functions of reproduction and sexuality, please see the overview section "The Reproductive System."

See also ARTERY; BLOOD STEM CELLS; NERVE.

uterine fibroids Benign (noncancerous) tumors of connective tissue and MUSCLE that grow from the walls of the UTERUS. Uterine fibroids, also called uterine leiomyomas or fibromyomas, may grow inward into the inner cavity of the uterus (submucosal fibroids), within the layers of the myometrium (muscular wall of the uterus), or outward from the myometrium into the abdominal cavity (subserosal fibroids). Pedunculated fibroids grow on stalks and can be submucosal or subserosal.

Uterine fibroids are very common. They may occur as isolated or clustered growths ranging in size from barely visible to the eye to as big as grapefruit. Uterine fibroids may cause symptoms when they press against other abdominal structures such as the BLADDER or RECTUM, when a pedunculated fibroid twists on its stalk, or when a fibroid dies and releases fluid and debris that irritates the surrounding tissues.

Symptoms and Diagnostic Path

Three fourths of women who have uterine fibroids have no symptoms; the doctor detects the fibroids during routine PELVIC EXAMINATION or ULTRASOUND performed for other reasons. When symptoms occur they often include

- low abdominal (pelvic) pressure or PAIN that often intensifies during MENSTRUATION
- heavy or prolonged menstrual bleeding
- bleeding between menstrual periods
- CONSTIPATION or DIARRHEA
- pain in the lower back or the upper legs

Uterine fibroids may also create FERTILITY problems when they are large enough or when they

grow in positions, especially near the openings of the FALLOPIAN TUBES, that prevent the implantation of a fertilized egg (ZYGOTE). Large fibroids may interfere with the growth of the FETUS, causing spontaneous ABORTION (miscarriage).

The diagnostic path includes pelvic examination and imaging procedures such as ultrasound, COMPUTED TOMOGRAPHY (CT) SCAN, or MAGNETIC RESONANCE IMAGING (MRI). The doctor may also perform HYSTEROSCOPY to view the inner uterus or laparoscopy to view the abdominal cavity. These procedures, performed with ANESTHESIA, also allow the doctor to also take small samples of the growths for further laboratory analysis.

Treatment Options and Outlook

Uterine fibroids that do not cause symptoms do not require treatment. Often, uterine fibroids shrink on their own with MENOPAUSE and then cease to cause symptoms. Medical treatments include

- NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS), which effectively relieve the discomfort of uterine fibroids when symptoms are mild
- hormones such as GONADOTROPIN-RELEASING HORMONE (GNRH) agonists (such as leuprolide) and ANDROGENS (such as Danocrine) that alter the hormonal balance in the body, causing the fibroids to shrink
- oral contraceptives (birth control pills), particularly progestin-only products, which may reduce symptoms with fewer risks and side effects than other HORMONE therapies

These drugs all have significant side effects and affect fertility during the course of treatment. Though these medications are effective, a woman can take them for only a limited time and the fibroids rapidly return when she stops taking the medication.

Surgical treatment options include removal of the fibroids (myomectomy), which preserves fertility, and removal of the uterus (HYSTERECTOMY), which ends fertility. Uterine fibroid embolization (UFE) is an option for some fibroids. For this procedure an interventional radiologist injects sterile polyvinyl alcohol (PVA) particles through a catheter inserted into the femoral ARTERY in the groin and threaded into the arteries that supply the fibroids. The particles block the arteries, cutting off the fibroid's BLOOD supply and causing it to die.

Risk Factors and Preventive Measures

Uterine fibroids are most common in women who are between ages 30 and 40. Though the cells that form uterine fibroids have more estrogen receptors (molecules that accept, or bind with, ESTROGENS) than normal myometrial cells and most fibroids recede with menopause, the correlation between estrogen and fibroids remains unclear. There are no measures to prevent uterine fibroids from developing.

See also ADENOMYOSIS; ENDOMETRIOSIS; SURGERY BENEFIT AND RISK ASSESSMENT.

uterine prolapse A circumstance in which the ligaments and muscles that support the UTERUS within the abdomen weaken, allowing the uterus to sag into the VAGINA. The weakness generally occurs as a consequence of multiple pregnancies that stress them or traumatic CHILDBIRTH that causes damage to them. OBESITY increases the risk for uterine prolapse. Less commonly, uterine prolapse may develop in a woman who has long-term chronic COUGH such as may occur with chronic BRONCHITIS or CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD).

The symptoms of uterine prolapse may include

- sensation of heaviness or pressure in the lower pelvis
- PAIN during SEXUAL INTERCOURSE
- lower BACK PAIN

Depending on the severity of the prolapse, the uterus and cervix may protrude into the vagina or through the entrance of the vagina (vaginal introitus). The diagnostic path includes PELVIC EXAMINATION, which is typically sufficient for the doctor to diagnose uterine prolapse.

Treatment for mild to moderate uterine prolapse is most often a vaginal pessary, a fitted device the woman inserts into her vagina to hold the uterus in position. Treatment for moderate to severe uterine prolapse is surgery either to repair the muscles and ligaments (sacral colpopexy) or to

remove the uterus (HYSTERECTOMY). Surgery provides permanent correction, though in some women the damage to the pelvic structures may later experience vaginal prolapse (sagging of the vaginal walls).

uterus The hollow muscular organ that supports and contains a PREGNANCY. Eight ligaments—one anterior, one posterior, two round, two broad (also called lateral), and two uterosacral—suspend the pear-shaped uterus in the lower central abdomen (pelvis), with the narrow end of the uterus angled somewhat downward. This suspension system allows the uterus, also called the womb, to expand during pregnancy. The FALLOPIAN TUBES join the uterus, one on each side of the wide upper section called the fundus. The fundus angles forward such that the uterus lies above the urinary BLADDER.

The lower section of the uterus is the CERVIX, a thick neck of muscular tissue that joins the uterus with the VAGINA, the passage to the outside of the body. In its nonpregnant state the uterus is about three inches long and an inch thick; in PREGNANCY the uterus expands to become nearly 10 times as large as its nonpregnant size. Within four to six weeks after CHILDBIRTH the uterus returns to nearly its prepregnant size. The uterus has two layers of structure: the outer myometrium and the inner endometrium.

The surgical OPERATION to remove the uterus is HYSTERECTOMY, which may be treatment for ENDOMETRIAL CANCER, severe ENDOMETRIOSIS or UTERINE FIBROIDS, or DYSFUNCTIONAL UTERINE BLEEDING (DUB).

The myometrium The myometrium is three layers of strong, smooth (involuntary) MUSCLE. The fibers of the innermost layer form two circular patterns that emanate from the fallopian tubes and extend to the cervix. The fibers of the middle layer occur in random patterns that run lengthwise, widthwise, and diagonally. These fibers primarily support the network of BLOOD vessels that nourish the myometrium. The outermost layer's fibers wrap diagonally (transversely) around the uterus.

The myometrium grows during pregnancy to accommodate the growing and enlarging FETUS. Through mechanisms doctors do not fully understand, the myometrium begins rhythmic and increasingly intense waves of contractions, synchronized across the three layers of muscle, that ultimately result in childbirth. The contractions stretch and thin (efface) the cervix and then push the fetus through the cervix, into the vagina, and out of the body.

The endometrium The inner structure of the uterus is the endometrium, a membranous tissue that contains abundant blood vessels and glands. The endometrium responds to the monthly hormonal cycle of estrogen and PROGESTERONE peaks and troughs, thickening when blood levels of ESTROGENS rise—a preparation for pregnancy—and sloughing when estrogen drops and progesterone rises—MENSTRUATION. When these hormonal cycles cease with MENOPAUSE, the endometrium enters a state of atrophy, in which it remains for the rest of the woman's life.

HEALTH CONDITIONS THAT CAN AFFECT THE UTERUS

ADENOMYOSIS	DYSFUNCTIONAL UTERINE BLEEDING (DUB)
ENDOMETRIAL CANCER	ENDOMETRIAL HYPERPLASIA
ENDOMETRIOSIS	PELVIC INFLAMMATORY DISEASE (PID)
PREGNANCY	UTERINE FIBROIDS

For further discussion of the uterus within the context of the structures and functions of reproduction and sexuality, please see the overview section "The Reproductive System."

See also HYSTEROSCOPY; OVARIES; SEXUAL HEALTH.

V–Z

VACTERL The acronym for a constellation of BIRTH DEFECTS that tend to occur in coincidence with each other. Doctors consider a baby who has three or more of the defects to have the VACTERL association, and will examine the baby closely for the other defects in the constellation. These defects include

- V: vertebral (spinal) anomalies
- A: ANAL ATRESIA (also called imperforate ANUS)
- C: cardiac (HEART) anomalies
- T/E: tracheoesophageal fistula (may also occur as tracheal fistula and ESOPHAGEAL ATRESIA)
- R: renal (kidney) anomalies
- L: limb anomalies

Occurring often enough that some doctors believe it, too, is part of the constellation, is a single-ARTERY UMBILICAL CORD (the normal umbilical cord has two arteries), which sometimes appears in the acronym as a final *S* (VACTERLS). VACTERL occurs sporadically (in a nonhereditary pattern); researchers do not know what causes it, nor do they understand the connections among the various defects. Some of the birth defects can be life threatening, such as the HEART malformation tetralogy of Fallot (a complex of four serious heart defects). Treatment, often surgery, attempts to correct the congenital anomalies.

See also CONGENITAL ANOMALY; CONGENITAL HEART DISEASE.

vagina The muscular passageway between the CERVIX and the VULVA (outside of the body). The vagina serves as the portal through which the menstrual flow leaves the body with MENSTRUATION, the erect PENIS enters during SEXUAL INTERCOURSE, and the FETUS passes during CHILDBIRTH.

The outer structures of the vagina are strong muscles that have the ability to vary the inner diameter of the vagina from its normal state in which the vaginal walls touch each other to four or five inches to accommodate the birth of a child. Deep folds of mucous membrane (the vaginal mucosa) line the vagina. The folds, called rugae, give the vagina its ability to expand. The vaginal muscles also relax to extend the depth (length) of the vagina, facilitating SEXUAL INTERCOURSE.
